In Memory of Hans Gerhard Vogel 1927–2011

Preface to the Second Edition

Both safety and pharmacokinetic aspects are important factors in the Research & Development of pharmaceuticals: safety pharmacology, toxicology and pharmacokinetics are the cornerstone disciplines of preclinical development, but the scope has widened both towards Research and towards Development over the last few years. In this book, all in-silico approaches, in-vitro, ex-vivo, in-vivo animal and clinical studies had to be taken into consideration. These studies are used to generate a lot of data which must be evaluated carefully. It was therefore necessary to include the conduct of studies but also the technologies to generate these data in a textbook like this. Since toxicology and safety pharmacology depend directly on exposure, it was also mandatory to cover PK aspects and technologies. All these aspects were included in the first edition of *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*.

Some of the methods described in the first edition have been introduced into the scientific community over the years and decades – for instance specific chromatography technologies like gas chromatography – and there were no novel tendencies to be observed between the dates of the first and second editions. These chapters were not modified since all the information included can still be regarded as "state of the art".

But there are other topics which have shown considerable development with many new insights and technologies. Transporters and their biology are the best example of these areas: these chapters have been completely modified since the first edition.

A third group of chapters had to consider some new aspects without it being necessary to modify them completely. These were amended by adding new results and experiences.

And last but not least, I want to thank again all the authors who contributed despite their very busy daily lives in the pharmaceuticals industry. And a special thank you to Hans Gerhard Vogel who was the Editor-in-Chief of the first edition and all of the *Drug Discovery and Evaluation* titles at Springer consisting of *Pharmacological Assays, Safety and Pharmacokinetic Assays* and *Methods in Clinical Pharmacology*. Gerhard Vogel passed away in 2011. He initiated the second edition of this title. Without him neither this second edition nor any of the other titles of *Drug Discovery and Evaluation* would ever have been completed.

Frankfurt, Germany 2013 Jochen Maas

Preface to the First Edition

Drug discovery and evaluation has been a sequential process for a long period of time. It started with the selection of the most active compound from a series of newly synthesized compounds with the help of special pharmacological assays. Safety aspects were considered by testing the selected compound in high doses in tests directed to indications other than the intended indication of the new compound. These tests were followed by pharmacokinetic studies, which were mainly aimed at confirmation of a suitable half-life time and of oral activity. Safety relied on acute and subacute toxicity studies, which gave information more on organ structure than on organ function.Toxicological and pharmacokinetic studies were adapted to the progress of studies in clinical pharmacology and clinical trials. This strategy has been changed during the last 15 years for several reasons:

Some negative effects on organ function, e.g., ventricular tachy-arrhythmia were detected too late. On the other hand, negative findings in chronic toxicity studies in animals turned out to be irrelevant for human beings.

New scientific approaches, e.g. combinatorial chemistry, high-throughput screening, in silico models, pharmaco-genomics and pharmaco-proteomics offered new possibilities.

The success rate in the pharmaceuticals industry and the introduction of new chemical entities to the market per year dropped dramatically, whereas the development time for new compounds increased, sometimes exceeding the patent protection. This forced a change of strategy:

- Parallel instead of sequential involvement of the various disciplines.
- The term "Safety Pharmacology" was coined.
- An International Conference on Harmonization (ICH) Safety Pharmacolog working group was founded.
- Easily accessible and most informative tests must be selected.

Exposure of drug to the body by pharmacokinetic studies on absorption, distribution, metabolism and excretion must be investigated at an early stage of development and can contribute to the selection of a compound for development.

Toxicology experienced major improvements by the introduction of new methods, e.g., in silico methods, toxicogenomics and toxicoproteomics.

These aspects stimulated our decision to publish this volume as a counterpart to "Drug Discovery and Evaluation. Pharmacological Assays" (Second Edition Springer-Verlag 2002). The current book contains three sections. Dr. Franz Jakob Hock shares with me the responsibility for the section "Safety Pharmacology"; Dr. Jochen Maas took over the responsibility for the section "Safety Pharmacokinetics" and Prof. Dr. Dieter Mayer for the section "Safety Toxicology".

As with the book on pharmacological assays, this book is intended to aid both scientists and students. The reader can find methods for selecting candidates for drug development at early stages, such as screening methods based on the stage of development, or methods up to advanced stages of development and which are considered necessary for international approval from the scientific and regulatory point of view.

Juni 2006 H. Gerhard Vogel

Acknowledgments

″I want to thank all authors of the PK-part for their tremendous work. It was often not easy to complete their individual chapters in addition to their busy daily activities in their respective companies. A special thanks goes to Dr. Roland Wesch who supported me in an optimal way to collect, review and edit all information received from the different authors″

Jochen Maas

About the Editors

Jochen Maas

Jochen Maas is appointed General Manager, Research & Development (R&D) at Sanofi Deutschland GmbH, as of October 1st, 2010, based in Frankfurt. He is a member of the Global R&D Management Board and of the German Management Board. He was appointed as head of the German hub R&D organization in 2012.

Jochen has huge experience in all phases of the R&D value chain. He started his career in PK, then he expanded his responsibilities to preclinical Development, preclinical and clinical Development and Research & Development. Afterwards, he was responsible for Global Research & Development in the Diabetes Division and acted as Vice President R&D Europe at sanofi-aventis.

Jochen also lectures in pharmacokinetics and administering medication as a professor at Gießen-Friedberg University of Applied Sciences.

He is a biologist and veterinarian. He has a doctorate in veterinary medicine including a specification in Radiology. He studied at the Universities of Zurich, Heidelberg and Munich. After joining the Group in 1992 as head of the pharmacokinetics laboratory, he held various R&D management positions in Germany and France.

Franz J. Hock

Since retiring from Aventis in 2002, Dr. Hock has leveraged his experience as a freelance consultant specializing in Safety Pharmacology. Dr. Hock was a research scientist at Hoechst, Hoechst Marion Roussel and Aventis from 1976 – 2002. He initially worked on methods in general pharmacology and nephrology, before becoming Head of a Laboratory devoted to pharmacological methods for drugs influencing memory and learning. He was ultimately Head of Laboratory for General/Safety Pharmacology at the Frankfurt site of Aventis Pharma Deutschland GmbH. Dr. Hock received his MSc in Neurobiology from the Technical University Darmstadt and his DSc in Zoology form the University Kassel, Department of Biology, Institute of Neuroethology and Biocybernetics.

He received the degree of Fachpharmakologe DGPT ("certified expert pharmacology") in 1981. In 1983 he spent a sabbatical year at the University of California, Irvine, at the Center for the Neurobiology of Learning and Memory (Director Prof. Dr. James L. McGaugh).

He lectured for several years to students in Biology at the University of Kassel und the Technical University of Darmstadt. He has published over 100 original papers on methods in pharmacology and on new compounds.

He is currently a member of the Task Force General/Safety Pharmacology German/ Swiss Pharmaceutical Companies. A member of several national and international scientific societies, Dr. Hock is a founding member of “Safety Pharmacology Society”, “Neurowissenschaftliche Gesellschaft e.V.” and “European Behavioural Pharmacology Society”. He served since several years as a member of the program Committee of the Safety Pharmacology Society. He is member of several domestic and international scientific societies.

Dieter Mayer

Dieter Mayer studied veterinary medicine at the University of Munich, Germany. Thereafter, he worked on a thesis on biochemical mechanisms of heavy metal intoxication at the Institute of Pharmacology and Toxicology at the Ludwigs-Maximilian-University of Munich.

In 1975 he joined Hoechst AG Frankfurt, Germany. He worked there at the Institute of Industrial Toxicology and was in charge of the safety assessment of Acesulfam, an artificial sweetener. Further projects consisted of fluorocarbons as replacements for chlorofluoro-carbons. He contributed to the development of several pesticides.

Dieter Mayer was a member of the German MAK (TLV) committee for about 12 years. He worked at the University of Davis, California and at the Centre International de Toxicologie (affiliation of Hoechst AG), Evreux, France, where he held the position of Scientific Director.

In 1986 he became Head of the central toxicology department at Hoechst AG. This entailed responsibility for the entire Hoechst portfolio, and hence also for pharmaceuticals. He was involved in the successful development of antiinfectives, cardiovascular drugs, several insulins, CNS drugs and anti-rheumatics. In 1998 he was promoted to Vice President of Lead Optimization (Toxicology, DMPK and Clin. Pharmacology).

Prof. Mayer has been teaching toxicology at the University of Frankfurt since 1991 and has authored more than 90 scientific articles, abstracts and oral presentations. Today Dieter Mayer is a Consultant for the global pharmaceutical industry and is a member of the Advisary Board of National German Research Associations.

Safety Pharmacology

Safety Pharmacology: Introduction

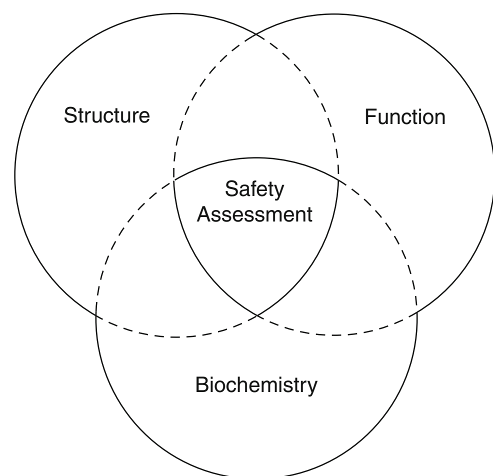
1

Franz J. Hock

The adverse effects of new drug entities in animals and humans can be manifested by changes in the structural, biochemical, or physiological status of the organism. In the preclinical safety assessment process, toxicological procedures have traditionally focused on the structural and biochemical consequences of drug actions. As a result, there has been a reliance on histopathological evaluation of organs and clinical pathology measures in the toxicological assessment of new drug candidates. Physiological or functional observations of drug action were mostly conducted outside of the safety assessment processes. The last decade has seen a growing awareness of the importance of physiological measures of drug toxicity. This awareness has been prompted by clinical issues of life-threatening effects, e.g., cardiovascular functions. These issues have prompted regulatory action and involvement with respect to "safety pharmacology."

Safety pharmacology refers to the assessment of adverse effects of drugs on functional and physiological systems including central and peripheral nervous system, cardiovascular system, respiratory system, and renal and gastrointestinal functions. The evaluation of functional or physiological toxicities plays a key role in the safety assessment process. It should be viewed as complementary to traditional assessments of toxicity based upon morphological or biochemical lesions. Safety pharmacology is not a new topic, but one with renewed interest in the pharmaceutical industry and the regulatory bodies governing the drug approval process.

Safety pharmacology can be thought of as one of the key areas to be integrated with structural and biochemical evaluations in the complete safety assessment program (see scheme below).



The authors of this section have assembled information to assist scientists in industry in (1) understanding the recent regulatory status and expectations for safety pharmacology testing and (2) the conduct of safety pharmacology studies in broad. As evidenced by their extensive experience, the authors share a deep commitment to the conduct of safety pharmacology studies and are leaders in this field of drug safety assessment. The emphasis of this section is to provide practical information and approaches to the assessment of central and peripheral nervous system, cardiovascular system, respiratory system, renal and gastrointestinal functions, and of other systems and functions involved in safety issues. Furthermore, in this section, new chapters such as on biologics, antibiotics,

monoclonics, oncology, stem cells, transgenic animals, etc., are added, showing recent developments in the field of safety pharmacology.

The following sections will detail approaches and options to assessing physiological functions as part of the overall safety assessment of new drug entities, classical and biologics, etc.

Finally, we would like to thank the authors for their contributions to this section.

Ray Lipicky http://spo.escardio.org/eslides/view.aspx?eevtid=40&fp=201 (Director, LIPICKY, LLC, A Consulting Company; retires from FDA in February 2002) started one of his presentations with the following slide:

"Safety" is of Increasing Importance
Although in a round about way is the major theme of my talk; it is among the most important factors shaping the next 10 years of development

WHAT IS SAFETY? (who knows)

Years ago Paul Leber (Neuropharm) said: "Safe" is what I say is "Safe"

Drugs known to kill have been approved if they were more effective than anything else available

Merck and FDA (Viox) said excess 5 Morbid/Mortal events/1,000 patient years requires coming off the market without any regard for benefit

For glucose control, recently an Advisory Committee recommended that prior to approval, for morbid/mortal events a RR >1.3 be rules out –but if you are "old" (or "relatively old") ruling out 1.8 is OK

Gerhard Zbinden (1979) formulated in this way:

> The adverse drug reactions which the standard toxicological test procedures do not aspire to recognize include most of the functional side-effects. Clinical experience indicates, however, that these are much more frequent than the toxic reactions due to morphological and biochemical lesions. . . .

2.1 Origins of Safety Pharmacology

Leber (2002) wrote in his paper: "For over 60 years, the United States has relied primarily on a federal system of premarket drug product clearance to ensure the quality of the nation's drug supply. When the premarket clearance system was first introduced in 1938 in the aftermath of the Elixir of Sulfanilamide tragedy in which over a 100 patients needlessly dies

F.J. Hock
Business Development Consultant, CorDynamics, Dieburg, Germany

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_1, © Springer-Verlag Berlin Heidelberg 2013

because of a drug manufacturer's carelessness (Jackson 1970), federal law required only that new drugs be tested and shown, prior to marketing to be 'safe for use.'"

Serious injury and/or death of volunteers and patients participating in early clinical trials are rare and thus very disturbing when it occurs (Bass et al. 2004a, b; Marshall 2001a, b; Miller 2000). The organ systems and functions most frequently responsible in these events are the central nervous (seizure), cardiovascular (hypotension, hypertension, and arrhythmia), respiratory (asthma/bronchoconstriction), and renal (glomerular filtration) systems, and the result is almost always a critical care emergency (Kinter et al. 1997). The origins of safety pharmacology are grounded upon observations that organ functions (like organ structures) can be toxicological targets in humans exposed to novel therapeutic agents and that drug effects on organ functions (unlike organ structures) are not readily detected by standard toxicological testing (see Mortin et al. 1997; Williams 1990; Zbinden 1984).

Already in the late 1960s, even more in the 1970s, major pharmaceutical companies, alerted by the thalidomide disaster, intensified the preclinical testing of drug candidates. In the USA, since 1962, a law requires that new drug products also be shown to be "effective in use" under the conditions of use recommended in their proposed labeling. Insofar as safety is concerned, the Act demands that a sponsor provide full reports of all tests necessary to establish that the product will be safe for use. On the other hand, Leber (2002) writes that no pharmacologically active drug substance is ever likely to be entirely free of risk. Accordingly, the agency maintains that a regulatory determination that a drug is "safe for use" is, in actually, a favorable "risk-benefit" determination.

For example, in the pharmacological laboratories of the former HOECHST AG, Germany, each compound proposed for development was thoroughly investigated under the term "General Pharmacology." In the specialized laboratories, e.g., for cardiovascular and respiratory function, nephrology, blood coagulation, psychopharmacology, neuropharmacology, analgesic and anti-inflammatory research, gastroenterology, diabetology, atherosclerosis, and endocrinology, the potential new drug was studied according to internal rules for which the head of the department of pharmacology was responsible. For the performance of the tests, the heads of the special laboratories were responsible. Tests rarely being used were performed in a laboratory for general pharmacology.

These rules emphasized:

1. Application in the routes proposed for clinical use (e.g., oral, intravenous).
2. Use of doses considerably higher than those found to be active in pharmacological tests for the proposed indication. If possible, at least ten times higher doses were used.
3. Use of the animal species, which was considered the most sensitive in the special indication; however, several species had to be studied.
4. Multiple dose application, if effects could not be detected after single application, e.g., in atherosclerosis research or in endocrinology.
5. In-depth analysis when unexpected results were found.

Unfortunately, these rules were never published partially because pharmacologists wanted to perform their studies without supervision by GLP. However, the results were published if the investigational drug reached the market (e.g., Omosu et al. 1988). Since only 5% of compounds proposed for development overcome all the hurdles, the majority of data were also not published.

As Kinter et al. (1994) reported, in many pharmacological laboratories prior to 1990, organ function testing was often conducted as an ancillary function of discovery research. The selection of specific studies for a candidate drug was based on concerns raised from its primary (those pharmacodynamic effects related to a drug's targeted indication; special pharmacology) or secondary (those pharmacodynamic effects unrelated to a drug's targeted indication; general pharmacology) pharmacology, or known effects associated with the drug's pharmacological, therapeutic, or chemical class. This ad hoc approach to safety evaluation led to nonsystematic decisions regarding study designs and organ systems studied. Often, the study designs employed were those available for the assessment of efficacy, not safety endpoints (e.g., blood pressure determinations in anesthetized felines). In addition, study designs employed dose levels that exceeded the projected clinical efficacy levels by small multiples, if any. Systemic exposures associated with those dose levels were seldom documented; indeed, investigators were sufficiently

Abschnitt, C 1; Okt. 1989) *Pharmakodynamik* • Wirkungsspektrum eines Stoffes ermitteln • Prospektive erwünschte Wirkungen • Wirkungen auf vitale Funktionen (allgemeine Pharmakodynamik) • Dosis-Wirkungs-Beziehung für erwünschte und unerwünschte Wirkungen sollen ins Verhältnis gesetzt werden	Notice to applicants (Part III F; Jan.1989) *Pharmacodynamics* Studies conducted to establish the pharmacodynamic effects and the mode of action should be evaluated in the following order: • Studies demonstrating desired therapeutic effects (special pharmacodynamics) • Studies demonstrating effects in addition to desired effects (general pharmacodynamics) • Studies to detect drug interaction	Guidelines for the format and content of the nonclinical pharmacology/toxicology section of an application (FDA; Feb. 1987) Part II. D. 1. Pharmacology studies should be presented in the following order, with pharmacodynamic ED_{50} in dose-ranging studies preceding mechanism of action studies • Effects related to the therapeutic indication (primary and secondary activities) • Effects related to possible adverse reactions • Interactions with other drugs	Guidelines for general pharmacology studies (MHW 1995) • Effects on general activity and behavior • Effects on the central nervous system • Effects on the autonomic nervous system and smooth muscle • Effects on the respiratory and cardiovascular systems • Effects on the digestive system • Effects on water and electrolyte metabolism • Other important pharmacological effects • And special additional tests

aware of this criticism that early organ function testing was often conducted using intravenous administration, regardless of the intended clinical route of administration (Kinter et al. 1997). These early organ function assessments were normally disjointed and disconnected from the results of the toxicology program. Attempts to add organ function endpoints to toxicology protocols were frustrated by the fact that data were collected without regard to the physiological status of the subjects and/or pharmacokinetic parameters (Lufy and Bode 2002; Morgan et al. 1994).

Prior to 1990, regulatory guidances on organ function testing were limited. There were some "guidelines," but each country or area had their own regulatory ones (Table 2.1). These guidelines were very unspecific except the Japanese one (see below). The international regulatory documents differ as well (Table 2.2). The US and European regulations provided only general references to evaluations of drug effects on organ system functions (Gad 2004; Kinter et al. 1994; Lumley 1994). Organ function assessments included with investigational new drug applications (INDs) and registrations (NDAs) were inconsistent and often viewed as unimportant (Green 1995; Proakis 1994). However, in Japan, the Ministry of Health and Welfare (now referred to as the Ministry of Health, Labour, and Welfare [MHLW]) had promulgated comprehensive guidances for organ function testing as early as 1975 (see Table 2.3). These guidelines described which organ systems would be evaluated (including central and peripheral nervous systems, cardiovascular, respiratory, gastrointestinal, and renal) as a first tier evaluation (category A studies) and made specific recommendations regarding study designs (including description of models, criteria for dose selection, and which endpoints would be included in the investigation). The guidelines also described a second tier of studies (category B) to be conducted based on the significant findings in the category

Table 2.2 Excerpts from international regulatory documents

• "… studies that otherwise define the pharmacological properties of the drug or are pertinent to possible adverse effects." *(**United States of America**, 21 CFR (Section 314:50, paragraph 2)*
• "… a general pharmacological characterization of the substance, with special reference to collateral effects." *(**European Economic Community**, Directive 91/507/EEC)*
• "A general pharmacological profile of the substance is required, with specific reference to collateral effects…Methods of screening will vary…but the aim should be to establish a pattern of pharmacological activity within major physiological systems using a variety of experimental models." *(**United Kingdom**, Medicines Act 1968, Guidance notes on applications for product licences, MAL 2, p. A3F-1)*
• "Secondary actions—studies related to secondary pharmacological actions of the new drug which may be relevant to expected use or to adverse effects of the new drug." "Other studies—pharmacological activities of the drug that may be pertinent to safety and which may or may not be relevant to proposed clinical trials…" *(**Canada**, RA5 Exhibit 2, Guidelines for preparing and filing drug submissions, p. 21)*
• "Studies should reveal potentially useful and harmful properties of the drug in a quantitative manner which will permit an assessment of the therapeutic risk… Investigations of the general pharmacological profile should be carried out." *(**Australia**, Guidelines for preparation and presentation of applications for investigational drugs and drug products under clinical trial exemption scheme, pp. 12, 15)*
• "New drugs should be studied in a biological screening program so as to define any action over and above that which is desirable for the therapeutic use of the product." *(**Nordic countries**)*
• "The objective of general pharmacological studies is to examine extensively the kind and potency of actions, predict potential adverse effects likely to manifest in clinical practice…." *(**Japanese** Guidelines for Safety Pharmacology Studies, 1995)*

A investigations. Because the Japanese guidelines were the most comprehensive of their time, they became the de facto foundation for organ function safety testing throughout the pharmaceutical industry (Kinter and Valentin 2002). The organ function studies included in categories A and B were intertwined with studies whose aim was to catalog additional pharmacological functions and activities (secondary or general pharmacology) in addition to the primary pharmacological function/activity. Kinter et al. (1994) first distinguished two subgroups of objectives embedded in the Japanese studies as safety and pharmacological profiling. This concept was enlarged upon by the International Conference on Harmonization (ICH) safety pharmacology expert working group to define three categories of pharmacological characterizations: primary and secondary pharmacodynamic, and safety pharmacology (see ICH S7A, Table 2.3).

During the same period, European, US, and Japanese regulatory agencies prepared positions on general pharmacology/safety pharmacology in the form of guidance and concept papers (Bass and Williams 2003; Kurata et al. 1997; Table 2.3). Draft documents appeared from Japan, Europe, and USA by 1998. Later that year, the Ministry of Health and Welfare and the Japanese Pharmaceutical Manufacturer's Association (JPMA) proposed to the ICH Steering Committee the adoption of an initiative on safety pharmacology. This proposal was accepted and given the designation of Topic S7.

The origin of the term safety pharmacology is obscure. It first appeared in drafts of the ICH guidelines "Non-clinical Safety Studies for the Conduct of Human Clinical Trials for Pharmaceuticals," Topic M3, and "Preclinical Safety Evaluation of Biotechnology-Derived Pharmaceuticals," Topic S6 (see Table 2.3). ICH S6 stated that "…The aim of the safety pharmacology studies should be to reveal functional effects on major physiological systems (e.g., cardiovascular, respiratory, renal, and central nervous system)…." The ICH Topic S7 Expert Working Group began their work in the first quarter of 1999, and a harmonized safety pharmacology guideline was finalized and adopted by the regional regulatory authorities over 2000–2001 (ICH S7A). The guidelines describe the objectives and principles of safety pharmacology, differentiate tiers of investigations ("safety pharmacology core battery," "follow-up," and "supplemental" studies), establish the timing of these investigations in relationship to the clinical development program, and embrace GLP procedures (when applicable).

A significant issue that was extensively debated by the ICH Topic S7 Expert Working Group was how to evaluate the potential of new drugs to produce a rare but potentially life-threatening ventricular tachyarrhythmia (torsade de pointes) in susceptible individuals (Ackerman 1998; Anderson et al. 2002; De Ponti et al. 2001; Haverkamp et al. 2000). The incidence of torsades de pointes with drugs that are targeted at noncardiac indications can be very low, for example, 1 in 120,000, and, hence, the imperative to find nonclinical surrogates to identify those drugs with the potential to elicit this serious cardiac arrhythmia (Malik and Camm 2001; Moss 1999; Thomas 1994;

Viskin 1999; Webster et al. 2002). The surrogates of cardiac ventricular repolarization prolongation have included in vitro assessment of drug effects on repolarizing cardiac ion currents (e.g., sodium current, I_{Na}, calcium current, I_{Ca}, rapid, delayed potassium rectifying current, I_{Kr}, slow, delayed potassium

rectifying current, I_{Ks}, and inward rectifying potassium current, I_{K1}) and cardiac cell action potential waveforms (Hammond et al. 2001; Redfern et al. 2003), and in vivo electrocardiography assessments of QT Interval Prolongation (with heart rate correction, QTc), monophasic action potentials, and effective refractory periods (Batey and Doe 2003; Champeroux et al. 2009, 2010; Hammond et al. 2001; Holzgrefe et al. 2007a, b; Spence et al. 1998; Vargas et al. 2008). The controversial issue is the accuracy of these models to identify problematic drugs, and how these data may be assimilated into an assessment of human risk (Kinter and Valentin 2002). Recognizing that resolution would not be easily forthcoming, the ICH S7 Expert Working Group proposed to the ICH Steering Committee that a new initiative be accepted to generate guidelines on the assessment of drugs for effects on cardiac ventricular repolarization. This proposal was accepted in November 2000 and was designated ICH Topic S7B, "Guideline on Safety Pharmacology Studies for Assessing the Potential for Delayed Ventricular Repolarization (QT Interval Prolongation) by Human Pharmaceuticals." The guidelines on safety pharmacology finalized at the same ICH meeting was redesigned Topic S7A, "Safety Pharmacology Studies for Human Pharmaceuticals." Recently, it was found that some compounds show a QT shortening. This finding is recognized as an emerging potential safety issue with a clear business impact (Del Rio et al. 2001; Deurinck and Traebert 2008; Himmel and Hoffmann 2010; Holbrook et al. 2009; Lu et al. 2008a, b; Pugsley and Curtis 2007; Regan et al. 2008). According to Lu et al. (2008a, b), drug-induced QT shortening is associated with a potential risk for ventricular tachycardia (VT) and ventricular fibrillation (VF), which is invariably fatal, whereas the QT prolongation–associated torsades de pointes has only an approximately 20% incidence of death. Lu et al. (2008a) concluded in their paper, that the current S7B regulatory guideline may be useful for predicting drug-induced QT prolongation; amendments to this guideline may be warranted in the future to address the potential liability for drug-induced short QT and the associated fatal arrhythmias (Shah 2010).

Shortly after the adoption of the ICH Topic S7B, the US Food and Drug Administration and the Pharmaceutical Research and Manufacturers of America proposed to the ICH Steering Committee the adoption of a parallel initiative to prepare guidelines on clinical testing of new therapeutics for their potential to prolong ventricular repolarization. This proposal was accepted as ICH Topic E14 entitled, "The Clinical Evaluation of QT/QTc Interval Prolongation and Pro-Arrhythmic Potential for Non-Antiarrhythmic Drugs." In November 2003, the ICH Steering Committee directed the ICH Topic E14 and S7B expert working groups to align their respective guidelines, in particular, the role that nonclinical findings will serve in the design of the clinical study to assess a drug's effect on ventricular repolarization (QT interval). Both guidelines were recommended for adoption at step 5 of the ICH process in May 2005 by the ICH Steering Committee. The Committee for Medicinal Product for Human Use (CHMP) of the EMEA has adopted both guidelines in May 2005 (Shah 2005a, b) and issued as CHMP/ICH/423/02 (S7B) and CHMP/ICH/2/04 (E14). The date for coming into operation of the S7B was November 2005, and in the Federal Register (FDA), it was published in Vol. 70, N 202, pages 61133–61134; October 20, 2005. The date for coming into operation of the E14 was November 2005, and it was published in the Federal Register, Vol. 70, N 202, pages 61134–61135, October 20, 2005.

2.2 Practice of Safety Pharmacology (ICH S7A)

Safety pharmacology is ". . .those studies that investigate the potential undesirable pharmacodynamic effects of a substance on physiological functions in relationship to exposure in the therapeutic range and above. . ." (ICH S7A, Table 2.3). Three primary objectives are encompassed in these investigations.

1. To provide a perspective of the potential pharmacodynamic risk posed to humans by exposure to a new therapeutic agent. This is accomplished through the pharmacodynamic characterization of the new drug on central (peripheral) nervous (Haggerty 1991; Mattsson et al. 1996; Moser 1991; Porsolt et al. 2002; Ross et al. 1998), cardiovascular (Bunting and Siegl 1994; Lacroix and Provost 2000; Kinter and Johnson 2003), and respiratory (Murphy 1994, 2002; Sarlo and Clark 1995) systems (safety pharmacology core battery studies), and other major organ systems (supplemental studies; e.g., gastrointestinal [Baldrick et al. 1998; Kinter 2003; Mojaverian 1996] and

renal [Chiu 1994; Kinter 2003]) as appropriately based on concern for human safety.

2. To investigate the underlying mechanism(s) of observed effects to refine and improve upon the integrated assessment of the risk posed by the drug when adverse findings have been noted in nonclinical or clinical investigations. These may be follow-up studies of the safety pharmacology core battery or the study of other major organ systems (supplemental studies) based on a potential clinical concern (Gad 2004; Kinter and Dixon 1995; Williams and Bass 2003).
3. To determine the temporal relationship between the pharmacodynamic responses noted with the test substance and the peak blood levels of parent drug and any major metabolites. This information will be used to identify the peak drug levels at the low-observed-effect level (minimal dose level tested that produces an effect; LOEL) and no-observed-effect level (maximum dose level tested without an effect; NOEL), the relationship between parent drug and/or major metabolite and the pharmacodynamic response, and whether the pharmacodynamic changes noted with the test material may be related to animal-specific metabolites. These data are critical to defining a margin of safety between the NOEL and the projection of plasma levels needed to achieve clinical efficacy. They also serve to define the human risk posed by exposure to the new drug (e.g., little risk if the response can be attributed to an animal-specific metabolite) and the possible timing of onset and recovery from any observed effects (Williams and Bass 2003).

The safety pharmacology core battery and any supplemental studies deemed to be necessary to assure that human safety are to be conducted in advance of initial clinical trials ("first in human" studies) so that a new drug can progress safely into the clinical phases with an appropriate level of monitoring. In situations where the adverse effects are judged to be potentially serious, or when unexpected pharmacodynamic effects occur in humans, the next tier of testing, investigational safety pharmacology studies (e.g., follow-up or supplemental studies), may be appropriate (ICH S7A; see Table 2.3).

The ICH S7A guideline has brought uniformity to the evaluations of new drugs for effects on organ functions, mandating with few exceptions, that all drug candidates will be evaluated in the safety pharmacology core battery studies and in follow-up and supplemental as appropriate to assure human safety (Pugsley et al. 2008). The cardiovascular, respiratory, and central (peripheral) nervous system functions were selected for the safety pharmacology core battery based on the concern that an acute failure of these systems would pose an immediate hazard to human life. The examination of additional organ systems (gastrointestinal, renal, etc.) may also be appropriate based on a cause for concern for human safety. The experimental models, endpoints, and study designs chosen should be relevant to the prediction of the potential human response. Preference is given to studying animals in the conscious versus the anesthetized states and in the unstressed/unrestrained versus stressed/restrained conditions, to the extent possible within animal welfare guidelines. The clinical route is the preferred route, unless otherwise justified, for example, intravenous rather than oral route to achieve higher blood levels of the parent drug, where oral bioavailability in the test species may be low. Data are collected for a period that has the potential to define the onset, duration, and recovery from possible pharmacodynamic effects. This data collection period would be initially based on the pharmacokinetic (or toxicokinetic) properties of a drug in the selected species and, at a minimum, encompass the time at which the maximum plasma concentrations of the parent drug and any major metabolites are achieved. The demonstration of reversibility/recovery from pharmacodynamic effects may be accomplished by waiting five or more half-lives before terminating the data collection. In the event that human-specific metabolites are detected in the early clinical phases, consideration would be given to nonclinical pharmacodynamic studies that would be appropriate to assure continued human safety.

2.3 Institutional Strategies

The impact of the implementation of the ICH S7A guideline on the organization, philosophy, and practices in safety pharmacology in the pharmaceutical industry shows some controversies and challenges.

In a survey, Valentin and Bass (2004, personal communication) showed the impact in various pharmaceutical companies. The types of safety

pharmacology studies conducted are different. During the precandidate drug selection phase, primarily in vitro and in vivo vascular studies were conducted. The focus in these studies was on cardiac repolarization. CNS studies were of lesser extent. In the postcandidate phase, the “core battery” of S7A, as well as “follow-up” and “supplementary” studies was performed. In late phases, during clinical development, studies followed on a case-by-case basis.

Should early safety pharmacology studies replicated in order to claim GLP compliance? This question was answered differently.

YES for those who think: it increases the statistical power, shows higher exposure of the test article, slightly different focus, GLP, “box-ticking” reasons.

NO for those who mentioned: studies sometimes acceptable by regulatory agencies, animal welfare (3Rs), limited resources, cost/time versus benefit, limited resources, avoid generating conflicting results (Wakefield et al. 2002).

The design and the execution of safety pharmacology studies are focused upon the safety of human volunteers and patients in clinical trials. ICH S7A and S7B strive for effective integration of safety pharmacology results with those of the nonclinical (toxicology) and clinical safety databases.

Overall, the ICH S7A and S7B guidelines are successfully implemented in the pharmaceutical world. The “core battery” is in general performed prior to “First in Man.” These guidelines increase the visibility of safety pharmacology within companies and increase focus by regulatory agencies.

2.4 Future of Safety Pharmacology

The future of safety pharmacology will depend, in part, upon the scientific and technological advances and regulatory challenges that envelop pharmaceutical development (Cavero and Crumb 2005; Porsolt et al. 2005). With advances in molecular biology and biotechnology and cancer (see guidelines S6(R1) (1997) and S9 (2009)), which allow for the identification of new clinical targets, newer pharmaceutical agents are being identified that act at these novel molecular sites in an attempt to ameliorate the disease condition. Inherent in the novelty of new targets is the risk of unwanted effects that may or may not be detected with current techniques. The scientific challenge facing safety pharmacology is to keep pace, to adapt, and to incorporate new technologies in the evaluation of new drugs in nonclinical models and identifying the effects that pose a risk to human volunteers and patients.

Recent examples include safety pharmacology’s embracement of modern electrophysiological techniques to evaluate the effects of new drugs on the ionic components of the cardiac action potential (Redfern et al. 2003) and telemetry techniques to permit the chronic monitoring of physiological functions in unstressed animals (Kinter and Johnson 1999; Kramer and Kinter 2003; Kramer et al. 1998). Efforts continue to construct databases relating the similarities and differences between animal and human responses to pharmaceutical agents (Igarashi et al. 1995; Olsen et al. 2000). As an example, nonclinical safety studies, including safety pharmacology studies, are typically conducted in normal, healthy, young adult or adult animals. However, these tests may not appropriately detect specific responses in humans at other ages (e.g., neonates, adolescents, and geriatrics) or those with underlying chronic diseases (e.g., heart failure, renal failure, and type II diabetes), conditions which may alter the pharmacodynamic response to a drug. In some cases, animal models that overexpress or are deficient in the unique targets, or are otherwise manipulated to model the human pathophysiological conditions, may provide additional focus and sensitivity to detect and interpret the potential unwanted effects of new drugs in terms of human risk (Hondeghem et al. 2001).

The future of safety pharmacology is also intertwined with international regulatory guidelines such as ICH Topics S6(R1) (1997), S7A (2000), S7B (2005), S9 (2009), and E14 (2005). The discipline is considered integral to the evolving regulatory strategies for safely accelerating the introduction of these drugs into the clinical phases (e.g., EMEA (CPMP), “Position Paper on Non-clinical Safety Studies to Support Clinical Trials with a Single Microdose” and the US Food and Drug Administration, Screening Investigational New Drug Application). Additionally, safety pharmacology is also considered important to newly emerging regulatory guidelines from US Food and Drug Administration, such as the “Safety Evaluation of Pediatric Drug Products and Non-clinical Studies for Development of Pharmaceutical Excipients.” The ICH M3(R2) (2009) guideline further

expanded the exploratory clinical trial approach with international consensus (Bass et al. 2011).

The introduction of pharmaceutics into the environment is gaining the attention of both regulators and pharmaceutical industry (Calamari 2003; Huggett et al. 2003; Kopin et al. 2002). While this is not currently the subject of any international environmental guideline, the use of organ function endpoints may become an important component in bridging safety data collected in mammalian vertebrates (including humans) to aquatic species for purposes of the identification of relevant target species and organ functions and the design of specific environmental toxicology studies.

Regulatory interventions in drug safety have become more and more stringent as evidenced continuous promulgation of novel guidelines (Table 2.3). Another ongoing challenge facing drug developers, regulators, and physicians is a need to find the correct balance between introducing new drugs to the market for unmet medical needs and assuring the safety of the clinical trial subjects and patients (Anon 2008).

3.1 General Considerations

3.1.1 Definition of Safety Pharmacology

Safety pharmacology studies are "those studies that investigate the potential undesirable pharmacodynamic effects of a substance on physiological functions in relation to exposure in the therapeutic dose-range and above" (Anonymous 2000). Safety pharmacology is an essential stage in drug development and includes studies evaluating the potential effects of a test substance on vital systems, including the cardiovascular and central nervous systems (CNS) (Lindgren et al. 2008; Pugsley et al. 2008). There has, unfortunately, been considerable confusion about the term "safety pharmacology," and many other kinds of study have also been included. This is no doubt explained by the multitude of terms which have been used to describe the area: general pharmacology, ancillary pharmacology, secondary pharmacology, high-dose pharmacology, and regulatory pharmacology (Porsolt 1997).

3.1.2 Scope of CNS Safety Pharmacology

What kinds of studies come within the scope of CNS safety pharmacology? The *European Agency for the Evaluation of Medicinal Products* has proposed a set of guidelines ICH S7A (Anonymous 2000) that came into effect in June 2001 and have since been adopted in the USA and Japan. The European guidelines include as core battery CNS studies "motor activity, behavioral changes, coordination, sensory/motor reflex responses, and body temperature" with the remark that "the central nervous system should be assessed appropriately."

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_3, © Springer-Verlag Berlin Heidelberg 2013

Follow-up studies should include “behavioral pharmacology, learning and memory, ligand-specific binding, neurochemistry, visual, auditory, and/or electrophysiology examinations, etc.” In general, core battery studies should be carried out prior to first administration in humans, whereas the follow-up studies should be carried out prior to product approval. A final recommendation is that core battery studies should be carried out in full accordance with GLP, whereas follow-up studies, because of their unique characteristics, require only assurances of “data quality and integrity.”

ICH S7A guidelines suggest a clear intent by the European and US authorities to free safety pharmacology from the constraints of a cookbook approach. On the other hand, their vagueness does not provide any clear idea of what could or should be done. In particular, only passing mention is made of drug abuse/dependence assessment, despite this evident safety concern for a large variety of pharmacological agents. For more recent discussions on safety pharmacology, see Porsolt et al. 2002, Bass et al. 2009.

3.1.3 In Vivo Versus In Vitro

CNS safety pharmacology makes use mainly of in vivo methods in conscious animals. The primary reason is that CNS function is best evaluated in an intact and freely moving animal. In contrast to cardiovascular safety pharmacology, where important aspects of function can be evaluated in anesthetized animals or even isolated organs or cells, behavior is the global result of multiple mechanisms, many unknown, and by definition occurs only in the conscious animal or person. Possible exceptions are drug effects on CNS electrophysiology, where drug effects on cerebral cells or structures can be investigated under anesthesia (Easter et al. 2009). On the other hand, CNS electrophysiology can also be investigated using EEG techniques in conscious animals with higher predictability for real-life situations.

3.1.4 Core Battery CNS Safety Pharmacology Studies

ICH S7A distinguishes between core battery studies and supplementary or follow-up studies (Bass et al. 2009). Core battery CNS procedures are typically simple tests, using traditional techniques, which can be carried out rapidly in a routine fashion. They are the first techniques to be employed in safety assessment and are frequently applied at the very beginning of the discovery process as a screen to eliminate substances with a potential for CNS risk. Because of their use early in the safety evaluation process, such studies are conducted almost exclusively in the rodent. Another requirement is that such studies be carried out according to GLP. Nevertheless, it is now recognized that it may be advantageous to identify potential CNS risks earlier in drug development using exploratory studies performed outside the constraints of GLP (Cavero 2009). ICH S7A recommends that core battery studies should include measures of drug-induced observable signs, measures of spontaneous locomotion, and motor coordination. Three other kinds of measure, originally recommended by the Japanese guidelines Category A but dropped from the ICH S7A core battery, are the convulsive threshold, interaction with hypnotics, and the pain threshold. In contrast to ICH S7A, it seems to us that such measures could usefully be included in a core battery of CNS safety pharmacology procedures. Decreases in the convulsive threshold are by no means negligible in the assessment of CNS safety. Several substances, including antipsychotics like clozapine, do not induce frank convulsions at any dose but clearly decrease the convulsive threshold. Even anticonvulsive activity, which in itself is not a risk factor, could be a useful predictor of cognition-impairing effects. Several anticonvulsants, such as benzodiazepines and NMDA antagonists, are known to impair cognition in addition to their anticonvulsant activity. Thus, the presence of anticonvulsant activity could represent a useful first screen for potential cognition-impairing effects (Porsolt et al. 2002). In a similar fashion, sleep-inducing or sleep-attenuating activity could be unmasked by a barbiturate interaction procedure. Benzodiazepines, for example, do not by themselves induce sleep, but their sleep-enhancing activity can be readily detected in interaction with barbiturates. The same is true for psychostimulants which may or may not induce signs of excitation in a primary observation procedure, but clearly block barbiturate-induced sleep. Finally, a drug-induced decrease in pain sensitivity would certainly constitute a CNS risk factor which could be assessed fairly simply using a nociception procedure. It has even been suggested that the presence of analgesic activity constitutes a predictor of abuse liability (Franklin 1998). Compared with current cardiovascular and respiratory procedures,

inclusion of such tests in a core battery would not represent a major expense, but would considerably improve the assessment of CNS risk. Protocols for such tests are included below (Sect. 3.2).

3.1.5 Supplementary CNS Safety Pharmacology Studies

Supplementary or follow-up studies are more wide ranging and cover cognitive function (dependence/abuse potential, learning, memory and attention, and brain function (EEG)). Because of their complexity, there exist no standard protocols, and there is no formal requirement that such studies be carried out in compliance with GLP. There is nonetheless a clear preference by regulatory authorities that even supplementary studies carried out in compliance with GLP as far as possible. A stringent requirement is that such procedures be carried out according to internationally accepted scientific standards of excellence. Protocols which we have found useful for evaluating such effects are also included below (Sect. 3.3).

3.1.6 Choice of Animal Species

Most of the core battery studies can be performed in the mouse or the rat. The protocols described below provide the rat version and have been standardized in our own laboratory using male Wistar rats weighing between 150 and 250 g at the beginning of the experiments, depending on the tests. Apart from general observation procedures, where the behavioral repertoire in the rat is richer than that in the mouse, there is no theoretical reason for preferring the rat. On the other hand, the rat is the species of choice for many other areas of drug development (chronic treatment studies, toxicology, biochemistry, pharmacokinetics). It is therefore preferable to use the rat for CNS core battery studies to ensure a maximum of coherence with other available data. Although the mouse is clearly more economical both in terms of cost and the quantity of test substance required for carrying out the experiments, such considerations are less relevant later in the drug development process (just before phase I), where larger quantities of test substance are available and the costs of such experiments are minor in comparison with other development costs.

For supplementary studies, the rat remains the species of choice. A possible exception is the use of primates which can be used under certain conditions as discussed in Sect. 3.3 for assessment of abuse potential (Moser et al. 2011b). The reason is not that drug effects clearly differ between the species, but more because primates are closer to man in terms of active doses and pharmacokinetics, thereby increasing predictability in areas of more complex CNS function.

3.1.7 Route of Administration

Test substances can be administered by different routes of administration. ICH S7A guidelines suggest that safety pharmacology studies should be performed using the same route of administration as that intended in man. Because in most cases drugs are administered by the oral (p.o.) route, the p.o. route is used most frequently for CNS core battery studies. On the other hand, there is no guarantee that rats have similar absorption and metabolism to man via the oral route. Indeed, some drugs, for example, the antipsychotics haloperidol or sulpiride, are poorly absorbed in the rat after oral administration but are given orally in man. The risk of poor absorption in the rat might indeed provide a justification for using a more effective route, intravenous (i.v.), intraperitoneal (i.p.), or subcutaneous (s.c.), for safety pharmacology studies, where the aim is to establish potential risk. Thus, showing an absence of adverse effect by a pharmacologically sensitive route should in principle provide the best estimate of safety.

3.1.8 Statistical Analyses

The aim of safety pharmacology is the detection of risk. It is therefore essential not to miss elements which could compromise the safety of a potential therapeutic agent. In other words, the number of false negatives should be kept to a minimum. False positives (erroneous detections of possible risk), although troublesome, are less serious and can usually be corrected by supplementary testing.

Translated into statistics, this implies that for safety pharmacology, the risk of type 2 errors (false negatives) should be decreased as much as possible, even if there is an increase in the risk of type 1 errors (false positives). In other words, the statistical tests

employed in safety pharmacology should err in the direction of oversensitivity rather than the reverse. A test substance found not to have significant safety risks based on preclinical studies, even after the use of oversensitive statistics, is more likely to be truly devoid of risk. As a consequence, the statistical analyses proposed for the CNS safety procedures described below (mainly two-by-two comparisons with control using Student's *t* tests) have been selected for maximal sensitivity to possible effects per dose at the acknowledged risk of making more type 1 errors. More conventional statistical procedures such as use of analysis of variance (ANOVA) followed by post hoc tests for two-by-two comparisons can also be used. Nevertheless, use of a too strict statistical procedure may generate false-negative results which are to be avoided in studies designed to detect risk.

3.1.9 Ethical and Animal Welfare Issues

As with all procedures involving living animals, important considerations in the choice of method are the ethical issues surrounding it. Most regulatory bodies have made pronouncements on this subject, and the reader should consult these documents for more detailed information. However, the guiding principles are to use as few animals as necessary and to avoid stressful procedures as much as possible.

In the field of safety pharmacology, where the aim is to assess the risk of inducing unwanted effects, the possibility of causing animal distress is potentially higher than in other areas of pharmacology. This is particularly true for CNS safety pharmacology studies which use primarily intact and conscious animals. The experimenter must therefore maintain awareness of these issues, not only in planning and devising the protocols but also during the experiments, where procedures for stopping the experiment in the event of well-defined events (e.g., pain or death) should be in place. Conditions should be fixed in advance such that these events are absent or exceptional and allow decisions to be made to stop the experiment if they occur.

Safety pharmacology generally uses larger group sizes than efficacy pharmacology, and it is important that the results are sufficiently reliable for regulatory decisions to be made. However, in some circumstances, methods exist to reduce animal use while at the same time maintaining scientific validity. One example is the supplanting of the traditional LD50 acute toxicity test, which uses a large number of animals to obtain very limited data. Similar data, with fewer animals and considerably more information, can be obtained using the Irwin procedure.

The test procedures described below have been selected and conceived to comply with the ethical requirements outlined above.

3.2 CNS Core Battery Studies

This section describes basic protocols satisfying ICH S7A recommendations for core battery CNS studies. Included are protocols for measuring general behavioral signs induced by test substances (Irwin test), effects on spontaneous locomotion (activity meter

test), effects on neuromuscular coordination (rotarod test), effects on the convulsive threshold (electroconvulsive shock (ECS) threshold and PTZ seizure tests), interaction with hypnotics (barbital interaction test), and effects on the pain threshold (hot plate test).

3.2.1 Irwin Test

PURPOSE/RATIONALE

The primary aim of the Irwin test, first described in the mouse by Irwin (1968) but easily adapted to the rat, is to evaluate the qualitative effects of the test substance on behavior and physiological function, from the first doses that have observable effects up to doses which induce clear behavioral toxicity or even death. The Irwin test also permits a reasonable estimate of the test substance's duration of action on the different parameters observed.

Because most measures involve subjective assessment of different aspects of the animal's behavior, the test must be performed in a highly standardized manner by well-trained observers to ensure reproducible findings on different occasions or at different observation times on the same day. Indeed, because of systematic changes in the behavior and reactions of test animals over a test day, drug-treated animals are always evaluated with reference to a simultaneously treated group of vehicle controls under nonblind conditions to gauge whether an observed effect is truly a consequence of treatment with the test substance.

PROCEDURE

Rats are administered the test substance and are observed simultaneously with a control group given vehicle. Although the test treatment can be blinded, the observer is always aware of which group received vehicle. All treated groups are compared with the same control simultaneously, with two or three animals within a treatment group observed at any one time.

Behavioral modifications, physiological and neurotoxicity symptoms, rectal temperature, and pupil diameter are recorded according to a standardized observation grid derived from that of Irwin. The grid contains the following items: death, convulsions, tremor, Straub tail, decrease in general activity, increase in general activity, jumping, abnormal gait (rolling, tiptoe), motor incoordination, altered muscle tone, loss of grasping, akinesia, catalepsy, loss of traction, loss of balance, forepaw treading, writhing, piloerection, stereotypies (sniffing, chewing, head movements), head twitches, scratching, altered respiration, aggression, altered fear, altered reactivity to touch, ptosis, exophthalmia, loss of righting reflex, loss of corneal reflex, analgesia, defecation/diarrhea, salivation, lacrimation, rectal temperature (hypothermia/hyperthermia), and pupil diameter (myosis/mydriasis). Further details of the evaluation of the signs/symptoms are provided in the following table (Table 3.1).

Observations are performed 15, 30, 60, 120, and 180 min after administration of the test substance and also 24 and 48 h later. The symptoms marked (*) are observed continuously from 0 to 15 min after administration. Depending on the pharmacokinetic properties of the test substance, observations can be conducted at shorter or longer times after administration.

Six rats are studied per group.

The test substance is usually evaluated at four doses, administered p.o. immediately before the test. For safety pharmacology studies, the lowest dose is close to the therapeutic dose as estimated in tests predictive of the indication, and the highest dose can be 100 or 300 times this dose if the substance's toxicity or physical characteristics permit administration of such a dose.

EVALUATION

Being mainly a qualitative assessment procedure, no formal statistical analysis is conducted. Most symptoms are evaluated by their presence or absence. Some (increased or decreased activity) are rated on a 3-point scale. Others (respiration, fear/startle, reactivity to touch) are scored in two directions. Finally, certain parameters (rectal temperature, pupil diameter) are measured quantitatively.

CRITICAL ASSESSMENT OF THE METHOD

The Irwin test serves at both ends of the drug discovery/development spectrum.

In the exploratory phase of drug development, it is frequently the first test employed in vivo. During this phase, the purpose of the test is to provide a rapid detection of the test substance's toxicity, active dose range, and principal effects on behavior and physiological function. A first estimate of safety is provided by the difference between the first doses inducing observable effects and those inducing frank behavioral

Table 3.1 Symptoms observed during the Irwin test in the rat

Symptoms	Observations
*Death**	Presence
	Indicate the time of death if <15 min
*Convulsions**	Presence
	Indicate the time of appearance if <15 min
*Tremor**	Presence
	Whole or part of body trembling
*Straub tail**	Presence
	Rigid tail held upright and tending to curve over the back of the animal
Decreased activity	Three intensities: +: After removing the cage cover and manipulation, the animal moves more slowly than controls ++: Under the same conditions, the animal moves very slowly +++: Under the same conditions, the animal does not move at all
Increased activity	Three intensities: +: After removing the cage cover and manipulation, the animal is slightly more active than controls ++: Under the same conditions, the animal moves rapidly (frequently stopping) +++: Under the same conditions, the animal moves very rapidly (occasionally stopping)
*Jumping**	Presence
*Abnormal gait**	Presence
	For example, Rolling gait. Motor coordination preserved, occasional staggering
	Locomotion on tiptoe
*Motor incoordination**	Presence
	Motor coordination impaired. Disorganized locomotion (e.g., crossing of paws, etc.)
Altered abdominal muscle tone	Increase (↑) or decrease (↓)
	Hardness or softness of the abdomen when pressed laterally between forefinger and thumb is compared with controls.
Loss of grasping	Presence
	When placed on a horizontal wire grid, the animal does not grasp grid when pulled backward by the tail
Akinesia	Presence
	When placed on a wire grid, the animal does not move when the grid is progressively moved toward a vertical position (about 30°)

(*continued*)

Table 3.1 (continued)

Symptoms	Observations
Catalepsy	Presence
	When placed in Buddha position (upright posture on its hind paws), the animal does not move
Loss of traction	Presence
	When placed on a horizontal bar by the forepaws, the animal fails to bring its hind paws up onto a second bar placed below the first one (three trials maximum)
*Loss of balance**	Presence
	Motor coordination impaired. The animal falls on its side when it moves
*Forepaw treading**	Presence
	Repeated stamping of forepaws without displacement
*Writhing**	Presence
	Coordinated contraction of abdominal muscles usually resulting in hollow flanks and stretching of hind limbs
*Piloerection**	Presence
	Fur standing on end
*Stereotypy**	Presence
	Abnormal repeated movements: Sniffing Chewing Head movements
*Head twitches**	Presence
	Rapid saccadic side-to-side axial movement of the head
*Scratching**	Scratching with fore- or hind paws anywhere on the body
*Altered respiration**	Increase (↑) or decrease (↓)
	Respiration rate is compared with controls
*Aggression**	Presence
	Biting attempts when approached toward head with a ballpoint pen
	Biting attempts toward the other animals or toward the experimenter
Altered fear/startle	Increase (↑) or decrease (↓)
	Animal's reaction (flinch, jump...) when fingers are snapped above cage is compared with controls
Altered reactivity to touch	Increase (↑) or decrease (↓)
	Animal's flight reaction to downward finger pressure on the hindquarters is compared with controls
Ptosis	Presence
	Eyelid partially or completely closed
Exophthalmia	Presence
	Protrusion of the eyeballs

(*continued*)

Table 3.1 (continued)

Symptoms	Observations
Loss of righting reflex	Presence
	When placed on its back, the animal does not right itself
Loss of corneal reflex	Presence
	When the corneal surface is lightly touched with the tip of a pen, the animal does not close eye
Analgesia	Presence
	When pinched at base of tail with forceps, the animal does not react (turning toward forceps, vocalization)
Defecation/ diarrhea	Presence
Salivation	Presence
	Dampness visible around mouth
Lacrimation	Presence
	Dampness visible around eyes
Hypothermia	Three levels based on mean temperature measured in treated and control animals: +: Decrease >1°C ++: Decrease >2°C +++: Decrease >3°C
Hyperthermia	Three levels based on mean temperature measured in treated and control animals: +: Increase >1°C ++: Increase >2°C +++: Increase >3°C
Myosis	Three levels based on mean pupil diameter measured in treated and control animals (1 unit = 1/30 mm): +: Decrease >10 units ++: Decrease >20 units +++: Decrease >30 units
Mydriasis	Three levels based on mean pupil diameter measured in treated and control animals: (1 unit = 1/30 mm) +: Increase >10 units ++: Increase >20 units +++: Increase >30 units

toxicity or lethality. Even when the test substance is intended for a nonpsychotropic indication, the Irwin test permits the choice of doses for subsequent tests. Furthermore, the Irwin test can frequently permit identification of the kind of activity exerted by the test substance in the psychotropic domain. As is illustrated in Figs. 3.1 and 3.2, clearly distinct and identifiable profiles are observed with drugs such as the antipsychotic haloperidol and the analgesic morphine.

Data obtained in the Irwin test can be grouped into major categories related to effects on general activity (decrease/increase), motor behavior/coordination, modification of pain threshold, autonomic signs, or other effects. Figure 3.1 provides an example of such a representation comparing the effects of amphetamine with the effects of diazepam. The modified presentation gives a more visual representation of the main effects of each substance and their duration of action, thereby facilitating comparison between substances.

At later stages of drug development (before phase I), when the test substance has been more fully characterized, the Irwin test provides a clear overall index of the test substance's margin of safety. Furthermore, although the test is mainly behavioral, it can give global indications of drug effects on vital functions such as respiration or intestinal motility. On the other hand, the test provides little information about effects which are not visible from direct observation, including the whole range of cardiovascular, pulmonary, and gastrointestinal parameters.

MODIFICATIONS TO THE METHOD

The Irwin test, although originally described in the mouse, was later applied to the rat (Esteve et al. 1988). Indeed, the principle of systematic observation of drug-induced symptoms using standardized observation criteria can be applied to a wide range of animal species and even constitutes the basis of symptom checklists in man. Every laboratory has its own manner of doing the Irwin test. That described above is what we have been practicing for over 20 years. ICH S7A simply requires that animals be observed on a systematic basis over a wide dose range. Alongside variants of the Irwin procedure, ICH S7A mentions another systematic observation procedure, the functional observation battery (FOB) more recently described by Mattson et al. (1996) as being functionally equivalent. This test, derived from classical toxicology, is more specifically used for testing neurotoxicity.

Example. Table 3.2 The profile of effects of diazepam (p.o.) in the Irwin test in the rat. Note the dose-dependent increase in decrease in general activity and decreases in reactivity to touch, traction, and muscle tone accompanied by abnormal gait

Observations were performed at 15, 30, 60, 120, and 180 min and at 24 h after administration. The symptoms which did not necessitate handling were also observed up to 15 min immediately following administration. Pupil diameter and rectal temperature modifications were evaluated by comparison of the mean scores obtained in treated and control animals.

Table 3.3 The profile of effects of caffeine (i.p.) in the Irwin test in the rat. Note the dose-dependent occurrence of increase in general activity followed by stereotypies (sniffing, head movements, head twitches), increased fear/startle, and reactivity to touch.

3.2.2 Activity Meter Test

PURPOSE/RATIONALE

Locomotor activity can be quantified in rodents by a variety of means. The method described below uses interruptions of photoelectric beams and is based on studies from Boissier and Simon (1965). The difference between Irwin estimations of drug effects on spontaneous activity and activity meter tests is mainly a question of quantification. Activity meter tests are generally carried out using automated apparatus with a larger number of animals and are, therefore, less labor intensive but permit more precise statistical analyses. The quantitative data obtained enable the generation of

contained within a darkened enclosure and connected to silent electronic counters. Each cage is equipped with four photocell assemblies (two at each end of the cage) 3 cm above the floor to measure the number of movements by each animal (one per cage) in the horizontal plane. Ten additional photocell assemblies are placed at even intervals 20 cm above the floor along the long wall to record rearing. The number of (horizontal)

crossings by each animal (one per cage) from one pair of photocells to the other at the extremities of the cage is recorded by computer at 10-min intervals for 40 min. A similar procedure is utilized for recording of rearing, except that individual photobeam breaks are recorded. The scores are cumulated over the (1) 0–20-min period, (2) 20–40-min period, and (3) entire 40-min observation period.

Ten rats are studied per group. The test is performed blind.

The test substance is usually evaluated at four doses, administered p.o. 60 min before the test, and compared with a vehicle control group.

Caffeine (24 mg/kg p.o.) and chlorpromazine (16 mg/kg p.o.), administered under the same experimental conditions, are used as reference substances.

The basic experiment therefore includes seven groups.

EVALUATION

The basic measure taken is the global effect of the test substance over the whole measurement period. More detailed information can be obtained by analyzing the drug effects over sequential time slots, for example, every 10 min. For example, some drugs (diazepam, nicotine) attenuate high activity levels (first 10 min) but increase low levels (last 10 min). Further analyses can compare the effects of the test substance on rearing with its effects on locomotion within the enclosure. Finally, comparison of single photobeam interruptions with paired interruptions of the beams at each end of the enclosure can permit distinctions between drug effects on small and large movements.

The data are usually analyzed using Student's *t* tests.

CRITICAL ASSESSMENT OF THE METHOD

Locomotion tests estimate whether a test substance possesses psychostimulant or sedative activity, but the data obtained must be interpreted with caution. Locomotion can be decreased not only because the animals are sedated but also because the animals have drug-induced motor impairment or are otherwise debilitated by the test substance. Even substances with marked psychostimulant properties can decrease activity meter scores because the animals are rotating rapidly in a small space or are showing other stereotyped behaviors. It is therefore unwise to interpret activity meter scores in isolation from direct observation (Irwin test above) or measures of neuromuscular coordination (rotarod test below).

Another complication with activity meter tests is the phenomenon of habituation. All animals placed in an unknown environment will tend to explore it more at the beginning of the exposure with a decline in exploration with time. This can be clearly seen in most activity meters despite the apparent simplicity of the test environment. Thus, when locomotion is followed over sequential time slots, an apparent increase or decrease in drug effect over time cannot simply be interpreted as a change in its pharmacological activity. The substance may be interacting with the process of habituation. It is for this reason that activity meters are not the ideal means of measuring the duration of drug action.

Because the activity meter evaluates spontaneous behavior, the behavioral baseline is intrinsically variable and subject to many kinds of influence, including lighting, apparatus cleanliness, ambient temperature, noise level, and even time of day. As a consequence, particular care has to be taken to ensure constant experimental conditions to obtain reproducible results. Furthermore, when comparing different drug treatments, it is important to take advantage of the fact that several animals can be evaluated simultaneously, by distributing the different treatments in a balanced fashion over the test period, and even in the positions within the experimental apparatus or of the observation chambers in the experimental room.

MODIFICATIONS TO THE METHOD

Locomotor activity can be quantified in rodents by a variety of means, including interruptions of photoelectric beams, activity wheels, changes in electromagnetic fields, Doppler effects, video image analysis, telemetry, or detection of vibrations generated by the animals (Reiter and McPhail 1979; Lynch et al. 2011). As has been suggested above, it is not very important how locomotion is measured because the main outcome measure is whether a test substance increases or decreases spontaneous locomotion.

More important is the time at which a test substance is administered in relation to placing the animal in the activity meter. Because of potential interactions of the test substance with the process of habituation, we think it is important to start testing when the drug effect has had time to reach its maximum, i.e., a certain interval after drug administration. If the animal is treated and

immediately placed in the activity meter, the kind of drug effect observed may critically depend on the interaction of the onset of drug action with the habituation process.

Another procedural variant, aimed to minimize the role of habituation, is to prehabituate the animal to the environment before administering the test substance. In this way, it is hoped to assess drug action on "baseline" behavior in already habituated animals. This approach appears to be a reasonable one but considerably increases the time and costs for conducting the test. Furthermore, there are cases where drug effects are dramatically attenuated in prehabituated animals. In particular, this approach is much less sensitive to drug-induced decreases in motor activity.

Example (See Fig. 3.2).

3.2.3 Rotarod Test

PURPOSE/RATIONALE

Locomotor coordination is most commonly assessed using a rotarod (Dunham and Miya 1957). The rotarod consists of a circular rod turning at a constant or increasing speed. Animals placed on the rod will naturally try to remain on the rod rather than fall onto a platform some 30 cm below. This test therefore provides an estimate of the animal's level of neuromuscular coordination. Drugs which are known to perturb neuromuscular coordination (e.g., benzodiazepines) clearly reduce the time the animals stay on the rod.

This test lends itself readily to automation with several animals being tested simultaneously on the same rod, each animal being separated by vertical barriers.

PROCEDURE

3.2.3.1 Habituation

Rats are placed on a rod (diameter 7 cm) rotating at a speed of 12 revolutions per minute for a 2-min period. If they fall off during this period, they are replaced on the rod. At the end of the habituation period, rats are placed on the rod under the same conditions as used during the test session (i.e., for a maximum of 3 min) and are not replaced on the rotarod if they fall off.

3.2.3.2 Test

The test session is performed at least 2 h after the habituation period. Rats are placed on the rotarod for a maximum period of 3 min. The number of animals which fall off before the end of this period is counted, and the latency to fall off is recorded (maximum 3 min).

Ten rats are studied per group. The test is performed blind.

The test substance is usually evaluated at four doses, administered p.o. 60 min before the test, and compared with a vehicle control group.

Diazepam (8 mg/kg p.o.), administered under the same experimental conditions, is used as reference substance.

The basic experiment therefore includes six groups.

EVALUATION

Two basic measures are taken, the number of animals per group which fall off the rod within the 3 min test and the drop-off times. The quantal data (number of animals falling) are analyzed using Fisher's exact probability test. The quantitative data (drop-off times) are analyzed using Student's *t* tests.

CRITICAL ASSESSMENT OF THE METHOD

The rotarod test is one of the oldest used in the behavioral assessment of drug action (Rustay et al. 2003). It provides a simple first estimation of whether a test substance has any effect on neuromuscular coordination and has been found sensitive to a variety of agents which are known to disturb it, for example, the benzodiazepines.

When preceded by the habituation procedure (described above), the test is very reliable and reproducible. Generally speaking, the doses impairing rotarod performance are higher than those affecting locomotor activity, except for drugs having particular effects on

motor coordination (notably, the benzodiazepines). Furthermore, in contrast to the activity meter test, the rotarod test is not particularly sensitive to environmental factors such as lighting, ambient temperature, or noise. This is no doubt due to the fact that the test imposes a behavior on the animal (staying on the rod), where the consequences of falling are mildly aversive.

On the other hand, the rotarod test can be considered only as an initial screen for neuromuscular impairment. More complex tests, for example, analyses of gait, are required to further understand the motor aspects, whereas electrophysiological procedures, for example, the electromyogram (EMG), are required for better understanding the neuromuscular aspects.

In contrast to most of the other core battery CNS tests, the rotarod is mainly unidirectional, detecting principally the capacity of substances to decrease neuromuscular coordination. On the other hand, this is not a serious limitation in that the risk factor evaluated is whether the test substance causes impairment. When used in conjunction with locomotor activity tests, the rotarod test provides a useful quantification of the margin of safety between doses of test substances which alter spontaneous activity and those which disturb motor function.

MODIFICATIONS TO THE METHOD

The sensitivity of the rotarod test can be increased by placing animals on a rod turning at an accelerating speed to measure the latency to fall (Bohlen et al. 2009). This procedure has been shown to provide a more graduated assessment of the motor-impairing effects of various anticonvulsants and benzodiazepines (Capacio et al. 1992).

3.2.4 Convulsive Threshold Tests

PURPOSE/RATIONALE

Tests for the convulsive threshold estimate whether a test substance induces changes in the probability of convulsions occurring either spontaneously or, more importantly, in association with other treatments (Lynch et al. 2010). Although overt convulsions can usually be detected using the Irwin procedure, proconvulsant activity can occur in the absence of overt convulsions and therefore needs to be evaluated in specific tests. The existence of anticonvulsive activity is less dramatic as a risk factor. Nonetheless, as suggested in the "General Considerations" above, such activity might be an indicator of potential cognitive disturbance. There is therefore a need, in CNS safety pharmacology, to include procedures which assess changes in the convulsive threshold in both directions.

Described below are two procedures whereby convulsions are induced either electrically (ECS threshold test), following Swinyard et al. (1952), or chemically (PTZ seizure test), following Krall et al. (1978). We recommend using two methods for inducing convulsions because of considerable past experience showing that congruent findings are not always obtained between the two methods. In terms of predictability, it seems important to obtain coherent findings between different means of inducing convulsions before concluding as to the presence or absence of risk.

PROCEDURES

3.2.4.1 ECS Threshold Test

Rats are administered ECS (rectangular current, 1.5 s, 200 Hz) via earclip electrodes connected to a constant current shock generator (Ugo Basile Type 7801).

Treatment groups of 20 rats are exposed to ECS as follows:

Animal n°1 is exposed to 30 mA of ECS. If animal n°1 does not convulse (tonic convulsions) within 5 s maximum, animal n°2 is exposed to 35 mA, with increases of 5 mA until the first tonic convulsion is observed. Once the first tonic convulsion is observed, the intensity of ECS is decreased by 2 mA for the next animal, and then the intensity is decreased or increased by 2 mA from animal to animal, depending on whether the previous animal convulses or not. If animal n°1 does convulse (tonic convulsions) within 5 s maximum, animal n°2 is exposed to 25 mA, with decreases of 5 mA until the absence of tonic convulsions is observed. At this point, the intensity of ECS is increased by 2 mA for the next animal, and then the intensity is decreased or increased by 2 mA from animal to animal, depending on whether the previous animal convulses or not. The minimum intensity given is 5 mA, and the maximum intensity given is 95 mA.

The first five animals, which serve to identify the threshold current, are not included in the analysis.

The results are represented as the mean current intensity administered to the final 15 animals of a group and as the percent change from control values.

The test is performed blind.

A positive percent change indicates an anticonvulsant effect. A negative percent change indicates a proconvulsant effect.

The test substance is usually evaluated at four doses, administered p.o. 60 min before ECS, and compared with a vehicle control group.

Theophylline (128 mg/kg p.o.) and diazepam (16 mg/kg p.o.), administered under the same experimental conditions, are used as reference substances.

The basic experiment therefore includes seven groups.

3.2.4.2 PTZ Seizure Test

Rats, placed in individual Makrolon cages (25 × 19 × 13 cm), are injected with PTZ (75 or 100 mg/kg s.c.). The occurrence and latency of clonic convulsions, tonic convulsions, and deaths are noted over a 30-min period.

The results for the number of convulsions and deaths are also represented as percent change from control.

Twenty rats are studied per group. The test is performed blind.

The test substance is usually evaluated at four doses, administered p.o. 60 min before PTZ, and compared with a vehicle control group.

Theophylline (128 mg/kg p.o.) or diazepam (16 mg/kg p.o.), administered under the same experimental conditions, is used as the reference substance.

The basic experiment therefore includes six groups.

EVALUATION

ECS, if sufficiently intense, induces immediate full clonic-tonic convulsions but only occasionally death. In contrast, with PTZ, clonic convulsions can be observed without necessarily being followed by tonic convulsions. On the other hand, when tonic convulsions occur, they are almost invariably followed by death.

With the ECS procedure, the primary measure is the mean electroshock intensity administered per group of 20 animals. If less current is required to induce a clonic-tonic convulsion after a particular treatment, this is reflected by a decrease in the mean intensity administered (proconvulsant effect). Conversely, if more current is required to induce a clonic-tonic convulsion, this is reflected by an increase in the mean intensity (anticonvulsant effect). In other words, the mean intensity administered is a direct representation of the electroconvulsive threshold.

With the PTZ procedure, pro- or anticonvulsant activity is indicated both by the frequency of the convulsant events (clonic convulsions, tonic convulsions,

deaths) and by their latency of occurrence. The cut-off time is indicated when a test substance completely blocks convulsions.

The ECS threshold procedure permits the assessment of both pro- and anticonvulsant activity within a single experiment. To evaluate proconvulsant risk in the PTZ test, a moderate dose of PTZ (75 mg/kg) is used to induce clonic and tonic convulsions in half the control animals and is validated by showing a significant difference with animals treated with theophylline. Conversely, for evaluating anticonvulsant activity, a higher dose of PTZ (100 mg/kg) is used to induce convulsions in all control animals. The experiment is validated with diazepam which completely suppresses convulsions.

In both procedures, quantitative data (mean shock intensity, latencies) are analyzed using ANOVA followed by planned post hoc comparisons, as appropriate. In the PTZ procedure, quantal data (number of occurrences) are analyzed using Fisher's exact probability test.

CRITICAL ASSESSMENT OF THE METHOD

It is generally accepted that there is a good correlation between potentiation or antagonism of experimentally induced convulsions in animals and effects observed in man (Kupferberg 2001). Most substances with antiepileptic properties in man antagonize experimental convulsions, whereas many substances which either induce convulsions or lower the convulsive threshold in man (certain CNS stimulants, some antipsychotics) show similar effects in animals. There are nonetheless differences in the efficacy of certain substances in antagonizing experimental convulsions. Drugs, identified by ECS generally act by modulating voltage-dependent sodium channels, whereas drugs identified by PTZ generally have a benzodiazepine-like mode of action, potentiating the inhibitory effects of GABA (Löscher 2002).

The existence of such differences is an argument for employing at least two different methods in a core battery for evaluating drug effects on the convulsive threshold. If signs of risk are apparent, further models can be employed to establish either the mechanism or the anatomical locus in the brain. To establish mechanisms, use can be made of different convulsive agents (strychnine, bicuculline, picrotoxin, NMDA). As far as anatomical locus is concerned, the kindling model can be used with recordings taken from different brain regions (amygdala, temporal lobe, hippocampus, prefrontal cortex) to establish the development and regional distribution of the convulsive phenomena (Ebert et al. 1997). The simple EEG trace recording from the cortex is also useful for identifying the existence of convulsive brain phenomena at doses inducing no overt behavioral effects. Signals from the cortex are sometimes recorded in parallel with the electromyographic techniques or by observation of the behavior of animals by video EEG to compare the changes in brain activity with the intensity of the overt seizure.

MODIFICATIONS TO THE METHOD

The ECS method described above involves titration of the shock level between successive test animals to determine the mean intensity required to induce convulsions after different treatments. This procedure represents a variant of the more habitual procedure where a set level of ECS is selected to induce convulsions in 100% of the animals (maximal electroshock). Another variant would be to select a low electroshock level (subconvulsant) to detect proconvulsant activity. In addition to evaluating both pro- and anticonvulsant activity within a single test, the present method possesses the advantage of generating quantitative data (mean intensity) as opposed to quantal data (frequencies), permitting more powerful statistical analyses.

Another ECS method evaluates the intensity needed to induce tonic convulsions in different groups of animals challenged with electroshocks of preselected intensities inducing seizures in 10–30%, 30–50%, 50–70%, and 70–90% of the animals. The median current strength (CS50) represents the current intensity required to induce tonic hind limb extension in 50% of animals.

The intravenous PTZ infusion seizure test is a modified version of the PTZ test and can be used to assess proconvulsant drug activity (Löscher 2009). The dose of PTZ needed to induce convulsions is determined for each animal. This test provides a sensitive parametric method for assessing seizure threshold in individual animals (White et al. 2008).

3.2.5 Barbital Interaction Test

PURPOSE/RATIONALE

Although not included in the ICH S7A core battery, simple tests evaluating the interaction between test substances and hypnotics can usefully be included in a CNS core battery. The additional expense is minimal, whereas such procedures provide useful information not provided by the other tests. For example, several substances with psychostimulant activity (caffeine, modafinil) induce frank signs of increase in general activity at higher doses, whereas this kind of activity can be detected at lower doses when tested by interaction with a barbiturate. Similarly, sleep-enhancing effects can be readily detected in barbiturate interaction procedures by many substances, for example, benzodiazepines and antipsychotics, which do not induce sleep even at very high doses when administered alone. Thus, interaction tests with barbiturates can serve to unmask stimulant or sedative activity not otherwise readily apparent. Furthermore, there is a high correlation between the effects observed in such procedures and those observed in more complex tests and in man.

A further consideration is which barbiturate to employ. We recommend the use of barbital because this substance, in contrast to many other barbiturates, undergoes no metabolism (Remmer 1972; Simon et al. 1992). For this reason, results obtained can be more readily interpreted in terms of a pharmacological interaction without confounding by pharmacokinetic or metabolic factors.

PROCEDURE

Rats, placed in individual Makrolon cages (25 × 19 × 13 cm), are injected with barbital sodium (150 mg/kg i.p.). The latency to sleep and the duration of sleep (maximum 6 h after barbital injection) are then recorded. Sleep is indicated by loss of the righting

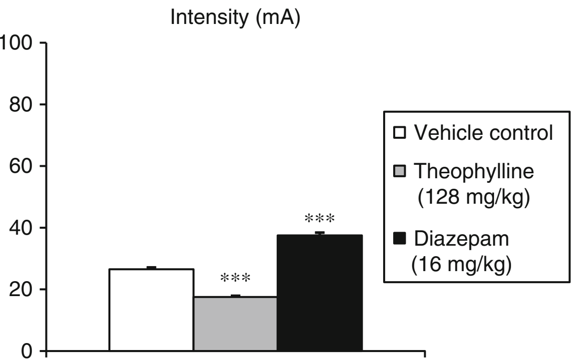

Fig. 3.4 Effects of theophylline and diazepam (p.o.) on the mean shock intensity required to induce tonic convulsions following ECS in the rat

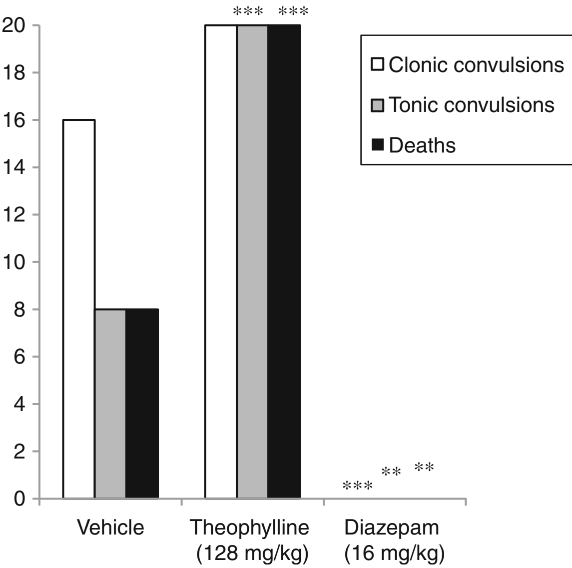

Fig. 3.5 Effects of theophylline and diazepam (p.o.) on the number of clonic convulsions, the number of tonic convulsions, and the number of deaths induced by PTZ in the rat

reflex. To avoid disturbing the experiment, no righting reflex test is performed before 50 min has elapsed after barbital injection (i.e., minimum sleep latency = 50 min).

Ten rats are studied per group. The test is performed blind.

The test substance is usually evaluated at four doses, administered p.o. 60 min before barbital, and compared with a vehicle control group.

Caffeine (16 mg/kg p.o.) and diazepam (8 mg/kg p.o.), administered under the same experimental conditions, are used as reference substances.

The basic experiment therefore includes seven groups.

EVALUATION

Barbital at 150 mg/kg i.p. induces sleep in 100% of the animals. The two principal parameters measured are the latency to sleep and the duration of sleep which are analyzed for statistical significance using Student's *t* tests. In addition, the number of animals sleeping is counted, and differences from control are then analyzed using Fisher's exact probability test.

A statistical problem arises when the test substance completely blocks sleep in some of the animals. In such cases, we recommend that parametric statistics be applied to the latency and duration data as long as a minimum of four animals show sleep, to avoid score bias by inclusion of floor and ceiling effects.

CRITICAL ASSESSMENT OF THE METHOD

For the reasons given in the "Purpose/Rationale" section above, barbiturate interaction tests yield useful information not readily provided by the other procedures in the core battery. Furthermore, the data obtained are highly correlated with results that could be expected in man. To our knowledge, no sleep-enhancing agent used in man has been found inactive in a barbiturate interaction procedure. Conversely, no clinically known enhancer of wakefulness, for example, caffeine, amphetamine, and modafinil, has failed to reduce or abolish barbiturate-induced sleep. Potential to cause drowsiness, as is observed with many antihistamines, is also clearly picked up in barbiturate interaction procedures as are the potential sedative effects of a variety of antipsychotics. The procedure therefore possesses high predictive validity.

On the other hand, this procedure does not provide information about drug effects on the components of sleep, for example, paradoxical versus slow-wave sleep, or on the cyclical changes which can occur during natural sleep over longer periods (24 h).

Although procedurally simple, barbiturate interaction procedures are extremely subject to small environmental changes (lighting, ambient noise and temperature, time of day) and therefore have to be performed under particularly highly controlled conditions to yield reproducible results.

MODIFICATIONS TO THE METHOD

Being one of the long-time standards in basic psychopharmacology, there are few major variants to the procedure apart from the kind of barbiturate employed. Several undergo clear hepatic metabolism, for example, pentobarbital and phenobarbital, thereby confounding interpretations because of pharmacokinetic and metabolic factors. Indeed, one modification of the method has been specifically employed to estimate enzyme induction in the liver, as indicated by more rapid barbiturate metabolism. Animals given a preexposure to a test substance are then exposed to a standard dose of phenobarbital (80 mg/kg i.p.) 24 h later and assessed for sleep duration. The presence or absence of a decrease in sleep duration is taken as an index of the hepatic enzyme induction produced by the test substance (Kushikata et al. 2003).

3.2.6 Hot Plate Test

PURPOSE/RATIONALE

The hot plate test (Eddy and Leimbach 1953) is a simple behavioral screen for estimating the effects of test substances on the threshold for pain sensitivity. It is based on the principle that rodents, placed onto a hot surface, will demonstrate the aversive effects of the stimulation

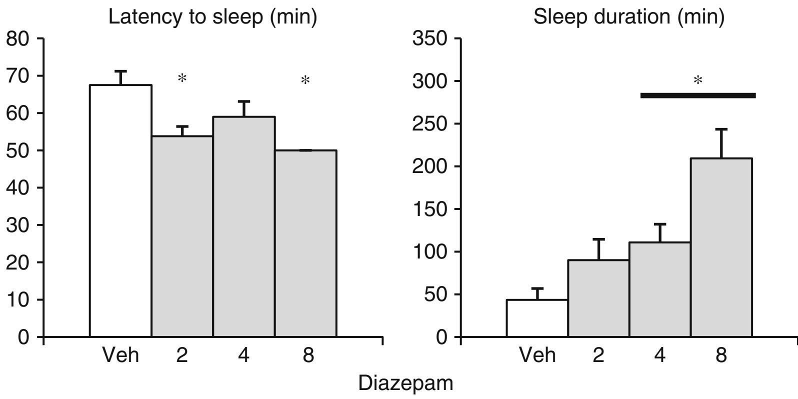

Fig. 3.6 Effects of diazepam (p.o.) on the duration of sleep induced by barbital in the rat. Administrations were performed 60 min before the test. *Different from vehicle control

first by licking their paws and subsequently by clear attempts to escape the situation (jumping). Substances changing the nociceptive threshold will either increase the latency to licking/jumping (analgesic effect) or decrease it (hyperalgesic effect).

PROCEDURE

Rats are placed onto a hot metal plate maintained at 52°C surrounded by a Plexiglas cylinder (height 26 cm; diameter 19 cm) (Apelex Model DS37). The latency to the first foot lick is measured (maximum 30 s).

Ten rats are studied per group. The test is performed blind.

The test substance is generally evaluated at four doses, administered p.o. 60 min before the test, and compared with a vehicle control group.

Morphine (128 mg/kg p.o.), administered under the same experimental conditions, is used as reference substance.

The basic experiment therefore includes six groups.

EVALUATION

The principal parameter assessed in the hot plate test is the latency to the first paw-lick response.

Data are analyzed for statistical significance using Student's *t* tests.

CRITICAL ASSESSMENT OF THE METHOD

The hot plate test is one of the most frequently employed screens for evaluating the nociceptive threshold. It is reliable and reproducible and remains robust in the face of moderate environmental variations. Most known analgesic substances show analgesia in the method which can therefore be considered as possessing a reasonable predictive validity. On the other hand, moderate analgesics, in particular those with a primarily anti-inflammatory profile (aspirin, paracetamol, ibuprofen), show less marked effects than major analgesics such as the opioids.

Of the two parameters measured (foot licking, jumping), foot licking appears more sensitive to the analgesic properties of test substances, whereas decreases in jumping can often reflect their locomotor effects. Other screening tests, for example, chemically induced writhing (phenyl benzoquinone, acetic acid), although revealing analgesic activity at lower doses, are sensitive to a wider range of substances and therefore yield more false positives.

The search for hyperalgesic effects is more delicate because standard drugs which cause hyperalgesia are rare and more difficult to demonstrate because of the particular conditions of administration required, for example, topical administration of capsaicin (Yoshimura et al. 2000).

The hot plate procedure possesses an advantage over other methods of thermal stimulation, for example, the tail-flick procedure (d'Amour and Smith 1941), in that it can be applied repeatedly in the same animals over a short period of time (2–3 h) without causing tissue injury, particularly if the maximum observation duration is 30 s. The hot plate procedure also constitutes a more global estimate of nociceptive reactivity because it represents a complex willed behavior rather than a simple reflex like the tail flick.

MODIFICATIONS TO THE METHOD

Different hot plate temperatures have been used, varying from 48°C to 58°C. Lower temperatures are in

principle more useful for detecting hyperalgesic activity. Although consistent with ethical requirements for decreasing pain, lower temperatures produce more variable responding and therefore require more animals to obtain statistically reliable data. A better way of satisfying the ethical requirement is to reduce the total possible duration of the test session. We have found that 30 s is largely sufficient to obtain measurable changes in the foot-licking latency in both directions.

Higher temperatures, although producing less variable data, reduce the range of analgesics which can be detected. The analgesic activity of most opioids can almost always be detected, but not milder analgesic activity of agents such as salicylates.

In addition to foot-licking latency, another parameter frequently measured is the latency to jumping attempts to escape from the apparatus. Jumping is less selective as analgesic parameter because it can be influenced by substances without known analgesic activity, but which cause either locomotor stimulation or inhibition, for example, antipsychotics. In our own procedure, with a 30-s cut-off, jumping is not reliably observed during the observation period under control conditions and is, therefore, not a useful parameter.

3.3 Supplementary CNS Studies

Supplementary CNS safety studies are more complex procedures, investigating test substance effects on their potential to cause drug dependence/abuse, cognitive processes, or electrophysiological brain activity. The following section is therefore divided into three subsections dealing with these different areas. As for the core battery studies described above, an essential aspect of CNS supplementary studies is that they are all performed in vivo, in the intact freely moving animal.

3.3.1 Drug Dependence and Abuse

Another subject, clearly within the notion of safety, is the assessment of a novel substance's potential to be abused or to induce dependence (Moser et al. 2011b).

Although dependence and abuse frequently occur together, they are not synonymous (Balster 1991). Drug dependence, as its name implies, refers to the inability of the dependent individual to function normally in the absence of drug. Dependence can be both physical and psychological and is defined by the emergence of withdrawal either upon administration of an antagonist or upon discontinuation of drug treatment. Psychological dependence is indicated by drug-seeking behavior (e.g., craving) that can occur even after long periods of abstinence, whereas physical dependence is demonstrated more objectively by signs ranging from changes in body temperature to life-threatening conditions such as status epilepticus or delirium tremens. Abuse, on the other hand, refers to misuse or overuse of a drug and is indicated

behaviorally by drug seeking and drug taking, many times in the absence of any evidence for physical dependence. The difference between dependence and abuse can be illustrated pharmacologically. For example, drugs such as heroin and alcohol are widely abused, and often their abuse is associated with marked physical and psychological dependence. On the other hand, marijuana and LSD are commonly abused, but typically under conditions where neither physical nor psychological dependence is apparent.

Studies assessing dependence or abuse liability are, in principle, required only for drugs acting on the CNS. Candidates for particular attention are psychostimulants, nicotinics, certain kinds of antidepressants, anxiolytics, sedative-hypnotics, and analgesics. Drugs with psychotomimetic potential also require evaluation, whereas antipsychotic agents are virtually never abused. Safety studies for abuse/dependence liability are rare for substances without CNS activity, although peripherally acting analgesics might also have to come under scrutiny.

The following section will describe protocols for evaluating both dependence and abuse. For reasons of homogeneity with the other procedures presented above, only protocols in the rat will be presented. Although results in the rat are generally similar to those obtained in nonhuman primates, the regulatory authorities, in particular the FDA, prefer primate studies for abuse evaluation because of a presumed increased predictability to man. The active doses and pharmacokinetics are likely to be closer between human and nonhuman primates, as are the kinds of overt behavioral effects observed.

3.3.1.1 Drug Dependence

Tests for drug dependence consist mainly of repeated treatment studies, followed by drug withdrawal, where withdrawal symptoms occur either spontaneously (nonprecipitated withdrawal) or after administration of specific antagonists, for example, naloxone (opioids) or flumazenil (benzodiazepines). Precipitated withdrawal tests are usually the most sensitive and require only very short periods of drug administration for demonstrating withdrawal phenomena. Clear jumping can be induced in mice by administration of the μ-opioid antagonist naloxone after as few as five pretest administrations of low doses of morphine (Saelens et al. 1971). Similarly, a decrease in the convulsive threshold can be induced by administration of the benzodiazepine antagonist flumazenil after as few as two benzodiazepine administrations (von Voigtlander and Lewis 1991). The relationship between these measures of "acute dependence and withdrawal" and the dependence and withdrawal that emerge after extended periods of drug treatment followed by discontinuation of treatment are far from clear. Because such acute tests might be less indicative of dependence potential than of a particular mechanism of action or affinity for a receptor, they will not be discussed further here.

Nonprecipitated Withdrawal Test

PURPOSE/RATIONALE

The aim of nonprecipitated withdrawal procedures is to evaluate whether sudden cessation of drug treatment is associated with the occurrence of identifiable withdrawal symptoms. The kinds of symptoms examined are changes in food intake, body weight gain, body temperature, and the occurrence of one or more overt behavioral and other symptoms, for example, tremor, teeth chattering, wet dog shakes, diarrhea, or piloerection. The occurrence of such signs is a first indication that the test substance induces drug dependence after repeated administration. An important advantage of nonprecipitated withdrawal procedures is that they can be used to evaluate a wide variety of substances, including those for which specific antagonists are not available.

More specific procedures can be employed to assess whether drug withdrawal induces changes in fearfulness, pain sensitivity, convulsive threshold, or even memory. On the other hand, it is frequently difficult to demonstrate effects on these parameters and the tests involved are particularly time-consuming. The procedure described below represents an initial screen which has been shown to be sensitive to several dependence-inducing drugs such as opioids and benzodiazepines (Goudie et al. 1993).

Whereas many CNS safety tests evaluate multiple doses, we recommend the inclusion of just two doses for nonprecipitated withdrawal studies. The low dose should be close to those inducing clear effects in the test predictive of the substance's therapeutic indication. The high dose should be the maximally tolerated dose as determined, for example, from an Irwin test. If it can be shown that the test substance can be repeatedly administered at a maximally tolerated dose under conditions where similar treatment with an appropriately chosen reference substance induces clear withdrawal signs, a reasonable conclusion would be that the test substance is unlikely to cause physical dependence.

PROCEDURE

Rats receive twice daily administrations of the test substance for 20 days (with the last administration on day 20 at about 10:00) and are then subjected to an 8-day observation period without drug treatment during which they are observed for changes in food consumption, body weight, and rectal temperature. In addition, they are observed for behavioral and physiological manifestations (e.g., jumping, tremor, hyperactivity, excessive grooming, and diarrhea). During the pretreatment phase, different groups of animals receive the test substance at two doses and are compared with a vehicle-treated control group.

Twelve animals are studied per group. The test is performed blind.

Morphine (32 mg/kg i.p. or 64 mg/kg p.o.), cocaine (32 mg/kg i.p.), chlordiazepoxide (64 mg/kg p.o.), or diazepam (16 mg/kg i.p.) can be used as the reference substance.

The experiment includes a control group pretreated with the vehicle twice daily for 20 days.

EVALUATION

Before assessing withdrawal effects in the absence of the test substance, it is important to assess the intrinsic effects of the test substance, to see whether repeated treatment itself influences the parameters observed. Body weight, food consumption, body temperature, and the occurrence of behavioral and physiological manifestations are therefore observed during the last 3 days of drug treatment. Changes occurring after cessation of drug treatment can thus be more accurately assessed in relation to the drug effects themselves. Although we recommend doing most behavioral tests blind, this is particularly important for the present procedure where many of the behavioral parameters are assessed subjectively.

Differences from control are evaluated on a day-by-day basis using nonpaired Student's *t* tests.

CRITICAL ASSESSMENT OF THE METHOD

The nonprecipitated withdrawal procedure represents a first screen for possible induction of drug dependence and has been shown to be sensitive to withdrawal effects with a variety of dependence-inducing agents including amphetamines, cocaine, opioids, and benzodiazepines. It therefore possesses face validity. On the other hand, it is remarkably difficult, under the conditions of the protocol described, to show signs of withdrawal after treatment with agents such as nicotine or 9-tetrahydrocannabinol (THC) (unpublished data from our laboratory). While absence of withdrawal effects with THC may reflect the absence of proven drug dependence with cannabinoids in man, the human drug dependence data with nicotine suggest that nicotine dependence does occur.

A principal weakness of the procedure using one, two, or three daily administrations is that the behavioral and physical signs induced are modest and very short-lived (2–3 days). Indeed, under conditions of oral, i.p., or s.c. administration, there are no dramatic manifestations as have sometimes been described in the literature, particularly with opioids (Grasing et al. 1996). Administration by the i.v. route produces more rapid onset of drug action and mirrors more closely human drug abuse behavior, but it is difficult to ensure repeated i.v. administrations or continuous i.v. slow infusion over longer periods (weeks) in rats to obtain the exposure necessary to induce signs of dependence. Certain authors recommend use of osmotic minipumps to ensure a more constant exposure to the test substance and a more abrupt discontinuation by surgical removal at the end of the exposure period (Kalinichev and Holtzman 2003). This has been reported with

nicotine (Semba et al. 2004), although we have not been able to reproduce this data in our own laboratory. A major problem with osmotic minipumps is that they require the test substances to be very soluble, and this is not always the case.

There is no easy way of ensuring that withdrawal from reference substances will induce dramatic behavioral changes. The experimenter is obliged to retain more subtle effects as indices of the dependence potential of the test substance. The method does possess the advantage that it is not mechanism bound and, therefore, may detect dependence-like phenomena with agents having no common neurobiological substrates. Absence of any signs of withdrawal after repeated treatment with maximally tolerated doses can be taken as a reasonable indicator of the absence of dependence liability.

MODIFICATIONS TO THE METHOD

The nonprecipitated withdrawal procedure described above represents an open-ended screen for dependence liability. The procedure can be rendered more discriminating, by preexposing the animals to the same administration schedule and then testing them in procedures with more specific indications. For example, withdrawal-induced fearfulness could be assessed by using a plus maze or a light-enhanced startle test appropriately calibrated to detect anxiogenic activity. Similarly, a withdrawal-induced decrease in the convulsive threshold could be evaluated using either an ECS or PTZ procedure.

More complex procedures for unmasking drug dependence liability could involve assessment of acquired positive reinforcing effects as a result of repeated treatment. Induction of conditioned place preference (see below) has been reported with different substances, for example, nicotine (Shoaib et al. 1994) and alcohol (Meert 1994), after the animals have been preexposed to repeated treatment with the substance, whereas no conditioned place preference can be induced with the same substances in the absence of pretreatment.

Use of telemetry for assessment of withdrawal is advantageous as compared with more traditional approaches as it can detect changes that would be missed if only intermittent observations were made. In addition, telemetry allows a measure of withdrawal effects without complications that might arise from interactions with the experimenter. This general approach, using a range of parameters that are not modified by the process of repeat testing, and which can be affected indirectly by general feelings of malaise brought on by discontinuation, is applicable to all classes of test substance without the need to make assumptions about their specific effects or their time course (Froger-Colléaux et al. 2011). Data collected by telemetry following treatment with chlordiazepoxide and morphine and ensuing withdrawal are presented in the examples below.

3.3.1.2 Drug Abuse

Drug abuse represents a more serious social problem than drug dependence because it involves a much greater variety of substances and because it can and does occur in the absence of dependence. Tests for abuse measure various aspects of drug-taking and drug-seeking behavior with the aim of establishing whether the test substance possesses positive reinforcing effects (Moser et al. 2011a).

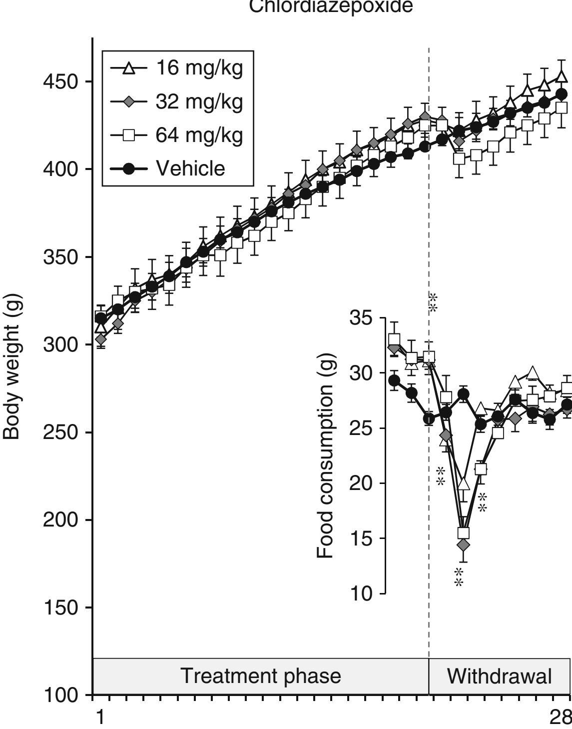

Fig. 3.8 Body weight gain and food consumption during treatment (days 1–20) and discontinuation (days 21–28) of chlordiazepoxide. Body weight was recorded during each day of treatment and discontinuation prior to the first administration each day. Food consumption was recorded over each 24-h period starting on day 18 of treatment. ** = $p < 0.01$ versus vehicle controls; ANOVA for each day followed by post hoc Student's *t* tests. Values are mean ± s.e.m. for $n = 8$

Indirect tests can assess whether the animal prefers to be in an environment associated with a substance with known positive reinforcing properties (conditioned place preference procedures) or whether the test substance has stimulus effects that resemble a drug with known positive reinforcing properties (drug discrimination procedures). The most direct test of drug abuse liability, however, is to assess whether animals will work to receive administrations of the test substance (self-administration procedures) (Moser et al. 2011b). Examples of the three approaches are given below.

Conditioned Place Preference Test

PURPOSE/RATIONALE

The principle of conditioned place preference is that an animal, repeatedly exposed to a distinct environment in the presence of a substance with abuse potential, will show preference for that environment when later given a choice because the environment has become associated with the rewarding properties of the test substance (Schechter and Calcagnetti 1993). If conditioned place preference can be established with a test substance, this suggests that the test substance possesses positive reinforcing effects and is therefore likely to be abused. If, on the other hand, the test substance has no such effects or even induces a conditioned place aversion, where the animal avoids the environment previously associated with the test substance, this suggests that the test substance is devoid of positive reinforcing effects or may even be aversive and is, therefore, unlikely to be abused.

PROCEDURE

Rats are given one session per day (a.m.) over 8 days. During sessions, which last 30 min, they are allowed to explore one side of a two-compartment box (35 × 35 × 70 cm). The two compartments are tactually and visually distinct (black/white striped walls with smooth floors versus gray walls with corrugated floors). The opening between the two compartments (12 × 12 cm) is closed by a guillotine door. Before each session, the animals receive a p.o. administration of either the test substance or vehicle. The test substance is always associated with the gray compartment. Thus, after 8 days, each animal will have been exposed to four pairings of test substance with the gray compartment and four pairings of vehicle with the striped compartment.

On the ninth day, in the absence of any treatment, the animals have free access to both compartments via the guillotine doorway which is left open, and the session is monitored and recorded on videotape. The time spent by the animal in each of the two compartments is scored from the video records and is broken down into 5-min segments over the 20-min test period. The number of crossings from one compartment to the other is also recorded.

Twelve animals are studied per group. The experiment is performed blind.

The test substance is usually evaluated at two doses and compared with a vehicle-treated control group.

Morphine (16 mg/kg i.p. or 64 mg/kg p.o.) can be used as reference substance.

EVALUATION

Before commencing conditioning, animals are generally given a 20-min pretest in the two compartments

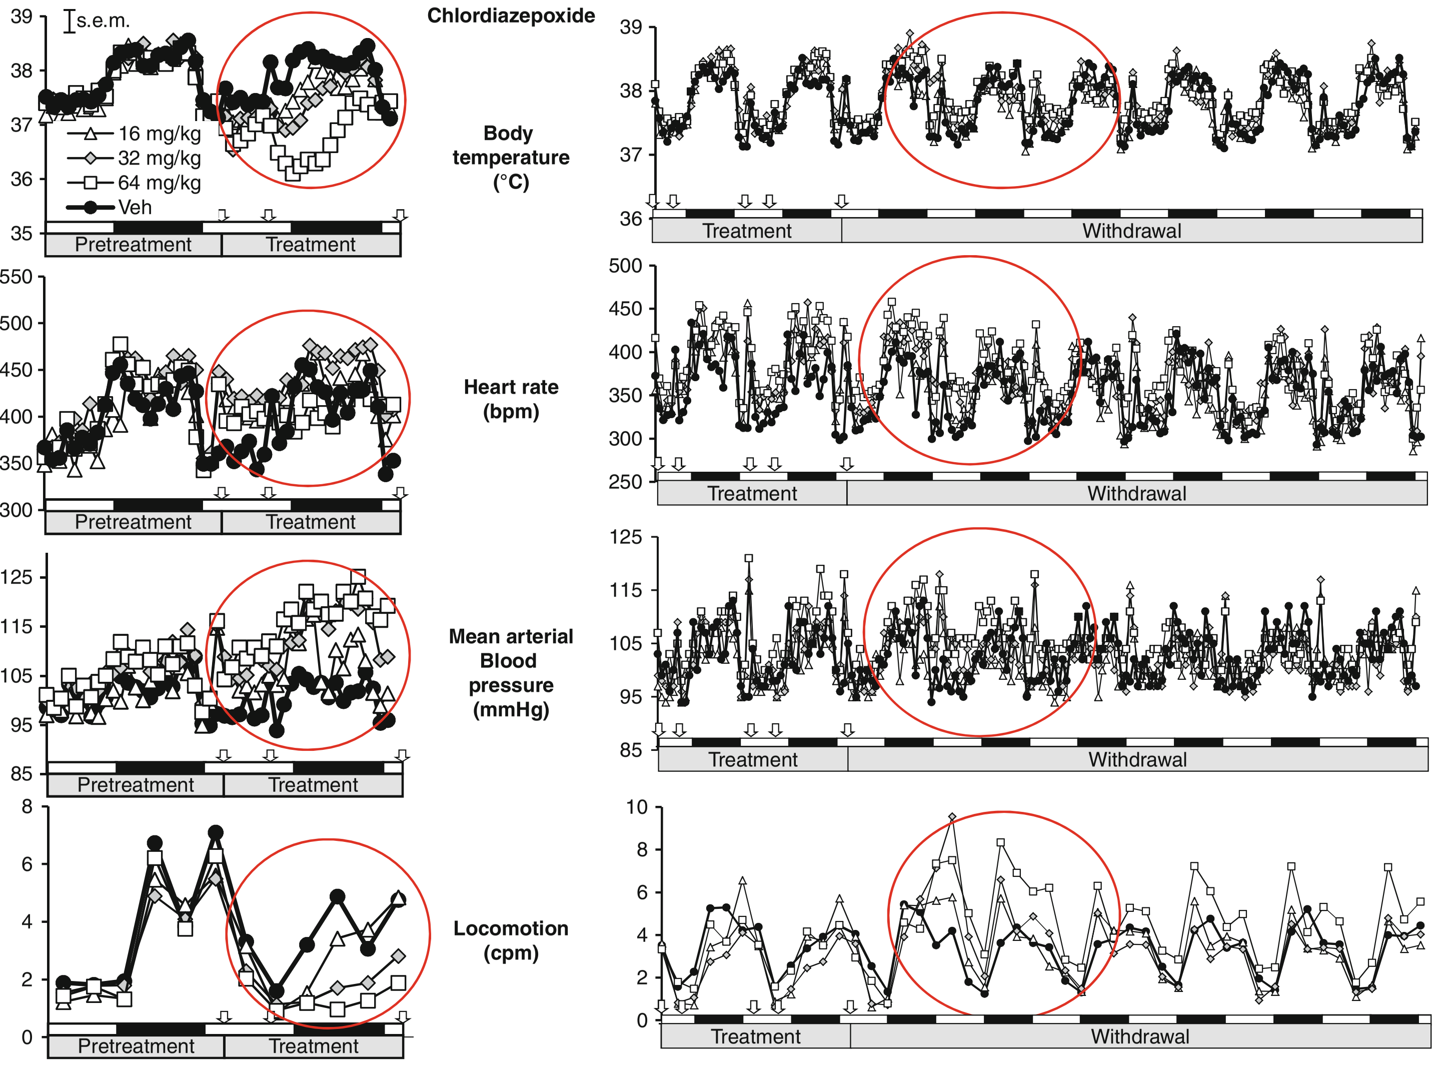

Fig. 3.9 The effect of chlordiazepoxide on body temperature, locomotion, heart rate and mean arterial blood pressure during the first and the last 3 days of treatment and the first 5 days of discontinuation. Error bars have been omitted for clarity, but for information, a value corresponding to the 75th percentile of all s.e.m. values is indicated for each graph. The *light* and *dark* segments indicate the light and dark phases of the 24-h cycle and the *arrows* indicate the times of drug administration

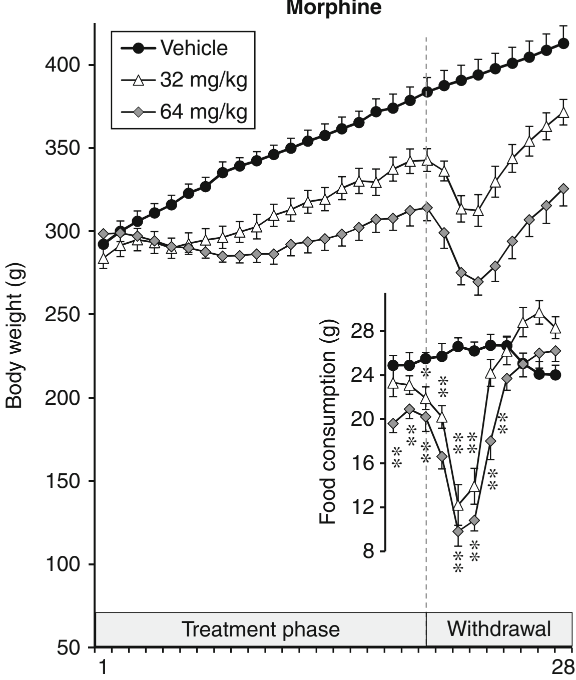

Fig. 3.10 Body weight gain and food consumption during treatment (Days 1–20) and discontinuation (Days 21–28) of morphine. Body weight was recorded during each day of treatment and discontinuation prior to the first administration each day. Food consumption was recorded over each 24-h period starting on Day 18 of treatment. For body weight, both treatment groups were significantly different from vehicle for each day of treatment from day 5 onward (pb0.01; ANOVA for each day followed by post hoc Student's t tests). $* = p < 0.05$, $** = p < 0.01$ versus vehicle controls; ANOVA for each day followed by post hoc Student's t tests. Values are mean ± s.e.m. for $n = 8$

with the guillotine door open, and the time spent in each compartment is measured. These data provide an initial assessment of any natural preference for either compartment in the absence of drugs and allow assignment of animals to treatment groups such that initial place preference is matched between the groups.

During the conditioning phase itself, where the animal in confined to one or the other compartment, no behavioral monitoring is undertaken.

The measure of time spent in each compartment on the test day (day 9) in the absence of the test substance is an indication of the animal's preference for each compartment. Measures of the number of crossings provide an indication of the animal's spontaneous level of activity under the conditions of the test. It should be noted that crossings are not an indication of the effects of the test substance on locomotion, because the animal is not under the influence of the test substance during the test. Clear decreases in the number of crossings are, nonetheless, systematically observed on the test day after previous conditioning with substances such as morphine and, therefore, appear to be part of the conditioned place preference process. On the other hand, no ready interpretation can be offered for these changes.

CRITICAL ASSESSMENT OF THE METHOD

Conditioned place preference appears to provide a fairly simple indication of whether a test substance exerts positive reinforcing effects. The existence of conditioned place preference with a novel substance therefore represents a clear first sign of abuse potential.

On the other hand, absence of conditioned place preference cannot be taken to indicate that the test substance is devoid of abuse potential. Indeed, the main weakness of the conditioned place preference paradigm is that several known substances of abuse (amphetamine, THC, nicotine, alcohol) do not readily induce conditioned place preference, if at all. Moreover, even with substances such as cocaine, the conditioned place preference which occurs is considerably less robust than that observed with morphine, for example. Cocaine place preference is generally observed only during the first 5–10 min of the test, in contrast to morphine where the effect is more clearly present over the whole test period. Even with morphine, the effect is observed only over a narrow dose range, 8–16 mg/kg i.p. or 64–128 mg/kg p.o., and is not clearly dose dependent (our unpublished data).

Further problems are encountered with substances such as THC, where place preference can be observed over a narrow range of low doses (0.5–1 mg/kg i.p.), but where place aversion is observed at higher doses (Maldonado and Rodriguez de Fonseca 2002). Conditioned place preference has been reported with nicotine, but only after a short pretreatment with nicotine before commencing place preference conditioning (Shoaib et al. 1994). We have been unable to replicate this finding in our own laboratory (our unpublished data).

Taken together, existing data with conditioned place preference suggest that it is rather insensitive to several known drugs of abuse (false negatives). On the other hand, the demonstration of conditioned place preference with a particular substance represents a danger sign which should not be ignored.

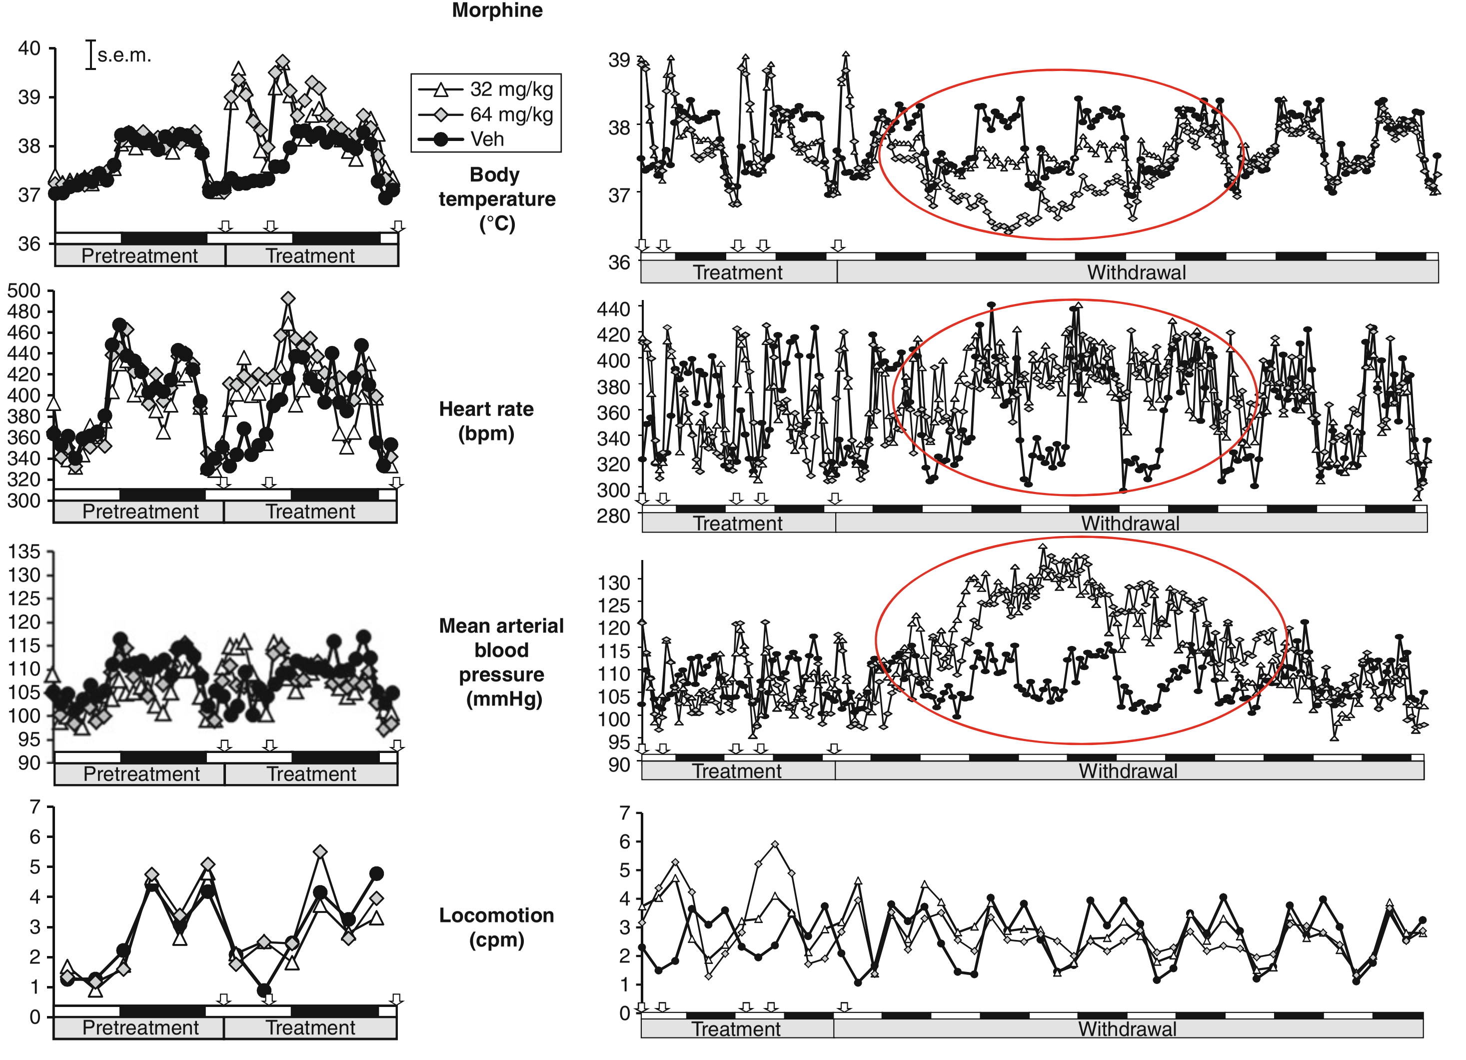

Fig. 3.11 The effect of morphine on body temperature, locomotion, heart rate, and mean arterial blood pressure during the first and the last 3 days of treatment and the first 5 days of discontinuation. Error bars have been omitted for clarity, but for information, a value corresponding to the 75th percentile of all s.e.m. values is indicated for each graph. The *light* and *dark* segments indicate the light and dark phases of the 24-h cycle, and the *arrows* indicate the times of drug administration

MODIFICATIONS TO THE METHOD

The procedure described above gives individual conditioning sessions on separate days. This procedure, while time-consuming, ensures that the animals enter each conditioning session in the absence of drug effects from a preceding session.

Shorter procedures are available where the animals are given two conditioning sessions within the same day (mornings and afternoons). With drugs such as morphine administered parenterally (i.v. or i.p.), the 5-h interval between the two sessions is sufficient to enable adequate place preference conditioning to occur, presumably because the drug effect from the morning session is no longer present in the afternoon. This assumption cannot be made when the test substance has a long duration of action or even when the test substance is administered by the p.o. or s.c. routes, where the drug effects typically last longer. If there is no clear pharmacological differentiation between two successive conditioning sessions, the absence of conditioned place preference could represent a "false negative" in that the animal is unable to discriminate the two compartments in terms of the presence and absence of the test substance. For test substances with a demonstrably short duration of action, the 2-sessions-per-day procedure represents a considerable economy in experimental time and, therefore, cost.

Another time-consuming aspect of the paradigm described above is the off-line visual analysis of the video recordings conducted after test completion. Considerable economies can be realized by use of commercially available automatic video image analysis systems. Once correctly validated, these systems offer a viable alternative to visual analysis, providing cost-effective and objective data evaluations compatible with the requirements of GLP.

Drug Discrimination

PURPOSE/RATIONALE

Another indirect procedure for evaluating abuse liability is drug discrimination where animals, by pressing on one of two levers in a Skinner box, can show that they can discriminate the presence of a particular drug of abuse (training drug) from vehicle. They are then given the new substance and can indicate by their choice of lever whether the new substance resembles the training drug (Colpaert 1987; Solinas et al. 2006).

The basic assumption of drug discrimination procedures is that if a test substance is perceived as being subjectively similar to a drug of abuse, it is also likely to be abused. Many drugs of abuse are capable of being discriminated in a drug discrimination paradigm in rats and include cocaine, amphetamine, morphine, phencyclidine, mescaline, THC, nicotine, and benzodiazepines (Colpaert and Slangen 1982). It is important to note that the ability of a drug to serve as a discriminative stimulus does not necessarily indicate any potential for abuse since certain drugs that are not abused,

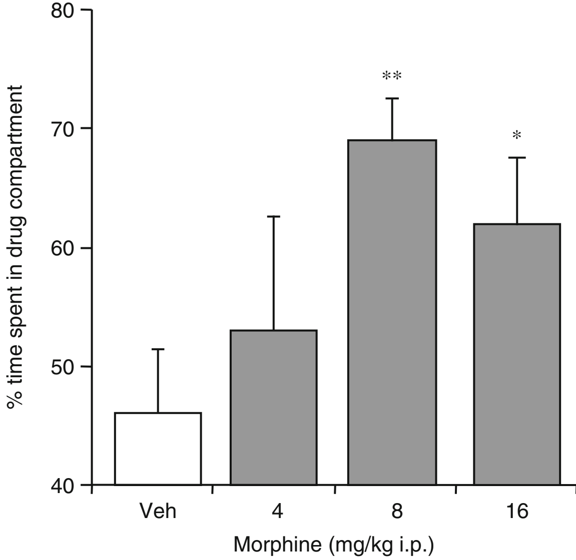

Fig. 3.12 Effects of morphine (i.p.) in the place preference test in the rat

for example, flumazenil (Gerak and France 1999), can be established as a reliable discriminative stimulus in animals.

PROCEDURE

Training

Sessions are given in commercially available operant chambers equipped with two response levers, and a food hopper. Initially, rats are submitted to lever-pressing acquisition sessions where a response on either the right or the left lever resulted in the delivery of a food pellet (i.e., FR1 schedule of reinforcement). The levers are inserted in the chamber at the beginning of the session and are withdrawn at the end of the session. The house light comes on at the beginning of the session and is extinguished at the end of the session. Sessions terminate after 45 min or after the animals completed 50 responses, whichever occurred first. At the end of this phase, animals which fail to acquire the lever-press response are discarded from the experiments. No administration is given during the acquisition of the lever pressing.

When animals receive 50 pellets in a session, the response requirement is increased to FR2 and discrimination training commences whereby only responding on one of the levers is reinforced. For a particular day, the active lever depends on the treatment administered (i.e., saline or drug.). The treatment is administered 15 min before the sessions. The allocation of the right or the left lever to the training substance (drug) is balanced out between animals. The response requirement is increased progressively across days to a final fixed ratio (FR) value of 10. Animals must make consecutive responses (1 FR) on a given lever in order to receive a food pellet, the FR value being reset to zero if an animal responds on the other lever prior to completion of the FR.

Saline and drug are administered across sessions according to alternating sequences of single and double alternation (e.g., drug, saline, saline, drug, drug, saline, saline, drug, saline, drug), with training sessions taking place on weekdays only. Two sequences are used so that the rats do not systematically all receive the same treatment each day. During the pretreatment period, animals return to their home cage prior to placement in the chamber. The session ends after the delivery of 50 food pellets or 15 min, whichever occurs first. At the end of this phase, animals which fail to discriminate within 75 sessions are discarded from the experiment. Training continues until the following criteria are satisfied:

(a) Eight of ten consecutive training sessions (this performance must thereafter be maintained for at least a further five sessions) (i.e., 80% of correct training sessions over 3 weeks)
(b) The two sessions (one saline and one drug session) just prior to a test session must be correct.
(c) The above criteria must be maintained between test sessions which are carried out with at least two intervening successful training sessions of which at least one must be a saline session and one an cocaine session.

The test sessions are identical to training sessions except that rats receive different doses of the test substance in a pseudorandom order, administered 15 min before the session. During test sessions, 10 responses on either lever result in delivery of a food pellet, with the FR value being reset to zero if an animal responds on the other lever prior to completion of FR10 (i.e., rats must make 10 consecutive responses on a given lever in order to receive a food pellet). Morphine (5 mg/kg i.p.), cocaine (8 mg/kg i.p.), diazepam (2 mg/kg i.p.), D-amphetamine (0.6 mg/kg i.p.), DOI (0.63 mg/kg i.p.), or THC (3 mg/kg i.p.) can be used, among others, as comparator drugs.

To ensure that 8–10 animals can be retained for drug testing, training is commenced with 12 animals per drug.

Drug Testing

Test sessions are identical to training sessions except that rats receive different doses of the test substance in a pseudorandom order, administered 15 min before the session. During test sessions, 10 responses on either lever result in delivery of a food pellet, with the FR value being reset to zero if an animal responds on the other lever prior to completion of FR10 (i.e., rats must make 10 consecutive responses on a given lever in order to receive a food pellet). The training dose of the training drug and saline are tested initially to confirm adequate stimulus control for testing. Thereafter, three different doses of the test substance (and the vehicle used for the preparation of the test substance, if needed) are studied using a Latin square design. On concluding test substance evaluation, the training drug and saline are tested again.

EVALUATION

Two basic measures are taken during drug discrimination procedures, the percent responses on the drug-associated lever and the response rate on both levers (in response per second).

The first parameter (percent responses on the drug lever) provides an estimate of the degree of generalization between the test substance and the comparator (training drug). No responding on the drug lever (i.e., 100% responding on the saline lever) would indicate that the test substance does not generalize to the training drug and that the test substance is therefore not recognized as being similar. Exclusive (100%) responding on the drug lever would indicate complete generalization to the training drug and that the test substance is therefore recognized as resembling the training drug. In cases where clear generalization occurs, a dose-response effect is observed and the data lend themselves to calculations of ED50s which represent the dose levels at which the test substance generalizes 50% to the training drug.

The second parameter (response rate on both levers) provides an estimate of the effects of the test substance on operant performance. If the test substance exerts marked sedative effects, the number of responses would normally be decreased. Response rate could even be increased if the test substance possessed psychostimulant effects. Interpretation of drug effects on operant performance is, however, not simple, because other factors can contribute to effects of the test substance on response rate. In the present procedure, where the effect of the reinforcement schedule (FR10) is to produce a high rate of baseline responding, test substances with either sedative or psychostimulant effects will generally decrease the rate of responding.

Although the test substance may generalize partially or fully to the training drug up to some dose, further increasing the dose will eventually decrease or completely suppress responding. Partial generalization, accompanied by a suppression of responding at higher doses, could suggest that the test substance does not fully share discriminative stimulus effects with the training drug. Alternatively, such a result could indicate that rate-decreasing effects occur at comparatively smaller doses and, thereby, preclude measures of discriminative stimulus effects. Partial effects of this type must be evaluated with great caution. However, if complete generalization occurs before the test substance suppresses responding, this suggests a clear similarity between the test substance and the training drug, at least within that particular dose range.

Discrimination results from animals that have had a low response rate (fewer than 50 responses) were not used for calculating the percentage of responding on the drug-associated lever. However, all data from all tests were used to calculate response rate.

No formal statistical analysis was performed on percentage of the total responses on the drug-associated lever. Response rate was analyzed, comparing the different treatments with saline (or vehicle) using paired Student's *t* tests.

CRITICAL ASSESSMENT OF THE METHOD

Drug discrimination procedures provide a unique opportunity for assessing subjectively perceived drug effects using purely behavioral criteria and quantitative measures. Furthermore, under appropriate training conditions, the method has been shown to be exquisitely sensitive even to minor changes in pharmacological activity, for example, between different benzodiazepines (Ator and Griffiths 1989) or even between different doses of the same drug (Walker et al. 2001). At the same time, the numerous published data show a high degree of selectivity within different substance classes. The perceived similarities between different psychotomimetics, for example, PCP and MK-801 (France et al. 1991) or opioids (France et al. 1995), provide cogent behavioral evidence for a common mechanism of action or even action at the same receptor subtype, whereas dissimilar discriminative stimulus effects provide suggestive evidence for action at different receptors or different actions at the same receptor. Thus, the greatest strength of drug discrimination is its pharmacological selectivity.

The interplay between generalization curves and drug effects on response rate can often provide behavioral evidence for the degree of similarity between a selected training drug and the test substance, or the dose range in which such similarity exists, or of the kind of action occurring at a target receptor including agonism, antagonism, inverse agonism, and the relative efficacy of those effects.

A further advantage of drug discrimination paradigms is that similar methodology can be used in a variety of species from mice (Shelton et al. 2004) to pigeons (Walker et al. 2001), to rats (Ator and Griffiths 1989), to monkeys (Gerak and France 1999), and even

to humans (Foltin and Fischman 1992), thereby permitting direct extrapolations across species.

The primary disadvantage of drug discrimination procedures is that they are time-consuming. This becomes most apparent when the procedure is used to characterize the perceived pharmacological profile of a new test substance, where it may have to be evaluated in numerous independent groups trained to recognize a variety of known drugs of abuse. Thus, characterization of test substances solely on the basis of drug discrimination procedures is likely to take considerable time.

The principal weakness of drug discrimination procedures for assessing abuse liability is that they provide only indirect evidence regarding abuse. If a test substance is discriminated as being similar to a known drug of abuse, this is taken to indicate that the test substance is likely to be abused in a similar manner. On the other hand, if a test substance does not share discriminative stimulus effects with any known drug of abuse, drug discrimination procedures alone provide no indication of whether the test substance is likely to be abused.

MODIFICATIONS TO THE METHOD

There are many variants in drug discrimination methodology whereby small procedural differences (fixed or variable interval instead of fixed or variable ratio reinforcement, probe trials with or without reinforcement to test for generalization, test sessions where either the chosen lever, i.e., that on which the animal emits say its first 10 responses, or both levers are reinforced) are practiced in different laboratories without marked differences in the results obtained.

A more important difference is whether to score the level of generalization by the percentage responding on the drug-associated lever or by the initial lever choice of the animal when exposed to the test substance. The former in theory permits a more quantified and graded estimate of the degree of generalization at the different doses and should, thereby, permit a more powerful statistical analysis. The latter might provide a more unbiased measure of discriminative stimulus effects since responding prior to food delivery, unlike responding after food delivery, cannot be influenced by contingencies of reinforcement. However, simple lever choice measures permit only quantal measures (proportion of animals choosing the drug-associated lever) at each dose investigated, with correspondingly less powerful statistical analysis. Again, there are no marked differences in the kinds of results reported by laboratories using the two approaches. One reason is that the distribution of scores between the two levers is essentially bimodal, with little variation at the two extremes and considerable variation around the 50% mark.

Another potentially useful drug discrimination approach is to establish whether the test substance itself can exert discriminative stimulus control as a training drug. If the test substance is poorly discriminable, more sessions will be required before achieving an adequate level of stimulus control or abandoning training. Indeed, failure to establish discriminable control over many training sessions constitutes suggestive evidence that the substance has few CNS effects, assuming that it has been administered in an appropriate dose and at an appropriate time prior to training sessions. While inability to establish discrimination with a test substance provides presumptive evidence for a lack of CNS effects that could predict little or no abuse potential, the opposite result is not true. That is, rapid acquisition of discriminative control with a test substance simply indicates that the substance has stimulus effects, perhaps mediated in the CNS. Because many CNS-acting drugs that are not abused are reliably discriminated by nonhumans (e.g., kappa opioid agonists; France et al. 1994), no predictions can be made regarding abuse potential based solely on ease of discrimination training.

Despite the time taken to train an animal to recognize a test substance, once the animals are sufficiently trained, they can be used repeatedly with a variety of drugs of abuse with the aim of identifying which of these substances generalize to the training substance (in this case, the test substance). In this fashion, it would be possible to establish the profile of perceived drug effects using the same animals tested with different drugs of abuse. This kind of procedure is rarely reported, but could represent a considerable economy in the number of animals required.

Self-administration

PURPOSE/RATIONALE

The most direct tests of abuse potential are self-administration procedures, where the animals can, by pressing on a lever, receive an i.v. infusion of the test substance via a pump system connected to an indwelling catheter (Brady and Griffiths 1976). Parallel methods have been used widely with rats and monkeys and provide substantially similar findings. More recently, self-administration procedures have also been developed using mice (Caine et al. 2002; Thomsen and Caine 2005). Virtually, all drugs which are abused in humans will induce or sustain self-administration behavior in animals. The self-administration paradigm is a clearly homologous animal model of human drug abuse with a consequently high level of face validity, construct validity, and predictive validity.

PROCEDURE

Experiments are conducted in ventilated, sound-attenuating operant chambers. Each chamber is equipped with a single lever located to the right of a 5 × 5 cm opening for food pellet delivery from a food hopper. A translucent stimulus light is located above the food hopper. Experimental events are controlled and monitored, and data are collected and stored, by a microcomputer and associated interface. Male rats (240–320 g) are housed individually and maintained under a noninverted 12/12-h light/dark cycle. Upon arrival, rats have restricted access to food for 5–7 days (15 g/rat/day then 18 g/rat/day after the surgery), after which, lever training begins under a continuous reinforcement (CRF) schedule of food presentation. Daily sessions comprise 45 min or 20 food presentations, whichever occurs first. Subsequently, the response requirement is increased to a fixed ratio (FR) 10. Once rats receive 20 food pellets in a single session under the FR10 schedule (typically within 5–10 days), food training is suspended and a chronic indwelling i.v. jugular catheter is implanted. Beginning at least 3 days after surgery, daily sessions (typical maximum duration of 120 min) are conducted during which rats can receive

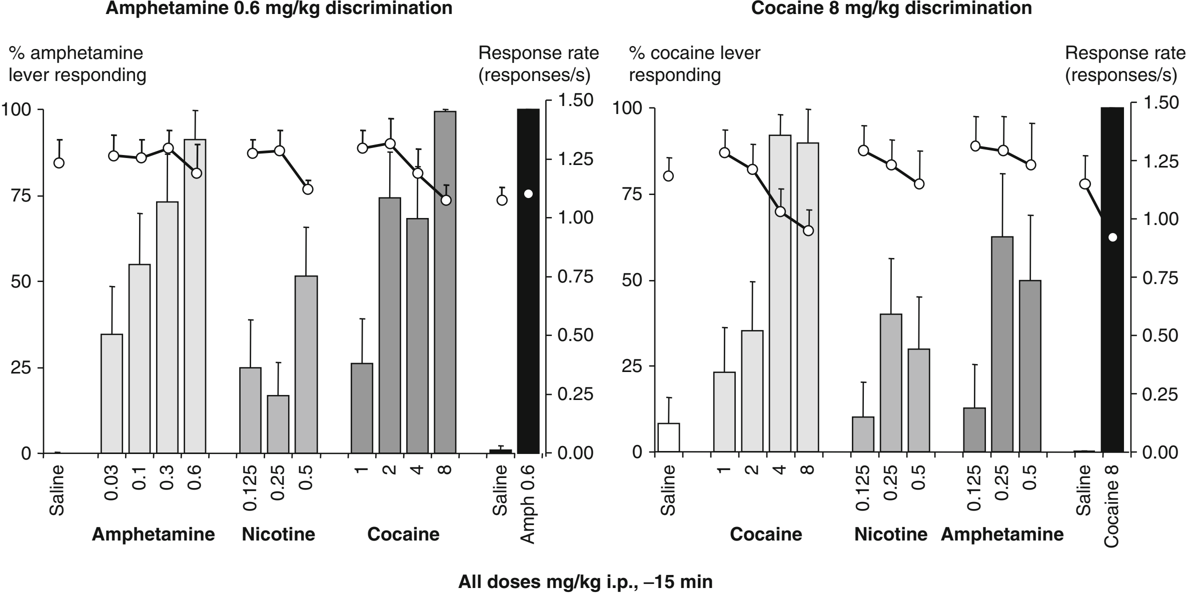

Fig. 3.15 Effects of nicotine and cocaine on drug discrimination in rats trained to discriminate amphetamine from saline and effects of nicotine and amphetamine in rats trained to discriminate cocaine from saline. There is a dose-dependent generalization to cocaine to the lever associated with amphetamine, whereas the converse is partially true. There is only partial generalization to nicotine in rats trained to discriminate amphetamine or cocaine from saline

a maximum of 50 i.v. infusions of the baseline drug (cocaine, 0.5 mg/kg/infusion) under the FR10 schedule. Immediately prior to the beginning of daily sessions, rats receive 1 noncontingent (i.e., "priming") infusion of the same solution that is delivered after appropriate responding during the session (baseline drug, saline, or test substance). A distinctive visual stimulus is displayed during periods when i.v. infusions are available. Each infusion is followed by a 30-s timeout, during which the chamber is dark and lever presses have no programmed consequence. The infusion duration is 4–6 s, and the infusion volume is approximately 138–210 μl (infusion rate 2.075 ml/min), depending on the weight of the subject and the solubility of the test substance.

Self-administration Testing

After responding for the baseline drug stabilizes (i.e., when the variability in the number of infusions delivered per session does not exceed ± 20% over three consecutive sessions), saline (the cocaine vehicle) is substituted for the baseline drug until the number of infusions per session is less than 8% or 40% of cocaine responding for three consecutive days. Following this training phase, rats are tested with 0.25 mg/kg/infusion of cocaine for at least 3 days to verify that lever pressing is contingent on a rewarding substance being available and that rats rapidly increase their lever-pressing behavior (i.e., within one or two sessions) and to a high level (>20 infusions per session) as soon as such a substance is available. This is followed by a test substance vehicle phase for at least 3 days, where lever pressing must rapidly drop to low levels (less 40% of cocaine responding). Once these four experimental phases are completed, a specified dose of the test substance is substituted for saline (or test substance vehicle) (for at least five sessions) until there are fewer than eight infusions over three consecutive sessions or until the number of infusions per session does not vary by more than ±20% over three consecutive sessions. Next, saline is substituted for the test substance until the criteria listed above are satisfied. Finally, the baseline drug (cocaine, 0.25 mg/kg/infusion) is substituted for saline until the criteria listed above are satisfied. Testing starts with a minimum of 10 rats per group with the objective of obtaining data from 8 rats that complete all phases of the experiment. Each subject is used to study only a single dose of test substance. A total of three dose levels of the test article are administered.

EVALUATION

The primary behavioral measure recorded is the number of infusions received during the session.

CRITICAL ASSESSMENT OF THE METHOD

The model described above is a so-called substitution procedure where the animal is first trained to respond for i.v. infusion of a known drug of abuse, in the present case cocaine. Once reliable self-administration is established, the test substance is substituted for cocaine to see whether the test substance continues to maintain self-administration behavior.

This procedure had several advantages. The first is that drug testing commences in an animal already shown to administer the reference drug. As such, the model possesses a high level of face validity in that the test substance evaluation is conducted in a drug-experienced animal. Moreover, even in the rat, there can be individual differences in the rate at which animals self-administer the reference drug, even after extensive training. Thus, the substitution procedure provides an assessment of the rate at which the test substance is self-administered compared with the reference drug, for individuals and for groups of subjects. Furthermore, evaluating the test substance in animals already shown to self-administer a reference drug of abuse decreases the possibility that a negative finding with the test substance is due either to the animal's low intrinsic tendency to self-administer or to other factors which might have prevented the animal from initiating self-administration. Thus, the substitution model represents a highly sensitive procedure for detecting positive reinforcing effects of test compounds which, in turn, have high predictive validity for abuse potential in humans. No self-administration behavior under these conditions suggests the absence of abuse potential.

A critical element in all self-administration procedures is the choice of the doses to be evaluated. If the doses are too high, it is possible that no self-administration will be observed because the high doses directly interfere with operant responding. Studying inappropriately high doses could therefore lead to the false conclusion that the test substance is devoid of abuse liability, whereas lower doses might clearly maintain self-administration. The best way to avoid overdosing is to conduct prior dose-finding experiments, using either an operant behavior schedule or a more simple measure of spontaneous locomotion, like the activity meter test described above. The highest dose chosen for the subsequent self-administration experiment should be one just below that inducing a clear effect on operant or spontaneous behavior. The choice of the lowest dose represents less of a problem in that it should be close to that found active in procedures used to evaluate the potential therapeutic activity of the test substance.

Use of an appropriate self-administration paradigm, such as the substitution procedure described above, is likely to be sensitive to a large variety of known drugs of abuse (Griffiths and Balster 1979; Griffiths et al. 1980), although certain substance classes, for example, nicotine (Corrigall 1999) and benzodiazepines (Broadbear et al. 2005), while clearly positive reinforcers under a limited range of conditions, are not as readily self-administered as opioids or cocaine. Indeed, the different self-administration effects of these diverse substance classes probably reflect their real-life abuse liability as indicated by "street use." On the other hand, the experimental literature describes self-administration in animals with several substances, for example, modafinil (Gold and Balster 1996), nomifensine (Aspen and Winger 1997), and bupropion (Bergman et al. 1989), which have never been associated with significant problems of abuse in humans. Thus, self-administration procedures in nonhumans can generate a certain number of apparent "false positives." Reasons for the absence of abuse in humans with some substances that maintain self-administration responding in animals could be related to the ease at which these substances can be put into an injectable formulation, pharmacokinetic factors such as their rapidity of absorption, their availability compared with other drugs, or to important differences between the self-administration doses and those which are active in the therapeutic indication.

MODIFICATIONS TO THE METHOD

The major variants of the self-administration paradigm, for the purposes of abuse potential studies, are substitution procedures and initiation procedures. With substitution procedures, animals are first trained to self-administer a reference drug and are then administered the test substance to see whether the test substance can substitute for the reference drug in maintaining self-administration behavior. The advantages of substitution procedures in CNS safety evaluation have been described above. Another advantage

of substitution procedures is that they permit reuse of the same animals for assessing different test substances or different doses of the same test substance. This becomes highly important when primates are used because of the cost of the animals themselves and of ethical issues surrounding the use of primates. Reuse is less of an advantage with rats because the practical lifespan of the assay (i.e., catheter patency) is significantly less with rodents.

Initiation procedures ask whether a drug-naïve animal will come to self-administer the test substance without any prior self-administration training. If a test substance induces clear self-administration in a drug-naïve animal, this constitutes even more compelling evidence of its abuse potential. On the other hand, initiation procedures for the same reason can be considered less sensitive, i.e., less likely to detect self-administration, and are therefore less appropriate for CNS safety pharmacology. Because there is typically no positive control in this type of initiation study, the failure to establish self-administration responding in naïve animals does not constitute adequate evidence for concluding there is no abuse potential.

Another important variant in self-administration procedures is the animal species used. The most frequently used animals are rats and nonhuman primates, usually macaques but also new world monkeys (capuchin, squirrel, marmosets) and baboons. More recent publications have described rapid self-administration procedures in the mouse (Caine et al. 2002) with consequent reductions in cost. There is no evidence that the data obtained between different species differ qualitatively in terms of the kinds of drugs showing positive reinforcing properties. On the other hand, primates, and in particular the macaque, are the species preferred by the drug registration authorities mainly because of their greater similarity to humans in terms of active doses and pharmacokinetics and because of the extensive literature on the behavioral effects of CNS-acting drugs in this species.

Analysis of self-administration behavior is mainly qualitative, indicating whether or not a test substance is a positive reinforcer in self-administration studies. Although there are clear differences between drug classes and even between individual animals, in the number of infusions taken during a test session, the number of infusions per session might not provide a clear reflection of the reinforcing effectiveness of a test substance because ongoing behavior can be affected by repeated drug delivery, potentially leading to suppression of responding or even lethality. The pharmacokinetic profile of a test substance is a major determinant of whether or not reinforcing effects are observed (i.e., in general, rapid-onset drugs are more reinforcing than slow onset drugs) and whether the number of reinforcers received throughout a test session reflects overall reinforcing effectiveness (i.e., in general, long-duration drugs can accumulate through the session, suppress responding, and, thereby, appear to be less reinforcing than might be the case). One alternative to the typical repeated dosing self-administration procedure is a second-order schedule of self-administration (e.g., Negus and Mello 2004). Under this schedule, nondrug stimuli (e.g., lights) that have been paired with drug delivery are presented under a schedule of reinforcement throughout the session and only a single drug injection is administered at the end of the session. Thus, behavior throughout a session is not affected directly by drug delivery since drug is administered only once, at the end of the session. Second-order schedules have not been used widely in abuse potential studies, perhaps because they require extensive training and because behavior under these schedules tends to respond less rapidly to changes in dosing conditions. Another indicator of the reinforcing effectiveness of a test substance can be the amount of work an animal will perform to obtain the test substance. This can be investigated with a progressive ratio schedule (e.g., Solinas et al. 2004) whereby the response requirement increases for every infusion or after a fixed period of time (Wilcox et al. 2000) until the animal ceases to lever press for a predetermined interval, defined as the breaking point. The presumption of progressive ratio studies is that the higher the breaking point, the greater the reinforcing effectiveness, although the same potential complications regarding pharmacokinetics that were noted above for simple (FR) schedule of self-administration also apply to progressive ratio schedules. Breaking point studies are usually undertaken as a supplementary investigation after a test substance has demonstrated positive reinforcing effects under other conditions.

3.3.2 Cognitive Processes

Tests of higher cognitive function find their place during the later phases of CNS safety assessment because they are more time-consuming to perform and cannot therefore be performed on a routine screening basis. Included under the term cognitive function are learning, memory, and attention. It is important that drugs be devoid of impairing effects on these functions, whatever their indication. It is thus essential that

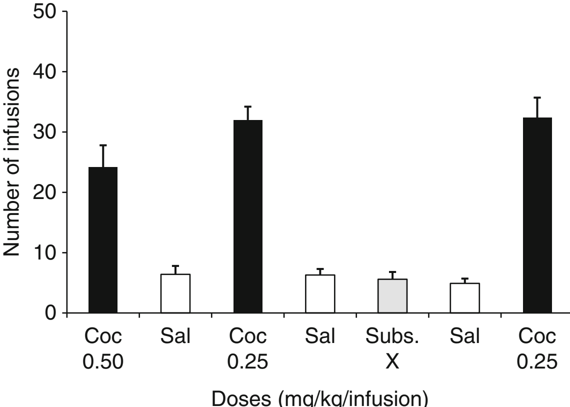

Fig. 3.16 Effects of cocaine in a self-administration procedure in the rat. Cocaine induces clear self-administration at the beginning and the end of the experiment, in contrast to saline which induces a low level of self-administration

CNS safety pharmacology provide procedures for evaluating these effects in animal studies. There is no standardized set of procedures in this area. The following procedures provide an indication of the kinds of protocols that can be applied. The list is by no means exhaustive.

3.3.2.1 Passive Avoidance Test

PURPOSE/RATIONALE

One of the simplest procedures for looking for adverse effects on learning/memory is the so-called one-trial passive avoidance task (Bammer 1982). A mouse or a rat receives an aversive stimulation in a recognizable environment and on a later occasion shows it has remembered by not going there (passive avoidance). Amnesia-inducing drugs (benzodiazepines, anticholinergics, NMDA antagonists), administered before the first exposure, attenuate the animal's memory for the aversive stimulus as shown by a decreased avoidance of the environment in which it was previously received.

PROCEDURE

The passive avoidance apparatus we use consists of two compartments, one (30 × 30 × 30 cm) brightly lit and the other (20 × 20 × 12.5) dark, connected by a small opening (8 × 8 cm) which can be closed by a guillotine door.

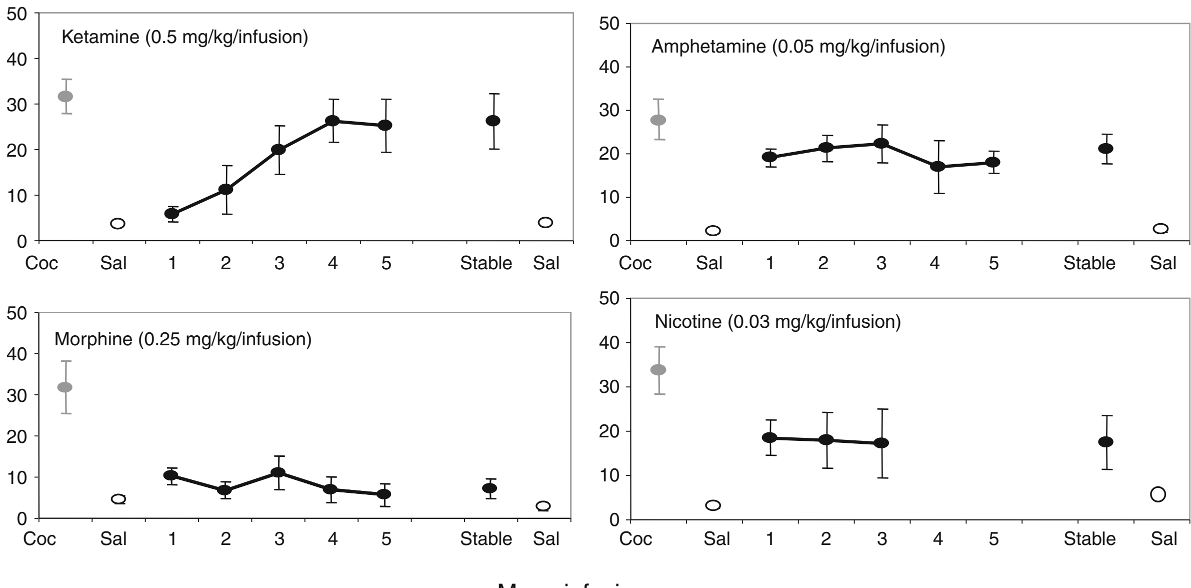

Fig. 3.17 Acquisition of four commonly abused substances (ketamine 0.5 mg/kg/infusion, amphetamine 0.05 mg/kg/infusion, morphine 0.25 mg/kg/infusion, and nicotine 0.03 mg/kg/infusion) in cocaine (0.5 mg/kg/infusion)-trained rats

For the first trial (T1), rats are placed individually into the lighted compartment. After 30 s, the door to the dark compartment is opened. When the rat has entered the dark compartment, the door is closed and the rat immediately receives a 0.8 mA shock (Coulbourn shock generator) for 2 s. The animal is removed immediately after the shock and is replaced in its home cage.

The animal is placed again 48 h later in the lighted compartment with the door closed for the second trial (T2). The door is opened after 30 s, and the animal's latency to cross to the dark compartment is recorded (cut-off time = 180 s).

Amnesia-inducing drugs cause a significant decrease in the step-through latency at T2.

Twenty rats are studied per group. The test is performed blind.

The test substance is usually evaluated at three doses, administered p.o. 60 min before T1, and compared with a vehicle control group.

Scopolamine (0.5 mg/kg s.c.), administered under the same experimental conditions, is used as reference substance.

The basic experiment therefore includes five groups.

EVALUATION

The principal measure taken is the animal's latency to cross to the dark compartment at T2. This score provides an estimate of the animal's retention of the shock received at T1. Because the latencies measured at T2 have a 180 s cut-off, the scores in the control group are abnormally distributed because of the presence of numerous ceiling scores. It is therefore essential to apply nonparametric statistics, for example, the Mann-Whitney U test, to analyze the data.

A second measure taken is the animal's latency to cross to the dark compartment during T1. This measure is used to estimate the intrinsic effects of the test substance on exploration/locomotion. These scores are more normally distributed than at T2 but, for reasons of homogeneity, should also be evaluated using the Mann-Whitney U test.

A clear drug effect on T2 latencies in the absence of an effect on T1 latencies can be more clearly interpreted as an effect on memory.

CRITICAL ASSESSMENT OF THE METHOD

Passive avoidance procedures provide the most rapid and apparently simple index of a drug's impairing

effects on memory. They are therefore suitable as a first screen for potential cognition-impairing activity. The fact that the learning occurs within a single trial distinguishes this procedure from all other procedures described below. On the other hand, passive avoidance procedures suffer problems of interpretation in terms of the memory/learning processes involved. Is a decrease in step-through latency at T2 due to the fact that the animal did not learn the association between the dark compartment and the shock or because it could not retain this learning over the inter-est interval? A decrease in T2 step-through latency could also reflect an impairment of attention at T1 or even a decrease in pain sensitivity induced by the test substance during the learning trial.

A further problem with passive avoidance procedures is that, despite their apparent simplicity, the results obtained are notoriously variable on separate occasions and between different laboratories (Bammer 1982). Although part of the explanation for the interlaboratory variability lies with the multiplicity of passive avoidance procedures (see below), even using the same procedure from day to day provides varying results. To counteract the variability, it is therefore necessary to include more animals per group.

Passive avoidance procedures are essentially useful for detecting impairing effects of test substances. It is more difficult to demonstrate cognition enhancement because of ceiling effects. In terms of safety pharmacology, this is not a major drawback as impairment represents the major cognitive risk.

MODIFICATIONS TO THE METHOD

The passive avoidance procedure exists in multiple versions, but basically consists of two paradigms, step-down and step-through. The procedure described above is a step-through procedure involving two compartments, light and dark, whereas the step-down procedure involves placing the animal on a platform just above an electrifiable grid floor. Both oppose the animal's natural tendencies (aversion to bright light or remaining in a restricted space) with avoidance of an electric shock.

With the step-through procedure, the dimensions of the apparatus can vary, in particular the relative sizes of the two compartments. In general, it is the light compartment which is larger. The size of the light compartment can radically change the latencies with which the animal crosses to the dark compartment and, thereby, influence the amount the animal learns about this new environment before receiving electric shock. The manner of delivering shock can also vary. With some procedures, the animal receives shock for a brief but fixed period. With other procedures, the animal receives shock until it has returned to the light compartment. The same is also true for the step-down procedure. Indeed, the existence of so many variants no doubt explains much of the variability of data between different laboratories. As yet, no single "best" method has been recommended.

Most passive avoidance procedures used in CNS safety pharmacology employ shock levels of sufficient intensity to induce a high level of avoidance, thereby providing a behavioral baseline suitable for assessing cognitive impairment. Other variants either use lower levels of shock to induce less than maximal learning during a learning trial to permit demonstrations of improved performance or use multiple trials for establishing learning curves. Multiple trial procedures permit the progress of learning to be monitored and the effects of test substances on the learning process to be assessed, thereby providing more readily interpretable data. On the other hand, multiple trials are time-consuming, decreasing the major advantage of one-trial procedures. Using lower shock levels in a one-trial procedure has the disadvantage of decreasing the interpretability because there is no independent means of establishing whether learning was present or whether the shock level was simply insufficient to sustain a passive avoidance response.

Another variant is the manner of administering the test substance. One of the interpretational problems with passive avoidance is the occurrence of other drug effects, for example, on pain sensitivity or attention, which can confound the interpretation in terms of memory. Some of these effects can be controlled by administering the test substance immediately after T1, with the intention of acting on so-called memory "consolidation." Posttrial administration has other problems, however. Administration of the test substance may have positive reinforcing or aversive effects which can influence the scores at T2. Another problem is their onset of action. A test substance with slow onset could miss the "consolidation" period altogether and thereby appear to be devoid of amnesic potential when this is not the case. The best general screening procedure therefore remains that where the test substance is administered before the learning session, despite some difficulties in data interpretation.

Passive avoidance procedures generally use intertrial intervals of 24–48 h and, thereby, measure longer-term memory. It is possible to shorten the intertrial interval to, for example, 1 h to assess drug effects on shorter-term memory. On the other hand, passive avoidance procedures are not very frequently used for comparisons of short- and long-term memory, probably because other procedures (see below) offer better possibilities of interpretation.

Example (See Fig. 3.18).

3.3.2.2 Morris Maze Test

PURPOSE/RATIONALE

Another fairly simple procedure, which allows a greater degree of interpretation, is the Morris water maze (Morris 1981). In this test, a mouse or a rat is placed into a circular tank containing water and has to find an escape platform in a fixed place just beneath the surface. The escape platform is not visible to the animal because the water has been rendered opaque. After swimming around for a certain time, the animal will eventually come across the hidden platform and climb up onto it to escape from the water. When placed again in the water on subsequent occasions, the animal will generally find the platform with increasing rapidity, indicating that it has learned the position of the platform. Although the maze is featureless, it is important that sufficient distinctive cues are present in the experimental room to allow the animal to orient itself.

PROCEDURE

The Morris maze we use consists of a circular water tank (150 cm in diameter) filled with water and maintained at 27°C with an escape platform (15 cm in diameter) 18 cm from the perimeter always in the same position 2 cm beneath the surface of the water. The water is made opaque by addition of milk powder rendering the platform invisible.

Rats are given a single training session on 1 day. A training session consists of four consecutive trials in the Morris maze separated by 60 s. For each trial, the animal is placed in the maze at one of two starting points equidistant from the escape platform and allowed to find the escape platform. The animal is left on the escape platform for 60 s before starting a new trial. If the animal does not find the platform within 120 s, the experimenter removes it from the water and places it on the platform for 60 s before beginning the next trial. During the four trials, the animals start the maze twice from each starting point in a randomly determined order per animal.

Twelve rats are studied per group. The test is performed blind.

The test substance is usually evaluated at three doses, administered p.o. 60 min before the session, and compared with a vehicle control group.

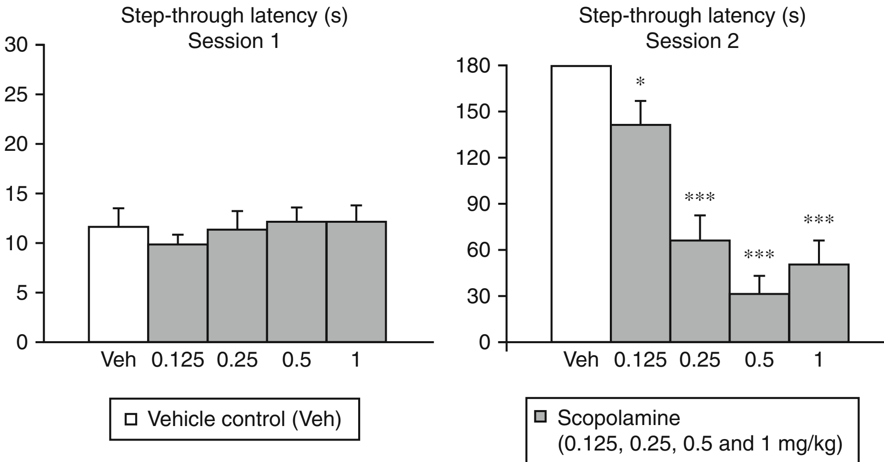

Fig. 3.18 Effects of scopolamine on passive avoidance behavior in the rat. Note the absence of effects of scopolamine on the step-through latency at trial 1 and the presence of a dose-dependent decrease in step-through latency at trial 2, indicating amnesia

Chlordiazepoxide (10 mg/kg p.o.) or scopolamine (0.5 mg/kg s.c.), administered under the same experimental conditions, is used as the reference substance.

The basic experiment therefore includes five groups.

EVALUATION

The principal measure taken is the escape latency at each trial. Decreases in the escape latency from trial to trial indicate learning. A drug-induced flattening of the learning curve therefore indicates impairment of learning. These effects can be analyzed statistically by comparing performance between the treated groups and vehicle control at each learning trial using Student's *t* tests. ANOVA with repeated measures (trials) provides a more sophisticated and sensitive assessment by including within the same analysis all the scores obtained per animal.

Another measure of interest is the animal's escape latency at the first trial. The absence of any treatment effect at the first trial, the animal's first experience of the test situation, can suggest that the test substance is devoid of intrinsic effects on swimming behavior which could confound interpretation of the subsequent data.

One other measure frequently taken, particularly when the animal's behavior is scored using computerized analysis of the video records, is the animal's swimming path during the trials. By this means, it is possible to quantify drug-induced changes in swimming patterns, for example, wall clinging (thigmotaxis), and to calculate the animal's swimming speed, thereby providing another assessment of the intrinsic effects of the test substance on swimming performance.

CRITICAL ASSESSMENT OF THE METHOD

In contrast to the one-trial passive avoidance procedure, the Morris maze permits the progress of learning to be evaluated within the test. Furthermore, subsequent learning can be compared with initial swimming performance. Both factors allow a clearer interpretation of drug effects. Moreover, the Morris maze depends on the animal's use of extramaze visual cues. The behavior can therefore be more readily interpreted in terms of the animal's capacity to learn to orient itself in space (spatial learning) and the effects thereon of the test substance.

Forcing the animal to swim is a powerful motivator and thereby induces a stable behavioral baseline, once the animal has experienced the escape platform. On the other hand, the situation represents a major stress for the animal, particularly if the animal has difficulty finding the escape platform on the first trial. When this happens, drug effects on emotional factors, for example, "behavioral despair" (Porsolt et al. 2002), could confound interpretations in terms of learning/memory. The random nature of the first discovery of the platform is therefore a factor which increases variability, whereas subsequent learning varies little from one occasion to the next and is more clearly interpretable.

The capacity to conduct multiple variants of the procedure (see further details below) endows the Morris maze with a wide range of possibilities for interpreting drug-induced change in cognitive function. This together, with its functional simplicity, no doubt explains the popularity of the procedure.

MODIFICATIONS TO THE METHOD

The two major variants of the procedure are the grouping of the trials and the inclusion or not of probe trials.

In our own basic procedure, four trials are given on a single day with a 60 s timeout between trials. It is possible to repeat the same procedure over several consecutive days in the same test animals. Although more time-consuming, repeated sessions on different days enable drug effects on short-term memory and long-term memory to be distinguished. Short-term memory is best assessed by examining performance on repeated trials on the same day. The decreases in escape latency from trial to trial are a direct reflection of the animal's retention from the immediately preceding trial. In contrast, long-term memory can best be assessed by examining day-to-day performance. Indeed, the purest measure of long-term memory is the change in escape latency on the first trials of each day. This measure reflects the animal's retention from the previous day without confounding from the new learning occurring on subsequent trials on the same day. Indeed, another variant of the procedure is simply to give a single trial on each day. In this way, the influence of within-day learning is totally excluded.

In terms of economy of experimentation, we recommend giving multiple trial sessions on consecutive days and analyzing them as described above.

Another modification is to include probe trials, where no escape platform is present. The retention measure is the time spent in the maze quadrant associated with the escape platform. An animal which remembers the location of the platform will spend more time in that quadrant of the maze. An essential requirement is that the probe trial remains short, say 1 min, to avoid the animal learning that the platform is no longer present. If new learning can be thus avoided, probe trials provide the most sensitive index of the animal's retention of the position of the platform, unconfounded by random elements (the animal finding the platform by chance).

Further modifications are the size of the swimming tank and the position of the escape platform. Both parameters differ widely between different laboratories. In general, larger tanks increase the difficulty for the animal to find the escape platform with a consequently flatter learning curve. Indeed age- or drug-related changes in Morris maze performance depend critically on such factors.

Examples (Figs. 3.19, 3.20).

3.3.2.3 Social Recognition Test

PURPOSE/RATIONALE

Social recognition refers to the fact that an adult rat, when exposed to the same juvenile rat on two occasions, demonstrates that it has recognized the juvenile by a decrease in the amount of investigatory behavior on the second occasion. Absence of a decrease in investigatory behavior at the second occasion suggests that the adult rat has forgotten the juvenile.

This simple model of memory differs from those described above in that it is based on a natural behavioral tendency rather than the situations imposed on the animal by exposure to aversive stimulation.

PROCEDURE

An unfamiliar juvenile rat (40–50 g, 3 weeks old) is introduced into the individual home cage (41 × 25 × 15 cm) of a mature adult rat (400–450 g, 3–4 months old) for 5 min. Following this first encounter (E1), the juvenile is returned to its isolation cage until a second encounter (E2) of 5 min with the same adult rat 30 min later.

Under such conditions, a mature adult rat recognizes the juvenile as familiar, as indicated by a reduction in the duration of social investigatory behavior at E2.

Twelve rats are studied per group. The test is performed blind.

The test substance is usually evaluated at three doses, administered p.o. 60 min before E1, and compared with a vehicle control group.

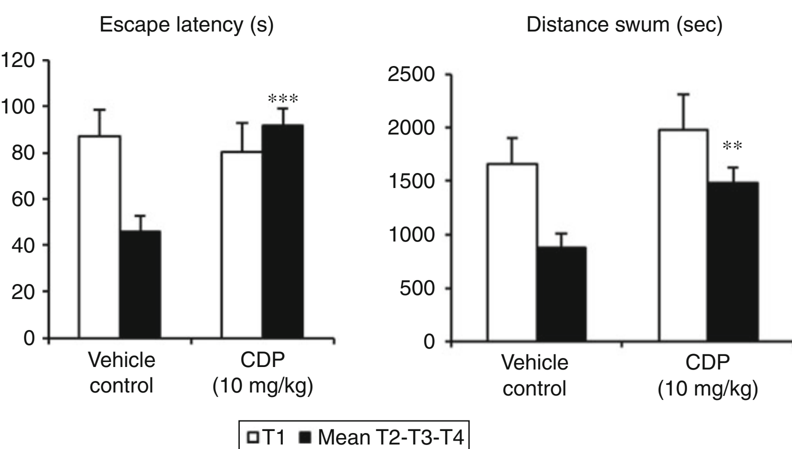

Fig. 3.19 Effects of chlordiazepoxide during the acquisition (single session) of a Morris maze task in the rat. Note the decrease in escape latencies and distance swum in the vehicle control group (short-term memory) and the absence of effect of CDP on performance at the first trial (absence of intrinsic effects on swimming performance). In contrast, it clearly attenuates this decrease (perturbing effect on short-term memory) during the last 3 trials

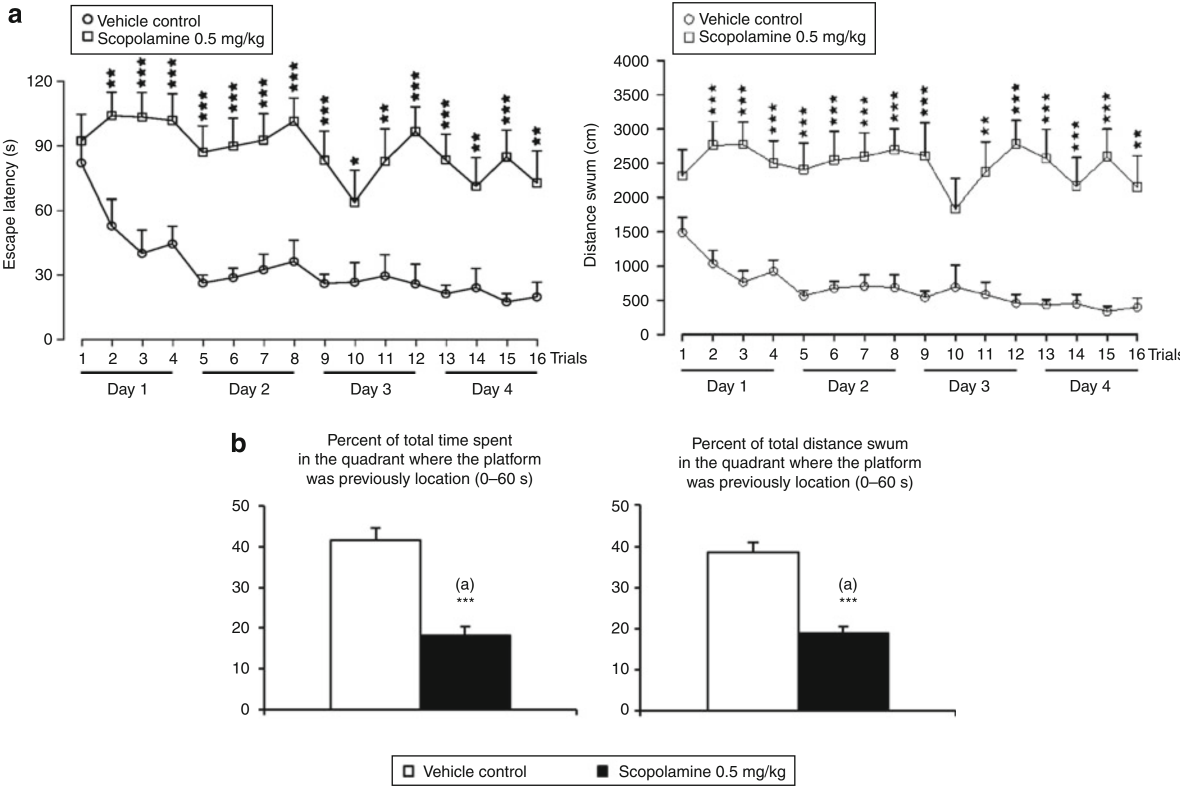

Fig. 3.20 (**a**, **b**) Effects of scopolamine on the acquisition and the retention of a Morris maze task in the rat. Note the clear decrease in escape latencies and distance swum in the vehicle control group from day to day (long-term memory) during the acquisition and the high percentage of time and distance swum in the target quadrant (clear retention) during the probe test. Scopolamine does not induce such a decrease in escape latencies and distance swum and clearly decreases the percentage of time and distance swum in the target quadrant (scopolamine-induced impairment)

Scopolamine (0.25 mg/kg s.c.), administered under the same experimental conditions, is used as reference substance.

The basic experiment therefore includes five groups.

EVALUATION

The time the adult rat spends investigating (sniffing, grooming, closely following) the juvenile is recorded at each encounter.

These two measures permit the calculation of a recognition index which consists of the ratio between the durations of investigation at E1 and E2 (E2/E1). A recognition index of close to unity suggests that the mature adult has not remembered its previous encounter with the juvenile. A recognition index significantly less than unity suggests recognition of the juvenile by the mature adult.

These effects can be analyzed statistically by comparing treated groups and vehicle control at each test session using Student's *t* tests.

CRITICAL ASSESSMENT OF THE METHOD

Social exploration is a natural behavioral phenomenon which occurs when animals are confronted with one another. The behavior is not induced by the experimenter but occurs spontaneously. Such a method possesses therefore a certain face validity in that it appears to resemble memories for social encounters as they occur in man.

Caution has to be applied with such anthropomorphic interpretations, however. Whereas the basis of human social recognition is mainly visual, the major component in rodent social recognition paradigms is more likely to be olfactory (Sawyer et al. 1984). Thus, drugs which affect rodent social recognition may do so

by mechanisms not pertinent to social recognition in man, for example, by changing olfactory cues. Whatever the mechanism, it is clear that animals show memory in social recognition paradigms and that this memory is subject to disruption by drug treatment. The data obtained in a rodent social recognition paradigm may therefore usefully complement data obtained using the more classical approaches described above, where the learning/memory phenomena result from experimental manipulation of the animal's motivational state. With social memory procedures, no prior animal training or habituation is required to obtain the sought-after behavioral effects.

A problem with social recognition procedures is that, being based on spontaneous behavior, they are particularly susceptible to environmental changes. Thus, to obtain reproducible findings, it is essential that all environmental factors (temperature, lighting, ambient noise and temperature, cage size, bedding, age and weight of experimental animals, and time of day) be kept as constant as possible.

Moreover, to ensure that the drug effects observed are not due to intrinsic effects of the test substance on social exploration, it is desirable to precede the main social recognition experiment by a prior dose-response experiment to ensure that the selected doses do not affect baseline social investigation.

MODIFICATIONS TO THE METHOD

The basic paradigm described above ensures conditions under which a high level of social memory is obtained under control conditions. Other approaches aim to attenuate the level of social memory with the hope of the test being sensitive both to memory impairment and enhancement. A decrease in social recognition under the same experimental conditions can readily be obtained by increasing the time interval between E1 and E2, for example, to 120 min. Under these conditions, a vehicle-treated control group of normal mature adult rats will show less or no social recognition memory for the juvenile, whereas clear social recognition memory can be observed with a 30-min interval between E1 and E2 (Lemaire et al. 1994).

3.3.2.4 Delayed Alternation Test

PURPOSE/RATIONALE

One of the most powerful techniques for studying behavior under well-controlled experimental

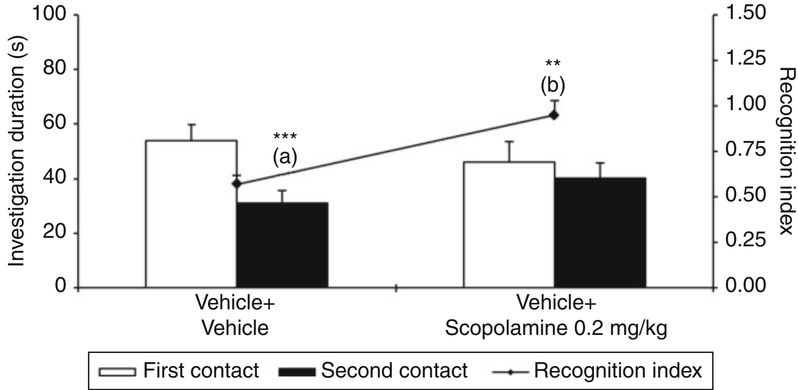

Fig. 3.21 Effects of scopolamine on social recognition memory in the rat. Note the clear decrease in social investigation in the vehicle control group between the first and the second exposure 30 min later (social memory) and the absence of effect of scopolamine on social investigation during the first exposure (absence of intrinsic effects of scopolamine on social investigation). In the scopolamine-treated animals, there is no decrease in social investigation at the second exposure, demonstrating impairment of social memory

conditions is operant behavior. The term operant behavior refers to a particular learned behavior whereby an animal obtains food reward or avoids punishment by pressing on a lever in a so-called Skinner box. Operant techniques permit a wide range of psychopharmacological effects (e.g., antipsychotic, antianxiety, antidepressant, analgesic) to be studied in a quantified fashion, using a standardized environment with a high degree of automation.

The technique also lends itself readily to the study of memory function, in particular by use of delayed responding procedures. In delayed responding, the animal is required to retain information over a short period (usually seconds) and then to show, by pressing an appropriate lever, whether it has correctly remembered the information (Dunnett et al. 1988). In the procedure described below, a rat in a Skinner box is presented with a lever, either on the left or on the right side of the food dispenser. The rat presses the lever, and the lever is withdrawn. Two levers are presented 2.5 s later, and the rat has to press the lever which was not presented previously to obtain a food reward (delayed alternation or delayed nonmatching to sample). If the rat presses the same lever as that previously presented, the lever is withdrawn, but no food is given. In this fashion, the animal can be trained to retain a piece of information (position of a lever) and, thereby, demonstrate its short-term memory capacity.

PROCEDURE

We use standard Skinner boxes (MED Associates, St Albans, VT 05478, USA) equipped with two retractable levers and a food distributor (Roux et al. 1994). The experiments are controlled and the data collected automatically using specialized software (MED Associates, St Albans, VT 05478, USA).

During the 7 days immediately preceding the experiment, the animals are placed on a restricted food regime (15-g standard diet per day) with free access to water. Before being given the standard diet each day, they are also given several 45 mg food pellets (those used as reward in the delayed alternation procedure) to habituate them to this novel food.

The delayed alternation experiment consists of two separate phases:

– Acquisition of lever pressing (single lever)
– Acquisition of delayed alternation (two levers)

Acquisition of Lever Pressing

The aim of this phase is to train animals, on the presentation of a single retractable lever, to press on it to receive a food pellet reward.

Animals are given daily 30-min sessions for about 5 days.

At the end of this phase, between 80% and 100% of the animals acquire the lever-press response. Animals which fail to learn are discarded from the experiments. If some animals are close to establishing steady lever-pressing behavior, they are given extra training with the aim of attaining at least 10 animals per group.

Acquisition of Delayed Alternation (Drug Test)

Subsequent to lever-press acquisition, all animals are submitted to delayed alternation sessions over 10 days. During this phase, the Skinner boxes are fitted with two retractable levers one on each side of the food distributor.

A training session consists of 36 successive trials separated by 10 s. Each trial starts by presenting the animal with one lever (left or right). When the animal presses on the lever, it is given a food pellet, the lever is retracted, and 2.5 s later, two levers are presented. The animal has to learn to press on the lever not previously presented in order to gain a food reward (delayed alternation). If the animal does not lever press within 20 s of a one- or two-lever presentation, the lever(s) is withdrawn, and the next trial commences 10 s later.

The test substance is usually evaluated at three doses, administered p.o. 60 min before each session, and compared with a vehicle control group.

Scopolamine (0.25 mg/kg s.c.), administered under the same experimental conditions, is used as reference substance.

The basic experiment therefore includes five groups.

Drug administrations commence at the beginning of delayed alternation training and continue over the weekend between the two test weeks. The experiment therefore includes a total of 12 administrations.

EVALUATION

Three principal measures are taken:

– Percent correct responses (the number of times the animal correctly alternates expressed as a percentage of the total number of trials)
– Simple reaction time (mean time taken to respond to a single-lever presentation)

– Choice reaction time (mean time taken to respond to a two-lever presentation)

Response accuracy reflects the animal's capacity to remember the lever previously presented and therefore represents a measure of short-term memory. Simple reaction times reflect the animal's rapidity to respond to an unpredictable spatial stimulus and therefore represent a measure of attention. Choice reaction times reflect the animal's rapidity to choose between two levers and therefore represent a measure of decision taking or information processing speed. Performance on all parameters improves over the acquisition period and therefore indicates the animal's capacity to learn a new task.

These effects can be analyzed statistically by comparing performance between the treated groups and vehicle control at each learning session using Student's *t* tests. ANOVA with repeated measures (trials) provides a more sophisticated and sensitive assessment by including within the same analysis all the scores obtained per animal.

CRITICAL ASSESSMENT OF THE METHOD

The delayed alternation task provides a clear index of the animal's short-term memory capacity. Because the animal can be given numerous trials (lever presentations) within a single test session of about 20 min, the procedure provides a very dense behavioral sampling from which to estimate the effects of a drug. Furthermore, measuring the animal's simple and choice reaction times provides additional information about drug effects on other aspects of cognitive performance more related to attention and information processing speed. The operant delayed alternation paradigm thereby provides a useful multiparameter measure of possible impairing effects of a test substance on cognitive function. Indeed, results obtained in our laboratory suggest that different classes of test substance can differentially affect the three parameters measured, demonstrating the usefulness of the procedure for characterizing drug effects.

One of the principal qualities of operant behavior is the stability of the behavioral baselines between different executions of the procedure. Even with the present learning task, where the behavior is by definition labile, the possibility of obtaining comparable results on different occasions represents a major advantage of the procedure. The stable behavioral baselines undoubtedly result from the highly standardized experimental environment, where the behavior is measured automatically and there is a minimum of experimenter influence. Automation also permits numerous animals to be tested simultaneously by the same technician, thereby offsetting the cost of the apparatus and the time-consuming nature of the training procedures themselves.

Despite the stability of the behaviors observed on different occasions, the use of a learning task where the behavior evolves markedly during the course of the experiment constitutes a sensitive background against which to evaluate drug effects.

In view of the above, we recommend the delayed alternation procedure as being the most useful single procedure for evaluating possible deleterious effects of test substances on cognitive processes.

MODIFICATIONS TO THE METHOD

Delayed alternation behavior can be studied at two phases, during acquisition (as above) or when performance has been stabilized after continued training.

Delayed alternation acquisition is probably the most sensitive procedure for detecting potential adverse effects of different kinds, but lends itself less readily to unequivocal interpretation. A flattening of the learning curve could reflect either a drug effect on learning itself or result from drug-induced impairment of the short-term memory necessary for correct performance of the task. If the animal cannot remember which lever was presented previously, it will have difficulty learning to alternate between the two levers.

This interpretational problem can be diminished by training the animals up to stabilized performance. Once stabilized, the behavior will more clearly reflect short-term memory because the learning component is no longer present. Indeed, once alternation performance is stabilized, it is possible to introduce delays of different lengths and thereby assess decreases in response accuracy as the retention delay is increased (delay-dependent forgetting). Thus, once animals have been trained up to stabilized performance, they can be used repeatedly to evaluate different drug treatments.

Another term for describing delayed alternation is "delayed nonmatching to sample." This terminology refers to the first lever presentation (left or right) as a sample and a subsequent response on the opposite lever (alternation) as a "nonmatching to sample." Another variant of the procedure therefore is "delayed matching to sample" whereby the animal must always

press on the same lever as that previously presented to obtain a food reward. Both procedures have been used in experimental studies of adverse drug action with essentially similar results. On the other hand, our own experience in aged rats suggests that age-related deficits in response accuracy during acquisition and stabilized performance are more readily demonstrated using a "nonmatching to sample" procedure.

3.3.3 EEG Studies

The Japanese guidelines suggested that electroencephalogram (EEG) studies should be conducted when necessary (Category B), whereas ICH S7A merely mentions electrophysiology examinations as part of the recommended follow-up studies. Electrophysiology covers a wide range of procedures from in vitro intracellular and extracellular studies to whole animal in vivo studies such as EEG. EEG itself is a very broad concept and refers to all aspects of the electrical activity of the brain, from superficial recordings outside the skull to depth electrodes recording from within the intracerebral structures at extracellular levels. As far as CNS follow-up safety pharmacology is concerned, two major EEG applications, the quantified EEG (QEEG) and the sleep/wake cycle, appear to be of particular relevance because they involve the conscious freely moving animal.

3.3.3.1 QEEG

PURPOSE/RATIONALE

QEEG makes use of the Fourier theorem to analyze the electrical power in the different frequency bands of the EEG (Itil 1981). Animals, with electrodes fixed to the skull (cortical leads) and sometimes also implanted stereotaxically in selected structures (e.g., hippocampus, striatum), are exposed to brief measurement periods during which they are either left free to move spontaneously or activated by means of a treadmill to ensure a stable heightened level of vigilance.

The EEG signals are continuously fed into a computer which divides them into short fragments which are decomposed by fast Fourier formation (FFT) into a series of sine waves. The spectral power, a measure proportional to the wave amplitudes, is then estimated and integrated over predefined frequency ranges. The frequency ranges studied in the rat closely match those which are used to characterize the human EEG: 1.5–4 Hz (comparable with the delta-band in the human EEG), 5–8 Hz (theta-band), 8.5–12.5 Hz (alpha-band), 13–35 Hz (beta-band), and 36–64 Hz (gamma-band). The total power 1.5–64 Hz is also calculated.

The protocol described below is for QEEG evaluation in the rat. Despite the considerable differences in function and structure between human and rat brain, psychoactive drugs showing effects in humans affect the rat brain similarly. Thus, the rat EEG is generally a reliable predictor for human CNS drug effects (Easter et al. 2009).

PROCEDURE

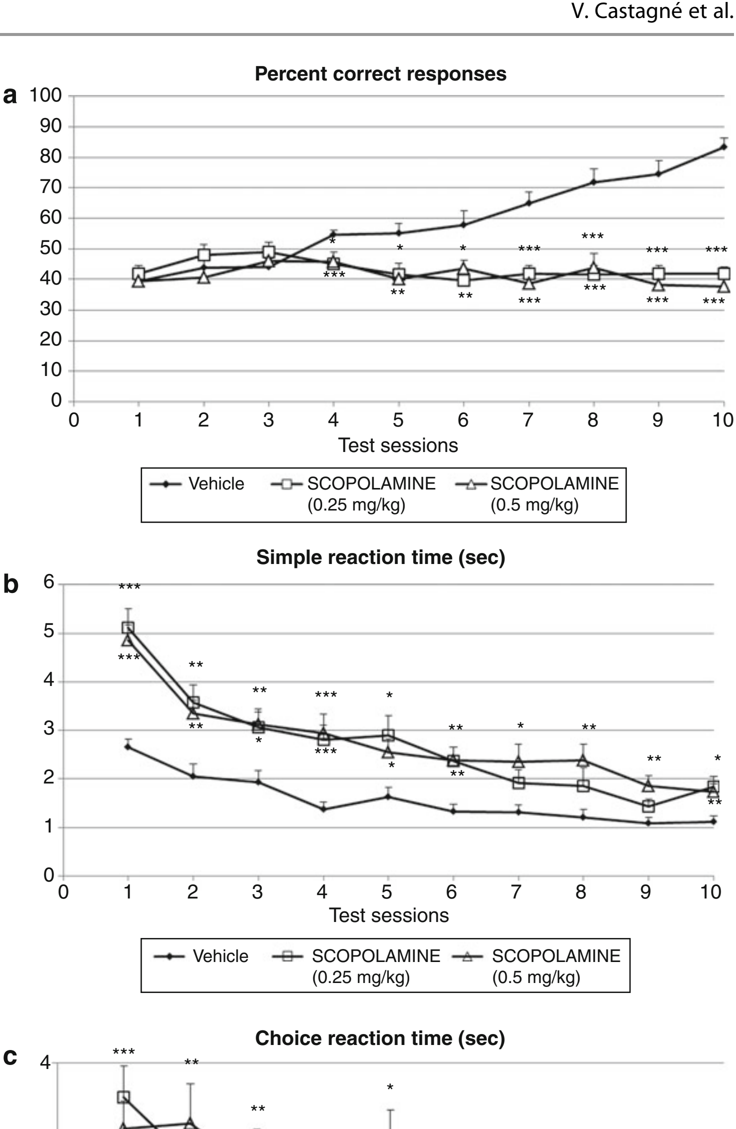
Animal Preparation

Rats are anesthetized (sodium pentobarbital 55 mg/kg i.p., plus supplementary doses of 5–10 mg/kg if necessary) and are implanted with two surface electrodes, consisting of miniature titanium screws, placed over the frontoparietal cortex, and two depth electrodes, consisting of twisted platinum-iridium wires, placed stereotaxically into the hippocampus CA1 area (Paxinos and Watson coordinates interaural, AP + 5.0 mm, L $\pm$ 2.5 mm, V + 7.0 mm). The electrodes are connected to small plugs, and the whole assembly is secured on the skull with acrylic dental cement. Following surgery, implanted animals are kept in individual Makrolon cages (30 $\times$ 18 $\times$ 19 cm) and are allowed at least 10 days to recover.

In order to ensure a minimum of eight animals completing the experimental treatments, a total of 14 rats are implanted.

Testing Procedure

Animals are placed individually on a stationary treadmill (30 $\times$ 10 cm) and are connected to a signal conditioning system (Coulbourn Model V75-01) via



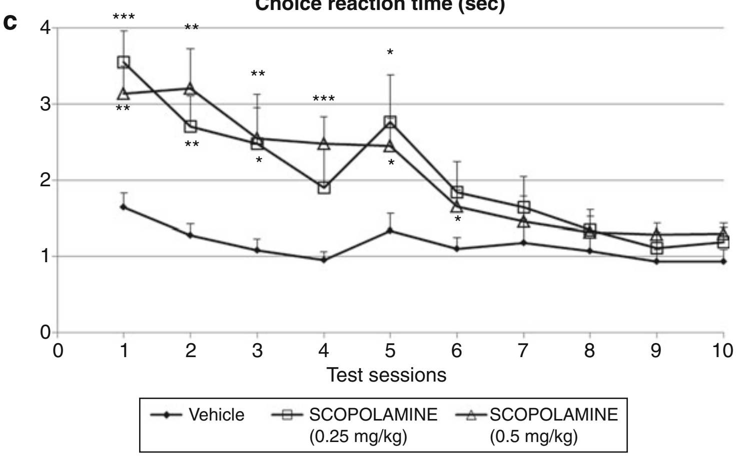


Fig. 3.22 (**a**–**c**) Effects of scopolamine on the three parameters measured during the acquisition of a delayed alternation task in the rat. Note that scopolamine significantly decreases the number of correct responses (impairment of learning/memory) and significantly increases simple reaction times (impairment of attention) and choice reaction times (impairment of information processing speed)

a shielded multicore cable, connected at one end to the plug on the animal's head and at the other end to a swivel mounted 30 cm above the center of the treadmill. Animals are then given a 60-min session with alternating periods of 10 min with the treadmill turned on (speed 1.5 m/min) and off.

Recording sessions take place between 10 a.m. and 5 p.m. with several animals recorded in parallel.

Before beginning drug testing, all animals are submitted to at least one habituation session (without administration) to ensure correct locomotion in the apparatus. The quality of electrical signals for each animal is also checked during this session.

Each animal receives all the treatments in separate 60-min sessions over periods of weeks. The testing procedure during each test week is as follows:

– Day 1: Control session (vehicle administration)
– Day 2: Drug test session (test substance administration)
– Day 3 to day 7: Washout period

Each animal is tested at the same time of day in the same treadmill during different test sessions.

Eight rats are studied per test substance and receive all the different treatments in an order balanced between the animals. The test is performed blind.

EVALUATION

EEG signals recorded by the signal conditioning system are filtered between 1 and 64 Hz and with a notch filter of 50 Hz. Amplification levels are adjusted to avoid saturation of the signal input to the computer. The differential output between the two cortical electrodes is digitized online at a sampling rate of 256 Hz/channel and the data stored in raw data files.

EEG is quantitatively analyzed by spectral analysis using a fast Fourier transform algorithm. In our laboratory, this analysis is performed using the specialized software (ecgAUTO). The mean total spectral power between 1.5 and 64 Hz and the power in five subfrequency bands (1.5–4, 5–8, 8.5–12.5, 13–35, and 36–64 Hz) are calculated for the periods during which the treadmill is on.

For each hour, the mean relative power (% of total spectral power) in the subfrequency bands delta, theta, alpha, beta, and gamma is estimated during treadmill-on phases.

To take into account interindividual variability in the EEG amplitudes, results are expressed as percentage change in the absolute power of corresponding spectra between vehicle and test substance.

The Wilcoxon signed-rank test (two-tailed) is used to compare baseline recordings and recordings after substance administration.

CRITICAL ASSESSMENT OF THE METHOD

Evaluation of drug effects on the EEG was already being performed in the early 1930s, by the discoverer of the human EEG himself, the psychiatrist Hans Berger. Visual analysis of EEG traces is nonetheless a time-consuming, painstaking procedure and, therefore, impractical on a routine basis for safety pharmacology. Apart from the subjective nature of visual trace analysis, subtle changes in EEG activity can often escape visual detection. With the advances in digital data processing, automatic EEG analysis (QEEG) has become possible and the potential usefulness of QEEG for drug screening has been recognized (Van Rinsen and Glatt 1993). Drug-dependent QEEG effects have been shown in various species (Krijzer and van der Molen 1987). Although QEEG has frequently been characterized as an efficacy pharmacology procedure for identifying specific drug activity (Krijzer et al. 1993), QEEG also has undoubted usefulness in safety pharmacology. The same techniques are used for both, but the interpretation is different. Whereas the efficacy approach emphasizes the pattern of power changes in various brain structures, the main question for the safety approach is the presence or absence of such changes.

While there is debate as to whether QEEG, by virtue of the different profiles observed, is capable of identifying specific classes of psychotropic agent, there is general consensus that the QEEG can detect basic stimulant, sedative, or even convulsant activity (Van Rinsen and Glatt 1993). This could have clear relevance for drug safety by corroborating in terms of brain activity, data obtained from behavioral observation. Furthermore, the QEEG can serve as a direct index of cerebral bioavailability, to determine up to which dose a new drug, intended for a non-CNS application, is devoid of effects on the brain (Danhof and Visser 2002).

Analysis of the EEG traces can permit early detection of pathological changes in brain activity, frequently in the absence of overt effects on behavior. This appears to be particularly true for recordings from subcortical structures such as the hippocampus. Like other parts of the limbic system, the hippocampus has a lower threshold for convulsions than the cortex. Early signs of seizures, whether intentionally induced with a convulsant or as a side effect of drug treatment, mostly appear first in the hippocampus. In man, the relevance of the hippocampus is demonstrated by its involvement in temporal lobe epilepsy (Quesney 1986). Moreover, the hippocampus is a key structure not only for pathological epileptic processes but also for memory processing (Squire et al. 2004). Thus, for safety pharmacology purposes, the hippocampus

constitutes a key structure for QEEG analysis. The results from such studies can be critical for deciding whether the development of a substance should be discontinued or shifted into another direction.

Even if EEG activity is usually assessed in the rat, larger species such as the dog are however widely used not only in drug development, to evaluate cardiovascular risk, but also in toxicology. We have data suggesting that the dog might be a particularly suitable species for evaluating human proconvulsant risk (Dürmüller et al. 2007).

MODIFICATIONS TO THE METHOD

Since EEG activity varies with the level of vigilance, the maintenance of a constant vigilance level is essential for QEEG studies. Free-floating vigilance levels can lead to unwanted variability in the EEG signal.

Several procedures have been described to keep animals awake. One is to stimulate the animals' somatosensory system, using tactile or auditory stimuli (Sala et al. 1995). This method is effective for short recording periods, but is neither practical nor reliable for longer-term recording because the animals habituate rapidly to sensory stimuli.

Another approach has been to invert the light/dark cycle and test the animals during their active period (Dimpfel et al. 1992). A persisting difficulty with an inverted light/dark cycle is that even nocturnal animals, such as the rat or the cat, will still show considerable sleep during the dark phase. Inversing the light/dark cycle is also time-consuming in that the animals require several days to habituate to the inversion, thereby increasing costs. It is also virtually impossible to eliminate all sources of disturbance, such as cage cleaning or ambient noise levels, without very sophisticated installations. A final disadvantage is that such inversions are not applied for other CNS safety pharmacology procedures, reducing the comparability of the data obtained.

For the above reasons, forcing the animals to remain active would appear to constitute the optimal procedure for maintaining a constant level of vigilance during QEEG studies. An equivalent approach to the treadmill is the use of a treadwheel (Glatt et al. 1983; Krijzer and van der Molen 1987). With both methods, animals can be kept awake for periods sufficiently long to permit adequate EEG sampling. We favor the treadmill approach because rats do not need any particular training, in contrast to the treadwheel approach where up to 30 days of habituation are necessary. Data obtained in our laboratory using a treadmill show clearly that spectral power is more variable during the periods of rest (data not shown).

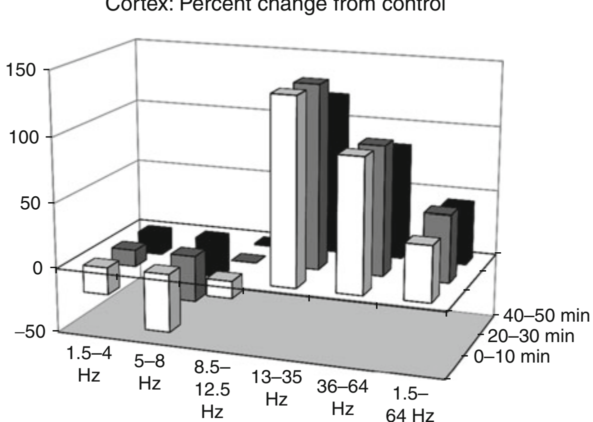
3.3.3.2 Sleep/Wake Cycle

PURPOSE/RATIONALE

Studies of the sleep/wake cycle are to be distinguished from QEEG by the fact that the animals are studied over



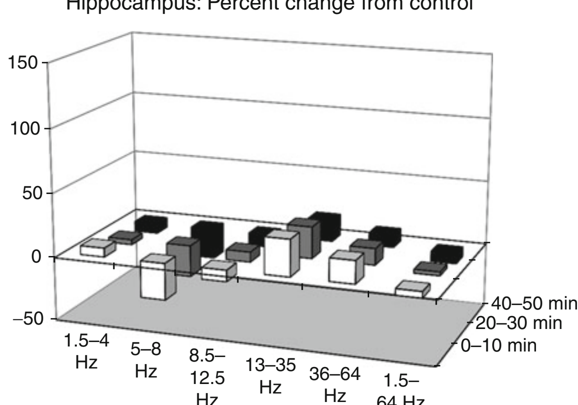


Fig. 3.23 Effects of diazepam on the power spectrum of the quantified EEG. Diazepam (8 mg/kg p.o.) decreases power in the lower frequency range, with an inversion of this effect at high frequencies in the cortex. The effects are weaker in the hippocampus. Similar profiles are observed with other benzodiazepines and benzodiazepine-like substances such as chlordiazepoxide or zolpidem (data not shown)

much longer periods of time (up to several days) (Jouvet 1969). In contrast to QEEG, the aim is to determine the effects of the test substance on spontaneous changes in sleep/waking activity in freely moving subjects and, in particular, whether the test substance induces alterations in the architecture of natural sleep. Although a power spectrum analysis can also be undertaken, the primary analysis is usually confined to changes occurring in the relative durations of the different phases of sleep, the hypnogram (Ruigt et al. 1989).

Although the rat is a nocturnally active animal with polyphasic sleep, experimental data show that sleep is similarly affected by drugs in both humans and rats (Lancel 1999). Thus, studies on the sleep-wake cycle in the rat offer the possibility to test drugs for their capacity to enhance sleep (efficacy pharmacology) or adversely affect the architecture of sleep (safety pharmacology). Unwanted sedative effects for nonhypnotics can be disclosed as well as sleep disturbance induced by both hypnotic and nonhypnotic drugs. From a safety pharmacology standpoint, the aim is to determine up to which dose the test substance is devoid of effects on sleep function.

PROCEDURE

Animal Preparation

Rats are anesthetized (sodium pentobarbital 55 mg/kg i.p., plus supplementary doses of 5–10 mg/kg if necessary) and are implanted with two surface electrodes, consisting of miniature titanium screws, placed over the frontoparietal cortex, and two depth electrodes, consisting of twisted platinum-iridium wires, placed stereotaxically into the hippocampus CA1 area (Paxinos and Watson coordinates interaural, AP −5.0 mm L ± 2.5 mm, V + 7.0 mm). A further two straight platinum-iridium electrodes are implanted into the neck muscle for recording electromyographic activity. The electrodes are connected to small plugs, and the whole assembly is secured on the skull with dental cement. Following surgery, implanted animals are kept in individual Makrolon cages (30 × 18 × 19 cm) and are allowed at least 10 days to recover. One day after surgery, the rats are moved with their cages for adaptation into the recording environment, which is a soundproof, ventilated, and temperature-controlled Faraday room (1.8 × 2.4 × 2.3 m). This room is kept under a 12/12-h light/dark cycle with lights on at 10.00 a.m. Following recovery, rats are subjected to a 2–3-day habituation period in the recording cages (30 × 40 × 48 cm) made out of Plexiglas with sawdust-covered floors, during which they get used to being connected via recording cables to the signal conditioning system (Grass Polygraph Model 7, installed with preamplifiers/amplifiers 7P5/DA and P511). The cables are connected at one end to the plug on the animal's head and at the other end to a turning commutator mounted on the top of the recording cage.

To ensure a minimum of eight rats completing all the experimental treatments, a total of 14 rats are generally implanted.

Testing Procedure

After the habituation period, the test substance is generally evaluated at two doses administered p.o. or i.p.

Recording sessions are performed as follows with nine rats recorded in parallel:

Day 1: Baseline session 1 (treatment 1); without treatment

Day 2: Baseline session 2 (treatment 1); vehicle administration

Day 3: Drug session 1; treatment 1 administration

Day 4 to day 7: No testing

Day 8: Baseline session 1 (treatment 2); without treatment

Day 9: Baseline session 2 (treatment 2); vehicle administration

Day 10: Drug session 2; treatment 2 administration

Administrations are performed at 10.00 a.m. (immediately after switching on the lights), and recording starts 15 min later and lasts 23 h. Half of the animals receive the high dose first and the other half the low dose first (balanced crossover). Each animal is tested in the same recording cage, with free access to food and water during the whole experimental period.

EVALUATION

EEG signals read into the signal conditioning system are filtered between 1 and 75 Hz for the cortex, 1 and 35 Hz for the hippocampus, and 10 and 3,000 Hz for the neck muscle, and all signals are notch filtered at 50 Hz. Amplification levels are adjusted to avoid saturation of the signal input to the computer. The differential output between the two cortical sites, the two hippocampal sites, and the muscle leads is digitized online at a sampling rate of 256 Hz/channel and the data stored in raw data files.

Sleep-wake cycle analysis is performed off-line using the specialized software (ecgAUTO) and the results presentation and statistical analysis with MS Excel.

Sleep-wake cycle analysis is based on power spectral analysis. A fast Fourier transform algorithm calculates from the raw EEG signal total power and the power of subfrequency bands for cortex and hippocampus from 8,192 data points which corresponds to a spectral point covering 16.4 s of real time EEG. For muscle activity, the total energy is calculated, i.e., the sum of the square amplitudes of the EMG over the same time periods/1,000. Under visual inspection of the spectral time-point curve, thresholds are placed manually between minima and maxima of the spectral amplitudes for the different frequency bands. The energy-time curve of the EMG is analyzed the same way. The program then automatically assigns individual spectral points to vigilance stages to form a hypnogram. These hypnograms together with the spectral power values are then transferred into Excel.

The latencies to the first occurrence of SWS and REM are calculated. Further, the absolute time spent in SWS, REM sleep, and wakefulness is calculated for the following time intervals: the total recording sessions (23 h), the half cycles (0–12 h and 12–23 h), and the five time segments (0–4, 4–8, 8–12, 12–18, and 18–23 h).

In addition, the ratio of alpha to delta spectral power, a measure which defines the depth of SWS and the proportion between total and active wake, is calculated for each interval. Differences between vehicle control and test substance are calculated for all variables and for each animal and averaged over the animals per treatment group. A paired *t* test is used for the statistical analysis of each comparison.

CRITICAL ASSESSMENT OF THE METHOD

Human sleep is generally subdivided in five phases, phase 1–4 sleep and REM sleep. Non-REM sleep in the rat has two phases, light sleep and deep sleep, corresponding to the human phases 1 and 2 and 3 and 4, respectively. Since it does not appear to be technically easy to implement an algorithm to differentiate between the two phases, rat sleep is rarely subdivided by computer programs. From a pharmacological point of view, such a differentiation may be of importance to show drug effects which deepen or lighten sleep without affecting other sleep parameters. To date, however, such drugs have not been described.

As with many other animal experimental models, most sleep-wake cycle studies are performed in normal rats. This is less of a problem for studies in safety than in efficacy pharmacology. In efficacy studies, a drug which may be useful to normalize sleep disturbances may not show effects when tested on the normal sleep-wake cycle. There are, on the other hand, sleep-wake cycle models which match human sleep disturbance.

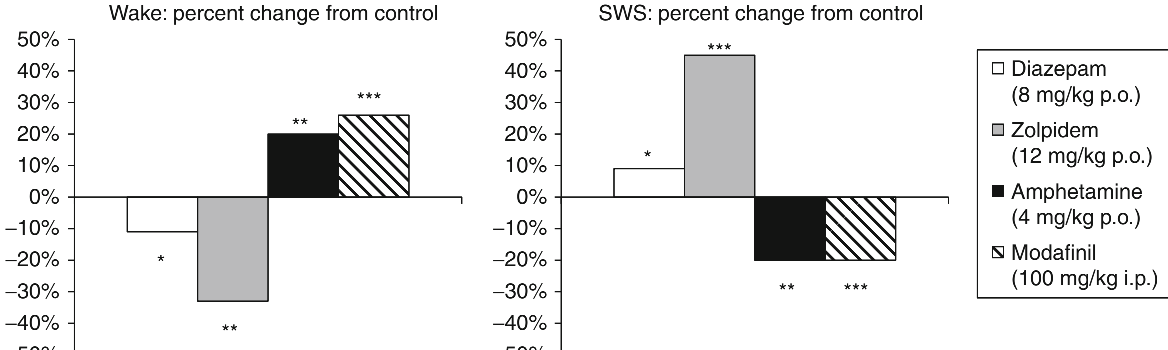

Fig. 3.24 Effects of diazepam, zolpidem, amphetamine, and modafinil on the sleep/wake cycle in the rat during the first 12 h after drug administration. Both diazepam and zolpidem decrease the amount of wakefulness and increase the amount of slow-wave sleep, whereas opposite effects are observed with amphetamine and modafinil

One example is sleep deprivation, another is selective CNS dopamine-depletion, to model sleep disturbance related to Parkinson's disease.

Computerized analysis of the sleep-wake cycle by means of spectral analysis requires that each phase of the cycle expresses its unique activity pattern. Under physiological conditions, this is the case, but may be less evident after certain drug administrations. In exceptional cases, computerized analysis may become impossible because of drug-induced abnormalities in the EEG. In these cases, however, visual analysis would also be impossible because the spectral analysis approach uses the same information as visual analysis. In these cases, measurement of more physiological parameters (see below) may be more helpful.

MODIFICATIONS TO THE METHOD

Telemetry is becoming increasingly used and is slowly replacing the cable technique even if it is relatively expensive. Indeed, telemetry permits simultaneous recording of physiological parameters such as heart and respiratory rate and body or brain temperature in addition to the electrical brain and muscle activity used to differentiate between the sleep-wake cycles phases. This may provide supplementary information about sleep dynamics and approach techniques closer to those used in human polysomnography. Video recording is also useful for capturing behavioral patterns in parallel with cerebral activity (Moscardo and Rostello 2010).

The drug administration time point is an important variable for sleep EEG experiments. Some drug effects are seen only when the drugs are administered before the dark or before the light phase of the cycle. Independent of pharmacokinetic considerations, most laboratories find that the "best" time for evaluating drug effects is several hours from the beginning of the light phase.

In recent years, a new mathematical approach, based on the theory of nonlinear dynamics has been used to analyze EEG signals through the sleep-wake cycle. This kind of analysis has not been shown superior to the commonly used spectral analysis for pharmacological studies. This may rapidly change with the appearance of more powerful computers. In contrast to spectral analysis, which is basically not more than an automation of visual analysis, nonlinear analysis could go well beyond the visual analysis of the EEG trace.

4.1 Background

The inclusion of pharmacological studies (also known as *general*, *secondary*, *or ancillary pharmacology*) in the safety evaluation of new drugs is a well-established practice (Zbinden 1966; Alder and Zbinden 1973). These studies contribute to the safety profile of potential new drugs and provide pharmacological data that can be used for optimization of further compounds and the ultimate selection of compounds suitable for clinical development. The emergence of safety pharmacology as a specialty area distinct from toxicology was facilitated by the appearance of the ICH S7A guideline in which the rationale for safety pharmacology studies was laid out, and study types were defined (The European Agency for the Evaluation of Medicinal Products. Human Medicine Evaluation Unit 2000). However, one topic in particular was instrumental in focusing attention on safety pharmacology studies, namely the concern about drugs causing severe ventricular arrhythmias, including torsades de pointes and, in some cases, sudden death. One must not forget, however, that the purpose of conducting cardiovascular safety pharmacology studies is not just to define a specific proarrhythmic risk but to examine potential effects on the peripheral vasculature, the heart, or any other effect that may secondarily lead to an activation or depression of cardiovascular performance (Sarazan et al. 2011).

Studies designed to detect potential drug-induced effects on the cardiovascular system need to include direct effects on myocardial contractile function as well as peripheral effects on the vasculature that can lead to reflex changes altering the autonomic tone of the heart. Therefore, the key physiological parameters

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_4,

© Springer-Verlag Berlin Heidelberg 2013

that need to be assessed include the heart rate and arterial blood pressure, best reported as both diastolic and systolic pressures since the evaluation of only mean arterial pressure can potentially miss important, drug-induced effects. An electrocardiogram is typically included in such a study to detect potential effects on myocardial depolarization and intramyocardial conductance and repolarization, either using limb leads or in some cases using an electrode attached directly to the heart. Overall cardiovascular performance is perhaps best assessed by measuring cardiac output, but this parameter is easiest to measure in anesthetized animal models with invasive techniques including flow probes or dye/thermal dilution approaches. Cardiac output is, however, the product of heart rate and stroke volume. Heart rate is easily measured, and stroke volume can be measured using various imaging techniques; echocardiography being the most widespread. Measurement of left ventricular pressure is also possible and allows one to assess changes in myocardial contractility using the maximal rate of pressure development in the left ventricle (LVdP/dtmax). Since drug-induced effects on myocardial contractility are not uncommon, it is highly recommended to include this type of assessment in cardiovascular safety pharmacology studies (Sarazan et al. 2011).

Numerous strategies for the conduct of cardiovascular safety studies have been suggested (Pourrias et al. 1999; Lacroix and Provost 2000; Champeroux et al. 2000; Gralinski 2000; Kinter and Valentin 2002; Guth et al. 2004) based on the regulatory requirements as well as the needs for efficient drug development. This chapter will present the methodologies included in most of these strategies.

4.1.1 General Considerations

The ICH S7A guidance on safety pharmacological studies for human pharmaceuticals (The European Agency for the Evaluation of Medicinal Products. Human Medicine Evaluation Unit 2000) states a preference for in vivo studies using experimental models with unanesthetized animals. This is a major deviation from previous general practice, based on the recommendations of the Japanese Guidelines for Nonclinical Studies of Drugs Manual (Japanese Ministry of Health and Welfare 1995), in which it was stated that anesthetized animal preparations are typically used for cardiovascular safety evaluations. The new regulatory preference for the use of conscious animals is based on the possible complicating effects that anesthetic agents can have on the cardiovascular system. For example, pentobarbital anesthesia is known to have direct effects on ventricular repolarization (Bachmann et al. 2002). Furthermore, nonoptimized anesthesia can lead to nonphysiological conditions that also may mask drug-induced effects. An example of this is the tachycardia often seen in animals overdosed with pentobarbital anesthesia. Thus, experimental models using conscious animals for measuring cardiovascular parameters will be highlighted. However, due to their great utility when carefully performed, cardiovascular models using anesthetized animals should still be included in the cardiovascular safety pharmacology portfolio and will therefore be addressed.

4.1.1.1 Conscious Versus Anesthetized Animal Use

Despite the theoretical advantages, the use of conscious animals brings with it new challenges for an effective study design. For example, the cardiovascular system of a conscious animal, as compared to an anesthetized animal is much more variable, as the animal reacts to its environment. Subtle, drug-induced effects may not be readily apparent in animals that are reacting to external visual or acoustic stimuli in the laboratory environment. Furthermore, drug-induced central nervous system effects, or any other drug-induced effect that impacts the animals' well-being (e.g., anxiety, gastrointestinal disturbances, etc.) may result in secondary effects on the cardiovascular system. These aspects can introduce a substantial amount of variability in the cardiovascular parameters measured, such as heart rate. Given the reliance of the QT interval duration on heart rate, a variable heart rate can also lead to challenges for the analysis and the assessment of proarrhythmic potential due to delayed ventricular repolarization. With the use of conscious animals, the amount of training needed to achieve the desired basal physiological conditions is associated with increased time, effort and, consequently, expense. Therefore, despite the preference for conscious animal studies for the safety pharmacological evaluation of new drugs, including the cardiovascular system, these models are complex and need a considerable amount of time and effort to conduct them optimally. Models using anesthetized animals are usually simpler

and highly stable models, in which a variety of invasive measurements (e.g., cardiac output, ventricular function, regional blood flow, etc.) can be made, that are not easily accessible in the conscious animal. Thus, there is still an important role for the use of anesthetized animals, particularly in the study of cardiovascular effects of drugs such that this type of model is still included in this text.

4.1.1.2 Animal Reuse and Dose Selection

The use of conscious animals for conducting cardiovascular safety pharmacology studies introduces the possibility of reusing animals. Techniques are available for obtaining the basic cardiovascular data (heart rate, arterial blood pressure, ECG, and even left ventricular pressure and LVdP/dt) without affecting the health status of the animal and without the need to euthanize the animal at the end of the study. The possibility of reusing animals will be affected by the doses of test article selected for use in the safety pharmacology studies. The ICH S7A guideline states that doses should include and exceed the therapeutic range with the goal of defining the dose–response relationship of any adverse effect observed. In practice, studies are typically designed to include therapeutically relevant doses of the test article and predefined multiples based on the expected side effect profile and needed therapeutic window for a given clinical indication. The dose applied should always be related to the actual plasma drug concentration achieved. Since drug-induced effects are most likely to coincide with the peak plasma drug concentration reached, the Cmax is usually the most relevant pharmacokinetic parameter for safety pharmacological assessments. The duration of the exposure is of interest to correlate to the reversibility of a given effect. As an example, a maximal dose could be selected to achieve a 30-fold higher plasma drug level than anticipated for therapeutic use for a non-life-threatening clinical indication. Alternatively, one may target a lesser maximal plasma drug level for compounds used to treat a life-threatening disease, where side effects may be acceptable when the overall benefit-risk assessment is positive. Additionally, for cytotoxic agents, one should seriously consider the use of an anesthetized animal model in which higher doses can be given without the fear of causing the animals distress and they are euthanized while still anesthetized. The study design in conscious animals should avoid discomfort or pain for the animals used, as emphasized in the ICH S7A guideline. Furthermore, safety pharmacology studies are usually single-administration studies in which effects, when seen, are usually fully reversible such that after an appropriate washout of the test article, the animals are suitable for use in further studies. This results in a reduction in the number of animals needed for conducting safety pharmacology studies but does introduce the need to monitor the health status of the animals to qualify them for further use.

4.1.1.3 Species Selection

The ICH S7A guideline proposes the use of relevant animal models without explicitly stating which animal species are most appropriate for use. For the cardiovascular evaluation of new drugs, the dog has been the preferred species in the past, and there is a wealth of comparative data available from studies performed using the dog (Gralinski 2003). As such, it is likely that the dog will remain the preferred species for such studies despite ethical pressure to limit the use of companion animals for drug testing. Use of the dog may be of particular advantage when the dog is also the species used for toxicological studies. Nevertheless, other animal species including the minipig, and nonhuman primates are considered to be appropriate models for cardiovascular safety pharmacology studies.

The rat is also a useful species for conducting cardiovascular safety pharmacology studies. However, since the evaluation of the electrocardiogram is an essential element of a safety pharmacology cardiovascular assessment, the rat is in this regard not ideal. The rat is not a suitable species for testing the effects of a drug on ventricular repolarization since its repolarization is not dependent upon IKr and IKs, as in larger mammalian species, but rather on I_{to}. Despite this limitation, the rat still is an attractive cardiovascular model for detecting effects on arterial blood pressure and heart rate, on the autonomic nervous system, or even other types of arrhythmia not related to altered ventricular repolarization. Technology is available for studying rats in the conscious state, and they may also be reused, as mentioned above in conjunction with dogs or other larger animals. The use of the rat as a cardiovascular model is probably best suited for early pharmacological testing of drug candidates and may provide useful data for lead optimization at a time when amounts of a given test article are not adequate to perform studies in the larger species used as

cardiovascular models. Finally, since the rat is still a standard species for toxicological studies, there is interest in knowing the cardiovascular effects of a test article in that species. Therefore, the conscious rat model is included in this text as providing a useful cardiovascular safety pharmacology model. Alternately, the guinea pig can be used for specific studies of effects on ventricular repolarization and offers interesting and relevant models for early detection QT prolongation and proarrhythmic properties (Yao et al. 2008) which may be particularly useful in early stages of development.

4.1.1.4 In Vitro Studies for Electrophysiological Effects

There is a clear association between drug-induced QT prolongation and arrhythmia and the blockade of myocardial IKr. This suggests the measurement of drug effects on IKr or a model mimicking IKr in studies in vitro. The minimal requirement for addressing the risk of QT-based arrhythmia appears to be two study types: (1) effects on IKr, the specific myocardial membrane current thought to be mechanistically responsible for most drug-induced QT prolongation and (2) effects in vivo on the QT interval of the electrocardiogram from an appropriate (i.e., nonrodent) animal model, the currently used biomarker for proarrhythmic risk.

The CPMP “points to consider” paper of 1997 (The European Agency for the Evaluation of Medicinal Products. Human Medicines Evaluation Unit. Committee for Proprietary Medicinal Products 1997) pointed out that a thorough electrophysiological characterization of a drug requires evaluation on multiple levels of physiological complexity. In particular, the assessment of the effects of a drug on the myocardial action potential is an important link between the possible effects on a single ion channel type (such as hERG) and the consequent effects seen in the electrocardiogram (such as QT prolongation). Models using isolated Purkinje fibers, papillary muscles, myocardial wedge preparations, or even isolated hearts were proposed to allow one to assess the effects of a drug on the integrated electrophysiology of the heart. These types of models have been shown to detect the effects of many of the known proarrhythmic agents that cause their action through action potential prolongation. However, comparative evaluations, most notably that organized by ILSI (International Life Sciences Institute), provided data suggesting that not all of the know proarrhythmic agents produced effects that could be easily detected in the dog Purkinje fiber model. The observation of such false-negative results leads to dropping this model as a mandatory study type. Nevertheless, the usefulness of this type of model is still acknowledged, and these studies may play an important role for early drug discovery in providing a more thorough risk assessment at a time when in vivo studies are still not feasible due the lack of adequate amounts of a test article. Thus, both in vitro study types (IKr and similar models, and myocardial action potential models) are included in this text.

4.1.1.5 Models of Repolarization-Dependent Arrhythmia

Perhaps the most convincing evidence that a drug is proarrhythmic would be to show a dose-dependent increase in the incidence of a torsades de pointes–like arrhythmia in an animal model. Indeed, the ICH S7B guidance also acknowledges the theoretical interest in the use of this type of model. However, due to the complexity of both these experimental models and their unclear relationship to a proarrhythmic activity clinically, there is no requirement to provide such data. Rather, there is simply the call for a further development of these types of models to determine their predictive value for risk in humans. There are a few models that appear to be useful, should one choose to evaluate proarrhythmic action of a drug directly, and these will be presented in this text. Whereas these models are not considered to be part of the basic cardiovascular safety pharmacology evaluation of a drug, they may be useful as follow-up studies.

4.2 In Vivo Experimental Models for Cardiovascular Safety Pharmacology

4.2.1 Cardiovascular Safety Studies in Conscious Dogs and Other Species

PURPOSE AND RATIONALE

The preferred model for performing safety pharmacology studies on the cardiovascular system according to the ICH S7A guideline is the conscious animal under unstressed, physiological conditions (The European Agency for the Evaluation of Medicinal Products. Human Medicine Evaluation Unit 2000). This includes the evaluation of drug-induced effects on systemic arterial hemodynamics and the electrocardiogram. Important cardiovascular parameters are, however, only accessible through invasive measurement techniques that can interfere with the physiological status of the animal subject. Telemetry-based systems allow one to monitor hemodynamic parameters including heart rate, arterial blood pressure, and the ECG (and, with some systems, left ventricular blood pressure and left ventricular dP/dt) with the animals in their home cage thereby serving to reduce the stress associated with the collection of data. It should be noted that the use of telemetry is not essential for the performance of this type of study. For example, animals can be trained to the laboratory environment such that they can be examined using light restraint (e.g., sling or chair) under physiological conditions.

PROCEDURE

There are two commonly used full-implant telemetry systems employed for this type of study (Data Science International (DSI), USA, and Integrated Telemetry Services (ITS), USA). They typically measure arterial blood pressure and a single electrocardiogram, but they can also be configured for the measurement of left ventricular pressure or multiple ECG leads. A single ECG lead with clearly definable wave forms is usually sufficient for detecting drug-induced effects, however. Beagles are frequently used for these studies, but larger dogs have the advantage of a simplified implantation procedure and, in general, lower heart rates at the time of the subsequent studies. There is some evidence that drug-induced effects on the QT interval duration are more pronounced in females. For the dog, this difference, if present, appears to be very small and can be disregarded such that animals of both sexes can be included in these studies. All animals should be adequately trained for adaptation to their home cage and laboratory environment prior to their being instrumented.

4.2.1.1 Instrumentation

The chronic implantation of the telemetry systems is a complex procedure requiring experience for the best results. For the best results, it is highly recommended to observe and learn the procedure at an experienced laboratory prior to embarking on one's own. The detailed information is meant only to give the reader a sense for the procedure and is not intended to be prescriptive.

The transducers of the telemetry implant are calibrated prior to implantation, and the unit is sterilized using a low-pressure ethylene oxide process.

Dogs are anesthetized with a combination of Rompun (xylazine hydrochloride, 1 ml/10 kg, i.v.) and Ketavet (ketamine hydrochloride, 0.7 ml/10 kg, i.v.) after premedication with Temgesic (buprenorphine, 0.2 mg/kg i.m.) and ventilated with 66% N_2O and 33% O_2 and 1% isoflurane. All procedures are performed under aseptic conditions using sterilized equipment.

For this example, the implantation of a T27 unit from ITS is described. The dog is placed in a lateral recumbency with the left side facing the surgeon. An incision is made in the fifth intercostal space, beginning from the dorsal tip of the scapula for approximately 20 cm. The latissimus dorsi, serratus dorsalis, and iliocostalis thoracis muscles are divided using a scalpel. The incisions are then covered with saline-soaked gauze. The battery and transmitter of the implant are positioned by making an 8-cm incision right-angled on an imaginary line between the sternum and the end of the costa fluctuans. A small pocket is opened between the external and internal oblique abdominal muscle layers, just large enough to place the battery (dorsal) and the transmitter (ventral) inside this "pocket." The pocket is closed using sutures of 2-0 vicryl (V517H) stitches. A pocket is opened for the switch-on antenna that is placed under the skin. The cables with both pressure transducers and ECG leads extending from the ventrally implanted transmitter are guided subcutaneously to the lateral incision. The antenna used to send the telemetry signals is guided subcutaneously from the ventral transmitter location dorsally toward the spine and then runs parallel to the spine for ~25 cm. The distal end is fixed in place with a suture. The small incisions required to place the antenna are then closed, and the initial ventral incisions required for battery and transmitter placement are closed.

The aortic pressure transducer is implanted next. The intercostal muscles are incised. A rib retractor is then inserted and gently and gradually opened to give the required access. Lung lobes are packed away with saline-soaked gauze to expose the aorta. The 5-cm segment of the descending aorta is then isolated to allow implantation of the aortic pressure transducer. The isolated segment is partly clamped proximally and distally to maintain blood flow underneath the clamp. A microscalpel is used to make a hole in the aortic wall, and the pressure transducer is introduced via this hole into the aorta using a Russian forceps. The transducer is sutured into place, and blood flow is restored.

The left ventricular pressure transducer is then implanted. The pericardium is opened so that the apex of the heart is exposed. The heart is gently held in one hand, and two stitches in the ventricular wall for fixation are made. A purse-string suture is made around the apex. A sharp spike is then placed into the apex of the left ventricle, and the transducer is placed into the ventricle and sutured firmly in place.

The lung is then inflated, and the intercostal muscles are sutured closed. The ECG lead is then fixed close to the sternum in the sixth intercostal space. The muscle layers are then closed, and the lungs are inflated once more to displace all residual air. The skin is then closed.

The gas anesthesia is then turned off, all incisions are treated with topical antibiotics and dressed, and dogs are allowed to wake up. Animals are extubated when their swallow reflex has returned. Analgesics and antibiotics (Temgesic and Tardomycel, benzylpenicillin-benzathine, and benzylpenicillin-procaine) are administered for 7 days following the procedure. Dogs are allowed to recover for 14–21 days before experiments using test substances are initiated.

Studies are conducted with the animals in their home cages that have been equipped with antennae to pick up the transmitted physiological signals. Drugs can be treated orally, intravenously, subcutaneously, or inhalatively (Markert et al. 2004). After treatment, dogs are returned to their home cages for the duration of the study that can last up to 24 h if needed. This is usually based on the duration of the expected drug exposure or possible pharmacological activity of the test article. Longer studies should allow for feeding of the animal and water should be available ad libitum.

4.2.1.2 Experimental Design

Studies can be conducted as group comparisons if sufficient numbers of animals are available. Alternatively, the use of a Latin square crossover experimental design allows for studies with fewer animals (e.g., $N = 4$).

The experiment starts after an equilibrium period of 60–120 min to allow the dogs to acclimate to the measurement pens. The administration of the test compound is started after a 30–45 min control period. Experiments involving intravenous infusions or frequent blood sampling are performed in smaller cages to allow close monitoring of indwelling catheters. Continuous measurements should not, however,

exceed 6–8 h without allowing for a short pause for exercise. Continuous measurements for up to 24 h are acceptable if the animals can be kept in larger cages.

EVALUATION

The hemodynamic and ECG parameters include systolic, diastolic, and mean aortic pressure; aortic pressure peak; systolic and end-diastolic left ventricular pressure; left ventricular pressure LV dP/dt max and dP/dt min; heart rate; and PQ, QRS, and QT intervals. NOTOCORD-software (or equivalent) is used for acquisition of data, whereas Excel (or equivalent) is used for data analysis. Data are summarized at predefined time points by calculating median values + SD. Of particular interest are time points corresponding to the time of Cmax.

4.2.1.3 Correction of the QT Interval for Heart Rate Changes

The QT interval duration is heart rate dependent. Correction of QT values for changes in heart rate is the most common procedure used to discriminate drug-induced changes in QT interval from physiologic changes of heart rate (nycthemeral cycle, emotional reactions) or direct or indirect drug-induced effects on heart rate. The use of correction formula derived from clinical data (Bazett, Fridericia, etc.) is not appropriate for use with dog ECGs. Individual correction of QT interval is now the preferred way to derive any QT heart rate correction. The principle of individual correction involves the establishment of individual QT/RR relationships for each animal during a treatment-free period. A 24-h period is usually sufficient to characterize QT values achieved at low heart rate levels, usually during the night period or at high heart rate levels during the daylight periods of activity. The slope of the QT/RR relationship is then derived individually for each animal and used in a correction formula to achieve a null slope when applied to the treatment free QT/RR relationship. The latest refinement of individual correction methods is the probabilistic method (Holzgrefe et al. 2007) and an individual correction method (Markert et al. 2011). In addition to individual correction, this method involves calculation of mean QT and RR values from a large number of successive beats, 250 beats at least in dogs for each time points. Its main advantage is to markedly reduce QT interval variability related to the autonomic nervous system rhythms and to the hysteresis phenomena (delayed adaptation of QT interval due to rapid heart rate changes). The probabilistic method achieves a sensitivity threshold less than 10 ms for the QT interval in conscious dog studies, i.e., similar to that obtained in clinical trials.

The QT interval is also dependent on body temperature. In conscious dogs, mean changes in the QT interval of 14 ms per degree of changes in body temperature have been reported (Van der Linde et al. 2008). Consequently, body temperature is a parameter that should always be recorded in parallel to QT interval measurements in conscious dogs for an accurate and reliable interpretation of cardiovascular safety studies.

4.2.1.4 Drug Exposure

It is essential to relate any drug-induced effect to the plasma drug levels achieved. It is possible to take blood samples during this type of study, but it must be accepted that this disrupts the hemodynamic status of the animals for up to 30 min. An alternative approach is to conduct pharmacokinetic studies in the same animals (or other similar animals) on another day.

4.2.1.5 Animal Reuse

Animals instrumented for this type of study may be reused. Since the instrumentation is fully implanted without externalization of wires or catheters, there is little risk of developing sepsis after successful implantation. The batteries are designed to provide long life well in excess of a year. After the completion of a given study and an appropriate washout time, further studies can be conducted. This is facilitated by the fact that studies are typically single-administration studies using doses that are not intended to cause irreversible effects. The qualification of animals for subsequent use should be based on the health status of the animals. Given the ease of obtaining hemodynamic data from these animals, one can maintain historical data on heart rate and blood pressure, parameters that are sensitive to the overall well-being of the animal. Additionally, clinical chemistry parameters can be monitored to detect possible effects on kidney and liver function.

MODIFICATIONS OF THE METHOD

4.2.1.6 Species

Similar telemetry-based cardiovascular safety pharmacology studies can be conducted in minipigs

(Stubhan et al. 2008) and monkeys (normally *Macaca mulatta* (rhesus) or *Macaca fascicularis* (cynomolgus), Authier et al. 2007). These two alternative species are of interest due to their use in toxicology studies where the dog is deemed inappropriate. The main technical disadvantage when using freely moving cynomolgus monkeys is the poor quality of ECGs when using subcutaneous electrodes which does not allow automated calculation of cardiac conduction times. For this species, epicardial placement of ECG leads or the ITS telemetry system is highly recommended to achieve an optimal quality of ECGs, enabling automation of determination of the QT interval (Holzgrefe et al. 2007). Pharmacological sensitivity to drugs causing QT prolongation in the cynomolgus monkey is close to that of beagle dogs (Champeroux et al. 2011). In cases of autonomic nervous system–mediated tachycardia, drug-induced QT prolongation might be masked or markedly reduced in conscious dogs (Champeroux et al. 2010). In such a situation, cynomolgus monkeys offer an interesting alternative animal model since this species seems to be less sensitive than dogs to effects of the autonomic nervous system on the QT interval duration.

Whereas rats are also used in toxicological studies, they are not appropriate for use in cardiovascular safety pharmacology studies since they are not sensitive to drug-induced effects on ventricular repolarization dependent upon a blockade of the myocardial rectifying current IKr. Rats may nevertheless prove useful for detecting hemodynamic effects of drugs, particularly early in drug research when amounts of test article may be limited (see below).

The guinea pig has been shown to demonstrate drug-induced effects on the QT interval duration (Hamlin et al. 2003) and is suitable for use with telemetry-based systems. However, their intolerance of arterial catheters limits their use for simultaneously measuring arterial blood pressure.

4.2.1.7 Critique of the Method

The telemetric assessment of cardiovascular effects of drugs is considered the gold standard model for safety pharmacology studies. Animals can be studied in optimized, physiological conditions with neither anesthesia-dependent effects nor with the possible interference from other external influences. This is thought to best mimic a clinical setting and thereby best demonstrate possible drug-induced effects. The reuse of animals instrumented for the telemetric assessment of cardiovascular parameters also allows for a reduction in the numbers of animals needed for such studies. The disadvantages of this experimental approach relate primarily to the costs for establishing and maintaining such a system, as well as the dedicated laboratory space required. Furthermore, a high level of training is required, particularly for the successful implantation of the telemetric equipment. Due to the fact that data can be collected continuously for a long period of time, attention has to be paid to the manner in which the collected data is collected, reduced, managed, and statistically evaluated.

4.2.2 Cardiovascular Safety Pharmacology Studies in Anesthetized Dogs and Other Species

PURPOSE AND RATIONALE

The basic parameters needed for a safety pharmacology evaluation of possible cardiovascular effects of drugs include heart rate, arterial blood pressure, and the electrocardiogram. These parameters can also be measured in anesthetized dogs or other appropriate animal species. One must recognize the potential influence of the anesthesia on the parameters measured, but this type of experimental model offers certain advantages. The use of an anesthetized animal allows for more invasive techniques to be applied, thereby giving a more in-depth evaluation of possible drug effects on heart and vascular function in a variety of perfusion beds. A well-performed study using an anesthetized animal model is characterized by a highly stable hemodynamic state with very low variability of the measured parameters. This translates into a high sensitivity for detecting possible drug-induced effects. The oral route is, however, not accessible in the anesthetized animals although intraduodenal administration may provide a reasonable alternative administration route if intravenous administration is not feasible or desirable.

Measurements possible in this model include end-diastolic and systolic pressure of the left ventricle, contractility of the heart (usually using peak positive LVdP/dt or LVdP/dt at a developed pressure of 40 mmHg), heart rate, cardiac output, and arterial blood flow in a given local perfusion bed. Test compounds can be classified in terms of a variety of pharmacological actions:

- Positive and negative inotropic effects
- Arrhythmogenic effects
- Hyper- or hypotensive effects
- Tachycardic or bradycardic effects

In summary, despite the preference for studies in conscious animals stated in the ICH S7A guideline, the use of anesthetized animals for assessing cardiovascular effects of drugs is a valid and useful approach with a variety of practical advantages in comparison to conscious animals.

PROCEDURE

Male or female dogs weighing between 15 and 25 kg are used. Various anesthesia regimens are appropriate for conducting this type of study including injectable anesthetics (e.g., pentobarbital, alpha-chloralose) as well as inhalative anesthetics (e.g., isoflurane). Animals are ventilated mechanically, and blood gas parameters should be monitored to confirm appropriate ventilation rate and depth. Venous and arterial catheters are placed either in the neck (A. carotis, V. jugularis) or groin (A. femoralis, V. femoralis) for vascular access and the measurement of arterial blood pressure (using external pressure transducer), blood sampling, and intravenous administration of test compounds.

Left ventricular pressure can be measured by use of a catheter-tip micromanometer placed in the left ventricle through the carotid artery. Alternatively, left ventricular pressure can be measured with a pressure transducer placed directly into the ventricle through the apex and secured with a purse-string suture; however, this approach requires a thoracotomy. The use of a solid-state manometer, as opposed to a fluid-filled catheter, is essential for the measurement of left ventricular pressure when one also wants to assess myocardial contractility using LV dP/dt, the derivative of the left ventricular pressure signal. Fluid-filled catheter systems do not have a frequency response capable of capturing subtle changes in LV dP/dt and give damped measurements.

Cardiac output can be measured using dye- or thermal-dilution techniques or by placement of an electromagnetic flow probe around the pulmonary

artery. Insertion of a pressure transducer or fluid-filled catheter into the pulmonary artery and pulmonary vein allows for the calculation of pulmonary vascular resistance. The measurement of flow through the proximal aorta may also be useful but does not include coronary blood flow and as such is not equivalent to total cardiac output. Selective arterial blood flow can be measured using either electromagnetic or Doppler flow probes around the vessel of interest. Commonly measured regional flows include coronary (circumflex or anterior descending arteries), femoral artery, or renal artery blood flow.

The electrocardiogram can be obtained using standard limb leads and/or precordial leads. A lead should be selected that is stable over time and that has a sharp demarcation at the end of the T wave to facilitate the measurement of the QT interval duration. One can also position a monophasic action potential electrode catheter through the femoral or carotid artery to obtain endocardial monophasic action potentials (see below Modification of the Method).

4.2.2.1 Experimental Course

It is imperative to allow sufficient time after the instrumentation is complete to achieve a stable, steady-state hemodynamic condition prior to administering a test compound. Continuous monitoring of arterial blood pressure and heart rate should demonstrate no changes in the parameters measured for at least 20 min. A test article can then be applied by the chosen route (intravenous, intraduodenal, inhalative) in doses appropriate for the compound. Sufficient time is then allowed for the development of any hemodynamic effects, if any (usually at least an additional 20–30 min), and further higher doses of the test article can then be administered. It is advisable to take blood samples at the end of each dosing interval for the determination of drug levels. The overall duration of the study can last for hours if care is taken to keep the animal's body temperature in a normal range and to replace fluids through the intravenous administration of warmed saline or other suitable volume replacement. Whereas possible drug-induced effects can be assessed by comparing data at each dosing interval to the pretreatment measurements, it is advisable to include a vehicle-treatment arm in which animals are treated identically but with an equal volume of the vehicle used. This is particularly important when excipients are needed to keep the test article in solution.

4.2.2.2 Parameters Measured

The following parameters should be measured in all studies:

1. Heart rate (HR) (beats/min)
2. Arterial blood pressure (BP, diastolic and systolic, mean) (mmHg)
3. Electrocardiogram (PR interval, QRS duration, QT interval) (ms)

If used, the following additional measurements can yield additional insight into possible drug actions:

1. Left ventricular end-diastolic (LVEDP) and peak systolic pressure (mmHg)
2. LV dP/dt or LV dP/dt_{40} (mmHg/s)
3. Cardiac output (CO, ml/min)
4. Regional arterial blood flow (ml/min)

Other parameters can be calculated from those measured including:

1. Stroke volume (SV = CO/HR) (ml)
2. Total peripheral resistance (TPR $=$ BPm/CO $\times$ 79.9) (dyn s/cm^5)
3. Left ventricular stroke work (LVSW $=$ (BPm–LVEDP) $\times$ SV $\times$ 0.333 $\times$ 10^{-3})
4. Left ventricular minute work (LVMW $=$ LVSW $\times$ HR)

Studies are typically conducted with at least four animals per treatment group (active vs. vehicle). Statistical analysis can be done using an analysis of variance for repeated measures.

4.2.2.3 Critique of the Method

Until the appearance of the ICH S7A guideline, this experimental approach was the most common for studying drug-induced effects on the cardiovascular system and was specifically mentioned in the Japanese guidelines for general pharmacology as the standard test. As such, there is a vast amount of experience with this type of study and a large amount of comparable data available. The primary reason why anesthetized animal models lost their primary role in pharmacological studies was due to the recognition of the possible effects of, particularly pentobarbital, anesthesia on ventricular repolarization and therefore on drug-induced effects on the measured QT interval duration (Bachmann et al. 2002; Weissenburger et al. 2000). Nevertheless, a well-performed study using anesthetized animals, as supported recently by the Japanese PRODACT investigators (Tashibu, et al. 2005), can provide a useful and sensitive model of detecting drug-induced effects on the QT interval duration.

Furthermore, some drug-induced cardiovascular effects, in particular on blood pressure, might be masked because of baroreflex-mediated compensatory mechanisms. Interestingly, most anesthetics reduce baroreflex sensitivity and might offer favorable conditions for detection of such important properties. The use of anesthetized animals becomes particularly interesting when heart rate is affected in conscious animals, because of possible interferences of direct or indirect neurobehavioral effects, direct cardiac effects, or baroreflex-mediated compensatory mechanisms.

MODIFICATIONS OF THE METHOD

Pigs (juvenile farm pigs or minipigs) may be used for this type of study and is an attractive alternative if the dog is not suitable for any reason. Adult domestic pigs are difficult to use due to their size, such that if adult animals are preferred, one of several breeds of mini- or micropigs may be used. The induction of anesthesia is different than with the dog, and typically, an intramuscular sedative is administered first (e.g., ketamine) followed by the anesthesia used for the remainder of the study. Halothane anesthesia should not be used in pigs due to a high incidence of hyperthermic reactions.

Hey et al. (1996) analyzed the ECG wave in anesthetized guinea pigs to determine QT interval, QTc interval, PR interval, QRS interval, and heart rate after the administration of the second-generation antihistamines ebastine and terfenadine. In separate studies in conscious guinea pigs, the effect of oral ketoconazole on the ECG parameters after oral ebastine and terfenadine was studied. Fossa et al. (2007) have assessed electrophysiological and hemodynamic effects of antidepressants in anesthetized guinea pigs.

Measurement of the monophasic action potential (MAP) in anesthetized dogs for evaluation of arrhythmogenic activity of drugs was recommended by Usui et al. (1998) and Weissenburger et al. (2000).

A quad-polar electrode catheter is inserted through the left femoral artery and positioned at the noncoronary cup of the aortic valve to record a His bundle electrogram. A bidirectional steerable monophasic action potential (MAP) recording/pacing combination catheter is inserted through the left femoral vein and positioned at the endocardium to obtain MAP signals. The signals are amplified with a DC amplifier.

The amplitude of MAP is measured as the distance from the diastolic baseline to the crest of the MAP plateau phase. The duration of the MAP signal is measured as an interval from the MAP upstroke to the desired repolarization level along a line horizontal to the diastolic baseline. The interval (ms) at 90% repolarization is defined as MAP_{90}. The heart is driven electrically through the pacing electrodes of the combination catheter. Stimulation pulses are rectangular in shape, about twice the threshold voltage (1.5–2.2 V) and of 1-ms duration. The MAP_{90} is measured during sinus rhythm (MAP_{90}(sinus)) and at a pacing cycle length of 400 ms (MAP_{90}(400)) and 300 ms (MAP_{90}(300)).

The effective refractory period (ERP) of the right ventricle is assessed with a programmed electrical stimulator. The pacing protocol consists of eight beats of basal stimuli in a cycle length of 400 ms followed by an extra stimulus of various coupling intervals. Starting in late diastole, the coupling interval is shortened by 5–10 ms steps until refractoriness occurs. The difference ERP–MAP_{90}(400) is calculated to predict the vulnerability of the myocardium.

The amplified MAP signals together with systemic blood pressure, left ventricular pressure, heart rate, and ECG are continuously monitored using a high-fidelity recording system or electronically.

4.2.3 Cardiovascular General Pharmacology Studies in Conscious Rats

PURPOSE AND RATIONALE

There is a clear preference for performing safety pharmacology studies for drug effects on the cardiovascular system in a nonrodent species in order to capture possible effects on ventricular repolarization. Nevertheless, it must be acknowledged that there may be great value in conducting studies to examine drug effects on the cardiovascular system in smaller animals such as rats. One reason is that toxicity studies are conducted in rats, and drug effects on cardiovascular parameters in rats is of relevance to such studies. Furthermore, cardiovascular studies in nonrodents (usually the dog) require substantially more compounds than studies in rats. Therefore, as part of the lead optimization, selection, and development process, cardiovascular studies in rats can be invaluable.

4.2.3.1 Telemetry System

Cardiovascular parameters such as arterial blood pressure and heart rate can be measured in conscious, free-moving rats using commercially available radiotelemetry systems (Deveney et al. 1998). Such systems include (1) an implantable transmitter with battery capable of sending the pressure signal from a fluid-filled catheter implanted into the abdominal aorta, (2) a receiver unit that detects the transmitted signal and converts it into a digital format, (3) a pressure reference module that adjusts the measured aortic pressure for atmospheric pressure, and (4) data acquisition software for data storage and computation.

The rats are anesthetized and undergo a one-time aseptic procedure to implant the aortic catheter distal to the renal arteries. The catheter is secured using cyanoacrylate glue. The transmitter and battery unit are placed in the abdomen and attached to the abdominal musculature using a suture. After closure of the surgical wound, the animals are given sufficient time to recover from the procedure before being used in a study, usually at least 1 week.

4.2.3.2 Experimental Procedure

Rats can be studied while still in their home cage. However, since the transmitter frequency used is the same for all animals, they must be held alone during the study. This means that in most cases, the rats are moved from multiple housing cages to single cages for the duration of a study. The cages are placed directly on the receiver units to provide a close contact between the receiver and the animal. The transmitters are turned on before starting the study; the transmitter units can be turned on and off using a magnet thereby lengthening battery life. A control period of up to an hour allows the animals to acclimate to the environment and to provide a steady state prior to administration of a test article. The oral administration of compounds is most convenient in rats, using gavage, but intravenous and intraperitoneal administration is also feasible. Inhalative administration of compounds is also possible by nebulizing the compound into a small exposure box or through the use of an application system bringing the nebulized compound to the nose of the animal. The initial 15–30 min following the administration of a compound is affected by the excitement inherent with the administration process. Usually within a half hour, the animals have returned to a relaxed hemodynamic steady state.

4.2.3.3 Study Design

Studies can be conducted with a group comparison or with crossover design. Individual parameters can be averaged over predefined time periods, but it may not always be possible to predict the time of drug-induced effects. Also, in freely moving animals, drug-induced changes may not be continuous, but there may be overall changes that may be missed if one assesses only short time periods. An alternative approach is to calculate areas under the parameter-time curve and test for drug-induced effects. In this way, the analysis is not restricted to a given time point. With crossover design, an appropriately long washout phase is needed between treatments. A treatment arm with vehicle is also useful to demonstrate the stability of the system. Measurements can be made continuously or at regular intervals as long as desired. Water is usually provided ad libitum, and food can be given should the measurements be needed over an extended time period.

Instrumented animals may be reused after appropriate washout periods on the assumption that the compounds in the doses tested cause no reversible damage. Since the cardiovascular parameters measured are sensitive to the overall well-being of the animals, changes in baseline conditions should be examined for detecting possible compound-related toxicities. Assuming such toxicities are not observed, animals can be maintained for over 1 year with appropriate care.

MODIFICATIONS OF THE METHOD

Due to the fact that whole body plethysmographs for rats are constructed out of plexiglass, they can be used in conjunction with telemetry systems without interfering with the transmitted signals. Therefore, this offers the opportunity to combine studies for determining cardiovascular function using telemetry, with whole body plethysmograph studies for simultaneously measuring respiratory function (Schierok et al. 2000).

4.2.3.4 Critique of the Method

The most important limitation of the rat as cardiovascular model for safety pharmacology studies is its lack of utility for detecting hERG-related drug effects. Whereas this is a substantial limitation, there are nevertheless other drug-induced effects that can be observed in the rat model including arterial blood pressure, heart rate, and contractile ventricular function. The rat, due to its rather small size, requires substantially less compound to perform a study in comparison to that what is needed for larger animals. Thus, this model can be used at an earlier time during drug optimization and selection when amounts of a given test compound are limited. One should keep in mind, however, that a rat instrumented for telemetric collection of cardiovascular data, if kept for longer periods of time, grows considerably in comparison to the "typical" laboratory rat and can grow to over 800 g.

4.2.4 Assessment of Effect on the Autonomic Nervous System in Conscious Rats

PURPOSE AND RATIONALE

Serious side effects can be expected from drugs able to impair the autonomic nervous system. The main risk is orthostatic hypotension for drugs which alter the baroreflex sensitivity, usually sympatholytic agents. Sympatholytic drugs can also be responsible for bradycardia as well as parasympathomimetic drugs. Conversely, parasympatholytics and sympathomimetics can be expected to induce tachycardia. Mechanisms involved in these interferences can be related to effects on the central nervous system as well as to peripheral effects on ganglionic systems and peripheral cardiovascular system. The conscious rat is an interesting model to assess possible effects on the integrity of the autonomic nervous system function because this species exhibits a good equilibrium between the sympathetic and parasympathetic components of the autonomic nervous system, allowing detection of both parasympatholytic/parasympathomimetic and sympatholytic/sympathomimetic properties.

4.2.4.1 Assessment of the Baroreflex Function

The integrity of the baroreflex function is assessed under dynamic conditions by causing very short decreases or increases in blood pressure (Rocchiccioli et al. 1989). This procedure leads to the activation or deactivation of the baroreflex system. In response to such short hypotensive and hypertensive events, one of the consequences of the activation/deactivation of the baroreflex is to slow or accelerate the cardiac rate, respectively. These short bradycardic or tachycardic events are very well correlated to blood pressure changes in terms of duration and amplitude. With this technique, it is possible to activate or deactivate partially or totally baroreflex function.

4.2.4.2 Experimental Procedure

Animals are instrumented with polyethylene catheters in the femoral artery for blood pressure measurement and the femoral vein for administration of vasoactive agents. Surgery is performed under short anesthesia with sodium pentobarbital (45 mg/kg, i.p.) 24–48 h before measurements. Arterial and venous catheters are exteriorized at the neck, placed in the protective sheath of a chest vest, and connected to a leak-proof rotating joint system placed above the cage, leaving the animals to move about freely. The baroreflex curve is built by causing short-lasting hypotension and hypertension alternately by bolus administration of nitroprusside (1–50 μg/kg) and phenylephrine (1–25 μg/kg) respectively. A total of 15–20 points over a period of 60–90 min is necessary to draw the

baroreflex curve. The baroreflex curve is then fitted to a sigmoid Emax model. The slope of the curve is an index of the baroreflex sensitivity. The lower plateau of the curve (blood pressure vs. heart rate) provides the maximum slowing capacity of the heart in response to hypertension. The upper plateau provides maximum acceleration capacity of the heart in response to hypotension. In rats, the lower and upper plateaus depend on parasympathetic and sympathetic systems, respectively. Consequently, changes in maximum slowing or acceleration capacity allow a direct assessment of drug effects on the autonomic nervous system.

4.2.4.3 Critique of the Method

Since 60–90 min is needed to construct the entire baroreflex curve, this method is not useful for assessing short-lasting effects (<1 h) on the autonomic nervous system. Usually, drugs are given by the oral route, and the baroreflex curve is constructed during the period corresponding to Cmax. Alternatively, drug infusion can be also used.

Although this method does not directly show signs of orthostatic hypotension, it provides direct evidence of the mechanism by which orthostatic hypotension might occur. Most anesthetics impair baroreflex function. Since this method is conducted in conscious animals, it provides direct assessment of drug effects on the autonomic nervous system and baroreflex sensitivity without the risk of interferences caused by anesthetics.

4.3 In Vitro Cardiac Safety Pharmacology Models

In vitro studies are particularly useful in the context of cardiac electrophysiology as most of the (off-) targets are distinct and clearly defined molecular entities with known biophysical properties that are easily accessible to modern molecular biology and single-cell electrophysiology. For example, recent work has highlighted the human ether-à-go-go-related gene (hERG) K^+ channel as the molecular target for a wide range of drugs whose administration is associated with an increased risk of an unusual life-threatening form of arrhythmia known as torsades de pointes. hERG is a potassium channel alpha subunit (coded by the KCNH2 gene) that, as a tetramer, makes up the ion-conducting pore of the channel responsible for IKr, an important contributor to the delayed outward potassium current. This suggests the evaluation of drug effects on IKr or a model mimicking IKr in vitro as part of a cardiovascular risk assessment. However, the delayed outward potassium current in heart muscle cells of several species including humans is comprised of a rapidly (IKr) and a slowly (IKs) activating component. Therefore, one should not forget that for special structural classes or special primary targets, screening for effects on different cardiac ion channels (e.g., the substrate for IKs, KV7.1/minK, or a variety of other channels) might be necessary.

The CPMP "points to consider" paper of 1997 (The European Agency for the Evaluation of Medicinal Products. Human Medicines Evaluation Unit. Committee for Proprietary Medicinal Products 1997) pointed out that a thorough electrophysiological characterization of a drug requires evaluation on multiple levels of physiological complexity. In particular, the assessment of the effects of a drug on the myocardial action potential is an important link between the possible effects on a single ion channel type (such as hERG) and the consequent effects seen in the electrocardiogram (such as QT prolongation). Models using isolated Purkinje fibers, papillary muscles, myocardial wedge preparations, or even isolated hearts were proposed to assess the effects of a drug on the integrated electrophysiology of the heart. These types of models have been shown to detect the effects of many of the known proarrhythmic agents having a QT prolongation as mechanism of action. However, comparative evaluations, most notably one organized by ILSI (International Life Sciences Institute), provided data suggesting that not all of the known proarrhythmic agents produced effects that could be easily detected in the dog Purkinje fiber model (Hanson et al. 2006). It was then suggested that this lack of sensitivity should lead to dropping this model as a recommended study type. Nevertheless, the usefulness of this type of model is still acknowledged, and these studies may play an important role for early drug discovery in providing a more thorough risk assessment at a time when in vivo studies are still not

feasible due the lack of adequate amounts of a test article, in vivo PK data, or test article formulations. Thus, both in vitro study types (isolated ion channel studies, and the integrated action potential models) are included in this text, although the action potential models are not an absolute regulatory requirement.

In vitro models for cardiac safety are available at several levels of complexity. The lowest level is represented by ion channel assays that aim at studying the interaction of a given test article with one isolated ion channel type in a heterologous expression system. Due to the strict focus on a single channel type, these assays usually provide unequivocal answers. However, it may be challenging to derive potential net effects in more integrated systems from such data. Therefore, follow-up in vitro assays may also be performed, for example, using isolated primary cardiomyocytes, acute primary tissue preparations, or whole acutely isolated organs. The use of heterologous expression systems provides the opportunity to study human channels, whereas primary cells, tissues, and organs need to be taken from a suitable animal species with very few exceptions.

4.3.1 "High-Throughput" hERG Assays

PURPOSE AND RATIONALE

The high number of drug-like small molecules inhibiting the hERG channel suggests the need to screen for this activity at an early stage of drug development. Indeed, this could be even addressed by screening drug libraries to identify compounds having this potential. Alternatively, one might consider using hERG activity as an early secondary screen of hits emerging from a first high-throughput assay. In either case, experimental approaches are needed that allow the testing of large numbers of compounds thereby necessitating a high degree of automation. Several test systems have emerged as potential high-throughput approaches for detecting effects on the hERG-mediated current IKr. It must be recognized, however, that these relatively new technologies are still in a development stage and have not gained acceptance by regulatory authorities. Nevertheless, they are mentioned in this text, at least briefly, since they may still provide useful approaches for early drug discovery. Such techniques have been reviewed and critically assessed previously (Netzer et al. 2001, 2003).

An important consideration when doing off-target screening using an increased throughput format is how this approach would drive decision-making. When screening for primary targets, false negatives are usually less critical than false positives as these would imply the waste of considerable follow-up work. When screening for an off-target, false negatives would lead to the very same situation and are very likely to occur due to limited solubility when screening at high concentrations or due to stickiness of lipophilic compounds due to an unfavorable surface to volume ratio of the liquid handling system.

4.3.1.1 Binding Competition Assays

Assay Principle

The principle of this type of assay is to determine the competitive binding of a test compound in comparison to a radio-labeled compound known to be a high-affinity ligand of the hERG channel. Radio-labeled, potent blockers of hERG such as [^{3}H]-dofetilide (Finlayson et al. 2001a, 2001b) or [^{35}S]MK-499 (Wang et al. 2003) can be used in conjunction with myocardial cells, stably transfected cell lines, or membrane preparations. With this approach, the hERG channels are fully blocked with excess, for example, [^{3}H]-labeled dofetilide. The test compound is then incubated with the hERG-dofetilide system and can compete for the binding sites initially occupied by

dofetilide as a function of its potency for binding the same site. The amount of displaced radioligand is determined in the supernatant by scintillation counting.

Critique of the Method

The test system has relatively low costs and can provide a high throughput. However, compounds that block hERG-mediated currents but do not compete for the radioligand's binding site will not be detected. Due to the heterogeneity of chemical structures known to block the hERG channel, it is assumed that many binding sites may exist. Moreover, this test system detects binding but does not demonstrate any change in the electrophysiological function of the channel proteins used. Indeed, there are differences with respect to results of electrophysiological assessments of drug activity. Using a [^{35}S]MK-499-based test system, astemizole and terfenadine produce IC_{50} results that compare favorably with electrophysiological recordings (Wang et al. 2003). In contrast, the measured value for cisapride using this assay is threefold higher than in electrophysiological studies, and MK-499 is 30-fold lower as compared to electrophysiological data (Wang et al. 2003). Such discrepancies also appear using a [^{3}H]-dofetilide-based system and may even be more pronounced. Thus, the specificity of the binding site for the radio-labeled compound, versus the test compound, may limit the usefulness of this approach.

4.3.1.2 Two-Electrode Voltage Clamp Systems Using Xenopus Oocytes

Assay Principle

In order to heterologously express ion channels, oocytes are injected individually with cRNA encoding for the channel protein of interest. Currents are studied using the two-microelectrode voltage clamp method: Two sharp electrodes are inserted into the oocyte, the first of which serves as a current injection electrode and the second as a probe for membrane potential. Voltage clamp is achieved by current injection controlled by a feedback amplifier which compares actual and command membrane potential. Ion channel inhibition is determined by reduction of injected current in relation to test item concentration. Voltage clamp experiments on Xenopus oocytes can be performed manually on single oocytes; however, systems have been developed that provide automated cRNA injection and voltage clamp measurements in a 96-well format (Leisgen et al. 2007). Although the 96 wells still need to be addressed sequentially, a higher throughput is possible as compared to manual systems.

Critique of the Method

Voltage clamping as a method to directly determine channel activity is currently the best method to quantitate the pharmacology of test articles with respect to ion channels. Heterologous expression in Xenopus oocytes is particularly superior over mammalian expression systems when a large variety of different gene products are intended to be screened, as transient expression is achieved by cRNA injection into individual oocytes. This saves the work of transient transfection or even establishment of a stable cell line for each gene product as it would be necessary with mammalian expression systems. Moreover, in most cases, a much higher expression level can be achieved than with a mammalian expression system. In the context of delayed repolarization, the advantage of individual injection of each oocyte with a suitable amount of engineered cRNA could become relevant when a test article's differential action on various human genotypes is to be determined or the analysis of the binding mode of a particular test article is desired using point mutations of putative binding sites.

However, it is known that in Xenopus oocytes, pharmacology is usually right-shifted (i.e., higher concentrations of test article are needed for a given effect) with respect to results from mammalian expression systems, most likely due to the large amount of yolk contained in the oocytes acting as a sink for the test article, especially in case wherein it is highly lipophilic (Witchell et al. 2002). Therefore, it is recommended to cross-check results with a mammalian system and, in case of a large shift, to use results not in absolute

numbers but rather for rank ordering. In some cases, measurements in Xenopus oocytes might even be impossible because the right shift drives the needed test article concentrations above their solubility limit.

Compared to the patch clamp technique (see Sect. 3.1.4), voltage clamping with two electrodes avoids the difficulties associated with seal resistance to access resistance ratio and hence is better amenable to automation.

4.3.1.3 Automated Patch Clamp Systems

Assay Principle

New systems are currently in development that attempt to incorporate the patch clamp technique (see Sect. 3.2) into an automated and, thereby, higher-throughput format. Whereas these systems cannot be described as being truly high throughput, their goal is to speed the study process through automation while preserving the manner in which a study in a mammalian expression system is usually conducted. Thus, cells heterologously expressing hERG are used, and a patch clamp methodology is applied. Patching of the cells, addition of the test article, and most of the data analysis is, however, done on an automated basis. There are systems that run in the "whole-cell" mode (see Sect. 3.2), whereas others are designed to gain electrical access to the cells in the "perforated patch" mode. In the "perforated patch" mode, the cell membrane is not ruptured as in the "whole-cell" mode but rather permeabilized using a pore-forming agent such as amphotericin. In order to boost success rates and current amplitude, systems have been developed which patch clamp several cells in parallel ("population patch"). For this method a vast excess of cells is needed in order to make sure that all holes in the planar substrate are occupied by a cell to prevent an empty whole from acting as a short circuit.

Generally, all automated patch clamp systems require cells in suspension.

Critique of the Method

A critical step to the performance of a patch clamp experiment is the formation of a tight, high-resistance seal between the cell membrane and the glass micropipette or hole in a planar substrate. The formation of this seal is one limiting factor with this experimental approach, with success rates in the order of 50–80%. The subsequent rupture of the patch to gain access to the cell interior is another critical step which often reduces the success rate of automated systems down to less than 50%. Alternatively, the use of the "perforated patch" method helps increasing success rates; however, the resultant recordings may not be optimal due to a high and instable access resistance and loss of control over the electrolyte composition in the cytosol.

In most automated systems, the options for fine-tuning the recording with respect to compensation of offset, series resistance, whole-cell capacitance, and leak currents are limited as compared to manual patch clamp.

The assay principle is not limited to hERG studies and, indeed, automated electrophysiology has been used frequently for primary target screening. However, on a given automated electrophysiology platform, each cell line, gene product, and assay protocol needs to be validated as both the cell line itself is critical for success rates, and the biophysical properties of the gene product are crucial for the question whether the limitations in fine-tuning options are acceptable.

As in all screening platforms, liquid handling is critical for data quality, as test article precipitation or adsorption to surfaces may compromise exposure of the target. In systems requiring a vast excess of cells in order to enhance the success rate for sealing, the high cell density might also act as a sink for the test article.

4.3.2 Manual Patch Clamp Studies

PURPOSE AND RATIONALE

The introduction of the patch clamp technique revolutionized the study of cellular physiology as it provided the first high-resolution and high-fidelity method of observing the function of individual ion channels in a variety of cell types. The goal of patch clamp electrophysiology for in vitro pharmacology is to analyze the effect of a given test article on ion channel conductance under strict control of the membrane potential and the driving forces for every ionic species.

In the so-called whole-cell mode of the patch clamp technique, the net current through all open ion channels contained in the membrane of a single cell is measured. The whole-cell mode is obtained by rupturing the membrane patch under the orifice of a patch pipette sealed to the cell membrane (Hamill et al. 1981). This is achieved by applying suction to the interior of the patch pipette. In the whole-cell mode, the cell interior is dialyzed by the electrolyte solution contained in the patch pipette. The resulting low-resistance electrical access to the cell interior combined with the dialysis of the cytoplasm with a defined electrolyte solution provides the basis for a successful recording.

The patch clamp technology is considered the gold standard methodology for the assessment of a test article's effects on ion channels as it provides functional data under the most precisely defined conditions. In its standard application, the patch clamp technique is a time-consuming sequential process which requires the permanent attention of highly skilled technical staff who is not only experienced in the delicate manipulation of single cells but also understands the complex biophysical processes behind ionic currents transmitted by channel proteins. Therefore, only a limited number of compounds can be tested using this approach.

According to ICH S7B, a manual patch clamp study so far is the only acceptable way to address potential hERG channel interactions. Other ion channel liabilities are not mentioned as mandatory studies in the ICH S7B guideline, but it is recommended to employ the same technique when performing supplementary studies addressing other ion channels.

4.3.2.1 Patch Clamp Studies in Heterologous Systems

Assay Principle

Heterologous expression in mammalian cell lines has become the most convenient assay system for patch clamp studies on a specific ion channel type in isolation. The whole-cell current for each individual cell is determined (base line recording, vehicle control), and then an arbitrary number of escalating concentrations of the test article are applied to the cells while the resulting changes in current are observed. In many cases, four concentrations escalating in a semi-log fashion and three replicates (cells) are sufficient to construct a valid concentration-response curve.

PROCEDURE

Cells are placed at the bottom of an incubation chamber superfused with a buffer solution which needs to be of appropriate electrolyte content for the particular ion channel to be analyzed. For hERG, a buffer of the following composition is suitable (mM): NaCl (137), KCl (4.0), $MgCl_2$ (1.0), $CaCl_2$ (1.8), sucrose (10), and HEPES (10) at pH 7.4 with NaOH. Patch pipettes are filled with an electrolyte solution which again needs to be adapted to the properties of the particular ion channel to be studied. For hERG measurements, the following composition is useful (mM): K-Aspartate (130), $MgCl_2$ (5.0), EGTA (5.0), ATP-K_2 (4.0), and HEPES (10.0), pH 7.2 with KOH. After reaching the whole-cell configuration, the net membrane current is recorded using a patch clamp amplifier in the voltage clamp mode. To elicit hERG-mediated potassium currents, cells need to be stimulated with a pulse pattern similar to the following: hold: −80 mV, activation/inactivation: +20 mV for 2,000 ms, deactivating tail current: −50 mV for 1,000 ms repeated at 10–20 s intervals. The peak tail current is used for analysis as current of interest. Other more sophisticated stimulation protocols are possible and results may depend on the specific stimulation protocol used. Drug effects on current amplitude are typically expressed as fraction of baseline current. Concentration-response data may then be fitted to a sigmoidal concentration-response curve model. It is generally recommended to check the concentration of the test article in the superfusate using a suitable analytical method. The superfusion buffers used are typically protein free, meaning that in comparison to the in vivo situation, one needs to consider potential protein binding of a compound. In case of very high protein binding, it is advisable to experimentally verify the expected protein shift.

Critique of the Method

HEK293 and CHO cells are most commonly used for this purpose. HEK293 cells may have an endogenous

transient outward potassium current (Snyders and Chaudhary 1996), whereas CHO cells do not have such a current (Teschemacher et al. 1999). The amount of background current in HEK293 cells may be variable between batches of cells and could interfere with hERG measurements, making CHO cells in this regard superior. HEK293 cells may, however, be more consistent in their level of heterologous expression in comparison to CHO cells (Witchell et al. 2002). Issues relating to the use of stably versus transient transfection have been reviewed (Witchell et al. 2002). The quality of data obtained by this assay is only optimal if the assay is performed in a best practice fashion. Poor quality results are likely to be obtained in case numerous technical details are not properly accounted for. The most common pitfalls leading to poor data include inadequate exposure to test article due to solubility or adsorption problems; incomplete equilibration with the test article due to slow on rate (some test articles may take up to 15 min to equilibrate with the target!), leaky cells, or poorly tuned recordings; and small assay window due to poor expression level, resulting in a low signal-to-noise ratio.

4.3.2.2 Patch Clamp Studies in a Native Environment

Assay Principle

Patch clamp techniques using isolated ventricular myocytes may be used to analyze a test article's effect on the complex interplay of the various ion channels contributing to the cardiac action potential. For this purpose, acutely isolated cardiomyocytes from several species may be used, but also cardiomyocytes differentiated from stem cells have recently emerged as attractive assay systems (Kattman et al. 2011). Patch clamping is performed in the same way as with heterologous systems. Depending on the desired study endpoints, cells may be kept in the current clamp mode (observation of action potential configuration, determination of refractory period) or in the voltage clamp mode (analysis of a net current).

Critique of the Method

Ion channel pharmacology is best studied in a heterologous, more or less, artificial environment; however, when the concerted action of all relevant ion channels in their native environment is to be studied, experimental conditions should be as close to the natural environment as possible. This is particularly challenging for the solution loaded into the patch pipette, as the dilution of intracellular protein kinases and phosphatases together with their substrates may considerably alter channel properties. Hence, the "perforated patch" technique may be appropriate in this case.

Patch clamping cardiomyocytes provides the advantage of analyzing net effects of multiple target drugs in an environment which contains these targets in their natural relative frequency. In contrast, it is advantageous only in rare cases to attempt to isolate these targets in their native environment. Pharmacological isolation is problematic as only few drugs exhibit the necessary selectivity. Biophysical means may help to separate, for example, fast inactivating channels from slowly inactivating channels; however, isolation of all molecular entities is impossible in most cases. Moreover, native expression levels of most ion channels are lower than in heterologous systems which results in small assay windows.

4.3.3 Myocardial Action Potential Configuration

PURPOSE AND RATIONALE

Studies of myocardial action potential configuration to assess the potential of a drug to affect ventricular

repolarization, and therefore a prolongation of the QT interval duration, focus on the pivotal role of hERG-mediated potassium current in mediating this effect. Nevertheless, it is well established that even a potent blockade of the hERG channel does not necessarily lead to a QT prolongation. For example, the calcium channel blocker verapamil does not lead to delayed repolarization at concentrations even above its IC_{50} for hERG. The reason for this apparent discrepancy is simply that the myocardial action potential configuration is the net result of the concerted activity of numerous ion channels, and effects on a given channel may be masked by the activities of other channels; further examples are given in Yuill KH et al. (2004). It is this recognition that suggests that drug profiling should examine the effects of a compound not only on hERG channels but on the overall myocardial action potential. This allows one to assess the physiological relevance of any activity on the hERG channel that may be present and, moreover, opens the possibility to recognize liabilities independent of hERG (The European Agency for the Evaluation of Medicinal Products. Human Medicines Evaluation Unit. Committee for Proprietary Medicinal Products 1997; Haverkamp et al. 2000). Whereas in vivo data will also add significantly to this preclinical risk assessment, performance of hERG channel assays together with action potential assays may provide an early risk assessment with a better correlation to the in vivo and clinical setting than with just one of these assays alone (Guth et al. 2004).

Drug effects on the myocardial action potential can be measured in myocardial tissue in vitro typically using Purkinje fibers, papillary muscles, ventricular wedge preparations (albeit less commonly), or the entire isolated heart (Franz 1991). The focus of all these approaches is to assess the action potential duration, measured usually in terms of the time to a reach a certain percentage of repolarization after the initial upstroke, for example, the time to 90% repolarization (APD_{90}). Additionally, some of these models may respond to delayed repolarization with early afterdepolarizations (EADs), thought to be a source for arrhythmia. The use of the myocardial wedge preparation also addresses the important issue of potential transmural differences in drug-induced effects on repolarization (Antzelevitch et al. 1999).

4.3.3.1 Studies in Isolated Purkinje Fibers

PURPOSE AND RATIONALE

Studies of Purkinje fibers in isolated Purkinje fibers can detect compound-induced effects on the action potential configuration and possible early afterdepolarizations. This type of study is a logical adjunct to studies examining effect on hERG-mediated current since it examines the potential relevance of any potential hERG-blocking activity on the overall myocardial action potential. Purkinje fibers from the dog or the rabbit have been used typically, while other species, including the pig (Gintant et al. 2001) may also be appropriate models.

CRITICAL ASSESSMENT OF THE METHOD

The Purkinje fiber is a noncontractile tissue, which facilitates electrode positioning and stability. In comparison to the papillary muscle or the monophasic action potential in the intact heart, drug-induced effects on the action potential duration are considerably larger in the Purkinje fiber model, particularly from the rabbit. Whereas this is not necessarily a disadvantage, the rabbit Purkinje fiber model has been viewed as possibly being too sensitive for drug-induced effects on repolarization. Furthermore, a low repolarization reserve has been reported in

rabbit Purkinje cells (Dumaine and Cordeiro 2007). Conversely, in the canine Purkinje model, not all hERG-blocking compounds produce the expected prolongation of the action potential. One notable example is terfenadine (Gintant et al. 2001), that even in supratherapeutic concentrations failed to prolong the action potential duration in this model. This has lead to action potential studies receiving secondary status from regulatory authorities due to the perception of a risk for false-negative results. Interestingly, 80% of torsadogenic agents exhibit mixed effects in the canine Purkinje model, corresponding to combined INa/ICaL and hERG blocking properties, while drugs causing QT prolongation show a more "pure" hERG blocking profile (Champeroux et al. 2005). Since INa and ICaL currents inhibition produces shortening in action potential duration and QT interval, these concomitant ancillary electrophysiological properties were proposed to be an aggravating factor which could enhance the transmural heterogeneity of the action potential duration and consequently the risk for torsades de pointes (Champeroux et al. 2011).

4.3.3.2 Studies in Isolated Guinea Pig Papillary Muscles

Assay Principle

Studies in isolated guinea pig papillary muscles can detect compound-induced effects on the action potential configuration as well as inotropic effects. This type of study is a logical adjunct to studies examining effect on hERG-mediated current since it examines the potential relevance of any potential hERG-blocking activity on the overall myocardial action potential. The most commonly used model is the guinea pig papillary muscle (Kii et al. 2005) due to its appropriate size; use of papillary muscles from larger species may be compromised by ischemia in the core of the muscle during the experiment, as oxygen supply for this type of preparation is diffusion-limited.

Critique of the Method

In contrast to the Purkinje fiber, the papillary muscle is a contractile tissue, lending it also for the measurement of contractile force, together with the action potential configuration. Since effects on the inotropic state of the myocardium can also affect the action potential, this is a useful secondary measurement to have to interpret possible drug-induced effects. However, the contraction of the muscle makes the placement of the electrode more difficult, and changes in the contractile function can lead to loss of the electrode placement in the course of a study.

As with the Purkinje fiber model, some compounds known to block hERG channels potently and to cause QT prolongation in the clinic do not demonstrate the expected action potential prolongation; this includes astemizole and terfenadine. In the case of the guinea pig papillary muscle, it has been suggested in conjunction with the PRODACT evaluation in Japan that the way in which the data are evaluated may be key for detecting the drug-induced effect on the action potential configuration (Kii et al. 2005). In conjunction with these studies, the investigators employed APD90-30, which is the interval between 30% and 90% repolarization, as a proarrhythmic marker. With this approach, these investigators were able to demonstrate effects of astemizole in the isolated guinea pig papillary muscle. However, terfenadine did not impact APD90-30; it was therefore suggested that other limitations must prevent terfenadine from demonstrating its expected APD prolongation in this in vitro setting.

4.3.3.3 Arterially Perfused Wedge of Canine Left Ventricle

Assay Principle

The M cells in the arterially perfused wedge of canine left ventricle are a unique myocardial cell type found in the deeper layers of the ventricular wall (Antzelevitch et al. 1999). These cells respond more sensitively to agents that block hERG channels and, as such, contribute to possible drug-induced transmural heterogeneity of ventricular repolarization and thereby the proarrhythmic potential. The perfused myocardial wedge preparation (Antzelevitch et al. 1996) is designed to allow the study of differences in drug action on transmural repolarization and may therefore provide a better assessment of a possible proarrhythmic potential of a test article.

Critique of the Method

The measurement of a transmural ECG together with local action potentials from across the ventricular wall of the dog provides one of the most sophisticated in vitro approaches for determining drug-induced effects on repolarization as well as having implications for proarrhythmic potential. This is why M cells of the midmycardial wall are most sensitive to drug-induced effects on repolarization and this contributes to a transmural heterogeneity of repolarization that provides a proarrhythmic substrate. Thus, objectively assessed, this model is perhaps the best in vitro model to examine drug-induced effects on repolarization of the heart. Its main disadvantage is the experimental complexity which makes it accessible only to the specialty laboratory and may require extensive training to master the technical aspects. A further complicating factor is the use of dogs for studies in which only small portions of the excised heart are utilized, which has both ethical and financial aspects that need to be considered.

4.4 Models for Proarrhythmic Potential

The goal of pharmacological profiling of drugs for effects on hERG channels, the action potential, or the ECG is ultimately to predict the potential for proarrhythmic activity. None of these approaches is fully predictive since even potent hERG-blocking drugs that produce a prolongation of the action potential duration in vitro and QT interval in vivo do not necessarily lead to an increased rate of arrhythmia in man based on clinical data; however, the number of unreported cases is rather elusive. Still, it would therefore appear useful to assess the proarrhythmic potential of a drug in a model designed to detect arrhythmias. Nevertheless, the available proarrhythmia models failed to win the confidence of regulatory agencies, and the use of them has neither been mandated nor widely recommended. Such models could, however, prove useful in cases where the results from other types of tests (hERG, action potential, in vivo) are not conclusive.

4.4.1 Studies of Arrhythmogenic Effects in Isolated Heart Preparations

PURPOSE AND RATIONALE

The evaluation of isolated heart preparations of arrhythmogenic, antiarrhythmic, and antifibrillatory effects in the Langendorff heart preparation is described in Sect. 3.1.2 of the book.

Generally, proarrhythmia isolated heart models are designed in two ways: either it is attempted to lower the arrhythmia threshold as much as possible in order to drive the probability of overt arrhythmia up to a degree which makes detection possible even in a study comprising as few as only a handful of preparations, or a sophisticated combination of several surrogate markers is sought which may yield an abstract proarrhythmic index; the validity of which may be shown using tool compounds for which clinical evidence exists.

As an example for the first option, Eckardt et al. (1998) and Johna et al. (1998) proposed the isolated perfused rabbit heart as a model to study proarrhythmia induced by class III antiarrhythmic drugs.

The other path is followed in a model developed by Hondeghem 1994. The assessment of proarrhythmic

potential is based on a more in-depth analysis of drug-induced effects on the action potential including action potential duration, instability of the action potential prolonging effects, reverse use dependency, and triangulation of the action potential. (Hondeghem 1994; Valentin et al. 2004). This information is synthesized into a proarrhythmic assessment that is claimed to discriminate between compounds that are proarrhythmic and those that are not, independently from their effects on the action potential duration per se. In fact, it is claimed that compounds that prolong the action potential but without being instable, reverse-use-dependent, nor causing triangulation are actually antiarrhythmic (Hondeghem et al. 2001).

4.4.1.1 Critique of the Method

Direct observation of overt arrhythmia is certainly the most convincing readout of an arrhythmia model. However, the measures used to drive an isolated heart to the threshold of arrhythmia (i.e., simulated hypokalemia) leave room for interpretation as it is not predictable how a 100% incidence of arrhythmia in a hypokalemia-driven model would translate into the incidence under normokalemic conditions.

In the search for a proarrhythmic index derived from several markers, the relative importance of instability, triangulation, and reverse use dependency contribute is unclear. The contribution of each of these markers may differ from drug to drug, and synergistic actions are likely. Nevertheless, drugs that lead to instability are considered to be the most problematic. Triangulation is, in general, a better predictor of proarrhythmic activity than reverse use dependency, making reverse use dependency the least predictive parameter of the three. The use of the rabbit is based on its having IKr as the main repolarizing current in the heart, but it has little IKs activity (Nattel 1999) and is therefore not sensitive for drugs that potentially affect this current. Furthermore, as with all in vitro test systems, effects due to metabolites of drugs are not detected. Nevertheless, the performance of this test system for differentiating between proarrhythmic drugs and nonproarrhythmic drugs has been impressive (Valentin et al. 2004). The model has not been reproduced outside of the laboratory that developed it, thereby limiting its availability and its acceptance.

5.1 General Functional Assessments

5.1.1 In Vivo Assessments

5.1.1.1 Assessment of Glomerular Filtration Rate (GFR) and Renal Blood Flow (RBF)

Assessment of GFR by Plasma Chemistry

PURPOSE AND RATIONALE

If a metabolic end product or protein is small enough to be filtered at the glomerulus and is neither extensively reabsorbed or secreted, the excretion rate is primarily determined by the glomerular filtration rate (GFR) (Price and Finney 2000), which is considered a sensitive index of functional nephron mass (Newman and Price 1999). Thus, assessment of the plasma level of such a constituent can serve as a biomarker of renal function, and several have been used extensively for this purpose.

The ideal endogenous marker of GFR, in addition to being primarily excreted through the kidney, freely filtered at the glomerulus and neither secreted nor reabsorbed by the tubule, should also be delivered in a steady fashion to the plasma, and be readily detectable using available technology. This requires that production of the substrate and its delivery to the plasma occurs at a stable rate and is not influenced by other disease or physiologic processes, and that the substrate is either non- or minimally protein bound (Price and Finney 2000). Several endogenous small molecules (urea, creatinine, 2-(a-mannopyranosyl)-L-tryptophan) or small (less than 66 kDa) proteins (cystatin C (γ-trace), prostaglandin D synthase (β-trace protein), α_1-microglobulin, β_2-microglobulin, and

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_5,

© Springer-Verlag Berlin Heidelberg 2013

retinol-binding protein) meet these criteria and have been used to assess GFR in many species.

PROCEDURE

Serum or plasma samples are collected from the test animals (if plasma is used, blood should be collected in heparinized tubes). Assay methods vary, and are outlined below:

Urea is most commonly assayed by combined urease methods, in which the urea is first converted to two ammonium ions. The ammonium generated is then measured by either enzymatic or chemical methods. Urea nitrogen values determined by this method (mg/ml) are converted to urea values by the use of appropriate factors (2.14 for urea in mg/ml, 0.357 for urea in mmol/l) (Newman and Price 1999; Emeigh Hart and Kinter 2005).

Creatinine is most commonly measured by the Jaffe reaction of creatinine with picrate to generate an orange chromogen. Several enzymatic assays (based on reactions with creatinase or creatinine deaminase) have also been developed. These are equal in sensitivity to the Jaffe method but are less likely to be subject to interference by endogenous or exogenous chromogens (this is of particular concern in the dog and mouse compared to other species) (Meyer et al. 1985; Finco et al. 1995; Finco 1997; Newman and Price 1999; Schwendenwein and Gabler 2001; Dunn et al. 2004). A recently developed HPLC assay has been shown to be much more sensitive than the Jaffe method for mouse plasma (Dunn et al. 2004).

2-(a-mannopyranosyl)-L-tryptophan (MPT) is measured by HPLC (Takahira et al. 2001). Cystatin C assays are all antibody based (nephelometric, agglutination or sandwich ELISA) (Pergande and Jung 1993; Finney et al. 1997; Jensen et al. 2001), and have been used successfully in dogs, rats, mice and cats (Hakansson et al. 1996; Bökenkamp et al. 2001; Braun et al. 2002; Martin et al. 2002).

Cystatin C assays are all antibody-based (nephelometric or sandwich ELISA), and there are several commercially available assays (Pergande and Jung 1993; Finney et al. 1997; Jensen et al. 2001). Although the antibodies used in these tests are specifically directed against human cystatin C there is significant homology across species (Poulik et al. 1981; Esnard et al. 1988) and these tests have been used successfully to detect cystatin C from dogs, rats, mice, and cats (Hakansson et al. 1996; Bökenkamp et al. 2001; Braun et al. 2002; Martin et al. 2002).

The majority of the additional small protein analytes used to assess GFR are detected by immunoassays with reagents specific for the human proteins, with variable cross-reactivity with analogous proteins from other species (Loeb 1998).

EVALUATION

Analyte levels are compared either to those of a concomitant control group (using appropriate statistical methods of the group size is large enough) or to laboratory-specific reference intervals for the species, strain, age, and sex in question. Elevation of analyte levels outside of the reference range indicate a decrease in GFR, with the magnitude of the elevation being roughly proportional to the degree of the decrement.

Despite these potential shortcomings, serum creatinine assessment has been considered the "gold standard" for assessment of GFR in humans, and is also widely accepted as an index of GFR in most animal species (Finco 1997; Starr et al. 2002). In humans, GFR can be reliably estimated from single point in time creatinine measurements, using one of several algorithms that correct for the effects of age and gender on muscle mass (Cockcroft and Gault 1976; Porter and Finn 1998; Newman and Price 1999). The most commonly used algorithm is that of Cockcroft and Gault (1976), which corrects for the effects of age and gender on muscle mass and is reasonably accurate in adults between 30 and 100 years of age:

$$\mathrm{GFR} = \frac{(140 - \mathrm{age}) \times \mathrm{weight(kg)} \times K}{72 \times \mathrm{Serum\ creatinine(mg/dl)}}$$

where $K = 0.85$ for women, 1.00 for men

A similar algorithm has been calculated for dogs. The study from which this was derived demonstrated no influence of diet, gender, or age on the predictive value of point-in-time plasma creatinine levels for GFR in this species (Finco et al. 1995):

$$\mathrm{GFR} = 2.6/\mathrm{Serum\ creatinine(mg/dl)}$$

A number of algorithms for calculation of GFR based on serum cystatin C measurements have been generated for adult humans; these also have been

shown to be applicable to children (Le Bricon et al. 2000; Filler and Lepage 2003; Hoek et al. 2003; Larsson et al. 2004; Grubb et al. 2005; Sjöström et al. 2005). All of them are based on the following relationship (with appropriate correction factors applied):

$$GFR = 1/\text{Serum cystatin C}$$

The accuracy of these methods is dependent upon the method used for serum cystatin C determination. Calculation of GFR using both methods simultaneously in the same patient will improve the accuracy of the final result compared to the use of either analyte alone (Tidman et al. 2008).

Measurement of both urea and creatinine and calculation of the urea:creatinine ratio can provide some useful information about the etiology of the underlying process. Since both creatinine and urea nitrogen are most commonly expressed in mg/dL, this ratio will be unitless if the raw data values for the analytes are used. However, in order for results to be compared between laboratories and across studies it is considered more accurate to convert the values for both analytes to their Standard International (SI) unit values (mmol/l for urea and μmol/l for creatinine, see "Fractional Excretion Methods" for conversion factors for common analytes) before calculating the ratio; alternatively, in order to keep the ratio unitless both analytes can be converted to their μmol/l equivalents by multiplying the creatinine value by 88.4 and the urea value by 357.

If the ratio is elevated as the consequence of elevation of both analytes the cause may be primary renal disease; however, extremely high urea:creatinine when both are elevated (where urea is elevated markedly out of proportion to creatinine) more likely indicates decreased renal blood flow (because decreased tubular flow enhances creatinine excretion while increasing urea reabsorption), urinary tract obstruction (for the same reason), or extravasation of urine into the peritoneal cavity (because urea is more readily reabsorbed than creatinine from the peritoneum). Elevation in the urea:creatinine ratio as a consequence of pure urea elevation can be seen with gastrointestinal hemorrhage, high protein diet (as a transient effect), increased protein catabolism, or loss of muscle mass (in this circumstance, plasma creatinine may be reduced). A decreased ratio can indicate early acute tubular necrosis but more likely pinpoints primary liver dysfunction (due to decreased urea synthesis), decreased protein intake, ingestion of high quality protein diets used in the management of renal failure, extremely muscular individuals, or circumstances of tissue anabolism (Baum et al. 1975; Newman and Price 1999).

LIMITATIONS OF THE METHOD

Effects on prerenal (dehydration, blood loss, altered vasomotor tone, age-related decreases in renal blood flow in rats) and/or postrenal factors (obstruction or extravasation of urine to the peritoneal cavity) may cause elevations of the commonly measured analytes that do not reflect effects on the GFR or loss of functional nephron mass. When these parameters are elevated as a consequence of primary renal injury, they cannot be used to determine the location of that injury (glomerulus versus tubule or tubule segment affected) (Baum et al. 1975; Corman and Michel 1987; Finco 1997; Newman and Price 1999).

The delivery of urea to the peripheral circulation is variable because the rate of synthesis is not constant, depending on both dietary protein intake and the functional integrity of the liver. Baseline plasma urea levels will be elevated in circumstances of increased protein catabolism, including increased dietary protein intake (particularly pronounced in dogs), gastrointestinal hemorrhage, fever, severe burns, corticosteroid administration, sustained exercise, or muscle wasting, whereas urea synthesis and baseline plasma levels decrease with low protein diets, modest food restriction in rodents, hepatic insufficiency, hyperglycemia, and decreased circulating plasma amino acid levels (Pickering and Pickering 1984; Finco 1997; Hamberg 1997; Tauson and Wamberg 1998; Newman and Price 1999). In extreme malnutrition, however, the effect of diminished protein intake is offset by increased urea synthesis resulting from muscle catabolism as well as concomitant decreases in renal plasma flow and dehydration, with the net result that baseline plasma urea levels are usually elevated (Levin et al. 1993; Benabe and Martinez-Maldonado 1998).

In contrast, creatinine is synthesized and delivered to the plasma at a fairly consistent rate and the rate of synthesis decreases as plasma levels increase, presumably due to a feedback control over synthesis (Watson et al. 2002a). Thus, the day-to-day plasma level in

a given individual does not fluctuate widely, which has the disadvantage of limiting the sensitivity of creatinine as an index of GFR. Consumption of high meat diets may elevate plasma creatinine and baseline levels will be elevated in individuals with higher muscle mass or following sustained exercise or acute muscle damage. Conversely, serum creatinine will be lower in individuals who have undergone loss of muscle mass (Finco 1997; Newman and Price 1999). Diurnal variations in serum creatinine levels have also been documented for humans (Finco 1997) and dogs (Loeb and Quimby 1999), with plasma levels in general being slightly higher in the afternoon in both species.

Because of the confounding influences of fluctuating plasma baseline levels, urea and creatinine elevations in plasma are in general not sensitive enough to detect low-level alterations (less than 75% loss) of GFR. Additional contributions to the lack of sensitivity of these analytes comes from the contributions of renal secretion and/or reabsorption to their overall excretion, (which can compensate for their decreased filtration) and to inherent imprecision in the assays used (Finn and Porter 1998; Price 2002; Starr et al. 2002; Shemesh et al. 1985). In general, urea will underestimate GFR due to extensive tubular reabsorption with decreased GFR (Baum et al. 1975; Kaplan and Kohn 1992; Newman and Price 1999), and creatinine tends to overestimate GFR because it is secreted by the tubule in many species and secretion increases both with reduced GFR and increase in some disease states that do not affect GFR or renal blood flow directly (Shemesh et al. 1985; Andreev et al. 1999; Newman and Price 1999a; Rocco et al. 2002; Sandsoe et al. 2002; Starr et al. 2002).

The Jaffe reaction for creatinine is subject to interference by numerous endogenous substrates and drugs or compounds (Schwendenwein and Gabler 2001; Sonntag and Scholer 2001; Dunn et al. 2004). This effect can be minimized by using appropriate substrate extraction or by the use of kinetic assessments. The urease assay is specific for urea, but increased circulating ammonia (such as occurs in aged plasma samples, metabolic disorders, and portocaval shunting) will react with the subsequent reaction and result in falsely elevated plasma levels (Newman and Price 1999).

Plasma 2-(a-mannopyranosyl)-L-tryptophan (MPT) may be a superior indicator of GFR. Unlike creatinine, its baseline plasma levels are not influenced by muscle mass. The point-in-time measurement of this tryptophan glycoconjugate correlated extremely well with the inulin clearance; furthermore, MPT clearance correlated better with inulin clearance (the "gold standard" for assessment of GFR) than creatinine clearance does, suggesting it may be a useful endogenous marker for GFR in many species. However, the renal handling of MPT has not been examined to determine if plasma levels may be influenced by either reabsorption or secretion (Horiuchi et al. 1994; Gutsche et al. 1999; Takahira et al. 2001). The analyte requires detection by HPLC methods, which will limit its utility in clinical or laboratory settings.

Plasma cystatin C has been extensively compared to serum creatinine measurements in human medicine, where it has been shown to be either identical or superior in sensitivity to serum creatinine as an index to GFR in all age groups and renal disease states. It may be superior to creatinine in prediction of alteration of GFR in circumstances of low-level impairment of renal function. It is also not affected by nonrenal diseases that augment creatinine secretion (Newman et al. 1994; Price and Finney 2000; Baigent et al. 2001; Buehrig et al. 2001; Donadio et al. 2001a, 2001b, 2001c; Woitas et al. 2001; Kazama et al. 2002; Laztera et al. 2002; Oliveri et al. 2002; Rocco et al. 2002). Cystatin C has been shown to be an equally sensitive marker of renal injury in the dog (Almy et al. 2002; Braun et al. 2002) and the rat (Bökenkamp et al. 2001), but not the cat (Martin et al. 2002), and its utility has not been explored in other species.

Other small molecular weight proteins in the serum that have been used as indices of GFR in humans are generally better predictors of low-level decrements of GFR than serum creatinine, but none of them are superior to serum cystatin C in this respect. Additionally, their serum levels in humans have been shown to be significantly influenced by age, inflammation or febrile illness, liver disease, and/or corticosteroid administration (Jung et al. 1987; Donaldson et al. 1990; Melegos et al. 1999; Donadio et al. 2001a, 2001b; Priem et al. 1999, 2001; Woitas et al. 2001; Bökenkamp et al. 2002; Filler et al. 2002). Furthermore, the cross-reactivity of the antibody detection reagents with other species and the usefulness of these markers in animal models have not been well established (Loeb 1998).

Assessment of GFR and RBF by Clearance Methods

PURPOSE AND RATIONALE

The renal clearance of a compound is the volume of plasma from which that compound is completely removed by the kidneys per unit time (Pitts 1968). The material removed from the plasma is generally excreted in the urine.

Clearance methods can be used for a variety of purposes:

1. Determination of effects on glomerular filtration rate (GFR) and renal blood flow (RBF)
2. Determination of the mechanism(s) involved in the renal excretion of a substrate (more in 1.E.1.1.2.2.3)

PROCEDURE

Clearance procedures can be conducted in all laboratory animal species; anesthetized or conscious animal models may be used. Measurement of arterial pressure

is advisable, especially in anesthetized preparations, to insure that renal perfusion pressure remains within the autoregulatory range (usually 80–120 mmHg). Vascular access ports can be helpful to provide continuous arterial access for pressure measurements (Mann et al. 1987).

Carefully timed and complete collection of urine is critical to clearance studies. Point-in-time samples are more easily collected from larger species, either by free-catch, urethral catheterization, manual compression of the bladder, or cystocentesis (withdrawal of urine from directly from the bladder with a needle and syringe). Catheterization may require sedation or anesthesia, especially in females of all species and in male pigs whose urethral recess makes this process difficult (Van Metre and Angelos 1999). Point-in-time samples from laboratory rodents may be obtained by taking advantage of the fact that these animals frequently urinate when they are handled or shortly after being removed from their home cage. A skilled, quick, and prepared operator with a ready small container or plain microcapillary tube may be able to obtain a small sample in the first instance (Loeb and Quimby 1999); in the second, the animal can be placed in a small confined space on plastic food wrap and observed carefully for urination, as it has been shown that most rodents will urinate within 20 min after removal from their home cages. The sample thus generated can be collected by micropipette (Kurien and Scofield 1999). Manual compression of the bladder can also be performed on rodents, and cystocentesis may also be performed by a skilled operator using a small (25 gauge) needle and syringe (Loeb and Quimby 1999). For repeated point-in-time urine samples from rats over short periods of time (1–2 weeks after the surgery), the urethra or the ureter can be cannulated. Cannulated rats can also be used to collect accurate and complete timed urine samples (Mandavilli et al. 1991; Horst et al. 1988). Care must be taken to ensure complete urine collection in catheterized/cannulated models by flushing the bladder with saline (adding the wash to the urine volume) and instilling air at the end of the collection to completely empty the bladder.

Timed urine collections in all species (including large animals) can also be obtained by the use of specially designed metabolism cages. The use of metabolic cages for timed urine collection is outlined in detail in "Urinalysis."

In all cases, samples must be collected in clean containers and must be kept free of contamination from food, drinking water, feces, blood, and bacteria. For best results, samples should be analyzed promptly (ideally within 1 h) after collection, but where analysis must be delayed, the sample must be protected from chemical degradation and evaporation, best accomplished by using collection containers that are appropriately sized for the species in question, tightly sealing the containers when possible, and keeping the specimen cold (4°C) until analysis. If chilled or frozen, samples must be allowed to equilibrate slowly to room temperature before analysis.

Either endogenous substances or exogenously administered tracers may be used in clearance studies. Creatinine and cystatin C have both been used as endogenous tracers for the determination of GFR. Either endogenous or exogenous creatinine clearance can be used to estimate GFR. For endogenous creatinine clearance, a single timed urine collection and matched plasma sample are used, with clearance determined as described below. Detection of creatinine by either enzymatic or HPLC methods are recommended if endogenous creatinine clearance is used, due to the limitations of the Jaffe method (outlined in "Assessment of GFR by Plasma Chemistry.") Exogenous creatinine clearance is performed by bolus administration of creatinine and determination of plasma clearance; the Jaffe reaction may be used for creatinine determination in this circumstance. This method compensates for the insensitivity of the Jaffe detection method at low creatinine concentrations in plasma by artificially increasing plasma creatinine levels and, additionally, removes the underestimation of GFR that results from the fact that endogenous chromagens are present in plasma but not urine (Brown 1994; Finco 1997, 2005; Watson et al. 2002b). In rats, exogenously administered cystatin C has been used to determine GFR. For this tracer, plasma clearance must be used to estimate GFR due to the fact that cystatin C is reabsorbed and degraded by the proximal tubule and does not normally appear in the urine (Roald et al. 2004; Tenstad et al. 1996).

Exogenous tracers are administered intravenously to achieve near steady state concentrations, generally by using a priming dose to load the plasma and extracellular compartments, and subsequent infusion to replace renal losses. Once steady state plasma tracer levels are approached, a series of timed urine

collections (clearance periods) are performed, with blood samples collected at the either the midpoint or beginning and end of the clearance periods. The urine and blood (plasma or serum) samples are analyzed for tracer(s) and the test compound.

Tracers for the determination of GFR must be freely filtered and then neither secreted nor reabsorbed from the tubular filtrate. This allows the assumption that the amount of plasma cleared of the tracer per unit time represents that which has been filtered through the glomeruli (i.e., GFR). A number of exogenous tracers meet these criteria. The fructose polysaccharide, inulin (mw ~ 5,200) is the most commonly used tracer in all species and serves as the "gold standard" to which others are compared (Finco 2005; Brown et al. 1996; Ragan and Weller 1999). Other indicators include isotopes of vitamin B_{12}, sodium iodothalamate, iohexol, and radiolabeled metal chelates of ethylenediaminetetraacetate (EDTA) and diethylenetriaminepentaacetic acid (DPTA) (Sarkar et al. 1988, 1991; Gaspari et al. 1997; Ragan and Weller 1999; Finco 2005). Other sugars such as the polyfructosan sinistrin (available commercially as Inutest®) and a commercially available artificial sweetener derived from sucrose (LC Sugar®) have also been used as tracers in both humans and animals (Perez-Rojas et al. 2005; Pill et al. 2005). As indicated above, clearance of the endogenous substances creatinine and cystsin C have also been used to evaluate GFR.

Tracers for the assessment of renal plasma flow must be completely cleared (combination of filtration and nearly 100% first pass tubular secretion to the urine) on first pass through the kidney. This allows the assumption that the volume of plasma cleared per unit time represents that which was either filtered by the glomeruli or bypassed the glomeruli and perfused the tubules. *p*-aminohippurate (PAH) is used for the assessment of RPF, because it is both freely filtered by the glomeruli and actively secreted by the organic acid transport pathway of the proximal tubule. First-pass PAH extraction by the kidneys varies from about 70–90% in rats, dogs, and humans (Brenner et al. 1976), but for the purpose of estimating RBF it is assumed to be 100%. Using this assumption, RPF is always slightly underestimated. Tetraethylammonium bromide (TEA), a substrate for the renal cation transporter, may also be used and is subject to the same limitations (Ragan and Weller 1999).

Inulin is measured colorimetrically, either by acid hydrolysis to generate a green product, or by a series of enzymatic reactions based on inulinase or one of several fructosidases. The resulting glucose is either oxidized using glucose oxidase and H_2O_2 and reacted with anthrone reagent to generate a colored product or is converted to glucose-6-phosphate or sorbitol with subsequent reduction of NADH, which is detected spectrophotometrically (Davidson and Sackner 1963; Day and Workman 1984; Sugita et al. 1995; Kuehnle et al. 1992). More recently, additional colorimetric electron acceptors have been developed which are equally or more sensitive and allow for adaptation of these methods to automated analyzers (Kimata et al. 2009). Similar enzymatic methods are used to detect the polyfructosan tracer reagents (Pérez-Rojas et al. 2005; Pill et al. 2005). A fluorescein-isothiocyanate (FITC) labeled version of sinistrin has been synthesized that can be measured fluorometrically, with comparable accuracy to the enzymatic methods (Pill et al. 2005). HPLC methods are used for the remaining exogenous GFR tracers. PAH and TEA are measured colorimetrically (Newman and Price 1999).

EVALUATION

Renal clearance (Cl) of any compound (X) can be determined by comparing the urinary excretion rate of compound X to the plasma concentration of compound X.

The urinary excretion rate is calculated as:

$$\text{Urinary excretion rate(mg/min)} = U_X(\text{mg/ml}) \times V(\text{ml/min})$$

Where U_x represents the concentration of substance X in urine (in mg/ml) and V represents the volume of urine collected per unit time (in ml/min). Thus, the clearance equation may be constructed:

$$Cl_x(\text{ml/minute}) = U_X(\text{mg/ml}) \times V(\text{ml/min})/P_X(\text{mg/ml})$$

where Px is the concentration of compound X in plasma (in mg/ml)

GFR is estimated by calculating the clearance of the tracer or endogenous substance. RPF estimated using PAH clearance is often designated effective renal

plasma flow (ERPF). Renal plasma flow is converted to renal blood flow (RBF) by dividing ERPF by the plasma fraction of whole blood, as estimated from the hematocrit (Hct):

$$RBF = ERPF/(1 - Hct)$$

The clearances of other compounds can be compared with inulin clearances to determine how the kidney functions in the elimination of the test compound. A clearance ratio is constructed by dividing the renal clearance of the test compound (X) by the renal clearance of inulin:

$$\text{Clearance Ratio} = CL_X, (ml/min)/Cl_{inulin}, (ml/min)$$

A clearance ratio <1.0 indicates reabsorption of the test substance following filtration, whereas active secretion will result in a clearance ratio of > 1.0.

MODIFICATIONS OF THE METHOD

For any of the tracers that meet the criteria specified above, plasma clearance may be used to estimate GFR or RPF as an alternative to renal clearance. This is the only method that can be used for cystatin C due to the fact that cystatin C is reabsorbed and degraded by the proximal tubule and does not normally appear in the urine (Tenstad et al. 1996). This eliminates the need for accurate timed urine collections, reduces inaccuracies resulting from matrix effects in the analyte assays, and allows the use of tracers that are not excreted into the urine.

Plasma clearance may be determined either after bolus administration of the tracer or by cessation of infusion following the establishment of a steady state plasma level as described above. Multiple timed plasma samples are then collected for the evaluation of the plasma tracer levels and calculation of clearance based on determination of area under the plasma concentration curve (AUC), as follows (Bailey et al. 1970; Frennby et al. 1996; Rönnhedh et al. 1996):

$$Cl = \frac{Q_{tot}}{AUC}$$

If volume of distribution is known or can be determined for a given tracer in any species, plasma clearance can be estimated from the plasma concentration of the tracer collected at a single point in time following the establishment of steady state plasma concentration after IV bolus administration, as follows (Jacobsson 1983):

$$Cl = [1/(t/V + 0.0016)] \times \ln[Q_{tot}/(V \times C_t)]$$

where Q_{tot} = total quantity of tracer injected, V = volume of distribution, Ct = plasma concentration at time t. The formula corrects for non-immediate mixing and nonuniform distribution of the tracer in plasma. Although the corrections were derived initially for inulin clearance in humans, they have been shown to be accurate for a number of tracers in humans and rats (Sterner et al. 1996; Orlando et al. 1998; Katayama et al. 2010).

Alternatively, tracers may be administered by continuous intravenous infusion until steady state is reached; at this point, plasma levels are determined at 3–5 time points from samples collected from the arterial system. The median arterial concentration is determined and clearance is calculated from the following formula:

$$Cl_X(ml/min) = \frac{Ix(mg/ml) \times Iv(ml/min)}{P_X(mg/ml)}$$

where Ix = concentration of the tracer in the infusion fluid, and Iv = infusion rate, and Px = median arterial concentration of the tracer at steady state.

Simultaneous determination of GFR and RPF (using either inulin or iothalamate combined with PAH in the infusate) has been performed in rats using this method (Rönnhedh et al. 1996; Fischer et al. 2000).

LIMITATIONS OF THE METHOD

First-pass extraction of PAH is highly variable both between species and between individuals within a species, which adds to the inherent inaccuracy of the estimate of RBF by this method. Furthermore, the test compound may interfere with the extraction of either PAH or TEA by competing for transport by the organic anion or cation transporters (Newman and Price 1999; Ragan and Weller 1999).

The limitations of the Jaffe method for creatinine determination have been discussed in Sect. 1.1.1. Exogenous creatinine clearance compensates for the insensitivity of the method as well as the interference by endogenous chromagens by artificially increasing the plasma creatinine concentration (Finco 1997).

Sinistrin (and consequently, FITC-sinistrin) are available in Europe but availability may be limited in other geographic areas. Similarly, LC sugar is only available in South America and is not currently available as a sterile injectable formulation suitable for repeated administration or clinical use. (Pérez-Rojas et al. 2005).

Assessment of RBF by Intravascular Doppler Flow Probes

PURPOSE AND RATIONALE

Probes utilizing electromagnetic or Doppler technology may be positioned around or within a renal artery to allow direct measurement of renal blood flow (Yagil 1990; Haywood et al. 1981). Detection of blood flow using Doppler systems is based on changes in the emitted ultrasonic frequency, a Doppler shift, caused by reflection of the signal of moving blood cells. The Doppler shift is proportional to the velocity of blood flow, as indicated by the following equation:

$$\Delta f = \frac{2 f_0 v \cos\theta}{c}$$

where Δf = Doppler peak frequency shift, f_0 = transmission frequency, v = instantaneous peak velocity, θ = angle of incidence of the beam to the bloodstream (assumed to be 0° for linear probes) and c = speed of sound in blood (1,570 m/s) (Chilian et al. 1982).

This technique is particularly useful when rapid or continuous assessment of effects on renal blood flow or assessment of renal vasoreactivity need to be assessed.

PROCEDURE

Doppler probes have been applied to rats, rabbits, cats, dogs, pigs, monkeys, and humans; these must be appropriately calibrated prior to experimental use. Animals are anesthetized and the probes are placed within the renal artery via the abdominal aorta, which may be accessed via the femoral or carotid arteries. The diameter of the renal artery at the placement site of the Doppler probe must be determined simultaneously to correct velocity measurements for determination of renal blood flow (see "Evaluation").

EVALUATION

A number of parameters can be derived from the Doppler measurements, most commonly including average peak velocity (APV), pulsatility index (PI), and resistive index (RI). Renal blood flow (in ml/min) can be calculated as follows:

$$\text{RBF} = \frac{\text{APV} \times \pi \times \text{D}^2 \times 60}{4}$$

where D = renal arterial diameter (Doucette et al. 1992).

Resistive index (RI) has been shown in several species to be positively correlated with tubular dysfunction or postrenal obstruction and its return to normal may serve as a prognostic indicator of resolution of tubular disease (Rivers et al. 1997; Shokeir et al. 1996; Tsuji and Taira 2001).

LIMITATIONS OF THE METHOD

Dopper probe assessment of velocity is accurate primarily in straight blood vessels of small diameter (<4.76 mm) and at relatively low flow rates (<200 ml/min), both of which may be exceeded in normal renal arteries in many species (Lerman and Rodriguez-Porcel 2001).

In dogs, acute, severe normovolemic anemia significantly altered renal artery Doppler parameters without having an influence on Doppler assessment of splanchnic blood flow; the technique may thus be inaccurate in anemic animals (Koma et al. 2006). Furthermore, it is invasive and the size of the test species to which it can be applied depends on the availability of appropriately sized and calibrated probes (Lerman and Rodriguez-Porcel 2001).

Assessment of GFR and RBF by Scintigraphic Imaging

PURPOSE AND RATIONALE

Radioactive indicators (^{99c} Tc-DPTA, ^{113m}In-DPTA, ^{99c}Tc-mercaptoacetyltriglycine) may be used to measure renal blood or plasma flows or glomerular filtration rate (Reba et al. 1968). These techniques require intra-arterial or intravenous administration of the tracer followed by monitoring of the amount of tracer in the kidneys with an external gamma camera (Fommei and Volterrani 1995).

In species where extrarenal clearance of tracers used in the determination of GFR or RPF is high or variable, external detection methods may actually be more accurate than plasma clearance methods because the extrarenal component of plasma removal is eliminated (Drost et al. 2003).

PROCEDURE

Tracer compounds with the same characteristics described earlier under clearance methods are utilized for the determination of GFR or RPF, but these are labeled with radionuclides suitable for scintigraphic imaging such as ^{99m}Tc, ^{131}I, ^{125}I, ^{67} Ga, ^{68} Ga, or ^{51}Cr. Tracers are administered either by intra-arterial or intravenous administration and are followed by monitoring the amount of tracer in the kidneys with an external gamma camera (Fommei and Volterrani 1995). External measurements of radioactivity retained in the kidney are made either at timed intervals (rate of accumulation, or slope method) or at a selected interval, usually corresponding to either first pass or peak level of the tracer (percent accumulation, or integral method) (Kampa et al. 2002).

$$\text{Predicted GFR } 1/4\ 0.44 \cdot \%\text{dose uptake} + 0.87$$

EVALUATION

With scintigraphic imaging, renal blood flow and and glomerular filtration rate are estimated using the Fick Principle:

$$Flux = \mathrm{DAk} * \frac{\mathrm{C1} - \mathrm{C2}}{\mathrm{X}}$$

(where A = area, x = distance, C = concentration and D = diffusion coefficient)

LIMITATIONS OF THE METHOD

These techniques do not yield absolute flow, but rather flow per unit volume or tissue mass. However, algorithms can be developed in the species of interest to allow conversion of tissue uptake to GFR or RBF expressed in standard units by simultaneous determination of plasma clearance of the tracer in preliminary experiments (Kelleher et al. 1991; Kampa et al. 2003), as the correlations between methods for any given tracer are in general high (Delpassand et al. 2000).

In general, assessment of GFR or RBF by external detection methods is less accurate than assessment by clearance methods, although the correction algorithm used for the external detection method can influence the degree of accuracy achievable (De Santo et al. 1999; Itoh et al. 2000; Itoh 2003). Integral methods (calculated based on the percent of the dose accumulated) are in general more accurate than rate of accumulation methods because they eliminate variability resulting from variable durations of the uptake phase (Kampa et al. 2003). Manual selection of the region of interest (ROI) for the collection of the scintigraphy data also improves the accuracy (Kampa et al. 2002).

MODIFICATIONS OF THE METHOD

Depending on the tracer used, either GFR or RBF can be estimated from the results. The table below lists

different tracers that can be used for the assessment of either GFR or RBF (Emeigh Hart and Kinter 2005):

Radiopharmaceuticals used for estimating:	
Glomerular filtration rate	Renal blood or plasma flow
^{3}H-inulin	^{3}H-para-aminohippuric acid (PAH)
^{14}C-inulin	^{14}C-PAH
^{14}C-carboxy inulin	^{99m}Tc-hippuran analogs
^{14}C-hydroxy-methyl inulin	^{99m}Tc-iminodiacetic PAH (PAHIDA)
^{131}I-chloroiodopropyl inulin	^{99m}Tc-mercaptoacetyltriglycine (^{99m}Tc-Mag3)
^{131}I-propargyl inulin	^{99m}Tc-mercaptosuccinyltriglycine (^{99m}Tc-MSG3)
^{125}I-diatrizoate	^{99m}Tc-N,N'bis(mercaptoacetyl)-2,3-diaminopropanoate (CO2-DADS-A)
^{125,131}I-iothalamate (Conray – 60)	^{125,131}I-iodopyracet (Diodrast)
^{131}I-diatrizoate (Hypaque, Renografin)	^{131}I-orthoiodohippurate (Hippuran, OIH)
^{51}Cr-,^{99m}Tc-,^{111,113m}In-,^{140}La-,^{169}Yb-EDTA	^{67,68} Ga-N-succinyl desferioxamine
^{51}Cr-,^{99m}Tc-,^{111,113m}In-,^{140}La-,^{169}Yb-DTPA	^{97}Ru-ruthenocenyl-glycine (Ruppuran)
^{57,58}Co-hydroxycobalamin	^{99m}Tc-thiodiglycolic acid
^{57,58}Co-cyanocobalamin	

In addition to their use in estimating glomerular filtration rate and renal blood flow, imaging techniques are extremely useful for viewing renal tissue in smaller animals.

Radiopharmaceuticals have been used for this purpose, but more recently, fluorescent probes and multiphoton microscopy techniques have been used to allow evaluation of blood flows in living animals in real time (Peti-Peterdi 2005; Kang et al. 2006). Regardless of the label or method, probes used for imaging should be rapidly and specifically extracted from blood by the kidney and retained for a sufficient period in the renal tissue to permit imaging. The ideal probe for imaging the renal parenchyma should be inert, 100% extracted in a single pass, irreversibly bound to the parenchyma, not accumulated by other tissues and not excreted in the urine.

Assessment of RBF by Microspheres

PURPOSE AND RATIONALE

Microsphere techniques can be used to assess blood flow in a number of tissues and organs (Rudolph and Heymann 1967) and have been extensively used to assess renal blood flow (Katz et al. 1971). Microspheres of a diameter that allows them to be contained in the microcirculation without separating from the bloodstream during circulation (usually 15 μm) are injected into the arterial circulation (either systemic or specific to the organ of interest), and the tissue is

subsequently harvested and the number or concentration of microspheres is evaluated. Distribution of the microspheres to the organ or tissue of interest is in proportion to blood flow and thus the numbers of microspheres lodging in organ pieces estimates the blood flow distribution.

PROCEDURE

Accurate determination of renal blood flow by microsphere methods requires that the microspheres are completely mixed in the central circulation, do not separate from the blood during circulation, are completely (100%) extracted in the first pass, are retained within the tissue of interest once deposited, and can be accurately measured (e.g., the label remains attached to the microsphere during tissue processing). Administration of the microparticle suspension (including the suspension vehicle used) must not disturb the circulation, either generally or to the organ of interest, and adequate numbers of microparticles must be administered to ensure that samples contain at least 200–400 microspheres each, which requires the administration of very large numbers of microspheres, especially in larger animals (Buckberg et al. 1971; Prinzen and Bassingthwaighte 2000).

Radiolabeled microspheres were the first ones developed and are most commonly used (many of the isotopes outlined in "Assessment of GFR and RBF by Scintigraphic Imaging" have been used for this purpose). Microspheres are administered by slow bolus injection into the left ventricle, at a dose sufficient to ensure delivery of adequate number of microspheres to the tissue of interest, as described above. During delivery of the microspheres, a reference sample of arterial blood is withdrawn at a measured rate to provide an estimate of the cardiac output. Following the injection, the kidneys are harvested and weighed and the microsphere count in representative weighed tissue samples is determined by liquid scintillation methods (McDevitt and Nies 1976; Prinzen and Bassingthwaighte 2000).

EVALUATION

The reference sample is used to provide an estimate of cardiac output (CO), using the following formula (McDevitt and Nies 1976):

$$\mathrm{CO} = \frac{Q_i \times \text{Reference sample withdrawal rate}}{Q_{rs}}$$

where Q_i = total quantity of microspheres injected and Q_{rs} = total quantity of microspheres in the reference sample.The renal blood flow (RBF) is then calculated based on the following relationship (Rudolph and Heymann 1967):

$$\mathrm{RBF} = \frac{Q_{kid} \times \mathrm{CO}}{Q_i}$$

Or, more simply (Glenny et al. 1983):

$$\mathrm{RBF} = \frac{Q_{kid} \times \text{Reference sample withdrawal rate}}{Q_{rs}}$$

where Q_{kid} = quantity of microspheres in the kidney.

MODIFICATIONS OF THE METHOD

More recently, microspheres have been developed that are labeled with colored or fluorescent dyes. Colored and fluorescent microspheres are extracted from tissues and blood by digestion (either with KOH or protease solutions) with potassium hydroxide and subsequent microfiltration; the dyes are then recovered from the filtered microspheres within a defined volume of an appropriate solvent, and their concentrations are determined spectrophotometrically, fluorometrically, or by HPLC methodology. (Kowallik et al. 1991; Glenny et al. 1993; Hakkinen et al. 1995; Mazoit et al. 1998).

Fluorescent microspheres may also be quantified using flow cytometry (FACS) following tissue extraction or in histologic sections, using manual counting of particles or automated image analysis methods. Both FACS and histologic techniques have shown good correlation to extraction methods and radionuclide techniques, and histologic methods have been used to evaluate regional differences in blood flow within a tissue with reasonable accuracy (Austin et al. 1993; Luchtel et al. 1998; Bernard et al. 2000; Kelly et al. 2000).

Microparticles may also be administered by intravenous injection in smaller animals such as rodents (Bernard et al. 2000; Schimmel et al. 2001), with acceptable results, provided adequate reference samples are collected.

LIMITATIONS OF THE METHOD

Although microsphere methods do provide accurate estimates of total renal blood flow when compared to

other methods, in general they cannot be used to evaluate regional blood flow in the kidney accurately because they are retained to a disproportionately greater extent in the cortex compared to the medulla, due both to trapping of microspheres in the glomeruli and "skimming" of microspheres at the arcuate arteries, resulting in disproportionately decreased delivery to the medulla (Clausen et al. 1979; Knox et al. 1984). However, changes in regional blood flows can be evaluated by determining differences in regional deposition of differentially labeled microspheres that are administered to the same animal before and after an experimental manipulation. If fluorescent microspheres are used for this purpose, the fluorochromes must be selected carefully to ensure adequate separation of the excitation and emission wavelengths to prevent "spillover" (Katz et al. 1971; Glenny et al. 1993). Thirteen such fluorochromes have been identified which do not result in spillover when administered simultaneously (Schimmel et al. 2001).

5.1.1.2 Assessment of Renal Tubule Functions

Urinalysis

PURPOSE AND RATIONALE

More than 99% of the reabsorption of glucose, protein, and electrolytes occurs in the proximal tubule. Electrolyte concentrations can be affected by other tubule segments, but even low-level changes in proximal tubular function will be reflected by increased urinary excretion of protein and glucose (Stonard et al. 1987; Finco 1997; Loeb and Quimby 1999; Newman and Price 1999; Aleo et al. 2002). Standard and modified urinalysis techniques can be successfully used to assess the effects of compounds on proximal tubule uptake processes (Katsuno et al. 2007).

PROCEDURE

Collection of a good quality sample from the test species is paramount to obtaining high quality data from the urinalysis (see "Assessment of GFR by Plasma Chemistry"). Timed urine collections in all species (including large animals) can also be obtained by the use of specially designed metabolism cages. A metabolism cage consists of an animal chamber mounted above an excrement collection system. The animal chamber must be equipped with feeder and waterer units if an animal is to be housed in the metabolism cage for more than a few hours. These need to be sized appropriately to the test species of interest (especially regarding the collection container, which must minimize surface area available for evaporation) and designed to eliminate contamination of the urine by food, drinking water, or feces. In selecting the size of the collection container, the anticipated urine volume should be considered: a mouse will produce 0.25–1 ml

in 24 h of urine; a rat, 10 ml; a hamster, 5–8 ml; a rabbit, 600 ml; and a dog or minipig, 500 ml or more (Loeb 1998; McClure 1999; Van Metre and Angelos 1999). Whatever type of metabolism cage is used, the following general precautions are offered:

1. For studies of >24 h duration, test animals should be acclimated to the metabolism cage for several days prior to study initiation. During this period, animals should be monitored frequently to insure that they learn to use the feeder and waterer systems properly. Test animals should be maintaining or gaining weight prior to study initiation.
2. Feeder and waterer systems should provide ample food and water to meet the animal's needs for the duration of urine collection and all separator systems should function properly. For chronic studies (>5–7 days duration), it is useful to have a complete exchange of feeder, waterer, and urine/feces collector and separator systems so that soiled units may be rapidly exchanged with clean, dry/filled units at regular intervals.
3. Cages should be decontaminated, cleaned, rinsed with distilled/deionized water, and thoroughly dried prior to use. Surfaces used to collect urine may be siliconized or sprayed with a suitable hydrophobic material (PAM®, General Foods) to facilitate urine collection.
4. All surfaces contacting urine should be rinsed with distilled/deionized water or appropriate solvents to collect any residuals at appropriate intervals.
5. To preserve the quality of the specimens during prolonged collection times, the opening of the collection vial needs to be small to prevent evaporation and the vial should be surrounded either with wet ice or frozen cold packs to chill the sample promptly once it is deposited (Loeb 1998; Loeb and Quimby 1999). Urine may also be collected under mineral oil to prevent evaporative losses. For very small or antidiuretic animals (e.g., hamsters, gerbils) placing the cage over a shallow pan of oil and skim feces from the surface may be necessary while collecting urine with a pipette from under the oil. To maximize the volume of the sample collected in rodents in metabolism cages, food should be withheld (this also reduces the risk of contamination of the sample) and water provided (Lee et al. 1998).

Routine urinalysis consists of visual assessment (color, clarity), volume, specific gravity or osmolality, pH, and quantitative or semiquantitative determination of total protein and glucose and microscopic evaluation of urine sediment (Weingand et al. 1996). Urine constituents can be measured semiquantitatively using commercially available "dipstick" test strips (Chemstrips®, Roche Diagnostics or Multistix®, Bayer Heath Care Diagnostics), which contain reagents for the determination of specific gravity, protein, glucose, ketones, bilirubin, urobilinogen, hemoglobin, nitrite, and leukocyte esterases (Newman and Price 1999). These strips may be read manually or using automated analyzers specific to each product.

If quantitative assessment of urine analytes is required (see under "Evaluation"), either urine volume or urine creatinine concentration must be measured and used to "normalize" the concentration of the measured analyte. This will negate the effects of differences in urine concentration between animals and allow for accurate comparison of the results. The daily excretion of creatinine is fairly consistent in all species and therefore its quantity in a spot urine sample serves as an accurate index of the 24 h urine output. This adjustment has been shown to accurately correct for incomplete timed urine sample collection in rodents (Haas et al. 1997a), and works well for other species. Urinary creatinine can be measured by the same methods used for plasma (see "Assessment of GFR by Plasma Chemistry").

EVALUATION

Urine volume, combined with assessment of urine concentration (specific gravity or osmolality) can serve as an index to renal function. With severe acute loss of functional nephron mass or renal perfusion, urine output is decreased (oliguria) or absent (anuria), while loss of the ability of the kidney to adequately concentrate urine results in the excretion of large volumes of dilute urine.

The commercially available dipstick reagents do not detect the low levels of glucose found in normal urine and thus positive results indicate significant glucosuria in most species (the exception is the gerbil, where dipstick positive glucosuria is normal due to the high urine concentration in this species) (McClure 1999). If glucosuria is detected, time-matched plasma glucose levels are needed to rule out that this result has not resulted from an increase in the filtered glucose load. If plasma glucose is normal, the appearance of glucose in the urine may indicate a functional deficit in the proximal tubule (Stonard et al. 1987; Finco 1997; Loeb and Quimby 1999; Newman and Price 1999; Aleo et al. 2002).

Because of inherent inaccuracies in the dipsticks when applied to animal urine (see below under "Limitations of the Method"), positive results by dipstick for protein (or glucose in some species and under some conditions) must be followed by detailed qualitative and quantitative assessment.

Quantitative assessment of urinary protein excretion is necessary to rule out a contribution from glomerular malfunction. In general, excretion of markedly elevated levels of protein is indicative of glomerular disease, whereas low-level proteinuria indicates tubular damage or very early/low-grade glomerular injury (Peterson et al. 1969; Finco 1997).

A number of different methods have been developed for quantitative assessment, including turbidometric, colorimetric (biuret and Lowry assays as examples) and dye-binding assays. All have their advantages and limitations; in general, biuret assays tend to detect all types of proteins with equal sensitivity but require fairly large sample volumes, turbidometric assays can suffer from lack of precision with variations in urine ionic strength, and dye-based methods may suffer from interference with exogenous and endogenous urine substances. The Folin phenol (Lowry), Coomassie brilliant blue, and Ponceau S methods have been recommended as being particularly precise for urine samples (Peterson et al. 1969; Dilena et al. 1983; Finco 1997; Newman and Price 1999).

Qualitative assessment (identification of the proteins excreted) is necessary to determine if low-level proteinuria has resulted from glomerular or tubular malfunction. Concomitant elevation of albumin and one or more of the low molecular weight proteins (which are freely filtered by the normal glomerulus) indicates that the proteinuria has resulted from decreased tubular reabsorption of proteins, while albumin elevation alone or concurrently with a high molecular weight protein (normally excluded from the filtrate by the glomerulus) indicates primary glomerular injury (Peterson et al. 1969; Finn and Porter 1998; Guder et al. 1998; Umbreit and Wiedemann 2000). Commonly used filtered low molecular weight proteins include retinol-binding protein (Price 2000, 2002; Aleo et al. 2002, 2003), α_2- or β_2-microglobulin (Viau et al. 1986; Loeb 1998; Finn and Porter 1998; Price 2000, 2002), and cystatin C (Finn and Porter 1998; Herget-Rosenthal et al. 2001; Uchida and Gotoh 2002).

LIMITATIONS OF THE METHOD

Because the commercially available dipsticks are designed for human use, they are inaccurate for a number of parameters in animal urine. The specific gravity reagents are completely inaccurate in all species. Dipsticks which use a glucose oxidase method for urine glucose can show a false positive result in species such as the dog and mouse with high urinary ascorbate levels or in urine contaminated with hypochlorite used as a disinfectant (Finco 1997; Loeb and Quimby 1999). For all glucose detection methods, administration of formulations that contain glucose or other metabolizable sugars in quantities should be avoided, as they may transiently overwhelm tubule reabsorption mechanisms and generate false positive test results.

Protein detection on the strips is based on a bromphenol blue method that is most sensitive for albumin (Newman and Price 1999), which means that proteinuria that does not result primarily from an increased albumin excretion may not be detected by this method. Furthermore, since these tests are designed for human urine, false positives are frequent in species like the dog, whose normal urine protein levels are just above the lower limits for humans (Finco 1997), and dipstick tests are invariably positive in male rats and mice which have normal high proteinuria (Loeb and Quimby 1999).

The sensitivity of the quantitative protein assays to the protein(s) of interest depends in large measure on which protein is used to generate the standard curve. Albumin is most commonly used because it is the most abundant protein in urine and while it is adequate for most methods (Dilena et al. 1983), it will in general underestimate the abundance of many other proteins of interest in urine (Guder and Hofmann 1992).

Qualitative assessment of urine proteins other than albumin is hampered in many species by the lack of suitable immunoassays; with the exception of cystatin C, commerically available antibodies do not cross-react with the animal proteins (Loeb and Quimby 1999; Uchida and Gotoh 2002). Assessment of urinary retinol excretion has been shown to be a sensitive index to retinol-binding protein excretion in the rat (Aleo et al. 2002, 2003).

MODIFICATIONS OF THE METHOD

Point-in-time samples from laboratory rodents may be obtained by taking advantage of the fact that these animals frequently urinate when they are handled or shortly after being removed from their home cage.

A skilled, quick, and prepared operator with a ready small container or plain microcapillary tube may be able to obtain a small sample in the first instance (Loeb and Quimby 1999); in the second, the animal can be placed in a small confined space on plastic food wrap and observed carefully for urination, as it has been shown that most rodents will urinate within 20 min after removal from their home cages. The sample thus generated can be collected by micropipette (Kurien and Scofield 1999).

For repeated point-in-time urine samples from rats over short periods of time (1–2 weeks after the surgery), the urethra or the ureter can be cannulated. Cannulated rats can also be used to collect accurate and complete timed urine samples (Mandavilli et al. 1991; Horst et al. 1988).

Electrolyte Excretion

Since one of the kidney's primary functions is maintaining electrolyte and mineral homeostasis in the face of fluctuating dietary intake and body needs, examination of plasma and urine electrolyte levels will provide some insight into renal function. Because of the large functional mass of the kidney, alteration of plasma electrolyte levels are usually not detected until the effect on renal functional is significant (pathologic). In contrast, urine electrolyte levels examined with knowledge of plasma levels and dietary intake can serve as an extremely sensitive

index to the effect of drugs or chemicals on the functional state of the kidney.

In animal studies, the diet can be carefully controlled and thus the intake (and hence the plasma electrolyte levels) can be assumed to be fairly constant. Provided there are no sources of significant electrolyte loss resulting from the experimental manipulations (e.g., vomiting, diarrhea, salivation), urine electrolyte levels will reflect effects on either GFR (determines the filtered load) or tubular secretion or reabsorption (determines the final urine electrolyte composition).

Fractional Excretion Methods

PURPOSE AND RATIONALE

Fractional excretion (FE) is the proportion of the filtered load of any analyte that is excreted from the plasma. If both tubular function and plasma electrolyte values are normal, increases in electrolyte FE values clearly reflect a decrement in GFR. With tubular malfunction, the direction of the change in FE values depends on the net direction of electrolyte transport (i.e., FE will increase for electrolytes that are primarily reabsorbed and will decrease for secreted electrolytes) (Finco 1997; Stockham and Scott 2002).

PROCEDURE

FE assessments can be performed in any species, as it requires only carefully timed complete urine collections and a concurrent assessment of GFR (see Sect. 1.1.1 and section "Urinalysis"). FE will be unitless if the urine collection period is expressed in minutes, thus (Finco 1997):

$$FE = \frac{\text{urine electrolyte concentration (mmol/l)} \times \text{urine (ml/collection period)}}{\text{GFR(ml/min)} \times \text{plasma electrolyte concentration (mmol/l)}}$$

To eliminate the need for both complete timed urine collections (difficult to do in most animals) and concurrent assessment of GFR, FE values are usually calculated based on point-in-time urine collections by using creatinine excretion during the same time period as an estimator of GFR (Finco 1997).

Animals are placed in appropriately sized metabolism cages for an appropriate period of time to allow collection of an adequate volume of urine (see section "Urinalysis" for methods). At the midpoint of the collection period a blood sample is obtained under appropriate anesthesia (note: the use of CO_2 for anesthesia will falsely elevate plasma potassium levels and render the method inaccurate) for determination of electrolyte and creatinine levels.

Plasma and urine electrolytes and creatinine are determined by standard methods (Durst and Siggard-Andersen 1999; Newman and Price 1999; Scott et al. 1999a). FE is calculated from the results as outlined below (Stockham and Scott 2002):

$$FE = \frac{\text{urine electrolyte concentration} \times \text{plasma creatinine concentration}}{\text{urine creatinine concentration} \times \text{plasma electrolyte concentration}}$$

LIMITATIONS OF THE METHOD

Because there are multiple transporters for most electroytes and solutes, FE will only reflect effects on the net tubular transport of solutes, and will most reliably highlight effects on the major transport pathway for any given solute. Effects on minor pathways usually do not alter FE but may contribute to inaccuracies in these methods. Because the major tubular transporter pathways are often localized to a single nephron segment, FE methods can sometimes be used to identify the specific segment affected by a test compound.

The inherent inaccuracy in the use of creatinine clearance as an estimator of GFR has been discussed previously (see section "Assessment of GFR by Plasma Chemistry"). If the Jaffe method for creatinine is used, the investigator must be aware of potential interference due to endogenous chromogens (the

error is magnified in species where these chromogens are present in higher concentration in the plasma than in the urine (dog, mouse) (Finco 1997; Dunn et al. 2004) or possibly the test compound (Sonntag and Scholer 2001). Additionally, plasma electrolyte levels may fluctuate as the result of eating or due to diurnal rhythms (Finco 1997). The impact of inaccuracies can be minimized by consistent timing of urine collection, fasting of animals before and during urine collection, and the inclusion of a concurrent untreated (vehicle control) group in all studies.

In order for FE values to be unitless, all analytes must be converted to their SI unit (or, if necessary, molar) equivalents. The table below lists some conversion factors for some of the more commonly used analytes.

Analyte	Conventional unit	Conversion factor	SI unit
Albumin	g/dL	10	g/l
Ammonia (as NH_3)	µg/dL	0.587	µmol/l
Ammonia (as NH_4)	µg/dl	0.5543	µmol/l
Ammonia (as nitrogen)	µg/dl	0.7139	µmol/l
Bicarbonate	mEq/l	1.0	mmol/l
Calcium	mg/dl	0.25	mmol/l
Creatinine	mg/dl	88.4	µmol/l
Galactose	mg/dl	55.506	µmol/l
Glucose	mg/dl	0.0555	mmol/l
Glutathione	mg/dl	0.032	mmol/l
Magnesium	mg/dl	0.411	mmol/l
Manganese	ng/ml	18.2	nmol/l
Phosphorus	mg/dl	0.323	mmol/l
Potassium	mEq/l	1.0	mmol/l
Retinol	µg/dl	0.0349	µmol/l
Sodium	mEq/l	1.0	mmol/l
Urea nitrogen[a]	mg/dl	0.357	mmol/l
Uric acid (urate)	mg/dl	59.48	µmol/l
General metric conversion (proteins)	mg/dl	0.01	g/l

[a]Conversion is to *urea* in mmol/l. See "Assessment of GFR by Plasma Chemistry."

Data from the following sources: http://www.globalrph.com/conv_si.htm; http://www.soc-bdr.org/rds/authors/unit_tables_conversions_and_genetic_dictionaries/e5196/index_en.html

MODIFICATIONS OF THE METHOD

FE of sodium (FE_{Na}) is most commonly used to assess tubular function, and to differentiate between prerenal and tubular causes of azotemia. Increases in FE_{Na} have been detected with acute tubular necrosis, while decreased FE_{Na} usually indicates decreased tubular flow rates resulting from decreased renal blood flow (Espinel 1976). However, in some cases where acute tubular necrosis or tubular malfunction is accompanied by decreased renal perfusion or tubular flow, FE_{Na} will decrease; conversely, FE_{Na} may be increased in cases where prerenal azotemia is accompanied by systemic acid–base imbalances and/or altered excretion of other electrolytes (Nanji 1981).

FE of magnesium (FE_{Mg}) has been shown to be the most sensitive index in detecting low-level tubular injury in humans (Barton et al. 1987; Futrakul et al. 1999; Kang et al. 2000; Oladipo et al. 2003). FE_{Mg} is also directly correlated to the magnitude of peritubular blood flow and serves as a sensitive marker for the presence of renal interstitial fibrosis (Deekajorndech 2007). Increased FE of calcium (FE_{Ca}) has also been shown to serve as a sensitive index of effects on renal function unrelated to overt renal injury (Lam and Adelstein 1986; Tuso and Nortman 1992; Eliott et al. 2000). The transporters for both Ca and Mg reside in the distal convoluted tubule and connecting tubule and are regulated by alterations in systemic pH; thus, concomitant increases or decreases in both FE_{Mg} and FE_{Ca} may be indicative of the presence of systemic metabolic acidosis or alkalosis, respectively (Nijenhuis et al. 2006).

FE of urea (FE_{Ur}) may be more useful than the FE_{Na} in distinguishing between prerenal and renal azotemia in humans, as it appears to more reliably reflect renal perfusion and does not change with diuretic administration, which can falsely increase FE_{Na} (Kaplan and Kohn 1992; Carvounis et al. 2002; Pépin et al. 2007). It thus may also be useful in making this distinction in animal models. Changes in the FE of urea also reflect changes in urine flow rates (in general, these values move parallel to each other because decreased tubular flow results in increased urea reabsorption) and can be used as an estimate of this parameter (Goldstein et al. 1969; Finco 1997). The methods used to detect urea in urine are the same as those used in serum (Newman and Price 1999).

FE of anions (ammonium, bicarbonate) can be used to determine the potential mechanism underlying systemic acid–base imbalances (Rothstein et al. 1990; Kim et al. 2001).

Quantitative Electrolyte Excretion

PURPOSE AND RATIONALE

Fractional excretion methods are useful in that they can identify alterations in analyte excretion with relative ease, as they require only point-in-time assessment of analyte concentration and do not require complete and timed urine collection. Greater sensitivity, however, is obtained with quantitative evaluation of electrolyte excretion. This method is more difficult, requiring carefully timed, complete urine collection, and because plasma levels are not evaluated there needs to be reasonable assurance that the changes in excretion seen do not result from alteration of the filtered load of the analyte in question (e.g., plasma levels and GFR remain consistent). In animal studies, where the diet is carefully controlled, these factors are not usually of concern.

PROCEDURE

The method can be used on any species, although rats are most commonly used. Animals are usually fasted but allowed access to water; if anesthetized animals are used, intravenous administration of balanced electrolyte solutions (e.g., lactated Ringer's solution) or 0.9% NaCl solution can be administered by intravenous infusion to ensure that plasma volume (and thus GFR) and electrolyte levels are maintained.

Urine is collected by any appropriate method (see "Urinalysis") over a specified period of time. If possible, the urinary bladder should be emptied before collection of test urine is initiated and at the end of the collection period; this can be accomplished in dogs by catheterization and in rodents by handling or manual expression of the bladder. If metabolism cages are used, special care must be taken to avoid evaporation of urine and contamination of the vials with feces or drinking water, as accurate determination of volume is important. The volume of urine collected is determined gravimetrically, and urine electrolytes are measured by standard methods (Durst and Siggard-Andersen 1999; Scott et al. 1999b).

Electrolyte concentrations need to be converted to their SI equivalents before calculation of electrolyte excretion (see "Fractional Excretion Methods").

EVALUATION

The volume of urine collected over the time period is defined as the urine flow rate:

$$V = \text{volume collected/time period (expressed in mL/min)}$$

and electrolyte excretion ($U_X V$) is defined as:

$$U_X V = \{[(\text{concentration of X in urine}) \times V]/\text{body weight in g}\} \times 100 (\text{expressed in mmol/min/100g})$$

As a general rule:

$$U_{Na}V + U_K V = U_{Cl}V$$

and

$$U_{Na}V + U_K V + U_{Cl}V + U_{Urea}V = \text{urine osmolality}$$

If the first equation is untrue, the assumption must be made that there are additional anions in the urine. Carbonic anhydrase inhibition (i.e., excess urinary bicarbonate) may be the reason for this finding if the ratio:

$$\frac{U_{Cl}V}{U_{Na}V + U_K V}$$

is less than 0.8.

Deviations in the second equation indicate electrolyte or nonelectrolyte "gaps" and suggest the presence of unusual solutes in urine.

Net natriuretic activity can be assessed by evaluation of the ratio:

$$\frac{U_{Na}V}{U_K V}$$

Values greater than 2.0 indicate a favorable natriuretic effect, and values greater than 10.0 indicate a potassium-sparing effect.

Assessment of Tubular Transport Processes

Assessment of Organic Anion and Cation Transport

PURPOSE AND RATIONALE

A number of transporters for organic anions and cations are present on both the lumenal and basolateral surfaces of the proximal tubules. These are essential to the secretion and/or reabsorption of a number of endogenous substrates as well as functioning in the elimination of xenobiotics. These transporters frequently function as ion exchangers and their activity is thus bidirectional, so that the net direction of transport (i.e., secretion or reabsorption) for any given substrate depends not only on the numbers and activity of the transporters on either side of the tubule but also on the presence and concentration of competing or cotransported substrates. This feature of tubular

transport has been one of the major challenges in the development of uricosuric agents for the treatment of hyperuricemia and influences the nature and impact of drug–drug interactions (Launay-Vachera et al. 2006; Terkeltaub et al. 2006). Compounds that affect either the expression or activity of transporters, are competitive substrates for them, or act as inhibitors of transport thus may affect not only the clearance of therapeutic agents but also that of endogenous metabolites (Wright and Dantzler 2004; Launay-Vachera et al. 2006).

PROCEDURE

The choice of substrate or inhibitor used depends on the transport process or specific transporter of interest. Table 5.1 lists the most commonly used substrates and their transporters (note: most inhibitors act competitively and are themselves substrates for the transporter in question).

Transport studies can be performed in any animal model from which urine and plasma may be collected readily. Inhibitors are administered 30 min–1 h before the administration of the test substance. Substrates are usually administered intravenously, and are detected in urine and plasma most commonly by colorimetric methods. The exception is glycylsarcosine, which is either used as a [^{14}C] radiometric tracer for clearance studies or as a [11C] PET tracer for in vivo uptake studies (Ocheltree et al. 2005; Nabulsi et al. 2005)

EVALUATION

Standard clearance, fractional excretion (FE), or excretion methods are used to assess the effects (see "Assessment of GFR and RBF by Clearance Methods" and "Electrolyte Excretion" for details).

LIMITATIONS OF THE METHOD

Significant sex differences exist in renal transporter expression and activity in rodents, with activity in males being generally greater than in females (Morris et al. 2003; Sekine et al. 2006). Sex hormone regulation of the same transporter can differ across species,

Table 5.1 List of most commonly used sub-strates and their transporters

Compound	Commonest use	Net transport direction	Transporter(s) affected	Comments
Tetraethylammonium (TEA)	Substrate	Secretion	OCT1, OCT2, OCT3	Most commonly used substrate
1-methyl-4-phenylpyridinium (MPP$^+$)	Substrate	Secretion	OCT1, OCT2	Can be used to differentiate OCT3-mediated transport
Tributylmethylammonium (TBuMA)	Substrate	Secretion	OCT3	Can be used to differentiate OCT3-mediated transport
Urate	Substrate	Secretion or Reabsorption (species dependent)	URAT1, OAT1, OAT3	URAT1 is selective for urate in human kidney but its ortholog has other OA transport functions in other species. Net transport is reabsorption in humans but secretion in animals
p-aminohippurate (PAH)	Substrate	Secretion	OAT1, OAT2, OAT3(?), OAT4	Most commonly used substrate. Questionable substrate for OAT3
Estrone sulfate	Substrate	Secretion	OAT3, OAT4, Oatp1	Oatps are homologues of bile acid transporters in the liver
Lucifer yellow	Substrate	Secretion	OAT1	Can be detected spectrofluorometrically
Phenolsulfonphthalein (Phenol red)	Substrate	Secretion	OAT3	Clearance has traditionally been used as a surrogate for urate transport
Glycylsarcosine	Substrate	Reabsorption	PEPT1, PEPT2	Equal affinity for both PEPTs, but renal reabsorption is primarily PEPT2 mediated
Probenecid	Inhibitor		OAT1, OAT2, OAT3, URAT1	Used therapeutically and experimentally
Cimetidine	Inhibitor		OAT3	Used to correct creatinine clearance for the contribution of tubular secretion
Benzbromarone Pyrazinamide	Inhibitor		URAT1	Selective for URAT1

Table 5.2 Common gender-related differences in renal transport processes[a]

Transporter	Selected substrate(s)	Species	Gender difference	Response to treatment with: Testosterone	Estrogen
Oatp[b]	Estrone sulfate Glutathione (GSH)	Rat	Male > female	Strong increase	Decrease
OAT1	Urate PAH PGE_2 Cysteine conjugates	Rat	Male > female	Increase	Strong decrease
OAT3	Urate PAH Cimetidine	Rat	Male > female	Increase	No effect
OAT2	PAH PGE_2	Mouse	Male > female		
OAT2	PAH PGE_2	Rat	Famale > male	Strong decrease	Weak increase
OCT2	TEA	Rat	Male > female	Increase	Decrease
MRP1	Lipophilic cations GSH, glucuronide & sulfate conjugates	Mouse	Female > male	Not determined	Not determined
MRP4	GSH, glucuronide & sulfate conjugates	Mouse	Male > female	Increase	No effect
SGLT1	Glucose Galactose	Rat	Female > male	Decrease	No effect

[a]Data from Morris et al. 2003; Wright and Dantzler 2004; Sabolić et al. 2006; Ljubojević et al. 2004, 2007.
[b]Note: net effect of Oatp transport is reabsorption, whereas for others the net effect is secretion.

and similar transporters can have different sex hormone regulation within a species. These must be taken into account both in designing experiments to evaluate effects on organic anion or cation transport systems as well as in evaluating the clinical relevance of those results. Some of the common gender-related differences in renal transport processes are outlined in the Table 5.2:

Many of the substrates, and all of the inhibitors, are not specific enough for accurate determination of the exact transporter affected by the test compound. Furthermore, redundancies in tubular transport processes exist that can mask the ability to detect alteration in function of any single transporter by even selective inhibitors.

MODIFICATIONS OF THE METHOD

The listed substrates and inhibitors may also be used in in vitro models such as isolated tubules or kidney slices. In the latter model, net transport is usually assessed by measuring either the disappearance of the substrate from the medium or, more commonly, the degree or rate of accumulation of the substrate over time in the tissue slice (Kirkpatrick and Gandolfi 2005).

Evaluation of Receptor-Mediated Endocytosis

PURPOSE AND RATIONALE

Reuptake of low molecular weight proteins that are freely filtered at the glomerulus (as well as some high molecular weight proteins) occurs primarily in the proximal tubule as the consequence of receptor-mediated endocytosis. For most of these, the process is mediated through megalin binding, either directly or subsequent to their binding to cubulin (a brush border membrane associated protein that is internalized following ligand binding and complex formation with megalin). The megalin-protein complexes are internalized, forming primary endosomes. These are subsequently acidified through the action of a number of proton exchange transporters, the most crtical of which are Na^{+}/H^{+} exchanger-3 (NHE3) and Cl-/H + antiporter-5 (ClC-5). The decrease in pH results in release of the proton exchange transporters, megalin and cubulin from the late endosomes, which are recycled back to the brush border, as illustrated in Fig. 5 (Leheste et al. 1999; Christensen 2002; Verroust 2002; Verroust et al. 2002; Guggino 2007).

In addition to its role in renal endosomal acidification, NHE3 is also critically important to the normal endocytic uptake of megalin-protein complexes. The two proteins are located in close association in the proximal tubule brush border and disruption of this association results in decreased or absent megalin mediated endocytosis (Biemesderfer et al. 1999; Gekle et al. 1999, 2004). Because the activity of NHE3 in the proximal tubule is primarily regulated by alterations in its turnover and/or trafficking to the brush border membrane (there exists a substantial intracellular pool within the proximal tubule that can rapidly exchange with the transmembrane, megalin-associated NHE3 pool), any physiologic, pharmacologic or toxic stimulus that affects the relative distribution of NHE3 within the proximal tubule cell can have a profound effect on megalin-mediated endocytosis and result in either increases or decreases in urinary low molecular weight proteins (Donnowitz and Li 2007).

PROCEDURE

A listing of endogenous substrates for megalin-mediated transport is found in Table 5.3. Several of these (listed in italics in the table) have either been used or proposed as biomarkers of renal tubular function. While the presence of either any or increased quantities of one or more of these proteins in the urine is considered evidence of alteration of renal tubular protein transport, greater sensitivity to detect detriments in renal protein transport has been shown by using fractional excretion or clearance methods (Tencer et al. 1998a).

Information from: Leheste et al. 1999; Moestrup et al. 1996; Marinó et al. 2001; Christensen 2002; Verroust 2002; Verroust et al. 2002; Gburek et al. 2003; Cutillas et al. 2004; Roald et al. 2004; Oyama et al. 2005; Meistermann et al. 2006; Wolff et al. 2006; Kobori et al. 2008.

Proteins in *italics* have been used or proposed as urinary biomarkers of altered tubular protein transport.

The proteins can be detected and quantified in plasma and urine samples by appropriately-validated ELISA methods. Mass spectroscopy methods have also been used (Meistermann et al. 2006). Assessment of urinary retinol excretion has been shown to be a sensitive index to retinol binding protein excretion in the rat (Aleo et al. 2002, 2003).

Table 5.3 List of endogenous substrates for megalin-mediated transport

Vitamin-binding proteins/ apolipoproteins	Hormones	Enzymes	Growth factors/cytokines	Miscellaneous
Apo-AI	*Angiotensinogen*	α-amylase	Angiogenin	*Albumin*
Apo-AIV	Insulin	Carbonic anhydrase	Chemokine 14	α_1-*Microglobulin*
Apo-B	Parathyroid hormone	Lipoprotein lipase	Complement factor B	α_2-HS-glycoprotein
Apo-E	Prolactin	*Lysozyme*	Complement factor C2	β_2-*Microglobulin*
Apo-J (clusterin)	Thyroglobulin	Plasminogen	Complement factor D	β_2-Glycoprotein I
Apo-H		Plasminogen activator inhibitor-1	Complement factor H	*Cystatin C*
Cubulin		Plasminogen activator inhibitor-1 (PAI-1)	Epidermal growth factor	Cytochrome c
Metallothionein		PAI-1-urokinase	IGF-binding protein-2	Fibronectin FN70
Retinol-binding protein		PAI-1-tPA	IGF-binding protein-4	Immunoglobulin light chains
Transferrin		Pro-urokinase	IGF-binding protein-5	Hemoglobin
Transthyretin			IGF-binding protein-6	Hemopexin
Transcobalamin			IGF-II	Lactoferrin
Vitamin D–binding protein			Neutrophil-activating peptide	*L-fatty-acid-binding protein*
			Pigment epithelium–derived factor	Myoglobulin
				Major urinary protein-1 (MUP-1)
				Orosomucoid
				Odorant-binding protein
				Zinc-α_2-glycoprotein

EVALUATION

Standard clearance, fractional excretion (FE) or excretion methods are used to evaluate the effects (see "Assessment of GFR and RBF by Clearance Methods" and "Electrolyte Excretion" for details).

LIMITATION OF THE METHOD

The usefulness of these assessments in animals are limited by the lack of suitable immunoassays, as in many cases, commerically available antibodies do not cross-react with animal proteins. Notable exceptions are cystatin C and β_2-microglobulin (Viau et al. 1986; Loeb and Quimby 1999; Uchida and Gotoh 2002).

MODIFICATION OF THE METHOD

More recently, the use of fluorescently labeled probe proteins (such as FITC-albumin) and multiphoton microscopy techniques have allowed evaluation of alterations in protein transport in real time (Peti-Peterdi 2005).

Evaluation of Tubular Function by Micropuncture

PURPOSE AND RATIONALE

Micropuncture is an important method for determining the effects of drugs or chemicals on single nephron function in the intact kidney, and can provide information concerning tubular handling of a drug or chemical. Micropuncture is a highly specialized technique that requires considerable equipment and experience to be utilized properly.

PROCEDURE

Studies may be done in small rodents and dogs, and studies in various strains of rats are most common. Munich-Wistar rats are frequently used for micropuncture studies because the glomeruli are visible and accessible at the surface of the kidney (Ramsey and Knox, 1996). The animals are fasted for 16 h before the beginning of the experiment, but have free access to tap water. After anesthesia the animals are placed on a thermostatically heated table. Following tracheotomy, the carotid artery and jugular vein are cannulated for blood pressure recording, blood sampling, and for infusion of compounds, respectively. The left kidney is carefully exposed by a flank incision and immersed in a vessel containing mineral oil at 37°C. Proximal tubules are identified under a microscope on the surface of the kidney and a micropipette (glass capillary tube of 8–10 mm external diameter) is inserted. A small amount of mineral oil or wax is infused to block retrograde flow of the perfusion fluid and the cannulated tubules then are infused with saline or appropriate balanced electrolyte solution containing inulin (H^3 or flourescein isothiocyanate conjugated) and a dye solution (lissamine green or other suitable dye) to assess the volume of absorption and identify the

perfused segments, respectively. The infusion rate/volume is determined by the size of the animal. Distal collection is done by identification of the perfused segment by its dye content; a second micropipette is then inserted, a distal oil or wax block is placed and the infusion fluid can be collected for subsequent analysis (Knox and Marchand 1976; Ramsey and Knox 1996; Lorenz et al. 1999; Wang et al. 1993, 1999).

EVALUATION

Fluid reabsorption (J_v) is assessed by comparing the inulin concentration in the perfusate to that in the collected sample, thus (Wang et al. 1993):

$$J_v = V_0 - VL$$

where VL is the collected fluid volume (normalized for the length of the tubular segment over which it was collected), and:

$$V_0 = VL(INL/IN_0)$$

where INL = concentration of inulin in the collected sample, and IN_0 is the inulin concentration in the perfusate.

The net flux of the desired analyte (J_X, where X is the anlyte of interest – Na, K, HCO_3, glucose, etc.), is calculated thus:

$$J_X = V_0[X_0] - VL[X]_L$$

where $[X]_0$ is the concentration of the analyte in the perfusion fluid, and $[X]_L$ is the concentration of the analyte in the collected fluid.

MODIFICATION OF THE METHOD

Inulin conjugated to fluorescein isothiocyanate (FITC) may be used in place of the radiolabeled inulin. The inulin concentration in the sample is assessed by comparing the fluorescence in the sample to a standard curve (Lorenz and Gruenstein 1999).

This technique can be applied to distal tubules as well as to proximal tubules. Distal tubules are identified at the surface of the isolated kidney following micropuncture and perfusion of a proximal tubule as described above. Once the dye reaches the superficial portion of the distal tubule, it is blocked with oil or wax and accessed both proximally and distally as described above (Levine 1985).

Evaluation of Tubular Function by Stop Flow Techniques

PURPOSE AND RATIONALE

This procedure is of historic value in the localization of transport processes along the length of the nephron. During clamping of the ureter, glomerular filtration is grossly reduced. The contact time for the tubular fluid in the respective nephron segments increases, and the concentration of the constituents of tubular fluid should approximate the static-head situation. After release of the clamp, the rapid passage of the tubular fluid should modify the composition of the fluid only slightly. The first samples should correspond to the distal nephron segment, the latest to glomerular fluid.

With introduction of micropuncture techniques (“Evaluation of Tubular Function by Stop Flow Techniques”), evaluation of segment-specific transport using whole kidney stop flow techniques has become less common. However, the observation that the conduct of stop flow studies in single nephrons resulted in pronounced vasoconstriction of the afferent arteriole of the affected nephron (Arendshorst et al. 1974) led to the application of this technique to the study of this phenomenon. Micropuncture stop flow methods are thus more commonly used to investigate tubuloglomerular feedback (TGF) regulatory mechanisms.

PROCEDURE

The whole kidney stop flow method was originally described by Malvin et al. (1958). Larger species (rats, dogs, and rabbits) are most commonly used. Animals are maintained under general anesthesia and intense osmotic diuresis (via IV perfusion with a hypertonic solution such as saline or mannitol) is initiated. Once diuresis has been established, a ureter is clamped for several minutes allowing a relatively static column of urine to remain in contact with the various tubular segments for longer than the usual periods of time. Thus, the operation of each segment on the tubular fluid is exaggerated. Then the clamp is released, and the urine is sampled sequentially. Small serial samples are collected rapidly, the earliest sample representing fluid that had been in contact with the most distal nephron segment.

The test substance of interest, along with inulin or another marker of glomerular filtration, is administered intravenously to equilibrium before the application of uretral occlusion. Blood samples are collected at the midpoint of the occlusion period for the determination of the test substrate and the glomerular marker (for subsequent assessment of clearance as described in "Assessment of GFR and RBF by Clearance Methods").

EVALUATION

In each sample the concentration of a glomerular marker, such as inulin, and the concentration of the substance under study are measured. The urine flow rate may be calculated by dividing the volume of sample collected by the collection interval (this is thus expressed in ml/min). Clearance of the test substance and the glomerular marker are calculated (see "Assessment of GFR and RBF by Clearance Methods"). Fractional excretion of the test substrate is calculated as described in "Fractional Excretion Methods," or by dividing the clearance of the test substrate by that of the glomerular marker (Tanaka et al. 1990).

MODIFICATIONS OF THE METHOD

An early modification of the whole kidney stop flow technique obliterates the renal pelvis dead space in dogs just prior to the ureteral obstruction. This allows stop flow experiments to be performed with less intense diuresis and still generate reliable determination of distal tubular fluid composition (Jaenike and Berliner 1960).

The clearance of endogenous substrates (e.g., urate, uric acid, electrolytes) may be used instead of those of exogenously administered compounds to assess tubular function (Shinosaki and Yonetani 1989; Tanaka et al. 1990: Shinosaki et al. 1991). Creatinine (either endogenous or exogenous) may be used in place of inulin as a marker of glomerular filtration (Young and Edwards 1964; Tanaka et al. 1990).

Stop flow techniques can be performed in isolated perfused tubular segments using micropuncture techniques (see "Evaluation of Tubular Function by Stop Flow Techniques"). The proximal and distal micropunctures are performed as described, but instead of immediately collecting fluid from the distal micropipette, pressure is applied equal to that of the perfusion pressure at the proximal pipette, until flow ceases at the infusing pipette. Sampling occurs following a period in which the perfusate remains static in the perfused tubule segment. Care must be taken, especially in mice, to prevent tubular leaking with excessive stop-flow pressures or infusion rates (Schnermann 1999).

Micropuncture techniques are used for evaluation of effects on tubuloglomerular feedback (TGF). Surface visible juxtamedullary nephrons in which the proximal segment and loop of Henle can both be identified and accessed are utilized. The proximal segment is accessed as described in "Evaluation of Tubular Function by Stop Flow Techniques," but a viscous oil is used to block the distal micropuncture site and the proximal site is used to record the stop flow pressure (SFP) just proximal to the blocked segment. The loop of Henle just distal to the stopped segment is accessed and perfused with Ringer's solution at varying rates of flow, usually over a range of 10–40 nl/min. The resulting decrease in SFP in the upstream segment of the nephron as a function of increased flow rate is plotted and the slope of the resulting line used to define the magnitude of the TGF response. Test compounds are added to the perfusate to determine their effect on the TGF response by evaluating the change in the slope of the SPF-perfusion rate line. The baseline (unperfused) SFP is be determined in the perfused nephron before initiation of perfusion; alternatively, the proximal segments of adjacent nephrons may be blocked in a similar fashion but left unperfused to serve as controls (Schnermann et al. 1973a; Wright and Schnermann 1974; Carlström et al. 2010).

As an alternative to measurement of SFP in the perfused nephron, constriction of its afferent arteriole may be visualized using a high contrast video system. The diameter of the afferent arteriole is then determined from the images and the linear relationship

between this parameter and the distal tubular perfusion rate is used as an index to the magnitude of the TGF response (Casellas and Moore 1990).

5.1.1.3 Assessment of Glomerular Function

Urinary Protein Markers of Glomerular Function

PURPOSE AND RATIONALE

The filtration of proteins across the glomerulus is limited primarily by their molecular radius, which is a function of molecular weight. The size limitation is a function of both the pore sizes of the glomerular capillaries as well as the maintenance of a net negative charge by the glomerular basement membrane (GBM). Low level structural or functional changes in podocytes (e.g., alteration in the cytoskeleton or the number or nature of cell–cell interactions), loss of the net negative charge on the GBM, or minor alteration in the contractile states of the mesangial cells serve to increase the effective diameters of primarily the small membrane pores, while more pronounced or prolonged structural damage to the glomerulus (especially the podocytes) increases the relative numbers of large pores present on the glomerular capillaries. The net result overall is increased excretion of protein into the urine. Slight increases in effective small pore diameter resulting from the former conditions will result in the appearance of smaller molecular weight proteins (i.e., those with molecular radii very close to the normal effective pore diameter, such as albumin, and to a lesser extent, IgG) in the urine, as the normal tubular uptake pathways for small molecular weight proteins will become rapidly saturated due to the increased tubular filtered load. In contrast, significant structural or functional changes in podocytes or glomerular mesangial cells will result in a relative increase in the numbers of larger pores, resulting in the appearance of larger molecular weight proteins (Tencer et al. 1998a, 1998b; Mundel and Reiser 2010; Tossidou et al. 2010).

PROCEDURE

Time-matched urine and blood samples are collected and determination of the concentration of the analyte(s) of interest are performed as described previously (see "Assessment of GFR by Plasma Chemistry", "Urinalysis" and "Assessment of Tubular Transport Processes").

Because increased albumin excretion is almost always the consequence of glomerular injury, it is generally considered the most sensitive index to low level glomerular injury. Sensitive detection of low level increases in urine albumin is best accomplished by the use of the antibody-based methods (turbidimetric or nephelometric) that are of higher sensitivity than colorimetric methods; the human-based reagents have been validated for cats and dogs and have been used in other species. Highly sensitive semiquantitative urine dipsticks have been developed that have been shown to be adequately accurate to detect microalbuminuria in humans, but these are not adequately sensitive to detect

microalbuminuria in animals (Sawicki et al. 1989; Pugia et al. 1997; Pressler et al. 2002; Gentilini et al. 2005; Murgier et al. 2009).

Albuminuria, accompanied by the excretion of high molecular weight proteins into the urine, is diagnostic for severe alterations in glomerular structure and/or function. Increased urinary excretion of one or more of a number of high molecular weight proteins has been used as an index to glomerular injury. IgG is most commonly used for this determination, but greater sensitivity and better correlation with the clinical and histologic diagnosis was obtained using extremely large proteins (either IgM or α_2-macroglobulin) (Tencer et al. 1998b, 2000). These are detected using antibody-based methods (described in "Evaluation of Receptor-Mediated Endocytosis").

EVALUATION

While increased urinary albumin concentrations alone are indicative of glomerular injury, the sensitivity of detection of clinically significant microalbuminuria is improved by the calculation of the urinary albumin: creatinine index (ACI), as follows:

$$ACI = U_{Alb}/U_{Creat}$$

where U_{Alb} = urinary albumin concentration, and U_{Creat} = urinary creatinine concentration (Tencer et al. 1998b; Kuwahar et al. 2008).

Greater sensitivity in the detection of alterations in glomerular function, as well as an indication of the nature of the underlying injury can result from evaluation of point-in-time serum and urinary concentrations of a selected large molecular weight protein and albumin and calculation of a selectivity index (SI), as follows:

$$SI = \frac{U_{HMW_{protein}}}{S_{HMW_{protein}}} \times \frac{S_{Alb}}{U_{Alb}}$$

where $U_{HMW\ protein}$ = urinary high molecular weight protein concentration, U_{Alb} = urinary albumin concentration, $S_{HMW\ protein}$ = time-matched serum high molecular weight protein concentration, S_{Alb} = serum albumin concentration (Tencer et al. 1998b, 2000).

MODIFICATION OF THE METHOD

Exogenous administration of endogenous proteins of variable molecular weights and effective radii is theoretically the most relevant means of determining alterations in glomerular function. Such methods have been successfully performed in rats using radiolabeled myoglobin, κ-dimer, neutral horseradish peroxidase, neutral human serum albumin, and native albumin (Lund et al. 2003). If this approach is used, proximal tubular protein transport and degradation of the labeled probes must be controlled or inhibited to prevent the introduction of errors to the resulting SI determination.

LIMITATIONS OF THE METHOD

As indicated in 1.E.1.1.12.3.2., many of the antibody-based assay methods used for the assessment of high molecular weight proteins are specific for humans and do not cross-react with those from commonly used test species.

Assessment of Glomerular Function with Probe Substrates

PURPOSE AND RATIONALE

To overcome the inaccuracies imposed by proximal tubular protein uptake and degradation on accurate assessment of glomerular filtration, probe substrates of defined effective radius, and/or net charge have been synthesized. These allow more precise determination of the relative contributions of pore size and basement membrane charge to alterations in glomerular filtration in any given state of injury. Furthermore, these tracers are designed to be essentially spherical under physiologic conditions, eliminating inaccuracy resulting from heterogeneity in three-dimensional conformation of protein substrates.

PROCEDURE

Commonly used tracer substrates include variably sized dextrans (linear polymers of glucopyranose) and Ficoll, a cross-linked copolymer of sucrose and epichlorohydrin. These are available in a wide range of molecular weights and effective radii, and can be sulfated to render them anionic without altering the effective radius.

The probe substrates are administered by IV bolus, followed by continuous infusion to anesthetized animals. Inulin or another tracer substance may be coadministered with the tracer for concurrent determination of GFR.Timed urine and plasma samples are collected for the determination of the urinary clearance of both the probe substrate and the GFR tracer (as described in “Assessment of GFR and RBF by Clearance Methods”) (Andersen et al. 2000; Asgeirsson et al. 2006)

Probe substrates (both for filtration or GFR) may be either radiolabeled or conjugated with fluorochromes. The appropriate liquid scintillation or fluorometric detection methods for each probe should be used to determine the concentration in plasma and urine.

EVALUATION

If two probe substrates are used, the fractional excretion (FE or θ) of the probe substrate relative to the GFR probe substrate (e.g., inulin) is calculated as described in “Fractional Excretion Methods”:

$$\theta = \frac{U_X \times P_{in}}{P_X \times U_{in}}$$

where U_x and P_x are the concentrations of the filtration probe in urine and plasma, respectively, and U_{in} and P_{in} are the concentrations of inulin (or alternate GFR probe substrate) in urine and plasma, respectively.

If only the glomerular filtration probe substrate has been administered, a sieving coefficient (θ) is calculated as follows:

$$\theta = U_X/P_X$$

where U_x and P_x are the concentrations of the filtration probe in urine and plasma, respectively.

MODIFICATION OF THE METHOD

Micropuncture techniques may be used, in which the filtrate within Bowman’s capsule is sampled to determine the concentration of the probe substrate. In this case, the sieving coefficient θ is determined as an index to the degree of filtration using the concentration of the probe substrate in the arterial plasma and the filtrate (Blouch et al. 1997; Venturoli and Rippe 2005).

LIMITATIONS OF THE METHOD

All polysaccharide probe substrates tested to date tend to have higher sieving coefficients than globular proteins of equivalent molecular weight or effective radii, and thus all will overestimate glomerular permeability and be somewhat insensitive to low level glomerular functional alteration. The results obtained with Ficoll are in general better correlated with results obtained using endogenous high and low molecular weight proteins to assess changes in glomerular function, due to the fact that Ficoll is more extensively cross-liked, rendering it more rigid and spherical than dextran under shear stresses associated with fluid flow. However, Ficoll has been shown to be more deformable (and hence more readily filtered than a globular protein of comparable effective radius) under conditions of increased ionic strength; additionally, there is a significant component of diffusion of Ficoll across the glomerular basement

membrane that contributes to overall filtration under conditions of low GFR. The use of these probes to assess alterations in glomerular permeability must therefore account for these limitations and the physiologic conditions under which they are administered in vivo must be strictly controlled (Bolton et al. 1998; Andersen et al. 2000; Venturoli and Rippe 2005; Rippe et al. 2006; Asgeirsson et al. 2007).

The use of two probe substrates concurrently will require the use of two different labels. Alternatively, chromatographic techniques to separate the two substrates within a plasma or urine sample will be needed.

5.1.1.4 Assessment of Renal Concentrating Ability

Solute-Free Water Excretion and Reabsorption

PURPOSE AND RATIONALE

Investigations of the clearance of solute-free water represent indirect methods for the evaluation of several aspects of renal function and provide information on the site and mechanism of action of agents within the nephron. The discovery of the countercurrent multiplier system as the mechanism responsible for the concentration and dilution of the urine has been the prerequisite for the identification of the site of action of diuretic drugs. A drug that acts solely in the proximal convoluted tubule, by causing the delivery of the increased amounts of filtrate to the loop of Henle and the distal convoluted tubule, would augment the clearance of electrolyte-free water (EC_{H2O}) during water diuresis and the reabsorption of electrolyte-free water (ETC_{H2O}) during water restriction. In contrast, drugs that inhibit sodium reabsorption in Henle's loop would impair both EC_{H2O} and ETC_{H2O}. On the other hand, drugs that act only in the distal tubule would reduce EC_{H2O} but not ETC_{H2O}.

PROCEDURE

These tests may be performed in any species from which urine and plasma can be readily collected, although low-level changes in concentrating ability may be more readily manifest in rats than in dogs (Sharratt and Frazer 1963; Osbourne et al. 1983). The general procedure involves initially placing the animals in a metabolism cage with unlimited access to water. After collection of a urine sample (16–24 h is best), the water is withdrawn and the urine is collected for the next 12–16 h. The urine specific gravity (or preferentially, urine osmolality) is measured and compared both with the value from the hydrated animal and the mean values from the water-deprived control group (Ragan and Weller 1999).

Assessment of renal urine diluting ability is more cumbersome but can be accomplished in rats by administration of an oral dose of water by gavage representing 5% of the animal's body weight. The animals are then placed in metabolic cages and the urine is collected every 30 min for the next 2 h (Sharratt and Frazer 1963). In dogs, water diuresis can be induced by oral administration of 50 ml of water per kg body weight and maintained by continuous infusion into jugular vein of 2.5% glucose solution and 0.58% NaCl solution at 0.5 ml/min per kg body weight. When water diuresis is well established, the glucose infusion is discontinued and control urine samples are collected by urethral catheter (Suki et al. 1965). The volume and specific gravity (or osmolality) of the collected urine is measured and the results expressed as the percent of the administered dose of water excreted during the time period. Time-matched plasma samples are collected for the determination of plasma osmolality.

EVALUATION

In addition to gross assessment of renal dilution or concentrating ability (as described above), quantitative evaluation of either osmolar clearance, freewater clearance (C_{H2O}), or solute-free water clearance (EC_{H2O}) may add additional sensitivity to the evaluation of these functions.

Osmolar clearance can be calculated as follows:

$$C_{osm} = (U_{osm} \times V)/P_{osm}$$

where C_{osm} = osmolar clearance, U_{osm} = urine osmolality (in mosm/kg water), V = urine flow (measured in ml/min) and P_{osm} = plasma osmolality (measured in msom/kg water). C_{osm} is expressed in ml/min. C_{osm} less than V indicates excretion of a dilute urine (i.e., excess water is being excreted), but C_{osm} greater than V indicates excretion of concentrated urine (i.e., excretion of excess solute).

Freewater clearance (C_{H2O}) provides an estimate of the amount of urine being excreted in excess that needed to clear solutes, and is calculated traditionally as follows:

$C_{H_2O} = V \times [(1 - U_{osm})/P_{osm}]$ (Wesson and Anslow 1952)

More accurate assessment of the ability of the kidney to appropriately regulate plasma tonicity and/or respond appropriately to antidiuretic hormone (ADH) can be made by calculation of electrolyte-free water clearance EC_{H_2O}. This formula takes into account only water needed to excrete excess "effective" osmolytes (in general, monovalent electrolytes and their associated anions) and is calculated as follows:

$EC_{H_2O} = V \times \{1 - ([Na^+ + K^+]_{urine}/[Na^+ + K^+]_{plasma})\}$, (Shoker 1994)

LIMITATIONS OF THE METHOD

In general, the sensitivity of either urine concentration or dilution tests to detect the effects of test compounds on renal function is quite low, regardless of species (Ragan and Weller 1999). Furthermore, these tests (especially the urine dilution test) may be significantly altered by extrarenal effects (e.g., vomiting, diarrhea, delayed GI absorption, altered adrenal cortical function). Calculation of osmolar, free water, and electrolyte-free water clearances require accurate assessment of urine flow rates, which will require accurate and complete collection of all urine produced during the time interval, not always easily accomplished in small animal species. Catheterized models should be utilized in this circumstance. In addition, calculated electrolyte-free water clearances may be influenced by the presence of excess effective osmolytes in either urine or plasma (e.g., in circumstances of hyperglycemia or metabolic acidosis/alkalosis) and the formula must be corrected to account for these if they are known to be present (Shoker 1994; Nguyen and Kurtz 2005).

Assessment of Medullary Osmolarity and Blood Flow

PURPOSE AND RATIONALE

The ability of the kidney to concentrate urine depends entirely on the maintenance of the renal medullary interstitium in a hypertonic state. Hypertonicity reflects two phenomena; water-uncoupled transport of osmotically active substances (sodium and urea, primarily) into the medullary interstitium, and the trapping of those solutes in the interstitium by the vasa recta countercurrent multiplier system. The hypertonic gradent is created by the active transport of sodium into the interstitium in the ascending

loop of Henle, and a combination of passive and facilitated transport of urea located in the collecting duct; the magnitude and effectiveness of the gradient is determined by the rate of plasma flow through the vasa recta (Pallone et al. 2003; Sadowski and Dobrowolski 2003). The method described allows simultaneous assessment of both parameters.

PROCEDURE

Male Wistar rats have been used in these experiments. Under appropriate anesthesia, the femoral artery and vein are cannulated for measurement of aortic blood pressure and infusion of fluids and test compounds, respectively. The left kidney is exposed and placed in a plastic cup as for micropuncture experiments (see "Evaluation of Tubular Function by Micropuncture"), except that the dorsal surface is placed at the top of the cup, facing the operator. The ureter is catheterized and a platinum-iridium admittance electrode is inserted along the corticopapillary axis from the dorsal surface of the kidney (the probe is sized to ensure correct placement of the recording surfaces within the inner renal medulla). The capsule is incised and a needle laser-Doppler (LD) probe is inserted adjacent to the admittance probe. Animals are maintained in intravenous infusions of balanced electrolyte solution to maintain plasma volume and ensure adequate renal perfusion.

Medullary blood flow (MBF) is assessed by the LD probe, which is connected to a perfusion monitor (Periflux 4001, Perimed). The number and velocity of erythrocytes moving between the two optical fibers of the LD probe is determined. Admittance (the reciprocal of impedence) is measured between the tip of the LD probe and the admittance electrode by a conductance meter connected to both of these, following the application of a measuring current at a frequency of 24 Hz. Following the experiment, the kidney is dissected to verify that the LD and electrode have been correctly placed.

EVALUATION

Medullary blood flow (MBF) is expressed in arbitrary perfusion units (PU), based on the voltage generated by the Doppler flux of the blood cells moving beneath the LD probe (roughly, the product of cell number X velocity, see Sect. 1.1.3). By definition, a 10 V signal from the detector is considered 1,000 PU. Admittance (Y) is expressed in millisiemens (mS), and is directly related to the ionic tonicity of the tissue (primarily due to the NaCl content). Effects in treated animals are expressed relative to those in untreated controls. If desired, urine may be collected from the ureteral cannula for excretion determinations (see Sect. 1.2.1.2).

LIMITATIONS OF THE METHOD

Because MBF is expressed in arbitrary units, only relative changes within a single animal can be detected, thus each animal must serve as its own control (although results between animals in the same study can be compared with the use of a calibration algorithm). Significant tissue damage, resulting in nonfunctional nephrons, does result from the placement of the equipment and thus the technique can only be applied to the innermost medulla (where the glomeruli originate below the depth of the damaged zone). The admittance recordings reflect only the concentration of NaCl in the medulla and thus changes in tonicity resulting strictly from changes in urea concentration cannot be detected by this method.

MODIFICATION OF THE METHOD

Regional changes in medullary tonicity and the steepness of the osmotic gradient can be detected using a system of three needle electrodes that allows assessment of admittance in the outer and inner medulla separately. This arrangement cannot be coupled with the LD probe because excessive tissue damage would result (Sadowski and Portalska 1983).

An admittance electrode surrounded by a steel cannula fitted to syringe pumps may be used in place of the needle electrode. This setup allows for direct infusion of test substances into the medulla so that local effects may be monitored (Dobrowolski and Sadowski 2004).

Diuretic Activity in Rats (Lipschitz Test)

PURPOSE AND RATIONALE

A method for testing diuretic activity of compounds in rats was described by Lipschitz et al. (1943). The test is based on water and sodium excretion in test animal compared to rats treated with a high dose of urea. The "Lipschitz-value" is the quotient between excretion by test animals and excretion by the urea control.

This method is primarily of historic interest and generally has been supplanted by more sensitive, specific, and/or mechanism-based assessments of diuretic activity. However, it is still being used in some circumstances to determine if an unknown substance has significant diuretic activity (primarily in the context of evaluating the pharmacologic activities of herbal remedies).

PROCEDURE

Male Wistar rats are most commonly used for these studies, although mice have also been used. Animals are housed (singly or in groups) in metabolic cages (see section "Urinalysis") and food and water are withheld for at least 15 h prior to the experiment. The test compound is administered by gavage in 0.9% NaCl solution to one or more groups of animals (to enable evaluation of dose responses or to compare different compounds), while the control group is given 1 g/kg urea in a similar dose volume. A separate control group is given only 0.9% NaCl solution by gavage. The total volume of fluid administered should be 25 ml/kg.

The total urine excreted is collected for 5 and/or 24 h post dosing for determination of urine volume and electrolytes. Standard methods are used to determine electrolyte concentrations (Na^+, K^+, and Cl^-) and quantitative electrolyte secretion is determined for each group (see "Quantitative Electrolyte Excretion").

EVALUATION

Urine volume (normalized to body weight and excretion time) is calculated for each group. Results are expressed as the "Lipschitz-value," that is, the ratio T/U, in which T is the response to the test compound, and U, that of urea treatment. Indices of 1.0 and more are regarded as a positive effect. With potent diuretics, Lipschitz values of 2.0 and more can be found. Calculating this index for the 24 h excretion period as well as for 5 h indicates the duration of the diuretic effect.

"Lipschitz-values" may also be calculated for electrolyte secretion. However, direct statistical comparison of these parameters (as well as urine volume) is more commonly done (Pallavi et al. 2011).

LIMITATIONS OF THE METHOD

The effects of weaker diuretic compounds may be masked by the degree of diuresis imposed by the water load in this test. Species differences in the predictive value of this test have been noted for some classes of diuretics (Heller and Ginsberg 1961).

MODIFICATIONS OF THE METHOD

Furosemide at a dose of 20 mg/kg may also be used as a reference diuretic. In this case, electrolyte excretion is also compared (as is the urinary Na^+/K^+ ratio) to determine relative natriuretic and kaliuretic potential of the test compound (Sangma et al. 2010; Suresh et al. 2010; Kondawar et al. 2011).

5.1.2 In Vitro Methods

5.1.2.1 Isolated Perfused Tubules

PURPOSE AND RATIONALE

The various tubule segments have different functional properties. The in vitro perfusion of isolated tubule segments (Burg et al. 1966a) is the method of choice if one has to identify the site and the mechanism of action of a pharmacological agent which has been shown to act on kidney function in clearance and micropuncture studies.

PROCEDURE

After its invention by Burg et al. (1966) this technique has been used successfully in the kidney tubule segments of several species: man, rabbit, rat, mouse, hamster, snake, birds, etc. In larger species, the tubule segments can be dissected from thin kidney slices (<1 mm thickness). Usually, dissection can be done using sharpened forceps or needles without the addition of proteases (collagenase). The segment is identified by its anatomical location and by its appearance. A 20–50X lens is used for dissection. Dark field illumination is helpful for the identification of the segment under study. Most segments are easily identified and dissected, but the thin loops of Henle and papillary collecting ducts are damaged easily by the mechanical dissection. Dissection is usually performed at 4°C in a Ringer type solution.

For smaller species, proximal tubule segments can also be isolated from the entire kidney using in situ collagenase perfusion techniques (Tyson et al. 1990). Following anesthesia, the kidneys may be perfused via the aorta (mice) or renal arteries (rats, rabbits) for 5 min to remove the residual blood; the kidneys and associated blood vessels are then removed and the perfusion continued for an additional 15–20 min with buffer containing 180 U/ml of Type I collagenase. The cortical tissue is then removed from the medulla and the tubules isolated as described above. The viability and function of tubules so isolated are comparable to those isolated without collagenase (Rodeheaver et al. 1990).

The dissected segment is transferred into the perfusion chamber by a transfer pipette. The perfusion chamber is mounted in the stage of an inverted microscope (20–400X). The chamber is usually kept at 37°C, and the bath perfusate is also preheated to this temperature. The bath perfusate (usually based on Dulbecco's modified Eagle's medium) will be modified depending on the tubule segment and process of interest. The actual perfusion is performed with two sets of concentric glass pipettes, one set at the perfusion end and one at the collection end of the segment. These pipettes are manufactured with special glass forge (Greger and Hampel 1981). The outer segment of the pipette applies suction to the isolated tubule and serves as a "holding pipette"; the inner segment acts as the "perfusion pipette." The latter has a tip diameter smaller than the inner diameter of the perfused segment and is placed in the proximal end of the segment of interest and the perfusion buffer is infused at a rate of 1–20 nl/min. The collection end of the tubule segment is sucked into a holding pipette. A sylgard pipette is advanced to seal the collection site. The holding pipette at the collection site will contain mineral oil in flux measurements to prevent loss of perfused fluid. Then a collection pipette is advanced through the oil to quantitatively collect the perfusate delivered by the tubule. The length of the perfused segment (between the perfusion and collection pipettes) should be measured.

EVALUATION

A number of different assessments can be made by this method :

Flux measurements. (Schafer et al. 1974; Edwards et al. 1999). The collection rate (Vc,nl/min) can be measured by the constant bore collection pipette by timed collections. Radioactive or other tracers can be added to either the lumen or bath fluid. Unidirectional fluxes, bath to lumen and lumen to bath, for any given substance can be quantified:

$$\mathrm{J_X = (V_C C_X)/L}$$

where $\mathrm{V_C}$ = fluid collection rate (volume/time), $\mathrm{C_X}$ = concentration of X (in bath or collection fluid), and L = length of the perfused tubule segment.

Permeability (Px) can be determined by adding a non-permeant substance (usually inulin) to the perfusion buffer, as follows:

$$P_\mathrm{X} = (V\mathrm{i} - V\mathrm{c})L - 1[\ln(\mathrm{Xp}\,In\mathrm{c}\,\mathrm{Xc} - 1\,In\mathrm{p}) + 1]$$

where L is the length of the segment, Xp and Xc are the concentrations of x in the perfusate and in the

collected fluid, and *In*c is the inulin concentration in the collected fluid.

Net fluxes of a substrate can be determined as the difference of the unidirectional fluxes or by the chemical determination of D_X (perfusate–collected fluid). This requires very sensitive methods. Electron probe analysis of Na+, K+, Ca^{2+}, Mg^{2+}, etc., has been used to determine the net transport of these ions in various tubule segments (Wittner et al. 1988). Flux studies are usually performed at low luminal perfusion rates of a few nl/min. Substances under study can be added to either the luminal and bath perfusate, and paired data can be obtained under control and experimental conditions (Burg and Green 1973; Stoner et al. 1974; Burg and Orlov, 1980; Burg and Stoner 1976; Dillingham et al. 1993).

Transepithelial electrical measurements. The collection pipette can be connected to the high impedance input of an electrometer. The voltage is referenced to the grounded bath. With identical solutions in the bath and in the perfusate and with high luminal perfusion rates (>10 nl/min), any transepithelial voltage recorded by the collection pipette (*V*te) must result from active transport of ionic substances across the tubular epithelium, with the magnitude of this voltage proportional to the degree of transport (Frömter 1984). Hence, the effectiveness of putative inhibitors of active transport can also be examined by the measurement of *V*te. According to Ohm's law, the determination of the flux of ions also requires the measurement of transepithelial resistance. Greger (1981) has introduced a method that utilizes a dual channel perfusion pipette. One channel is used for perfusion and the other for current (*I*te) injection. The current is defined by a resistor chosen such that the deflection in *V*te generated by this pulse is in the order of 10–20 mV. Transepithelial resistance (*R*te) can now be calculated from Δ*V*te and *I*te. The ratio of *V*te and *R*te is called equivalent short circuit current. It is directly proportional to active transport (Greger 1985). The measurement of *V*te and *R*te is much more efficient than flux studies for pharmacological screening, provided that the process under study produces a transepithelial voltage. Several substances can be examined in one single tubule in strictly paired fashion (Schlatter et al. 1983; Wangemann et al. 1986). The time resolution of the measurements is on the order of 1 s, whereas that of flux studies is several minutes at best.

Intracellular electrical measurements. Greger and Hampel (1981) have developed a method for the use of impalement techniques in the isolated perfused tubule. Very fine tip microelectrodes (Ø < 100 nm) are used to impale the tubule cell across the basolateral membrane. The simultaneous measurement of *V*te, *R*te, and basolateral membrane voltage (*V*bl) allows for a complete analysis of voltages and resistances (Greger 1985; Ullrich and Greger 1985). Ion selective microelectrodes can also be used in impalement studies, and the cytosolic ion activities for, for example, Na^+, K^+, Cl^- can also be determined (Greger 1985). These methods are all rather difficult to perform. They are of high relevance for the understanding of the function of a given tubule segment and for the detailed description of the mechanism of action of a drug, which in preceding studies has been shown to act in a given tubule segment.

MODIFICATIONS OF THE METHOD

Fluorescent dyes for the monitoring of Na^+, K^+, Cl^-, Ca^{2+}, and pH are more commonly used currently. These dyes can be used in the in vitro perfused tubule (Nitschke et al. 1991). The inverted microscope is equipped with an appropriate illumination and filter wheel for excitation. The emission is measured by photon counting or by a video camera.

The perfusion and collection pipettes may be used as electrodes to determine V_{te} as outlined above. The isolated tubule is solute-clamped at a high perfusion rate, and the potential difference between the perfusion and recording pipettes represents the net active transport of substrates across the tubular epithelium (Frömter and Geßner 2001).

5.1.2.2 Isolated Perfused Kidney

PURPOSE AND RATIONALE

The isolated perfused kidney is a valuable tool for assessing effects on the function on the entire kidney (vasculature and tubules), with several caveats (see below under "Limitations of the Method"). This model can be used either in situ and/or isolated in vitro.

PROCEDURE

Kidneys from rats, dogs, rabbits, and pigs have been used. The donor animals are fasted overnight prior to surgery, but have free access to water. After the abdominal cavity is exposed by a ventricular incision, the renal artery is cannulated via the superior mesenteric artery without interruption of flow. Thereafter, the kidney is continuously perfused with a perfusion solution (usually Krebs-Ringer or Krebs-Henseleit buffer that is oxygenated) circulated by a peristaltic pump. The venous cannula is introduced into the vena cava below the renal vein, and the ureter is cannulated last. The kidney is freed from the perirenal fat, not disrupting the renal capsule. Ligatures around the renal artery and vena cava above the renal pedicle are tied. The kidney is then removed from the animal and placed in a Plexiglas chamber. The perfusion pressure is maintained at a level appropriate for the species in question by adjusting the speed of the perfusion pump. All procedures to be performed on the kidney should be completed within 2–4 h of isolation.

EVALUATION

After the equilibration period, clearance periods of 20 min are used. Urine samples are collected and perfusate is obtained at midpoint of the clearance period for the evaluation of overall kidney function. For determination of glomerular filtration rate (GFR) and fluid transport, inulin or another suitable non-reabsorbed substrate is introduced into the arterial cannula and clearance is assessed (see Sect. 1.1.2). Electrolytes are determined in urine by standard flame photometry. Fractional excretions of water, electrolytes, and test compounds are calculated (see Sect. 1.2.1.2).

LIMITATIONS OF THE METHOD

Isolated perfused dog kidneys have been reported to be less stable than those of other species, with glomerular filtration and renal flow markedly decreasing after only 1 h of perfusion. The in situ-perfused isolated dog

kidney seems to be more stable. Distal tubule functions are impaired in isolated perfused kidneys in all species. Urine acidification, concentration, and dilution functions are also abnormal, and effects on these cannot be assessed in these models (Kirkpatrick and Gandolfi 2005).

5.1.2.3 Patch Clamp Technique in Kidney Cells

PURPOSE AND RATIONALE

In the different parts of the kidney (proximal tubules, distal tubules, collecting ducts) fluid is reabsorbed and substances may be transported either from the tubule lumen to the blood side (reabsorption) or vice versa (secretion). Besides active transport and coupled transport systems, ion channels play an important role in the function of kidney cells. The various modes of the patch clamp technique (cell-attached, cell-excised, whole-cell mode) (Neher and Sakmann 1976; Hamill et al. 1981) allow the investigation of ion channels. In addition, the investigation of other electrogenic transport mechanisms, such as the sodium-coupled alanine transport can be studied.

PROCEDURE

The patch clamp technique can be applied to cultured kidney cells (Merot et al. 1988), to freshly isolated kidney cells (Hoyer and Gögelein 1991) or to cells of isolated perfused kidney tubules (Gögelein and Greger 1984). The latter method shall be described in more detail.

Segments of distal superficial proximal tubules of rabbit kidney are dissected and perfused from one end (see Sect. 1.2.1) (Burg et al. 1966b; Greger and Hampel 1981). The non-cannulated end of the tubule is freely accessible to a patch pipette. Under optical control (differential interference contrast optics with 400´magnification) the patch pipette can be moved through the open end into the tubule lumen and is brought in contact with the brush border membrane. After slight suction of the patch electrode, gigaseals form instantaneously, and single potassium or sodium channels can be recorded in the cell-attached or inside-out cell-excised mode (Gögelein and Greger 1984, 1986a).

In order to obtain exposed lateral cell membranes suitable to the application of the patch clamp method, pieces of the tubule are torn off by means of a glass pipette (diameter about 40 μm). In order to facilitate the tearing off, the tubules are incubated for about 5 min in 0.5 g/l collagenase (Sigma C 2139) at room temperature. After tearing off part of the cannulated tubule, clean lateral cell membranes are exposed at the non-cannulated end. The patch pipette can be moved to the lateral cell membrane and gigaseals can be obtained. It was possible to investigate potassium channels (Gögelein and Greger 1987) and nonselective cation channels (Gögelein and Greger 1986b) in these membranes.

As cells are still part of an epithelial layer and, therefore, are intracellularly coupled, the whole-cell technique is not appropriate in this preparation. On the other hand, cotransport systems can only be investigated by the whole-cell method because the transport rate of a single event is much too small to be resolved in a similar manner as single ion channel events. Consequently, cells of rabbit proximal tubules are isolated as described in detail elsewhere (Hoyer and Gögelein 1991; Heidrich and Dew 1977). After euthanasia, the kidneys are rapidly excised and placed in ice-cold

solution (mmol/l): 150 K-cyclamate, 10HEPES, 1CaCl2, 1MgCl2, pH7.4. The following steps are performed on ice: After decapsulation, superficial cortical slices of about 0.5 mm thickness are dissected and minced with a scalpel. The tissue is homogenized in a Dounce homogenizer by three strokes with a loose-fitting pestle. The homogenate is then poured through graded sieves (250, 75, and 40 μm) to obtain a population of single cells. Since the predominant tubule section of the cortex of the rabbit kidney is the pars convoluta of the proximal tubule, it can be concluded that the majority of the isolated cells in the cell suspension are of proximal tubule origin. By light microscopy, cells are identified by long microvilli distributed over the entire cell surface and can easily be discriminated from remaining erythrocytes, cell detritus, and tubular fragments.

By application of the whole-cell mode of the patch clamp technique to freshly isolated cells of convoluted proximal tubules, the sodium-alanine cotransport system could be investigated in detail (Hoyer and Gögelein 1991).

EVALUATION

In isolated perfused renal tubules, concentration response curves of drugs that inhibit ion channels can be obtained with the patch clamp technique. In isolated cells of the proximal tubule, the whole-cell mode of the patch clamp technique enables the investigation of the sodium-alanine cotransport system. The apparent K_m values for sodium and L-alanine can be recorded.

MODIFICATIONS OF THE METHOD

Schlatter (1993) recorded membrane voltages of macula densa cells with the fast or slow whole-cell patch clamp method. The effects of diuretics and the conductance properties of these cells were examined.

5.1.2.4 Isolated Brush Border Membrane Vesicles

PURPOSE AND RATIONALE

Alterations in electrolyte excretion or tubular transport processes assessed in vivo (Sections "Electrolyte Excretion" and "Assessment of Tubular Transport Processes") are limited by the fact that multiple transporters may be involved in the net transport of the probe substrate or electrolyte in question. The use of isolated brush border membranes allows investigation of the mechanisms underlying the alterations by evaluating changes in the abundance or activity of specific transporters in response to specific disease states or following exposure to toxicants and drugs. Additionally, the transport kinetics for specific substrate-transporter combinations can be determined, and the ability of drugs or toxicants to act as substrates for or inhibitors of specific transporters can be evaluated in these preparations.

PROCEDURE

Brush border vesicles can be prepared from any species, but are usually prepared from male Sprague

Dawley rats using a Mg^{++} precipitation method. Animals are euthanized by exsanguination under anesthesia and the kidneys are removed immediately. All steps for the preparation of brush border membrane vesicles are carried out at 4°C. Renal cortex is homogenized for 2 min in a medium containing 250 mM mannitol in 10 mM tris-HEPES buffer (pH 7.5) using an appropriate homogenizer (Polytron or teflon-glass). MgCl or $MgSO_4$ is added to the homogenate (to generate a final concentration of 10 mM) and the mixture is stirred on ice for 20 min. The homogenate is then centrifuged for 10 min at 2,000×*g*, and the resulting supernatant was centrifuged for 20 min at 35,000×*g*. Subsequently, the supernatant is discarded and the loosely packed membrane-rich layer is gently separated from the pellet and resuspended manually in a buffer that will generate the appropriate intravesicular conditions for the experiment in question (e.g., for urate transport the most commonly used buffer is 150 mM mannitol and 2 mM $MgSO_4$ in 50 mM potassium phosphate buffer, pH 7.5). The final supernatant is centrifuged at 35,000×*g* for 15 min and the procedure is repeated twice more. The final suspension is prepared to a protein concentration of 10–20 mg/ml, which may be either kept at 4°C for immediate use or frozen and stored at −80°C until use.

The degree of purity of the brush border membrane preparation is assessed by measuring the enrichment of a marker enzyme. Either alkaline phosphatase or γ-glutamyl transpeptidase may be used for this purpose. Tenfold or greater enrichment of the activity in the preparation relative to the baseline homogenate is considered acceptable.

Rapid filtration methods are used to determine the activity of the transporter in question. After preincubation of the brush border membrane vesicle preparation for 1–2 h at 37°C in the appropriate buffer to the experimental conditions and transporter of interest (usually identical to the suspension buffer used in the final brush border membrane vesicle preparation as described above), the uptake of [^{14}C]-labeled substrate or radioactive electrolyte isotope (e.g., [^{22}Na] is used to evaluate NHE3 transport) is initiated by adding the substrate in an approximately 10X excess volume of buffer to the membrane suspension. At a timed interval (usually 10 s) after the addition of the incubation medium, uptake is stopped by the addition of a large excess (200X) volume of ice-cold (4°C) incubation buffer. The incubation mixture is passed through a 0.45 μM Millipore filter, which is then washed 2X more with 3–5 ml of the ice-cold incubation buffer. Corrections are made for the radioactivity nonspecifically bound to the vesicles or the filters by generating an identical incubation preparation to the experimental condition but which is carried out at 4°C. The radioactivity present in this sample is subtracted from that in each of the active conditions to generate the substrate uptake in the preparation (expressed as susbstrate quantity/mg of protein).

EVALUATION

Membrane transport processes that can be described by Michaelis–Menten kinetic relationships can be characterized using isolated brush border membrane vesicles. Lineweaver–Burke double-reciprocal plots of transport velocity and substrate concentration allow determination of V_{max} and K_m values from the Y and X axis intercept values, respectively (Runge et al. 2006). IC_{50} values for transport inhibitors can be calculated using least squares linear regression techniques or curve fitting software available within a number of commercially available software programs (Excel add-in, Graphpad Prism, and SigmaPlot).

MODIFICATIONS OF THE METHOD

Isolated basolateral membrane vesicles can be used in a similar fashion to evaluate transport processes (see section "Assessment of Organic Anion and Cation Transport" for a list of substrates and inhibitors). Percoll gradient density centrifugation methods are used to generate these preparations. Renal cortices are homogenized at 4°C in 12 mM Tris-HEPES buffer (pH 7.4) containing either 300 mM mannitol or 250 mM sucrose. The homogenate is diluted 1:1 with buffer and centrifuged for 15 min at 2,500×*g*. The resulting supernatant is centrifuged for 20 min at 20,000×*g*, and the upper fluffy layer of the pellet is suspended in buffer by ten strokes with the homogenizer. Percoll is then added (13% vol/vol), and 36 ml aliquots of the resulting suspension are centrifuged for 30 min at 48,000×*g*. The top 6 ml of each aliquot is discarded and the next 6 ml is removed and diluted tenfold with intravesicular buffer and washed three times at 48,000×*g* for 15 min. The final pellet is resuspended in intravesicular buffer and may be either used immediately or stored at −80°C until use. The degree of purity of the basolateral membrane preparation is assessed by measuring the enrichment of the

marker enzymes Na^+-K^+-ATPase or leucine aminopeptidase. Tenfold or greater enrichment of the activity in the preparation relative to the baseline homogenate is considered acceptable (Edwards et al. 1997; Shimada et al. 1987). Rapid filtration methods similar to those used for brush border membrane vesicle preparations are used to determine substrate uptake.

Western blot analysis may be used to determine the presence, identity, and purity of the transport proteins present in the membrane preparations, which may be useful in determining the exact uptake pathway(s) relevant to the substrate or inhibitor in question. Comparison of kinetic parameters determined in vesicle preparations where multiple transporters are present to those determined for pure transporters expressed in stably transfected renal cell lines may help to clarify the role of selected transporters in clearance of substrates or activity of inhibitors (Takahashi et al. 1998).

Replacement of Mg^{++} with propylene glycol for precipitation of brush border membrane vesicles results in the generation of preparations of equivalent purity to those generated by traditional methods, while preventing alteration of the surrounding membrane lipids which may alter transporter functions (Basivireddy and Balasubramanian 2003).

5.2 Assessment of Renal Injury

5.2.1 Assessment of Renal Injury by Routine Urinalysis

PURPOSE AND RATIONALE

Urinalysis provides a unique opportunity to selectively and noninvasively "sample" a single target organ by examination of its end product. The levels of proteins and small molecules normally filtered, excluded from filtration, secreted, or reabsorbed by the tubules can be used as indicators of the functional status of certain nephron segments, while injury can be assessed by examination of the urinary sediment for cellular components indicative of tubular injury.

PROCEDURE

Procedures for collection of high quality urine samples and assessment of secreted analytes are outlined in section "Urinalysis." Five ml of the urine is then centrifuged at 700 g for 5 min and the sediment is examined microscopically for the presence of cells, casts, crystals, and miscellaneous components. Samples for which urine sediment evaluation is to be performed must not be frozen.

If medullary injury is supected, the urine may also be evaluated for the presence of phospholipid by thin layer chromatography or HPLC. As with other analytes, quantitative assessment of urinary creatinine and normalization of the phospholipid concentration is necessary.

EVALUATION

The presence of greater than 1–2 erythrocytes or neutrophils per high-power field confirms a positive result of dipstick analysis for blood or leukocyte esterase. Increased number of hyaline casts (small numbers are

normal in most species), or the presence of granules (cells or cellular debris) within casts may be indicative of tubular injury. The presence of renal tubular epithelial cells in urine sediment strongly indicates tubular injury (Stonard 1990; Hofmann et al. 1994; Finco 1997; Finn and Porter 1998; Newman and Price 1999).

Small numbers of lipid droplets (representing neutral lipid, lipoprotein, or phospholipid) are considered normal in dogs, cats, mice, and humans (Gross et al. 1991; Streather et al. 1993; Finco 1997). Increased excretion of lipid droplets (which may cause increased urine turbidity) may indicate glomerular injury, as does increased excretion of phospholipid and/or lipoprotein. Increased urinary phospholipid excretion has been described as antecedent finding to microscopic evidence of papillary injury in experimental renal papillary necrosis in rodents. Unlike the profile seen with glomerular injury (de Mendoza et al. 1976; Gherardi and Calandra 1982; Neverov and Nikitina 1992), concomitantly increased levels of lipoprotein have not been described following papillotoxins; conversely, increased urinary sphingomyelin is detected in renal papillary necrosis (Thanh et al. 2001) but elevated levels are not detected in the urine humans with nephrotic syndrome (Mimura et al. 1984). The level and nature of the excreted lipid can be determined by thin-layer chromatography and comparison to known standards (Mimura et al. 1984; Thanh et al. 2001).

LIMITATIONS OF THE METHOD

The dipstick reagent for blood detects hemoglobin but cannot distinguish between free hemoglobin (possibly due to intravenous hemolysis) or intact erythrocytes and also cross-reacts with myoglobin (present in urine as the consequence of muscle injury). Examination of the sediment is needed to determine if erythrocytes are present in urine. Addition of ammonium sulfate to the urine (which precipitates hemoglobin but not myoglobin) can help differentiate the two pigments (Graff 1983).

5.2.2 Assessment of Renal Injury by Urine Proteins

PURPOSE AND RATIONALE

The combination of qualitative and quantitative assessment of the normally excreted urine protein can serve as a reliable indicator of the nephron segment(s) affected by the injury. Proteins may also appear in the urine as the consequence of their release from damaged nephrons. Many of these are unique to the kidney; those that are not are either too large to pass an intact glomerular filter or have not been shown to circulate in plasma. Furthermore, several of these are both upregulated and shed to the urine, thus increasing their sensitivity as injury biomarkers.

PROCEDURE

Twenty-four hour urine collection is preferred for best accuracy, although point-in-time samples can be used. Urine samples are collected from the species in question by appropriate methods (see "Urinalysis"). Total protein and creatinine are determined by appropriate methods and a urine protein:creatinine ratio is calculated ("Urinary Protein Markers of Glomerular Function").

Most of the proteins used as biomarkers of renal injury are measured by immunometric methods. Newer methods based on proteomics technology (concentration of proteins by acetone precipitation or ultracentrifugation, separation by 2-day gel electrophoresis, or chromatographic techniques with subsequent identification and quantitation by mass spectrometry) have been used experimentally (Bandara and Kennedy 2002; Chapman 2002; Thongboonkerd et al. 2002a, b).

EVALUATION

All analytes need to be converted to their SI unit equivalents prior to calculation of excretion ratios (see "Fractional Excretion Methods"), which will not be unitless in this circumstance. Protein:creatinine ratios of >1.0 are considered indicative of significant renal proteinuria in most species (Gregory 2003). Excretion of markedly elevated levels of protein (protein:creatinine ratio >5.0) is indicative of glomerular disease, whereas low-level proteinuria indicates tubular damage or very early/low-grade glomerular injury (Peterson et al. 1969; Finco 1997; Gregory 2003).

Increased albumin usually indicates glomerular injury, although it is not a specific marker for any one nephron site (Guder and Hofmann 1992; Price et al. 1996; Finn and Porter 1998). High levels of albumin in urine are invariably the result of glomerular malfunction. Low level increases in urine albumin, especially in circumstances where total urine protein excretion is not elevated ("microalbuminuria") can result either from increased glomerular filtration or decreased tubular reabsorption, and albumin values in this range must be interpreted in comparison to the excretion of other protein biomarkers. Concomitant elevation of albumin and one or more low molecular weight proteins indicates tubular malfunction, while albumin elevation alone or concurrently with a high molecular weight protein indicates primary glomerular injury (Peterson et al. 1969; Finn and Porter 1998; Guder et al. 1998; Umbreit and Wiedemann 2000). Calculation of the relative clearance of albumin and either immunoglobulin or transferrin is a useful indicator of the degree of glomerular injury (the higher the ratio, the more severe the damage) (Tencer et al. 1998b, 2000).

Elevation of any of the filtered low molecular weight proteins in urine is an indication of a primary defect in tubular uptake, either as a consequence of decreased nephron mass or competition for the endocytic pathway by a competing substrate. This is discussed in detail in "Evaluation of Receptor-Mediated Endocytosis."

Increases in the urinary levels of proteins that are either shed or secreted into the urine from the site of injury may be more sensitive than alterations in filtered proteins in detecting renal injury. A number of these are listed in Table 5.4. Most of these are early response or structural proteins and serve some protective or repair function in damaged tissue. Two of these (KIM-1 and clusterin) have recently been accepted by both the FDA and EMEA as fully validated biomarkers of tubular injury in preclinical animal studies.

LIMITATIONS OF THE METHOD

The majority of assay methods for excreted low molecular weight proteins are based in immunometric methods (gel immunodiffusion, nephelometry, or ELISA) and the antibodies do not cross-react with homologous proteins in animal urine (section "Evaluation of Receptor-Mediated Endocytosis").

Although there are published antibody-based methods for many of the kidney-specific proteins listed above, antibodies have only recently become commercially available for some of them (specifically, KIM-1, CYR-61, NGAL, and Pap A1). Where the antibodies are readily available, cross-reactivity across species has not always been established (these have in general been used only in human and/or rat). Heart- and kidney-specific isoforms of fatty acid–binding protein exist that may cross-react in some species with the LFBP antibodies; additionally, α-2 μ-globulin, a normal component of male rat urine, is homologous to K-FABP and may cross-react with the antibodies to LFBP.

Table 5.4 Endogenous renal proteins excreted in response to injury[a]

Protein	Nephron segment	Species	Expression	Comments
Fibronectin	Glomerulus (Proximal tubule?)	Human Rat	Constitutive and upregulated	Precedes microalbuminuria in diabetes Plasma contribution may be a factor with severe glomerular injury Decreased tubular proteolytic degradation may contribute to increased urinary levels With chronic glomerular injury, upregulation contributes to increased urine levels
Collagen IV	Glomerulus	Human Mouse Rat	Constitutive and upregulated	Basement membrane specific Precedes microalbuminuria in diabetes With chronic glomerular injury, upregulation contributes to increased urine levels
Liver fatty acid–binding protein (L-FABP)	"Glomerulus"	Human	Upregulated	Source is proximal tubule; upregulated and secreted in response to glomerular injury/proteinuria Small contribution (up to 3%) from serum-derived L-FABP with glomerular injury or concurrent liver injury Homologues (kidney and heart FABPs) exist in both human and rat kidney; these differ in distribution and regulation but may cross-react with antibodies to L-FABP. H-FABP in rat urine may reflect increased serum levels secondary to myocardial damage. α-2μ-globulin (normal component of male rat urine) is homologous to K-FABP and may cross-react with antibodies
α-Glutathione-S-transferase	Proximal tubule	Human Rat	Constitutive	Antibody appears to have good cross-species reactivity Highest urinary levels seen with selective straight (S_3) segment toxicants in rats Sensitive index of damage (brush border loss) in the absence of overt necrosis May be measured with either enzymatic or immunoassay
Clusterin	Proximal tubule	Rat Monkey	Upregulated	Elevated rapidly (1 h) in both acute and chronic injury; stays elevated as long as the stimulus is present Upregulation/secretion specifically indicates injury; not seen with nontoxic homologues that do not cause necrosis Some upregulation seen in medulla with oxidative stress Plasma contribution with glomerular injury a possibility Antibodies commercially available
Kidney Injury Molecule-1	Proximal tubule	Rat Mouse Human	Upregulated and Increased release	Biomarker for acute tubular necrosis/ischemia Transmembrane protein; ectodomain is shed to the urine following acute injury High degree of upregulation and/or increased shedding demonstrated in rat kidney with injury (improves sensitivity False negative results frequently seen Antibodies to rat and human exist, not commercially available
Neutrophil Gelatinase-Associated Lipocalin (NGAL)	Proximal Tubule	Human Mouse Rat	Upregulated and increased secretion	Highly upregulated (>100X) with renal injury Secreted in response to ischemia and direct nephrotoxic insult Either urine or plasma levels can be measured Equally predictive and prognostic with acute or chronic injury Protease resistant (better persistence in urine) Commercial reagents for standard analytical platforms available for human, rat and mouse
IL-18	Proximal tubule	Human Mouse	Upregulated and increased secretion	Early biomarker Upregulation in response to ischemic insult Not affected by nephrotoxicants ELISA assay not commercially available

(*continued*)

Table 5.4 (continued)

Protein	Nephron segment	Species	Expression	Comments
Cysteine-rich protein 61 (CYR61)	Proximal straight tubule	Mouse Rat	Upregulated and increased secretion	Rapid upregulation and secretion into urine (3 h post injury) with renal ischemia High heparin affinity allows concentration of the protein (using heparin-Sepharose) for detection of low levels BUT also complicates assay (necessary for accurate detection)
π- Glutathione-S-transferase	Distal tubule	Human	Constitutive	Questionable sensitivity (excretion in urine only seen after azotemia is apparent) Antibodies are very isoform-selective
μ-Glutathione-S-transferase	Distal tubule	Rat	Constitutive	Similar distribution to π-GST in humans Questionable sensitivity (excretion in urine only seen when azotemia is apparent)
Pap X 5 C10 antigen (Pap A1)	Papillary collecting ducts	Rat	Constitutive	Of several papilla-specific antigens identified, this one is most consistently released to urine after papillary toxicant administration Present in urine as complexes with Tamm-Horsfall mucoprotein Monoclonal antibody not commercially available Protein is rat specific and is of unknown identity and function

5.2.3 Assessment of Renal Injury by Urine Enzymes

PURPOSE AND RATIONALE

Urinary enzyme activity provides a means to determine the presence and location of renal tubular injury as opposed to an index to the functional status of the nephron. With few exceptions (lysozyme and alanine aminopeptidase are the most notable of these), the enzymes most commonly used in these determinations are quite large (greater than 80 kDa) and thus their appearance in the urine results from leakage from damaged tubular cells, not from increased filtration or decreased uptake (Plummer et al. 1986).

Urine enzymes provide several advantages over urine protein for the assessment of tubular injury (Stonard et al. 1987; Vanderlinde 1981; Price 1982; Plummer et al. 1986; Clemo 1998; Dubach et al. 1988; Westhuyzen et al. 2003):

- Increased sensitivity – Enzyme levels in urine are frequently elevated in advance of overt evidence of renal malfunction and can be used to predict its onset
- Dose-response – The amount of enzyme activity in the urine accurately reflects the degree of tubular injury present
- Ease of analysis – Most use chromatographic assays, which have been well validated for the same enzymes present in plasma and can be performed on automated equipment
- Utility in a variety of species – Activity as opposed to antigen mass is measured, so cross-reactivity of antibodies or probes across species is not a consideration
- Repeatability – Enzyme measurements over time can be used to determine the reversibility or progression of renal lesions
- Ability to localize the injury to a specific nephron site/subcellular location – Serves as an index to the severity of the underlying injury. As a general rule, brush border enzymes indicate less severe damage than cytosolic, mitochondrial, or microsomal enzymes

For best results in determining the presence and site of nephron damage, a battery of enzymes as opposed to a single biomarker should be examined, especially since the most sensitive assay is highly variable, depending on the toxicant and species. Additionally, since many of the enzymes are not completely specific to a selected nephron segment, use of a battery of tests allows more precise localization of the site of injury (Price 1982).

The most commonly used enzymes and their segment specificity are outlined in Table 5.5:

PROCEDURE

Urine samples are collected and maintained as described in section "Urinalysis." There are some special considerations in sample collection and handling that are critical to accurate assessment of urine enzyme activity (Vanderlinde 1981; Price 1982; Plummer et al. 1986; Mueller et al. 1986, 1989; Loeb et al. 1997; Clemo 1998; Jung and Grutzmann 1988; Loeb 1998):

- Contamination of collected specimens must be carefully avoided, as enzymes present in feces, food, or bacteria can contribute significantly to the activity present in the urine
- Enzyme activity can also result from increased numbers of erythrocytes, leukocytes, or epithelial cells in the urine. Prompt centrifugation of urine to remove contaminating cells will help to mitigate this source of error, and examination of the resulting sediment will allow the investigator to discard the results from heavily contaminated samples
- Normal urine frequently contains a variety of low molecular weight substances (urea is a notable example) that can inhibit the enzymes of interest. The toxicant may also act as an inhibitor. These substances usually can be removed by dialysis, dilution, Sephadex filtration, ultrafiltration, or gel filtration

Table 5.5 Most commonly used enzymes and their segment specificity[a]

Enzyme	Nephron segment	Cellular location	Comments
N-acetyl-β-D-glucosaminidase (NAG)	Proximal tubule Papilla Glomerulus	Lysosomal	Widely used in humans (screen for nephrotoxicity) and all common toxicology species Excretion rate is consistent in a 24 h period, assessment in spot samples normalized to creatine accurately reflects 24 h excretion Increased activity usually indicates proximal tubular (PT) injury but is not specific (also seen with glomerular disease, obstructive nephropathy, and papillary injury). Concurrent elevation of a brush border enzyme increases specificity for PT injury Increased urinary activity seen with pregnancy (humans), age (rats), and gender (dogs – contribution from seminal fluid in males)
Lysozyme (muramidase)	Proximal tubule	Lysosomal	Contribution to urine levels from both plasma (small protein, readily filtered) and leakage from damaged tubules – thus not specific. Increased plasma levels from nonrenal diseases (leukemia, inflammation, or other neoplasia) may result in increased urine activity, especially with altered tubular uptake. Extremely variable secretion rate over a 24 h period limits usefulness with timed or spot urine samples Immunochemical as well as enzyme assays exist (poor cross-reactivity of antibodies across species)
β-galactosidase	Proximal tubule	Lysosomal	Elevated following some glomerular toxicants before proteinuria evident Pronounced diurnal variation in basal excretion rate in humans Increased urinary activity following testosterone treatment in mice
β-glucuronidase	Proximal tubule	Lysosomal	Contribution to urine activity from preputial gland in male rat Increased urinary activity following testosterone treatment in mice, pregnancy in humans Pronounced diurnal variation in basal excretion rate in humans
β-glucosidase	Proximal tubule	Lysosomal	Pronounced diurnal variation in basal excretion rate in humans
Alanine aminopeptidase (AAP)	Proximal tubule	Brush border Microsomes	Appears in urine earliest with acute tubular necrosis Renal and serum isoforms exist, but serum isoform is smaller (90 kDa versus 230 kDa), not normally filtered. May contribute to activity with concomitant glomerular disease Some increase in urine activity may result from nonrenal diseases Basal excretion rate higher in male rats and humans, but not in dogs; higher in rats with age
Leucine aminopeptidase	Proximal tubule	Brush border	Elevations also seen in early glomerular diseases, preceding microalbuminuria
Neutral brush border endopeptidase EC	Proximal tubule	Brush border	Assay substrate is also cleaved by leukocyte elastase; concomitant pyuria many falsely elevate activity
γ-glutamyl tranferase (GGT, γ-glutamyl transpeptidase)	Proximal tubule (particularly S_3 segment in rodents)	Brush border	Somewhat unstable in urine relative to other enzymes (even with added stabilizers), should be assayed quickly after collection Within a day variation of excretion rate noted in dogs, may limit accuracy of spot sample assessment even with creatinine correction Basal excretion rate higher in male rats Increased urinary activity seen with pregnancy
Alkaline phosphatase (intestinal var.)	Proximal tubule (S_3 segment "specific")	Brush border	Increased urine activity seen with pregnancy Use of this enzyme as a selective marker of S_3 involvement requires isoenzyme characterization (by ELISA) as well as determination of activity More resistant to shedding than other brush border enzymes, indicates more severe damage

(*continued*)

Table 5.5 (continued)

Enzyme	Nephron segment	Cellular location	Comments
α-Glutathione-S-transferase (GST) (ligandin)	Proximal tubule	Cytosol	Usually assessed by ELISA as quantity of protein but rapid assay for enzyme activity is also available (activity assay also detects μ and π isoforms)
Lactate dehydrogenase (LDH)	Entire nephron	Cytosol	Most commonly used as an indicator of distal tubule damage; not segment specific
Aspartate aminotransferase (AST)	Entire nephron	Mitochondria (Cytosol)	Enzyme levels are highest in proximal tubule (particularly convoluted segment) and thick ascending limb, tracking mitochondrial density

[a]Material from: Coonrod and Paterson 1969; Ceriotti 1976; Maruhn et al. 1977; Koenig et al. 1978; Vanderlinde 1981; Price 1982, 2002; Higashiyama et al. 1983; Nakamura et al. 1983; Davey et al. 1984; Guder and Ross 1984; Hysing and Tolleshaug 1986; Grötsch et al. 1985; Mueller et al. 1986; Gossett et al. 1987; Nishimura 1987; Stonard et al. 1987; Jung and Grutzmann 1988; Verpooten et al. 1989; Houser and Milner 1991; Taylor et al. 1992; Casadevall et al. 1995; Bedir et al. 1996; Price et al. 1996, 1997; Taylor et al. 1997; Clemo 1998; Finn and Porter 1998; Loeb 1998; Montagne et al. 1998; Ohata et al. 1998; Holdt-Lehmann et al. 2000; Lofti and Djalali 2000; Vlaskou et al. 2000; Van Kreel et al. 2002b

- The effects of dilution and pH on enzyme activity must also be considered, as these factors are highly variable in urine samples. Most enzymes are very labile to acid pH and the activity of many can be decreased substantially in concentrated urine
- Enzymes are generally less stable in urine than they are in high protein matrices such as serum or plasma (especially true for γ-glutamyl transpeptidase). Assays must be performed within 2 h of sample collection or a stabilizing substrate needs to be added to the sample, preferably during collection. Albumin, ethylene glycol, glycerol, or erythritol will satisfactorily preserve the activity of most commonly used enzymes when the samples are stored at −20°C

Either 24 h urine collection or timed urine samples collected at the same time each day is recommended, with the activity expressed per unit of time (Price 1982; Plummer et al. 1986). If the assessment is to be repeated with time, the samples should be collected over the same time period on each day because there is pronounced diurnal variation in excretion rate of some enzymes (Maruhn et al. 1977; Price 1982; Gossett et al. 1987). For spot urine samples or those where accurately timed collection is not possible, normalization of activity per unit of creatinine can be done and this has been shown to be reasonably well correlated to 24 h enzyme activity (Vanderlinde 1981; Grauer et al. 1995). Diet and age-matched controls must be included if enzyme activity is to be normalized to creatinine, to control for the effects of these variables on creatinine excretion (Plummer et al. 1986; Casadevall et al. 1995).

Most of these assays can be performed using the same automated equipment that is used for plasma, but the assays will need to be validated separately for urine to ensure that the matrix (urine versus plasma) does not interfere with the method and that the enzyme levels present in urine, either endogenously or following injury, are within the limits of linearity. Immunoassays (ELISA) are commercially available for α, π or μ -glutathione-S-transferase in the rat and human (Biotrin International, Dublin).

EVALUATION

Enzyme activity enzyme activityis expressed either per unit of time or per unit of creatinine. Normalization of enzyme activity per unit of volume or osmolality is not recommended because of the high degree of variability of these parameters (Price 1982; Plummer et al. 1986).

LIMITATIONS OF THE METHOD

5.2.3.1 General Limitations of Urine Enzyme Analysis

The correct sample handling methodologies have not been well validated for all enzymes in all species and it may require some effort on the part of the investigator to determine the need and optimal method for sample preparation.

The inherent limitations of the Jaffe method for determination of creatinine have been discussed

(Sect. 1.1.1). Factors which result in reduced excretion of creatinine without acute tubular injury (e.g., chronic renal disease in aged animals with pronounced loss of nephron mass, prerenal reduction of GFR) will also result in reduced urine creatinine and falsely elevated enzyme activity when normalized to creatinine (Price 1982; Plummer et al. 1986; Casadevall et al. 1995).

5.2.3.2 Limitations of Specific Enzymes

NAG is not specific for the proximal tubule, but also increases with papillary injury and glomerular disorders. Concomitant evaluation of one of the proximal tubule-specific brush border enzymes (LAP, GGT, or IALP) allows correct interpretation of the NAG increase. There are also significant increases in basal excretion as a function of age in rats and gender in dogs (higher in males), so age and sex-matched controls must be used.

GGT is notoriously unstable in urine and must be assayed very rapidly, even in the presence of urine stabilizers (Loeb 1998). There is high diurnal variation in baseline excretion rate in dogs that cannot be corrected in spot urine samples by creatinine normalization, so timed urine collection must be used with this enzyme in this species (Gossett et al. 1987).

LAP is also seen in the urine with very early glomerular disease (Bedir et al. 1996). The assay substrate is also a substrate for leukocyte esterase and thus increased neutrophils in the urine (pyuria) will cause a false positive result (Vlaskou et al. 2000).

Due to size limitations, most enzymes present in plasma are not filtered into the urine but there are some exceptions (e.g., lysozyme); these will be increased in the urine if tubular function (and uptake of filtered protein) is decreased. In addition, if glomerular injury accompanies tubular injury, leakage of larger molecular weight proteins may occur and plasma source enzymes that ordinarily would not be filtered may appear in urine. AST, LDH, and IALP may thus appear in urine.

5.3 Experimental Models of Renal Disorders

5.3.1 Models for Evaluation of Uricosuric Agents

In most species, uric acid (the primary end product of purine metabolism) is further metabolized by uricase to allantoin prior to excretion. Humans have a relative deficiency of uricase and, thus, have both higher circulating and urinary levels of uric acid. In excess, high circulating levels lead to pathologic precipitation of urate crystals in varios tissues ("gout") while high urinary levels can result in the formation of urate calculi, one of the most common causes of urinary tract obstruction in humans. Evaluation of therapeutic interventions for these pathophysiologic states requires the use of relevant animal models.

5.3.1.1 Naturally Occurring Animal Models

PURPOSE AND RATIONALE

Hyperuricemia occurs naturally in only two animal models. The Dalmatian dog has excessive uric acid excretion and relatively high plasma levels. This is due to an autosomal recessive trait that results in defective activity of uricase (urate oxidase) in situ in the liver (Yü et al. 1971; Safra et al. 2005). Some authors have described defective tubular reabsorption of filtered urate in Dalmations (Kessler et al. 1959), but more recent evidence indicates that urate transport is normal (Bannasch et al. 2004). The Cebus monkey (Cebus albifrons), like humans, has a relative deficiency of uricase (Fanelli et al. 1970; Terkeltaub et al. 2006). Either model may be used to evaluate compounds that decrease urate synthesis or to evaluate the effectiveness of uricosuric drugs.

PROCEDURE

Standard clearance or fractional excretion methods (see Sect. 1.1.2 and "Quantitative Electrolyte Excretion") for uric acid are used. Urine and plasma uric acid are assessed by a colorimetric combined uricase-catalase method (Kageyama 1971).

EVALUATION

The results from groups of animals receiving test compound are compared to those of controls. Alternatively, each animal may be used as its own control in sequential experiments.

LIMITATIONS OF THE METHOD

Abnormal urate handling in the Dalmatian is a recessive trait, and thus not all Dalmatians are suitable. Animals must be screened first to ensure that urate metabolism is abnormal. Both animal models are expensive and can be difficult to obtain in adequate numbers.

Yü TF, Gutman AB, Berger L, Kaung C (1971) Low uricase activity in the Dalmatian dog simulated in mongrels given oxonic acid. Am J Physiol 220:973–979

5.3.2 Artificial Animal Models

PURPOSE AND RATIONALE

In species with high uricase activity, experimental hyperuricemia can by induced by the administration of enzyme inhibitors. Allantoxanamide blocks uricase and also increases endogenously synthesized uric acid in rodents (the latter effect is inhibited by allopurinol) (Johnson and Chartrand 1978). These models can be used to test the effects of xanthine oxidase inhibitors as well as uricosuric agents (Hropot et al. 1984).

PROCEDURE

Sprague Dawley rats are treated by intraperitoneal (ip) injection of at least 150 mg/kg allantoxanamide. The

effects of this dose will last up to 6 h following administration. Standard clearance or fractional excretion methods may be used (see Sect. 1.1.2 and "Quantitative Electrolyte Excretion"), or plasma levels of uric acid may be followed over time. Urine and plasma uric acid are assessed by a colorimetric combined uricase-catalase method (Kageyama 1971).

EVALUATION

Serum uric acid concentrations are evaluated at a set point in time following test article treatment. The percentage decrease in serum uric acid levels is calculated:

$$\text{Percent decrease} = [(C_C - C_T)/(C_C - C_N)] \times 100$$

where C_C, C_N, and C_T are the uric acid concentrations (mg/dl) of control (inhibitor treated), normal (untreated), and test article (inhibitor + test article treated) groups.

MODIFICATION OF THE METHOD

Potassium oxonate or oxonic acid may be used as uricase inhibitors in rats as an alternative to allantoxamide, as the former can be toxic in high doses. Potassium oxonate at a dose of 250 mg/kg, ip is given 1 h before treatment with test compounds (Nguyen et al. 2005). Chronic (7 days or more) treatment of rats with a combination of potassium oxonate (2%) and urate (3%) in the diet results in marked hyperuricemia with renal urate crystal deposits; omission of the supplemental uric acid results in moderate hyperuricemia with no renal pathology (Stavric et al. 1969; Mazzali et al. 2001). Oxonic acid at a dose of 750 mg/kg/day results in a milder hyperuricemia in rats, which may be a more physiologically relevant model of human hyperuricemia (Khosla et al. 2005).

A homozygous knockout mouse model has been developed (UOX-/-) that is deficient in urate oxidase (uricase). Plasma and urine urate levels are markedly increased in these animals. They can be difficult to maintain, as there is high prenatal and preweaning mortality due to urate crystal nephropathy and severe diabetes insipidus (Wu et al. 1994), which can partially be ameliorated by ensuring adequate water replacement (Kelly et al. 2001). These animals have been successfully used to evaluate the pharmacologic effectiveness of uricase replacement therapies (Sherman et al. 2008).

A homozygous knockout model has been developed (GLUT9-/-) that is deficient in one of the urate transporters (SLC2A9, or GLUT9) known to be associated with clinically significant hyperuricemia in humans. There are two variants, a systemic knockout and a liver-specific knockout. The former model develops moderately increased plasma and urine urate levels, but suffers from the same mortality limitations as are seen in the UOX-/- animals. The liver specific variant develops high plasma and urine urate levels (due to decreased hepatic uptake of urate and conversion to allantoin) but does not develop nephropathy (Preitner et al. 2009; Stark et al. 2009; Woodward et al. 2009).

5.3.3 Animal Models for Chronic Renal Failure

5.3.3.1 Partial Nephrectomy Models

PURPOSE AND RATIONALE

Subtotal nephrectomy in rodents has been used by many investigators as a model for chronic renal failure, particularly because they recapitulate many of the systemic changes such as anemia, cardiomyopathy, hypercholesterolemia, secondary hyperparathyroidism, hypertension, glomerular and arterial sclerosis, and vascular calcification that accompany this condition in humans (Shobeiri et al. 2010). The oldest and most commonly used of these models is the 5/6 nephrectomized rat model (Chauntin and Ferris 1932).

These models are commonly used to evaluate the effects of renal insufficiency on the kinetics of drugs which rely primarily on renal excretion (to predict the need for dose adjustment in patients with renal insufficiency). They may also be used to evaluate the effects of drugs intended to alter the course of renal failure or one of the comorbidities associated with chronic renal failure. The 5/6 nephrectomized rat is considered the "gold standard" model for the evaluation of erythroid-stimulating agents (erythropoietin and erythropoietin-mimetic agents).

PROCEDURE

A modification of the original procedure is more commonly used at present as it results in improved survival (Aunapuu et al. 2003; Shobeiri et al. 2010). Male Sprague-Dawley or Wistar rats weighing 230–280 g are normally used for these studies. The surgery is performed in two stages with a week's recovery between each surgical modification. Prior to the first incision, the animal is given 20 ml/kg normal saline subcutaneously. On a heated table, a midline laparatomy is performed 1 cm below the xiphoid bone cartilage and the abdomen is opened. The left kidney is isolated and brought out of the abdomen by grasping the fat at the lower pole of the kidney. The perirenal fat is bluntly dissected (sparing the adrenal gland), so that the renal artery and vein may be clearly identified. Two if the three branches of the left renal artery are ligated (decreasing the functional capacity of this kidney by ~67%) and the kidney is returned to the abdominal cavity, which is then closed with clips or sutures. Following a 1 week recovery, a second (smaller) midline laparotomy is performed starting 0.5 cm from the xiphoid bone cartilage. The right kidney is isolated and cleared of the surrounding fat (sparing the adrenal gland) to identify the renal artery, vein, and ureter. These structures are ligated, cauterized proximal to the kidney and the right kidney is then removed. Animals are allowed to recover for at least 1 week before being monitored for the onset of renal failure.

EVALUATION

Onset of azotemia (increases in serum creatinine, urea, and/or phosphorus of 2–4X over baseline) can be detected as early as 1 week postsurgically in this model, with the onset of severe changes occurring 4–8 weeks post surgery. Survivial of these models for up to 36 weeks has been described, which can be improved by the administration of low protein and low phosphorus-containing diets, prevention of secondary hyperparathyroidism (by administration of vitamin D analogs and phosphate-binding agents or by parathyroidectomy), and prevention of hypertension (Cruz et al. 2007; Shobeiri et al. 2010).

MODIFICATIONS OF THE METHOD

Similar surgical methods can be used in mice, although the poles of the remnant kidney are ablated by electrocautery as opposed to ligating two of the three renal arteries. The contralateral kidney is then removed following a recovery period of 1–3 weeks. The latter method allows smaller animals to be used and improves survival because blood loss is minimal. Onset of anemia and azotemia in this model occurs within 1 week following surgery, with survival up to 15 weeks (Gagnon and Duguid 1983; Gagnon and Gallimore 1988; Kennedy et al. 2008).

Large animal 3/4 and 5/6 nephrectomy models (rabbits and dogs) have also been described. These models use unilateral nephrectomy combined with either surgical excision or electroablation of renal tissue for consistent results. The dog model is commonly used

to evaluate effects of renal insufficiency on drug disposition, as it results in a milder degree of renal failure than is seen with the rodent models. While these models do recapitulate many of the comorbidities common to chronic renal failure in humans, rabbits appear to be resistant to the development of hyperparathyroidism, and dogs do not develop the glomerular changes seen in rodents (Brown et al. 1990; Duffee et al. 1990; Fine 1991; Vaneerdeweg et al. 1992; Toutain et al. 2000; Bas et al. 2004; Feng et al. 2010).

A 5/6 nephrectomy model in chickens has been described. An incision is made along the left side of the abdomen extending into the peritoneal cavity. The right ureter is identified and ligated just proximal to its junction with the cloaca. The left ureter and renal vein are ligated with a single suture near the middle of the left kidney. Azotemia is assessed by measuring plasma uric acid levels at intervals beginning 2–6 days post surgery. The method resulted in elevation of plasma concentration of uric acid, the major product of protein catabolism in avian plasma, to levels 2–4 times normal for periods as long as 3 weeks (Hartenbower and Coburn 1972).

Surgically altered (5/6 and 3/4 nephrectomized) rats and mice may be purchased from commercial vendors. Two such sources are Charles River Laboratories (http://www.criver.com/en-US/ProdServ/ByType/Surgical/Pages/home2.aspx) and Taconic Farms (http://www.taconic.com/wmspage.cfm?parm1=691).

A modified surgical approach has been used to reproduce acute renal failure (renal ischemia-reperfusion injury) in rats, rabbits, and pigs. Animals are anesthetized and subjected to unilateral nephrectomy with occlusion of the remaining kidney or bilateral renal occlusion using atraumatic vascular clamps before renal perfusion was reestablished. The duration of renal ischemia varies between 30 and 120 min (longer durations are needed for larger animals and bilateral occlusion models). Azotemia is detectable as early as 1 day post surgery, with recovery occurring between days 7 and 14 (Williams et al. 1997; Salehipour et al. 2010; Abreu et al. 2011).

5.3.3.2 Immune-Mediated Glomerulonephritis Experimental Models

PURPOSE AND RATIONALE

Various immune-mediated glomerulonephritis experimental procedures have been used as models for glomerulonephritis in human beings. Most of them were developed in rats and mice, although other species (rabbits, guinea pigs) are occasionally used. The correlations between the animal model and the human disease that each one recapitulates is based on common features of the renal histopathology and disease pathogenesis, although in many cases the inciting autoantigen is not the same between the human disease state and the animal model.

These models have been used to investigate the pathologic mechanisms involved in renal injury in these disease states, as well as to evaluate the effects of experimental treatments on the course of disease. They are not as commonly used to evaluate the effects

Table 5.6 Summary of the more common experimental models of immune-mediated glomerulonephritis

Model name/ generation	Antigen or agent	Species	Strain(s)	Comments
Antineutrophil cytoplasmic antibody (ANCA) vasculitis/ passive or active	Myeloperoxidase	Rats Mice	Brown Norway Spont. Hypertensive (SHR) MPO -/-	Model for Wegener's granulomatosis (combination of crescentic glomerulonephritis and small vessel vasculitis) Antigen is the same in the rodent and human model Heterologous MPO immunization (or homologous in MPO -/- animals) needed to generate the disease
Heymann nephritis/ Passive or active	Megalin (gp330) (specifically, a 14 amino acid (aa) peptide within the second LDL receptor domain)	Rats	Sprague-Dawley	Model for human membranous glomerulonephritis Characterized by glomerular subepithelial immune complex deposits (IgG and C5–9 complexes) Original antigen was a complex of megalin and its receptor-associated protein, but later studies showed purified megalin (or the 14 aa epitope) was sufficient to induce disease. Megalin is present in rat glomeruli but not in human (corresponding human antigens are phospholipase A2 receptor, aldose reductase and Mn-superoxide dismutase) Complement fixation is required for disease progression
IgA Nephropathy/ Active	*Staphylococcus aureus* 20 AA membrane peptide	Mice	Balb/C	Model for human immunoglobulin A nephropathy Immune complexes contain both IgA and IgG, as well as complement components Antigen is the same between rodent model and human disease (associated with MRSA infection) Multiple immunizations needed to reproduce the disease
IgA Nephropathy/ NA	Various trichothecene mycotoxins (nivalenol, vomitotoxin)	Mice	Balb/C (normal and high IgA) B6C3F1	Induced by dietary exposure to low levels (∼25 PPM in normal Balb/C or B6C3F1 mice Lower levels (12 PPM) result in disease in mice with high endogenous circulating IgA levels Results from reduced intestinal clearance of IgA and increased circulating levels Increased circulating IgA results in circulating IgA immune complexes which become deposited on the glomerular basement membrane
Mercuric chloride/ NA	Mercuric chloride	Rats	Brown Norway	Model for human Goodpasture's syndrome (antigens are similar) Results in the generation of anti-glomerular basement membrane antibodies (including laminin, collagen type IV, and fibronectin) Anti-myeloperoxidase antibodies have also been described Induction is by 3X weekly subcutaneous administration for 2 weeks at 2 mg/kg Onset of disease is at 14 days following the first injection Deposits contain IgG and C3 components

(*continued*)

Table 5.6 (continued)

Model name/ generation	Antigen or agent	Species	Strain(s)	Comments
Nephrotoxic serum nephritis/ passive (active in XenoMouse® model)	Anti-glomerular basement membrane antigens (primarily non-collagenous domains of type IV collagen)	Rats Mice Rabbits Guinea pigs	Multiple, but primarily Wistar-Kyoto (WKY) DDY C57/Bl6 XenoMouse®	Multiple rat strains have been used, but the Kyoto-Wistar is exceptionally sensitive. Model for human rapidly progressive glomerulonephritis and Goodpasture's syndrome XenoMouse® model generates human IgG antibodies upon immunization with human Type IV collagen epitopes, resulting in disease
Pristane-induced lupus-like syndrome/ NA	Pristane	Mice	C57Bl/6 Balb/C	Single IP injection of 500 μl of pristane induces disease Anti-DNA and anti-RNA antibodies result from apoptosis of lymphoid cells and peritoneal epithelial cells in the peritoneal cavity in a pro-inflammatory cytokine milieu Although antibodies detected 2–4 months post injection, disease onset requires ~6 months following pristane injection. Onset, magnitude and nature of the autoimmune responses are all highly variable

of renal impairment on the clearance of drugs, as tubular function is not affected until very late in the disease process.

Table 5.6 (derived from material in the references for this section) summarizes the more common models of immune-mediated glomerulonephritis.

PROCEDURE

Traditionally, these models are generated by the intravenous or intraperitoneal administration of preformed heterologous antibodies (usually immunized rabbit serum for rodent models and bovine serum for rabbit models) against the renal antigen of interest (passive models). They may also be generated by direct immunization of animals with either crude or purified preparations of the antigen of interest, usually combined with complete Freund's adjuvant to ensure a robust immune response (active models). A single dose of antibody or immunization is usually sufficient to incite disease, although repeat dosing is generally more effective and results in more severe disease.

EVALUATION

The specific disease model being used will determine the optimal time point for the initiation of experimental manipulations (see "References" for details). End points generally include evaluation of the degree of azotemia (serum creatinine and/or urea levels), magnitude of proteinuria, and histologic evaluation of the kidneys. Special stains and/or immunostains for basement membrane components, Ig and complement components, and infiltrating immune/inflammatory cells may be incorporated in the evaluation.

Numerical data may be evaluated using appropriate statistical methods. Statistical evaluation of severity scores for histologic findings is not appropriate.

MODIFICATION OF THE METHOD

In some of the animal models listed in the table above, toxicants are used to initiate the onset of immune-mediated disease. The generation of the immune response is either due to the modification of endogenous proteins (thereby generating neoepitopes against which cross-reacting antibody responses are generated) or interfering with the normal clearance mechanisms for endogenous antibodies, resulting in their accumulation within the glomerulus and subsequent complement fixation with glomerular injury.

Naturally Occurring Disease Models

PURPOSE AND RATIONALE

Spontaneous immune-mediated glomerulonephropathy occurs in several strains of rats and mice. These models have been used as surrogates for disease states of similar pathogenesis in humans. They may better reflect the pathogenesis of some of the immune-mediated glomerulonephropathies than the experimental models do in that the natural models tend to recapitulate the gender predilections and genetic alterations characteristic of the human conditions. The use and evaluation of these models is similar to those outlined in Sect. 3.3.1.

An overview of some of these disease models (derived from material in the references for this section) is presented in Table 5.7.

Table 5.7 Overview of some naturally occurring disease models

Disease state	Species	Strain	Comments
Crescentic glomerulonephropathy	Mouse	Kinjoh (SCG/Kj)	Model for Wegener's granulomatosis/polyarteritis nodosa in humans (BXSB/Mp x MRL/Mp-lpr/lpr)F1 hybrid strain Gender differences in incidence (females > males) Early onset of renal disease (first lesions by 9 weeks of age, overt proteinuria by 2 months of age) Anti-myeloperoxidase antibodies detected in these animals
IgA Nephropathy	Mouse	DDY	Hallmark is high circulating IgA levels due to decreased renal IgA clearance (defective IgA secretory mechanisms or secondary to altered glomerular basement membranes) Pathogenesis may be related to increased circulating TGF-β, which results in increased production of glomerular collagens I and IV and fibronectin Severity is less than is seen in immune-mediated form
Systemic lupus erythematosis (SLE) glomerulonephritis	Mouse	MRL/MP-lpr/lpr	Renal arteritis as well as glomerulonephritis Pathogenicity of the antibodies produced varies from individual to individual within the strain Defect is in apoptosis of lymphocytes Anti-DNA and anti-myeloperoxidase antibodies have been identified Sex hormone dependent; estrogen exacerbates the severity of disease
Systemic lupus erythematosis (SLE) glomerulonephritis	Mouse	(NZBxNZW)F1	Cross between two highly inbred strains: New Zealand Black (NZB/BlUmc) and New Zealand White (NZW/OuUmc) As an F1 hybrid, more heterogeneous than the MRL model and thus more closely representative of the human syndrome Six strains, with variable onset, severity and penetrance of renal disease allows selection of strain based on disease phenotype desired. Glomerular lesions and circulating "LE" cells closely resemble human SLE nephritis Glomerular lesions associated with deposits of anti-DNA antibodies Onset of disease between 4 and 6 months of age, with death by 8 months of age Sex hormone dependent; estrogen exacerbates the severity of disease while testosterone and progesterone decrease it

5.4 Assessment of Effects on Lower Urinary Tract

5.4.1 In Vivo Methods

5.4.1.1 Micturition Studies

PURPOSE AND RATIONALE

The response of the urinary bladder to filling with increasing volumes of fluid is a common procedure for evaluating bladder function in both animals and humans. Urine storage and timely expulsion of bladder content are produced through the coordinated activation of a series of both voluntary actions and involuntary reflexes. These involve a number of neurotransmitter systems (glutamic acid, glycine, enkephalins, serotonin, α_1- and α_2- adrenergic, muscarininc, $GABA_A$ and $GABA_B$, and tachykinins), afferent signals from the bladder wall and urothelium, and inputs to the bladder originating in the central and peripheral nervous systems (De Groat 1975; Andersson 1993; Ferguson and Christopher 1996; Andersson and Wein 2004). In view of this complexity, in vivo models were developed for the quantitative analysis of the effects of drugs on the function of the vesicourethral complex (Maggi et al. 1986).

PROCEDURE

Assessment of effects on urinary bladder contractility and response has been performed in anesthetized rats, hamsters, guinea pigs, dogs, cats, and minipigs (Postius and Szelenyi 1983; Petersen et al., 1989: Imagawa et al. 1989; Häbler et al. 1990, 1992; Seif et al. 2004; Tai et al. 2004). A vein (usually a jugular) is cannulated for drug injection. Body temperature is kept constant by means of a heating pad maintained at 37°C. Through a midline incision of the abdomen, the urinary bladder is exposed and emptied of urine by application of a slight manual pressure. A 20 gauge needle is inserted through the apex of the bladder dome for 3–4 mm into its lumen. The needle is connected to a pressure transducer by means of polyethylene tubing (1.5mmOD and 1.0mmID) and the whole system filled with saline. The tubing is provided with an internal coaxial polyethylene tubing (0.6mmOD and 0.3mmID) inserted through a side hole and sealed by a drop of epoxy resin. The second tubing serves for intravesical infusion of fluid and is connected, through a peristaltic pump, to a saline reservoir.

Intraluminal pressure signals are delivered to an amplifier and displayed on a four channel polygraph. Warm saline-soaked cotton wool swabs are laid around the exteriorized organ to maintain its temperature and to keep it moist in experiments involving the topical application of substances on the bladder dome.

After a 15 min equilibration period at zero volume, variations in intraluminal pressure are recorded in response to continuous infusion of saline at a rate of 2.8 ml/h at 37°C for 30–40 min by means of a peristaltic pump connected to the polyethylene tubing inserted into the bladder. This infusion rate simulates the maximal hourly diuresis within the physiological range. In each preparation, the infusion is continued until micturition occurs. Micturition is referred as the emission of several drops of fluid during a sustained phasic contraction of the detrusor muscle, which is followed by return to zero or, in any case, to a value lower than that recorded just before micturition. Alternatively, the micturition reflex may be defined as the onset of high amplitude (>5 mmHg) pressure contractions in the urinary bladder in response to a distention stimulus (Oyasu et al. 1994; Lecci et al. 1988).

For both intravenous and topical administration, substances are dissolved in saline.

EVALUATION

In each experiment, the following parameters may be evaluated:

- Minimum intravesical pressure = minimal pressure recorded (index of resting bladder tone)
- Pressure threshold = intraluminal pressure value recorded just before micturition
- Volume threshold = the volume of infused saline required to obtain micturition
- Maximal amplitude of micturition contraction
- Frequency of micturition contractions
- Residual volume after micturition

The effect of substances on the compliance and responsiveness of the bladder wall is evaluated by comparing these parameters in treated animals with those of controls.

MODIFICATIONS OF THE METHOD

Rapid bolus infusion of saline into the urinary bladder, as opposed to continuous infusion, may be used to evaluate the responsiveness of the urinary bladder to distention. Volume responses in the parameters outlined above are evaluated (Lecci et al. 1988).

The urinary bladder may be catheterized in intact animals under anesthesia via the urethra, and the urethral catheter can then be attached to the pressure transduction system. Animals so treated may be recovered and used in multiple experiments. Alternatively, the effects of compounds applied intravesically can be examined, which allows elucidation of the neurotransmitters critical in generation of the micturition reflex (Lecci et al. 1988).

Animals surgically prepared, as described above, may also be recovered following replacement of the urinary bladder in the abdomen with exteriorization of the bladder cannula percutaneously. These animals may then be used to evaluate the effects of either systemically or intravesically applied compounds (Yaksh et al. 1986; Conte et al. 1988).

Ultrasonic methods of determining bladder volumes resulting in a micturition response have been used in rats (Horváth et al. 1994) and minipigs (Seif et al. 2004). These methods compare favorably with the results obtained by direct instillation of fluid into the urinary bladder, although in general volumes tend to be underestimated. Some of the techniques described have the advantage of being noninvasive and applicable to conscious, free-moving animals.

MODIFICATION OF THE METHOD

Either chemical (6-hydroxydopamine, reserpine) or surgical (section of hypogastric nerves) sympathectomy in animals produces model a of detrusor hyperreflexia and urine dropping, mimicking cystometric finding in human disease (Maggi et al. 1987).

Evaluation of micturition frequency can be evaluated in conscious animals. This can be done either by placing the animal in a restrainer over a urine collector. The collector is then secured to a Statham UC3 strain transducer, the output of which was amplified by a Gould bridge amplifier. Data are then monitored on a polygraph (Harada et al. 1992). More recently, this method has been simplified by the use of an infared photodiode sensor and matched phototransistor that can detect the appearance of urine flowing from the bottom of a metabolic cage, recording the frequency of these events. This method produces results comparable to the original cup-fore transducer methods (Argentieri and Argentieri 2002).

Effects of systemically or intravesically administered drugs on the upper urinary system may be detected during the course of cystometrography, as described by Tillig and Constantinou (1996). Additional catheters are placed into the renal pelvis (to measure renal pelvis pressures and to infuse the renal pelvis with a contrast-enhancing dye, indigo carmine). A videomicroscope is used to visualize the transport of indigo carmine infused into the renal pelvis and ureters (an index to urine transport in the upper urinary system). Standard cystometrography parameters (bladder pressure and micturition responses) were recorded during continuous infusion of the bladder with saline.

Simultaneous evaluation of bladder pressure and urine flow rates has been performed in dogs (Moreau et al. 1983), rats, and guinea pigs (Conte et al. 1991; Van Asselt et al. 1995). A single urethral catheter is used both to instill saline into the bladder and measure bladder pressure, urethral pressure, and urethral flow.

5.4.2 In Vitro Methods

5.4.2.1 Isolated Renal Pelvis

PURPOSE AND RATIONALE

Periodic contraction of the renal pelvic wall is important to the process of concentration of urine in the renal medulla as well as the propulsion of urine from the kidney into the bladder (Santicioli and Maggi 1998; Knepper et al. 2003). The isolated renal pelvis has been used to examine the effects of compounds on this activity. Rabbits, rats, and guinea pigs have been used (Maggi and Giuliani 1991, 1992; Maggi et al. 1992a, b, c, 1994, 1995; Giuliani and Maggi 1996; Santicioli et al. 1995, Santicioli and Maggi 1997; Patacchini et al. 1998; Bigoni et al. 1999).

PROCEDURE

Following appropriate anesthesia and euthanasia, a kidney and its attached ureter are removed and placed in oxygenated Krebs solution or other appropriate balanced electrolyte solution. The renal pelvis is carefully dissected from the renal parenchyma, separated from the ureter, cut and connected to threads to record motility along the circular axis. The preparation is suspended in a 5 ml organ bath and mechanical activity

recorded by means of an isotonic transducer (load 1mN). Transmural electrical field stimulation is made by means of platinum wire electrodes placed at the top and the bottom of the organ bath and connected to a GRASS S88 stimulator. Square wave pulses (pulse width 0.5 ms, 60 V) are delivered in trains of 10 s duration at frequencies of 5–10 Hz.

Experiments commence after a 60–90 min equilibrium period after which amplitude and frequency of spontaneous activity has reached a steady state. Test compounds are added to the bath and any effects on spontaneous activity (amplitude and/or frequency of spontaneous contraction) are assessed after an appropriate incubation period (up to 60 min following the addition of the test compound). As controls, concentration response curves to noradrenaline (decreased motility) and acetylcholine (increased motility) are performed by noncumulative addition to the bath at 20 min intervals, with washout in between concentrations. Parallel preparations (subjected to the same duration of incubation but without added test or control compounds) are monitored concurrently to correct for any effects of muscle fatigue during prolonged incubation (Davidson and Lang 2000).

EVALUATION

The amplitude and frequency of spontaneous contractions are assessed and the Motility Index (MI) is calculated as follows:

$$\mathrm{MI} = \left(\sum \mathrm{amp}/5\right) \times \mathrm{F}$$

where Σamp/5 is the mean amplitude of five contractions (in mN) and F is the frequency (in min^{-1}) of those five contractions. Concentration-response curves are generated by plotting the concentration versus the MI (either raw or expressed as a percent of control, using the parallel incubation as the control) (Davidson and Lang 2000).

MODIFICATIONS OF THE METHOD

Circumferentially cut strips from the proximal renal pelvis can be used instead of the whole renal pelvis, as this portion of the renal pelvis has the highest frequency of spontaneous contraction (Zhang and Lang 1994; Lang et al. 1995; Lang and Zhang 1996; Teele and Lang 1998). In larger species, the pacemaker region (the pelvic-calyceal junction) and pelviureteral junctions can be identified, isolated, and studied separately (Kimoto and Constantinou 1990, 1991; Lang et al. 2002).

Electrical activity in isolated smooth muscle cells of the renal pelvis can be determined as an index to renal pelvic motility in situ. The frequency of slow wave generation by membrane depolarization is correlated to renal pelvic motility (Seki and Suzuki 1990).

5.4.2.2 Propagation of Impulses in the Ureter

PURPOSE AND RATIONALE

The ureter smooth muscles are normally electrically and mechanically quiescent, with contraction resulting from electrical input from a pacemaker region in the proximal renal pelvis. However, spontaneous activity and progressive peristaltic contractions can result from activity originating independently in the ureter, and the effectiveness of impulse propagation initiated by the renal pelvic pacemaker is modulated by factors originating in the ureter itself (Santicioli and Maggi 1998; Lang et al. 2002). Suppression of action potentials at any site of the ureter will theoretically suppress the propagation of contraction and peristalsis (Weiss 1992). The isolated ureter provides a system by which effects on peristalsis in the entire ureter, or any of its segments, can be examined.

PROCEDURE

A number of species (most commonly rats and guinea pigs) have been used for whole-mount or strip preparations. Following appropriate anesthesia, the whole kidney and ureter are excised and placed in a Petri dish containing oxygenated Krebs solution for dissection. Segments (length depends on the species from which collected) representative of the proximal, middle and distal ureter may be collected. The segments are attached to a force-displacement transducer and are incubated in Krebs buffer or appropriate balance electrolyte solution gassed with 95% O_2/5% CO_2 and maintained at 32–37°C. The preparation is allowed to equilibrate for at 30–60 min, until the amplitude and frequency of spontaneous or induced contractions have stabilized, before experimental manipulation.

The frequency and amplitude of spontaneous contractions are recorded. Alternatively, contractions may be induced either by electrical field stimulation, transmural electrical simulation, the application of circumferential tension (stretch response), or by the addition of 40 mM KCl to the preparation. Once the contractions have stabilized, the test compound is added (Teele and Lang 1998; Yamamoto and Koike 2000).

EVALUATION

The frequency and amplitude of contraction are recorded, and the motility index (MI) may be calculated as outlined in E.1.4.2.1. Data are expressed as a percent of the control value and appropriate statistical analysis is performed. Concentration-response curves may be plotted and pA_2 or pD_2 values may be calculated (Arunlakshana and Schild 1959; Van Rossum 1963). Hill coefficients and EC_{50} values may also be calculated (Weiss et al. 2002).

MODIFICATIONS OF THE METHOD

Ureter preparations have been made from pig or human tissues collected from the abattoir or following

surgery, respectively. Ideally, no more than 20 min should elapse between tissue collection and incubation. Tissues are placed into cold (4°C) Krebs buffer or suitable balanced electrolyte solution and cut into rings of 0.5–1 cm in length. The rings are attached to a force transducer, suspended in an organ bath at 37°C, and allowed to equilibrate for up to 1.5 h while the frequency and amplitude of spontaneous contraction is measured. If the preparation demonstrates acceptable and stable frequency and amplitude of spontaneous contraction within this time period, it is considered suitable for experimental use. In pigs, the washout period between treatments is variable and thus the preparation is monitored for return to pretreatment baseline before the next treatment is applied. In human tissue, spontaneous contraction seldom occurs and electrical stimulation (trains of 300 ms at an interval of 200 s and impulses of 200 mA with a duration of 6 ms at a frequency of 50 H) is required. A washout period of 20 min between treatments is used (Weiss et al. 2002).

The evaluation of regional differences in response, and the effect of regional responses on adjacent regions, can be evaluated in a whole ureter preparation where each region remains physically attached but can be isolated for the application of test compounds or stimuli. The entire ureter is dissected and placed in a three-compartment organ bath which enables a separate superfusion of different parts of the organs. Two Perspex partitions are used to separate the proxima (renal), middle, and distal (bladder) ends. They include a window covered with condom rubber: a small hole (about 300 mm) is made in the rubber to enable the passage of the ureter. The proximal portions of each segment are pinned to a Sylgard support, and the distal portions are connected to isotonic transducers for recording of mechanical activity. Each compartment is perfused separately and electrical field stimulation can be applied to any compartment by means of two wire platinum electrodes positioned in parallel with the two sides of the ureter (Meini et al. 1995).

5.4.2.3 Isolated Urinary Bladder and Internal Urethral Sphincter

PURPOSE AND RATIONALE

Isolated urinary bladder preparations are useful for evaluating the effects of compounds on smooth muscle contractility and resting tone. Modifications allow for the evaluation of effects on specific urinary bladder regions and on inputs from either the urothelium or nervous system inputs.

PROCEDURE

Rats and guinea pigs have been used for whole bladder preparations. Following appropriate anesthesia, the abdomen is opened to remove the bladder and the urethra. After excess fat and connective tissue is removed, the preparation is placed en bloc into appropriate balanced electrolyte solution (Tyrode's or Krebs buffer) bubbled with 5% CO_2 and 95% O_2. The urethra is cannulated and connected to a pressure transducer, and the bladder is filled with a volume of solution adequate to evoke a contractile response. The bladder preparation is allowed to equilibrate for 30 min before any experimental manipulations are performed. The amplitude and frequency of pressure changes are recorded (Birder et al. 1998; Drake et al. 2003).

Alternatively, contractility can be assessed visually. Surface blood vessels or externally applied markings

(India ink or carbon particles) are used as landmarks. Video image recording of the bladder preparations are made during the experimental manipulations. Still images from the video are evaluated and the change in linear distance between pairs of landmarks is used as an index of contractility (Drake et al. 2003).

EVALUATION

The values are expressed or plotted as the means ± SE and pA2 values are calculated (Arunlakshana and Schild 1959). Data are analyzed using appropriate statistical methods.

MODIFICATIONS OF THE METHOD

Isolated regions or longitudinal strips of urinary bladder from a number of species, including humans, may be used to study the effects of compounds on isolated regions. Longitudinal strips (usually from the detrusor region) are most commonly used. Following harvest of the bladder as outlined above, the region of interest is cut from the bladder wall. Ligatures are placed on both ends of the strips and one end is attached to a tissue holder and the other to a strain gauge force-displacement transducer connected to a polygraph on which isometric tension changes are recorded. Each of the strips is then placed into a tissue bath containing Krebs-Ringer solution bubbled with 95%O_2 + 5%CO_2 at 37°C. Resting tension is adjusted to 1 g during an equilibrium period of at least 2 h. The contractile and relaxant responses are measured as increases or decreases from the resting tension, and contractile responses to stimulation can also be assessed with electrical stimulation of the preparations (Burnstock et al. 1978; Hills et al. 1984; Maggi et al. 1985; Pietra et al. 1990). Strips from the trigone region can be harvested from larger species and similarly evaluated (Klarskov 1987; Thornbury et al. 1992).

Contractile responses to nervous stimulation can be assessed in whole isolated bladder preparations. The pudendal nerve remnants can be identified near the ureter and can be attached to electrodes for stimulation of the bladder. Alterations in the contractile responses by the test compound are considered to result from effects at the neuromuscular junction (Hukovic et al. 1965; Weetman 1972; Dhattiwala and Dave 1975).

Denervated urinary bladder preparations (whole or strips) can be used to determine the degree of effect on nervous system inputs. Following appropriate anesthesia, the pelvic plexus is accessed in rats by a ventral midline incision and both pelvic ganglia are obliterated by electrocauterization. The animals are allowed to recover for at least 4 days before the urinary bladder is harvested as described above; during this period, the neurotransmitters downstream from the nervous system inputs become inactive and only the autonomous inputs remain. Differences in response between the denervated urinary bladder preparation and one harvested from a sham-operated animal are considered to result from neural inputs. The urinary bladders of the denervated animals must be manually emptied on a daily basis during the 4 day recovery period (Birder et al. 1998; Brauerman et al. 2006).

Inputs from the urothelium can be assessed in isolated urinary bladder smooth muscle preparations. Following preparation of strips from the urinary bladder, the urothelium is gently peeled away from the cut surface and the strips are mounted as described above. Effects on the capsaicin-mediated nitric oxide pathways located in the urothelium can be assessed in these preparations (Birder et al. 1998). Effects on the release of neurotransmitter substances from the epithelial strips removed from these preparations can also be examined; following isolation, the epithelial strips are incubated in Krebs buffer of suitable balanced electrolyte solution. Following a 20 min equilibration period, the strips are stimulated either mechanically (by stroking with a glass rod or pinching with forceps) or electrically (using field stimulation of the incubation medium). The neurotransmitter substance of interest is analyzed in the bath solution and dose-response curves are generated (Downie and Karmazyn 1984).

Isolated proximal urethral preparations can be made from a number of species. Following appropriate anesthesia, the bladder and urethra are harvested and either circular sections (rings) or transverse strips of 2–4 mm in length are collected from the proximal urethra. These are mounted in appropriate tissue holders and connected to an isometric force transducer and immersed in gassed balanced electrolyte solutions as described above. Electrodes are introduced to stimulate relaxation in the preparations. (Andersson et al. 1983, 1992; Teramoto et al. 1997; Von Heyden et al. 1997). Similar preparations can be made from human tissue, which is obtained from male patients undergoing cystourethrectomy en bloc because of bladder cancer. Rings of tissue were taken from the membranous and supra- and infracollicular parts of the prostatic urethra (Andersson et al. 1983; Kunisawa et al. 1985).

5.4.2.4 Effects on the Isolated Urethra

PURPOSE AND RATIONALE

The relaxation response in the urethra results in a combination of decreased intraurethral pressure, increased urethral diameter, and urethral shortening resulting in a flaring of the urethral orifice. A number of neurotransmitters and mediators are involved in this process, with each affecting a different stage of the process. (Brading 1999; Andersson and Wein 2004) The urethra is difficult to study in situ because of the large amount of surrounding connective tissue, which can be overcome by the use of a whole-mount preparation (Jankowski et al. 2004).

PROCEDURE

Female rats or guinea pigs have been used. Following appropriate anesthesia, the bladder and urethra are exposed via a lower midline incision, and a catheter is inserted in the urethral lumen, extending the entire axial length and exiting from a hole placed in the bladder dome. The urethra is secured to the tubing with sutures at both ends to maintain the correct in vivo length after dissection, and is measured. The pubic bone is then cut at a position lateral to the urethra and then separated and resected. The exposed urethra was gently removed from the ventral vaginal wall and the whole bladder-urethra unit was immediately placed in cold, oxygenated suitable balanced electrolyte solution bubbled with 21% O_2, 5% CO_2, and 74% N_2.

The catheter is removed so that the urethra may be secured inside the experimental apparatus, which provides a controlled fixed intraluminal pressure via an adjustable static fluid reservoir (the intraluminal pressure is controlled by adjusting the height of the reservoir). The mounted urethra is then enclosed in a bathing chamber filled with the same gassed, balanced electrolyte solution at 37°C. The preparation is allowed to equilibrate for at least 30 min before testing. A laser micrometer is positioned to measure urethral outer diameter at chosen locations along the axial length. Proximal, mid, and distal regional measurements were performed by positioning the laser at axial positions 25%, 50%, and 75%, respectively,

from the apex of the bladder, based on in vivo length. Both pressure and outer diameter (OD) measurements are recorded simultaneously.

The test compound of interest is added to the bath and pressure and OD measurements are obtained following a 30 min equilibration period. Pressure-diameter (P-D) responses are generated by incrementally increasing the pressure, in 2 mmHg steps, from 0 to 18 mmHg, and OD data are collected at 10 Hz over a 1 min period for each 2 mmHg step. The OD data are then averaged for each incremental increase to obtain a discrete value for each value of applied pressure.

Contractile responses can be evaluated in this preparation as well. The urethra is exposed to a fixed intraluminal pressure of 8 mmHg, which causes the tissue to be predilated and allows for a contractile response to be generated. The OD resulting from this 8 mmHg applied pressure is measured at a single axial location (i.e., proximal, mid, or distal) 30 min after pressurization. The test chemical of interest is added to the bath and the preparation is exposed for 30 min; at the end of this time, a series of 100 OD measurements (taken at 1 Hz) are collected at the same location and are averaged.

EVALUATION

The P-D response data are used to generate tissue compliance (C) as follows:

$$C = [D_{max} - D_{min}/D_{min}] \times (P_{max} - P_{min})^{-1}$$

where D_{max} and D_{min} represent the OD at the maximum (P_{max}, 18 mmHg) and minimum (P_{min}, 0 mmHg) applied pressures, respectively.

Contractile responses are assessed by determining the percent change in mean OD before and after the addition of the test compound.

MODIFICATION OF THE METHOD

With careful dissection, the pudendal nerves can be identified and left intact during the diisction of the urethra from the guinea pig. These nerves can then be attached to electrodes and alterations of effects of neural inputs can be assessed. In this preparation, contractile responses were assessed by measuring changes in isometric tension and intraluminal pressure changes were also recorded (Walters et al. 2006).

5.4.2.5 Effects on the External Urethral Sphincter

PURPOSE AND RATIONALE

In most species, the resting pressure profile responsible for continence depends on the striated muscle present in the external urethral sphincter (Brading 1999). The external urethral sphincter shows a steady tonic discharge under resting conditions. As the bladder fills, there is initially an increase in this activity. When the rise in tension in the bladder wall leads to reflex contraction, the activity in the external urethra sphincter ceases and in remains quiescent during voiding. Parlani et al. (1992) used the external urethral sphincter of the rat as an in vitro model to evaluate the activity of drugs on the smooth and striated components of the urinary bladder outlet.

PROCEDURE

Either rats or rabbits have been used. Under appropriate anesthesia, the external urethral sphincter (Watanabe and Yamamoto 1979) is isolated from the perineal muscles and surrounding connective tissue and removed in toto. The preparation is placed in oxygenated Krebs solution, and a ring is taken from its middle region. In this area the urethra is encircled by bundles of striated muscle fibers partly interlaced with urethral smooth muscle. The rings are cut to obtain strips that are suspended in a 5 ml organ bath containing Krebs solution at 37°C. A mixture of 96% O_2 and 4% CO_2 is bubbled into the organ bath.

The preparations are connected by means of a silk thread to an isometric strain gauge under a constant load of 1 g. The contractile activity is recorded on

a polygraph. Field stimulation is carried out by means of two platinum wire electrodes placed at the top and the bottom of the organ bath and connected to a Grass S11 stimulator. The preparations are allowed to equilibrate for at least 60 min.

Electrogenic stimulation of the preparation allows assessment of the effect of test compound on contractility. Square wave pulses are delivered at an intensity of between 10 and 60 V, a frequency of 40 Hz, and a duration between 0.1 and 1 s; using 0.5 s trains of 0.5 ms pulses at 15 s intervals. Once the amplitude of the electrically induced contractions is stable, the preparations can then be exposed to test compounds and the amplitude is again measured until stable. A 90 min rest period following washout is required between treatments (Morita et al. 2000).

EVALUATION

The contraction amplitude is expressed as a percentage of the control value. Concentration response curves can be plotted and EC_{50} values calculated if desired.

LIMITATIONS OF THE METHOD

The striated muscle of the external urethral sphincter is easily damaged during removal. If this occurs, the cells will become depolarized and refractory to electrical stimulation (Brading 1999). Testing of the preparation in the absence of drug at the beginning and the end of the experiment will control for this.

6.1 Respiratory Function Assays: General Approach

The objectives of a safety pharmacology study of the respiratory system are to determine whether a drug has the potential to produce a change in respiratory function and to establish whether this change is a liability. Such changes can result from either the primary or secondary pharmacological properties of a drug or from organ dysfunction resulting from the toxicological properties of a drug.

The respiratory system consists of two functional units, the pumping apparatus and the gas exchange unit. As such, a complete assessment of respiratory function in safety pharmacology must include an evaluation of both of these components. The pumping apparatus includes those components of the nervous and muscular systems that are responsible for generating and regulating breathing patterns, whereas the gas exchange unit consists of the lung with its associated airways, alveoli, and interstitial area that contains blood and lymph vessels and an elastic fibrous network.

The function of the pumping apparatus is to ensure the appropriate movement of gases between the environment and the central airways, which is evaluated by measuring ventilatory patterns. Ventilatory parameters must include measures of respiratory rate, tidal volume, and minute volume, since normal ventilation requires that the pumping apparatus provide both adequate total pulmonary ventilation (minute volume) and the appropriate depth (tidal volume) and frequency (rate) of breathing. If a change in these parameters occurs, inspiratory flow (mean or peak), expiratory flow (mean or peak), fractional inspiratory time

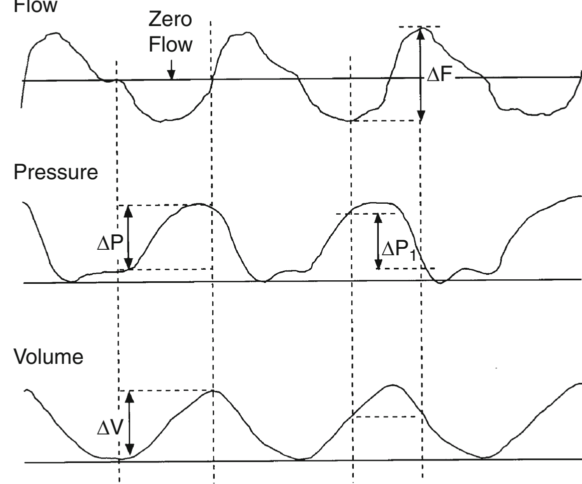
Functional Endpoints

V_E	-	Minute Volume (V_T x f)
f	-	Breathing Rate
V_T	-	Tidal Volume
PIF	-	Peak Inspiratory Flow
PEF	-	Peak Expiratory Flow
FIT	-	Fractional Inspiratory Time $\frac{(T_i)}{(T_{tot})}$

Fig. 6.1 Tracings of lung airflow and lung volume changes during spontaneous breathing in a conscious rat. Airflow was measured directly using a "head-out" plethysmograph chamber. The functional endpoints can be automatically calculated for each breath using a data acquisition and analysis software system



Functional Endpoints

Dynamic Compliance $= \frac{\Delta V}{\Delta P}$ (At zero flow points)

Dynamic Resistance $= \frac{\Delta P_1}{\Delta F}$ (At isovolume points)

Dynamic Conductance $= \frac{\Delta F}{\Delta P_1}$ (At isovolume points)

Fig. 6.2 Tracings of lung airflow, transpulmonary pressure, and lung volume changes during spontaneous breathing in a rat. Airflow was measured directly using a "head-out" plethysmograph chamber, while pleural pressure was measured using a pressure-sensitive catheter placed into the esophagus within the thoracic cavity. The functional endpoints can be automatically calculated for each breath using a data acquisition and analysis software system

(inspiratory time/total breath time), and time between breaths (expiratory pause or apnea) should be evaluated to help define the mechanism (see Fig. 6.1).

The function of the gas exchange unit is to ensure that gas which enters the airways from the environment reaches the alveoli during inspiration and is removed from the alveoli during expiration. This is accomplished by maintaining patent (open) airways and elastic recoil in the parenchyma of the lung. The function of the gas exchange unit is evaluated by measuring the mechanical properties of the lung. This is most effectively accomplished in conscious animals by obtaining dynamic measurements of airway resistance or conductance (to assess airway patency) and lung compliance (to assess elastic recoil). Airway resistance (measured as total pulmonary resistance) defines the change in pleural, airway, or transpulmonary pressure (ΔP) required to produce a defined change in lung airflow (ΔF) and is calculated as ΔP/ΔF, while conductance is calculated as ΔF/ΔP. To calculate dynamic resistance or conductance, the ΔP and ΔF are measured for each breath at the same lung volume during inspiration and expiration (usually between 50% and 70% of tidal volume) (see Fig. 6.2). By selecting isovolumetric points, the dependence of ΔP on elastic component of the lung is removed, leaving ΔP dependent only on resistance to the flow of gas in the lung and airways. Another method for assessing airway resistance involves measuring the excursions of the thorax and abdomen during breathing. During normal breathing, the thorax and abdomen move in synchrony during both inspiration and expiration. A shift from this synchronous movement to asynchronous movement can be quantified as a phase angle shift. Such phase angle shifts have been used as indexes of airway resistance (see Fig. 6.3). Dynamic compliance is calculated by measuring the differences in airway or transpulmonary pressure (ΔP) and volume (ΔV) that occur at the beginning and end of each inspiration (i.e., at zero flow points) (see Fig. 6.2). By selecting zero

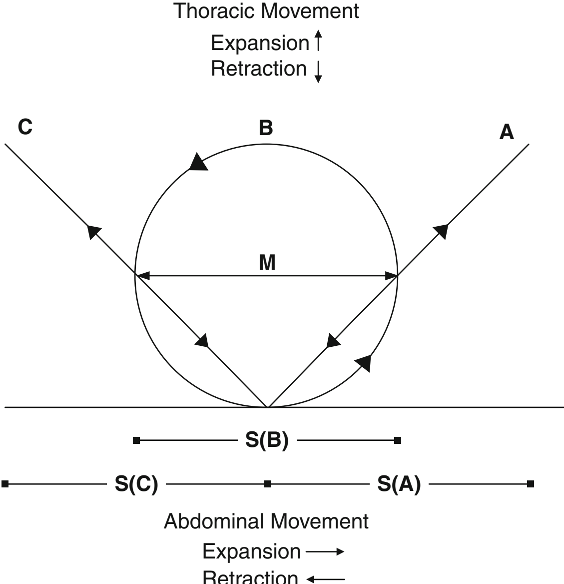


Fig. 6.3 Konno-Mead loops showing synchronous and asynchronous movements of the thorax and abdomen. Thoracic movement is plotted on the *y*-axis and abdominal movement on the *x*-axis. Phase angle (θ) defines the degree of synchrony and is calculated as $\theta = \sin^{-1}$ (M/S) where M = distance between abdomen-thorax loop intercepts when measured at one half the distance between maximal and minimal thoracic excursion and S = maximal abdominal excursion. (**a**) M/S = 0; θ = 0°—movements are synchronous. (**b**): M/S = 1; θ = 90°; movements are asynchronous. (**c**) M/S = 0(−); θ = 180°—movements are in opposite directions (paradoxical)

flow points, the dependence of ΔP on tissue and airflow movement is removed, leaving ΔP dependent only on the elastic component of the lung.

Supplemental studies in safety pharmacology are designed to investigate mechanisms of action or to help further characterize the liability of a drug effect. To help understand the mechanisms and liabilities associated with respiratory function changes, it is important to determine whether a drug-induced change in ventilation is acting through a mechanism involving the central or peripheral nervous system, and whether a drug-induced change in respiratory function has an effect on arterial blood gases.

Because the safety profiles defined by safety pharmacology studies can have a significant impact on the successful development of new therapeutic agents, it is important that the techniques and assays used in safety pharmacology studies minimize the occurrence of false negative and false positive results. For this reason, techniques that provide direct measures of respiratory parameters should be used. A direct measure is one that provides the endpoint of interest, in contrast to an indirect measure that provides a surrogate endpoint, which requires certain assumptions and/or calculations to estimate the true endpoint. Furthermore, because most drugs are intended for use in conscious patients and most anesthetics, analgesics, and sedatives can alter ventilatory reflexes, respiratory drive, and airway reactivity, safety pharmacology studies evaluating the effects of drugs on respiratory function should utilize conscious animal models. Based on the above, the respiratory function assays covered in this chapter will focus primarily on new technologies that provide direct measures of respiratory parameters in conscious animals and are considered to be most appropriate for use in safety pharmacology studies. Alternate techniques, which provide either indirect measures of respiratory function (e.g., barometric or whole body plethysmography) or use anesthetized models, have been described elsewhere (see "References") and will not be covered in this chapter.

6.2 Respiratory Function in Conscious Rats

PURPOSE AND RATIONALE

The rat is considered an appropriate species for general use in safety pharmacology studies of the respiratory system. The physiology of the respiratory system has been well characterized in this species and much of the information on drug-induced effects on ventilatory control and mechanisms of airway disease have been obtained in the rat. The rat is also readily available from animal vendors, is easy to handle and train, has a relatively stable breathing pattern, and has the appropriate temperament for conscious respiratory measurements. Furthermore, the techniques for measuring respiratory functions in rats are well established, and the rat is commonly used in toxicology studies. Selecting a species that is used in toxicology studies provides additional supportive information including (1) pharmacokinetic data that can be used to define the test measurement intervals, (2) acute toxicity data that can be used to select the appropriate high dose, and (3) toxicology/pathology findings that can be used to help define the mechanism of the functional changes measured in safety pharmacology studies. Although this technique has been developed in the rat, it is also applicable to other small animals.

PROCEDURE

To provide a direct measure of ventilatory parameters, a head-out plethysmograph chamber is used, while measurement of pleural pressure is used to provide a direct measure of airway resistance and compliance.

6.2.1 Pleural Pressure Measurements

6.2.1.1 Catheter Placement

Pleural pressure is measured chronically in conscious rats by surgically implanting a fluid-filled polyurethane catheter (length = 10 cm; O.D. = 0.7 cm) attached to a pressure-sensitive radiotelemetry transmitter (Model TA11PA-C40, Data Sciences International, St. Paul, MN) beneath the serosal layer of the esophagus and within the thoracic cavity (see Fig. 6.4).

6.2.1.2 Surgical Procedure

Surgery is initiated by anesthetizing the rat with isoflurane (2–3%) delivered by inhalation in 100% oxygen. The surgical area is prepared by shaving the abdomen with surgical clippers and scrubbing with a Betadine® and 70% ethanol wash. Once the area has been prepared, an abdominal incision (approximately 4–5 cm in length) is made along the linea alba. The lobes of the liver (within the abdominal cavity) are refracted to expose the esophagus and the lobes gently packed against the abdominal wall using moist 2 × 2 in. Versalon® (or equivalent) squares. The esophagus is isolated approximately 2 cm below the Hiatus oesphagicus (junction with the diaphragm), a 22-gauge needle (1 in. in length with an approximate 90° bend) is inserted into the esophagus between the serosa and muscularis layers, and the needle is tunneled cranially into the thoracic cavity (see Fig. 6.4). It is important to keep the esophagus completely straight while the needle is being inserted since the needle can reemerge through the serosa layer and enter into the pleural space. This will generally lead to encapsulation of the catheter tip and result in a loss or dampening of the pressure signal. Care must be taken not to advance the needle too far up the esophagus (generally no more than 1.5 cm) since the needle may come into close contact with the heart, causing a cardiac pressure signal. Once the needle is advanced to a point approximately 1 cm beyond the diaphragm junction, the needle is removed and the catheter from the telemetry transmitter unit advanced up the channel. During this step, care must be taken not to apply pressure to the catheter for risk of damaging the fluid-filled catheter and telemetry unit. A pair of vessel cannulation forceps (5 1/8" Roboz Surgical Instruments, Rockville, MD) can be used to successfully advance the catheter without damaging the unit. Pleural pressure should be monitored during these procedures to ensure an optimal signal is obtained. Pleural pressures during isoflurane-induced anesthesia should be between approximately 8 and 20 cm H_2O. The signal may be altered by slowly moving the catheter up and down the channel in the esophagus. Once a maximal and

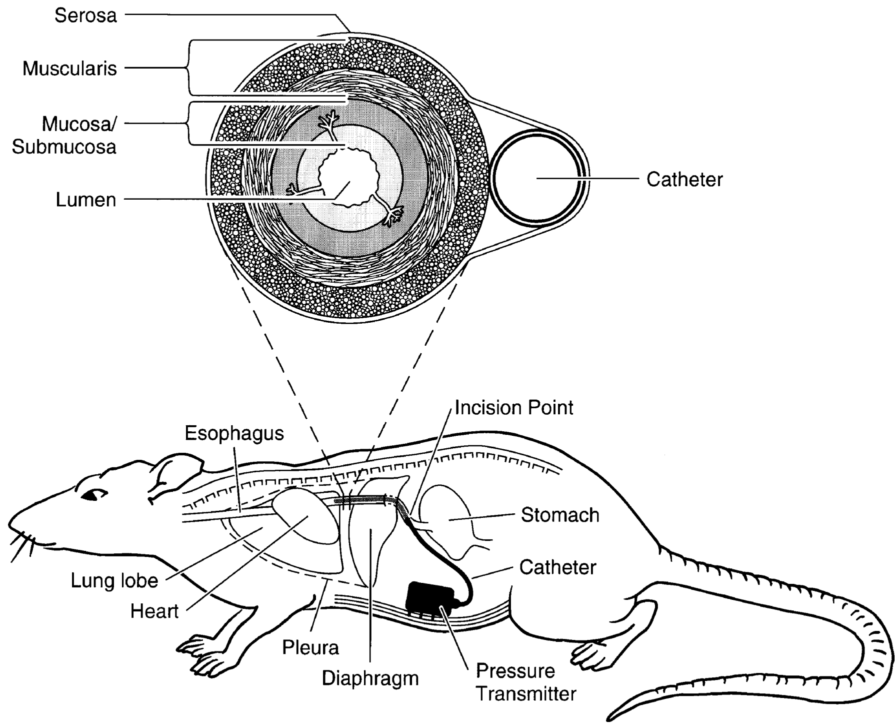

Fig. 6.4 Drawing of a rat showing placement of the pressure-sensitive subpleural catheter and radiotelemetry transmitter for chronic measurement of pleural pressure in conscious animals. The enlargement is a cross section through the esophagus showing the position of the catheter between the serosal and muscularis layers

acceptable pleural pressure signal is obtained, the catheter is secured in place using medical grade tissue adhesive (Vetbond™ or equivalent) and a small cellulose patch. The body of the transmitter unit is secured to the abdominal wall with nonabsorbable suture during the closure of the abdominal musculature. The skin layer is closed with absorbable suture and/or surgical wound clips.

6.2.1.3 Surgical Recovery and Training

If wound clips are used, they are removed approximately 8–10 days post surgery. Rats are placed in clean polycarbonate boxes with soft bedding for approximately 7–10 days, observed daily for any signs of distress, and weighed at least twice weekly. A rat may initially lose 10% of its body weight after surgery, but should begin gaining weight by day 5 post surgery. Prior to the initiation of a study, all rats must be trained to the plethysmograph chamber by placement in the chamber on three to five occasions. The first training session should be conducted prior to surgery to eliminate any rat that does not accept the chamber. The duration of time in the chamber should be at least equal to the time selected in the study. Rats can tolerate these types of chambers for up to a maximum of approximately 6 h.

6.2.2 Lung Airflow and Lung Mechanics Measurements

Changes in lung airflow are measured in conscious, restrained rats using a head-out, volume displacement plethysmograph chamber (approximately 1–3 L capacity) (Fig. 6.5). In this type of chamber, the head is exposed to ambient conditions, while the trunk is enclosed in the chamber. A seal is made around the neck using neoprene collar (1/8 in. thickness). Pressure changes within the chamber are measured using a differential pressure transducer with a sensitivity of approximately ± 2 cm H_2O (Model MP-45-14, Validyne Engineering, Northbridge, CA) and the pressure changes converted to flow rates using a pneumotach port (1 in. diameter opening with six layers of 325 mesh stainless steel wire cloth). The analog flow signal is conditioned using a preamplifier and then converted to a telemetry (frequency) signal using a voltage analog to frequency converter (Model C12V, Data Sciences International, Inc. (DSI), St. Paul, MN). A telemetry receiver (Model RLA1020 or RPC-1, Data Sciences International, Inc., St. Paul, MN) is placed beneath the plethysmograph chamber to transmit the pleural pressure telemetry signal in parallel with the chamber flow signal to a software

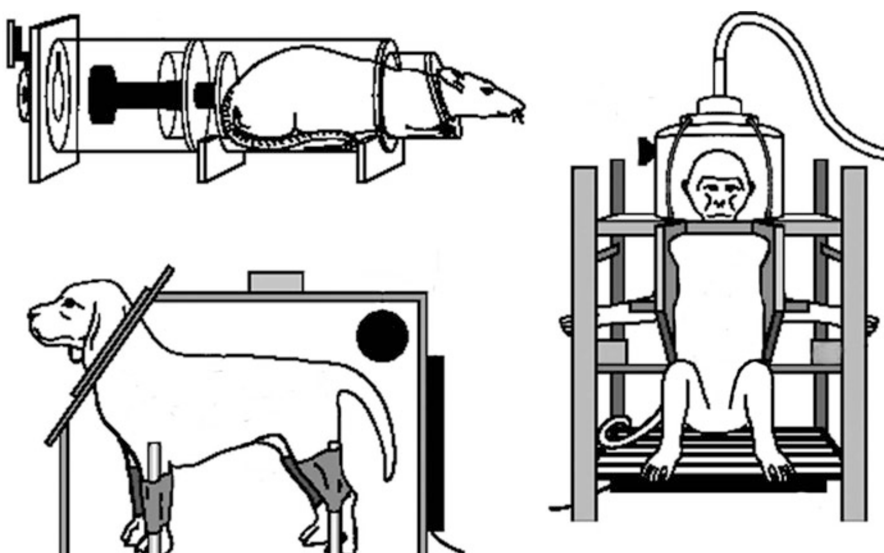

Fig. 6.5 Plethysmograph chambers for the direct measurement of ventilatory parameters. The rat and dog are in "head-out" chambers, while the monkey is in a "head-enclosed" chamber. For all chambers, an airtight seal is made around the neck using a 1/8 in. thick neoprene collar

application (e.g., DSI Dataquest ART analog system) that converts the telemetry signals into calibrated analog voltage signals and places the signals in phase by correcting for any differences in signal transmission times. The analog signals are then sent to a data acquisition and analysis software application (e.g., Life Sciences Suite Po-Ne-Mah Physiology Platform P3 with PCR application, Gould Instrument Systems, Inc., Valley View, OH) for calculation of ventilatory and lung function parameters (see Figs. 6.1 and 6.2).

6.3 Respiratory Function in Monkeys and Dogs: Restrained Methodologies

PURPOSE AND RATIONALE

Species other than the rat may be required to address specific study requirements. For example, the development of humanized monoclonal antibodies or other biotechnology-derived proteins requires species that have homologous target proteins and do not produce an antigenic response to the drug. In such cases, the nonhuman primate is generally required. Since both dogs and monkeys are used in toxicology studies of new drugs, either of these species may also be required to investigate pathological changes that are suspected of having an effect on the function of the respiratory pumping apparatus or gas exchange unit. Since telemetry transmitters with sufficient power to transmit two pressure signals have been developed for larger animals, the use of monkeys and dogs also has the advantage of allowing the measurement of both respiratory and cardiovascular functions. The procedure below is described for the cynomolgus monkey (*Macaca fascicularis*); however, this procedure is also applicable to the dog or other large animals.

6.3.1 Pleural and Arterial Pressure Measurements

6.3.1.1 Catheter Placements

Pleural pressure is measured chronically in conscious monkeys by surgically implanting a fluid-filled polyurethane catheter (length = 35 cm; O.D. = 1.2 mm) attached to a pressure-sensitive radiotelemetry transmitter (Model TL11M3-D70-PCP, Data Sciences International, Inc., St Paul, MN) beneath the serosal layer of the esophagus and within the thoracic cavity. Arterial pressures may also be measured by implanting a second fluid-filled polyurethane catheter (length = 35 cm; O.D. = 1.2 mm) attached to the same radiotelemetry transmitter into the abdominal aorta.

6.3.1.2 Surgical Procedure

Monkeys are premedicated with acetylcholine (0.025 mg/kg, i.m.) and flunixin meglumine

(1 mg/kg, i.m.). Anesthesia is induced with ketamine (10 mg/kg, i.m.) and maintained with isoflurane (1–3%) delivered by inhalation in 100% oxygen. The monkey is then placed in semi-dorsal recumbency, scrubbed, and draped for aseptic surgery. A feeding tube is passed down the esophagus and into the stomach. A midline laparotomy is performed and the body of the telemetry unit is sutured to the abdominal wall. Two silastic retaining beads are placed 5 cm from the tip of one of the pressure catheters, and two retracting sutures are placed in the stomach just below the cardia. The esophagus is identified at the point where it passes through the diaphragm and an anchoring suture is pre-placed at this site. A small incision is made through the serosal layer of the esophagus and a modified groove director is inserted between the serosal and muscularis layers and advanced cranially through the diaphragm along the dorsolateral aspect of the esophagus, using the feeding tube as a guide. The pressure catheter is advanced into the pleural cavity until the beads are located at the pre-placed suture and the groove director is withdrawn. The pleural pressure is visually verified and a negative deflection is confirmed with each respiratory effort. The catheter is either retracted or advanced until a maximal change in pressure (>4 mmHg) was obtained. The catheter is secured using the pre-placed suture.

To monitor arterial blood pressure, a 4 cm incision is made over the right femoral region and the femoral artery is isolated. A trocar is used to pass the blood pressure catheter from the abdomen to the femoral incision. An arterotomy is made in the femoral artery and the catheter introduced 10 cm into the artery and secured using standard techniques.

6.3.1.3 Surgical Recovery and Training

After surgery, the monkeys are allowed to recover for at least three weeks prior to the start of the study. All monkeys are observed daily for signs of pain or distress, and body weights are obtained at least weekly. All monkeys should be acclimated to handling, chair restraint, and the helmet used for respiratory measurements on at least three occasions prior to the start of each study. In addition, prior to implantation of the telemetry device, each monkey should be acclimated to the restraint chair and helmet for approximately 60 min on at least six occasions to ensure that the animals have the appropriate temperament.

6.3.1.4 Lung Airflow and Lung Mechanics Measurements

Changes in lung airflow are measured in conscious, restrained monkeys using a restraint chair equipped with a clear plastic helmet that seals around the neck and isolates the head from the rest of the body (see Fig. 6.4). The helmet is adapted to serve as a volume displacement plethysmograph by attaching a pneumotachometer (Model 4500A, Hans Rudolph, Inc., Kansas City, MO). A bias flow of approximately 5 L/min of room air is used to ensure that all monkeys have an adequate air supply for breathing. The helmet is cylindrical and has a height of 13.5 cm, a diameter of 20 cm, and an internal volume of approximately 4.2 L. Room air is pulled into the helmet through the pneumotach attached to the upper side of the helmet and is exhausted through six evenly spaced openings around the base of the helmet to ensure uniform flow. A vacuum system is attached to the output line of a six-port manifold at the top of the helmet using flexible plastic tubing (I.D. = 1.27 cm) with the openings at the base of the helmet connected to the manifold using flexible plastic tubing (I.D. = 0.635 cm).

Pressure changes within the helmet are measured using a differential pressure transducer with a sensitivity of approximately ± 2 cm H_2O (Model MP-45-14, Validyne Engineering, Northbridge, CA). The analog flow signal is conditioned using a preamplifier and then converted to a telemetry (frequency) signal using a voltage analog to frequency converter (Model C12V, Data Sciences International, Inc., St. Paul, MN). The restraint chairs are positioned in close proximity to individual telemetry receivers (Model No. RMC-1, Data Sciences International, Inc., St. Paul, MN) to ensure signal transmission. The pleural pressure signal is transmitted in parallel with the chamber flow signal to a software application (e.g., DSI Dataquest ART analog system) that converts the telemetry signals into calibrated analog voltage signals, and places the signals in phase by correcting for any differences in signal transmission times. The analog signals are then sent to a data acquisition and analysis software application (e.g., Life Sciences Suite Po-Ne-Mah Physiology Platform P3 with PCR application, Gould Instrument Systems, Inc., Valley View, OH) for calculation of ventilatory and lung function parameters (see Figs. 6.1 and 6.2).

6.4 Respiratory Function in Monkeys and Dogs: Non-restrained Methodologies

PURPOSE AND RATIONALE

Methods currently available for measuring ventilatory parameters in conscious monkeys and dogs utilize a head-out or head-enclosed plethysmograph chamber, or a face mask equipped with a pneumotachograph attached to the snout of the animal. These methods require restraint and, consequently, allow for only short, periodic measurements. Because of these limitations, respiratory inductive plethysmography (RIP) was recently adopted for use as a possible method for continuous monitoring of respiratory parameters in non-restrained dogs for extended periods of time. A similar methodology is currently being developed for monkeys. However, a validation of this methodology in the monkey has not yet been published. RIP utilizes straps containing inductive coils placed around the thorax and abdomen to measure lung volume changes. A continuous, low-voltage electrical current is passed through the inductive coils and current changes, which are proportional to the changes in length of the inductive coil straps, are produced by the expansion and contraction of the thorax and abdomen during breathing. Changes in the inductive current are used to continuously monitor changes in the circumference of the thorax and abdomen and analysis software can be used to calculate volume changes and breathing rate. Linear measurements of both thorax and abdomen are obtained based on the principle that lung expansion consists of two degrees of freedom of motion. These motions are independent and consist of the circumferential expansion and elongation of the lung, the latter of which is caused by depression of the diaphragm and is measured by expansion of the abdomen. Impedance technology combined with telemetry has also been used to measure thoracic movement during breathing in dogs. This methodology, however, does not include separate measurement of abdominal movement and, consequently, its application for assessing ventilator and airway resistance measurements in conscious, non-restrained dogs and monkeys is limited.

A comparison with a standard method for measuring ventilation (facemask with attached pneumotachograph) demonstrated that ventilatory parameters (tidal volume, respiratory and minute volume) can be accurately measured in the conscious dog and, importantly, that changes in posture do not have a significant effect on tidal volume measurements. The absence of postural effects allows this methodology to accurately assess ventilatory parameters in ambulatory subjects. RIP expands current methodologies in that it allows for continuous monitoring of ventilatory parameters over extended periods of time. This added capability will allow for respiratory monitoring during both the awake and sleep states, which is significant since control of respiratory drive differs between the awake and sleep states and drug-induced effects such as sleep apnea or sleep-disordered breathing can have adverse health consequences. Combined with cardiovascular telemetry, this methodology will also allow for the combined monitoring of cardiovascular and respiratory parameters in conscious, non-restrained dogs.

PROCEDURE

6.4.1 Animal Acclimation

Non-restrained dogs are acclimated to wearing a custom-fit jacket, which contains the inductive coil straps and an accelerometer, by placing the jacket on each animal for increasing periods of time up to a target time of approximately 26 h. Acclimation to the jacket on at least one occasion for a period of 4–6 h and a second occasion for 20–24 h is considered an appropriate acclimation schedule, as indicated by the acceptance of the animal of the jacket and no overt evidence of animal stress. Only approximately 10% of dogs are rejected because of poor behavior related to acceptance of these procedures.

6.4.2 Ventilatory Measurements

Ventilatory parameters and an index of airway resistance (phase angle) can be obtained by measuring

thoracic and abdominal excursions using RIP. Respiratory parameters obtained using RIP involve fitting dogs with a custom-fit jacket equipped with inductive sensor straps woven into the jacket to fit around the chest and abdomen to detect chest and abdomen excursions. Respiratory data are transmitted wirelessly from a transmitter inside the jacket to a receiver for input into a data acquisition and analysis system (e.g., Data Sciences International, St. Paul, MN or EMKA Technologies, Falls Church, VA). The analysis software sums the thoracic and abdominal waveforms for each breath to calculate respiratory rate, tidal volume, minute volume, inspiratory and expiratory times, and flows and apneic times (times between breaths). The phase angle (θ) is determined for each breath by plotting the abdominal movement on the abscissa and the thoracic movement on the ordinate to produce figures that are commonly referred to as Konno-Mead loops. The phase angle is calculated using the following equation: $\theta = \sin^{-1}(M/S)$, where θ is the phase angle, M is the distance between the intercepts of the thoracic-abdominal loop on a line drawn parallel to the *x*-axis and which is placed at one-half the distance between the maximal and minimal thoracic excursion, and S is the maximal abdominal excursion (see Fig. 6.3).

The distance between the inductive straps must be adjusted such that one strap is located at the level of the fourth to fifth rib and the other located just caudal to the ribcage. These locations provided for stable measurements, as strap adjustments are not required for measurement periods of up to 24 h. Volume measurements should be monitored during the adjustment of inductive strap tensions to ensure maximal sensitivity. Certain behaviors (e.g., eating/drinking, barking, jumping, panting) noted in non-restrained dogs can produce abnormal volume waveforms that are excluded from data analysis. These behaviors are relatively infrequent and generally account for less than approximately 5% of the total recording time over a 24 h period.

To calibrate volume measurements of the RIP system, a qualitative diagnostic calibration (QDC) and a fixed volume calibration are performed each time the jacket is placed on an animal. QDC computes a calibration factor (k) that defines the proportional relationship between abdominal and thoracic volumes using breaths of constant tidal volume. Fixed volume is used to calculate the total volume amplification factor (M) and uses a known tidal volume that is obtained using a pneumotachograph attached to a facemask that fits over the snout of the dog. Analog flow waveforms from the pneumotachograph are detected by a differential pressure transducer (e.g., Model MP-45, Validyne Engineering, Northridge, CA). The calibration procedure involves (1) fitting the animal with a jacket containing the inductive straps and placing the animal on a table in a prone (standing) position, (2) allowing the animal to take normal breaths for a period of approximately 5 min and calculating the ratio of the standard deviations of the abdominal (ΔV_{AB}) to thoracic (ΔV_T) excursions (ratio = k), (3) placing a face mask with a calibrated pneumotachograph on the animal's snout, and (4) adjusting the amplifier gain until the pneumotachograph and RIP system tidal volume values are identical (amplifier multiple = M). The calibrated tidal volume (ΔV_{cal}) is then calculated using the equation $\Delta V_{cal} = M[(K\Delta V_T) + \Delta V_{AB}]$.

6.5 Distinguishing Central from Peripheral Nervous System Effects of Drugs

PURPOSE AND RATIONALE

Many drugs stimulate or depress ventilation by selective interaction with the central or peripheral nervous system. Thus, distinguishing a central from peripheral site of action is an important part of characterizing the

mechanism of a drug-induced change in ventilation. Noninvasive methods for evaluating the central and peripheral effects of drugs in conscious animals have been developed and involve measuring effects of the test drug on agents known to selectively stimulate ventilation by activating either central or peripheral mechanisms. An assay developed by Murphy et al. (1995) provides a simple, noninvasive method for distinguishing the central from peripheral nervous system effects of respiratory depressant drugs in conscious rats. This technique, however, can also be applied to larger animals such as the dog or monkey. The procedure involves exposing rats for 5 min to an air mixture containing 8% CO_2 (central chemoreceptor stimulant) followed by an intravenous bolus injection of 300 μg/kg sodium cyanide (peripheral chemoreceptor stimulant) and comparing the changes in minute volume and mean inspiratory flow (respiratory drive) before and after drug treatment. Morphine sulfate (3 mg/kg, intravenous), an opioid analgesic that depresses ventilation through a central mechanism, and carotid body denervation (peripheral depressant) were used to initially develop this procedure. The central respiratory depressants phenobarbital (200 mg/kg), xylazine (3 mg/kg), L-2-phenylisopropyladenosine (L-PIA) (1 mg/kg), and gamma-hydroxybutyric acid (GHBA) (300 mg/kg) were subsequently given intravenously to confirm the validity of this procedure. Using this assay, a centrally acting respiratory depressant can be identified by its inhibition of CO_2-induced stimulation of minute ventilation and enhancement of the NaCN-induced stimulation of mean inspiratory flow, whereas a peripherally acting respiratory depressant can be identified by its lack of effect on CO_2-induced stimulation of minute ventilation and its inhibition of NaCN-induced stimulation of mean inspiratory flow.

PROCEDURES

6.5.1 Gas and Sodium Cyanide Exposures

Rats are exposed to gas mixtures using a two-chambered plethysmograph. The body of the animal is enclosed in a head-out chamber that is used to measure ventilatory parameters, while the head is enclosed in a cylindrical plastic headpiece that is attached to the front of the body chamber. A neoprene collar (1/8 in. thick) placed around the neck of the animal is used to seal the plethysmograph chamber and separate the head and body chambers. Specific gas mixtures are delivered from compressed gas tanks to the head chamber at a rate of 2 L/min. All animals are acclimated to the chamber by placement in the chamber for at least three 15-min periods on three separate occasions with compressed air flowing through the head chamber at a rate of 2 L/min. Prior to drug treatment, a catheter is inserted into a tail vein for administration of sodium cyanide. The catheter is exteriorized from the plethysmograph chamber through an opening that is made airtight by sealing with clay. Tail vein catheterization is accomplished using a 1/2 to 3/4 in. butterfly needle (23–25 gauge) attached to an extension set with syringe attachment. The gas mixtures contain either normal breathing air (21% O_2, 79% N_2) or elevated CO_2 (8% CO_2, 21% O_2, 71% N_2). All animals are first exposed to the normal air mixture for 5–10 min and then to the elevated CO_2 mixture for 5 min. The mean value for the 5–10 min exposures to air and high CO_2 are calculated for minute volume and the difference used to quantify the stimulatory effect of CO_2. Following CO_2 exposure, rats are exposed to the normal air mixture until the ventilatory parameters return to normal (generally 5–10 min). Sodium cyanide (300 μg/kg) is then administered as a bolus injection using the tail vein catheter. The peak change in mean inspiratory flow is measured during the 1–3 min period of ventilatory stimulation following the sodium cyanide injection.

6.5.2 Measurement of Ventilatory Parameters

Ventilatory parameters are measured using a head-out, volume displacement plethysmograph chamber (approximately 1–3 L capacity). In this type of chamber, the head is exposed to ambient conditions, while the trunk is enclosed in the chamber (see Fig. 6.4). A seal is made around the neck using neoprene collar (1/8 in. thickness). Pressure changes within the chamber are measured using a differential pressure transducer with a sensitivity of approximately $\pm$ 2 cm H_2O (Model MP-45-14, Validyne Engineering, Northbridge, CA) and the pressure changes converted to flow rates using a pneumotach port (1 in. diameter opening with six layers of 325 mesh stainless steel wire

cloth). The analog flow signal is conditioned using a preamplifier and then sent to a data acquisition and analysis software application (e.g., Life Sciences Suite Po-Ne-Mah Physiology Platform P3 with PCR application, Gould Instrument Systems, Inc., Valley View, OH) for calculation of ventilatory parameters. The values for minute volume and mean inspiratory flow are determined for each breath and average values calculated for every 0.1 min. The mean inspiratory flow (a measure of respiratory drive) is calculated by dividing tidal volume by inspiratory time and minute volume is calculated by obtaining the product of tidal volume and respiratory rate (see Fig. 6.1).

6.6 Continuous Measurement of Expired CO_2

PURPOSE AND RATIONALE

Changes in ventilatory parameters help define the mechanism and potential cause of a respiratory disorder, whereas changes in the partial pressure of arterial CO_2 ($PaCO_2$) define the physiological consequences, or liability, of a ventilatory change. A ventilatory disorder resulting in a decrease in $PaCO_2$ is defined as hyperventilation, whereas an increase in $PaCO_2$ is defined as hypoventilation. Obtaining samples of arterial blood for CO_2 analysis by needle puncture or arterial catheterization during ventilatory measurement is not considered practical since the acute insertion of the catheter or the restraint procedure needed for needle insertion and blood collection can often interfere with respiratory measurements. This is especially true for smaller animals. Furthermore, a blood sample only assesses blood gas status over the short time period that the sample is taken. Measuring changes in the peak concentration of expired CO_2 (end-tidal CO_2) during each breath has been developed as an alternative method for monitoring arterial CO_2 tension in humans and larger animals. End-tidal CO_2 measurements can be performed noninvasively and can be used for the continuous monitoring of arterial CO_2 during ventilatory measurements in conscious animals. With the use of microcapnometry, Murphy et al. (1994) developed a technique that could monitor end-tidal CO_2 in conscious rats during ventilatory measurements. The development of this technique in rats is important as the rat is a model commonly used for assessing ventilatory function in safety pharmacology. This assay was validated by showing that the changes in end-tidal CO_2 were sensitive to changes in ventilation, are sensitive to drug-induced respiratory stimulation or depression, and are quantitatively (linearly) related to changes in arterial CO_2 and O_2 tensions and arterial blood pH.

PROCEDURES

6.6.1 Ventilatory Measurements

Ventilatory parameters are measured using a head-out, volume displacement plethysmograph chamber (approximately 1–3 L capacity). In this type of chamber, the head is exposed to ambient conditions, while the trunk is enclosed in the chamber (see Fig. 6.4). A seal is made around the neck using neoprene collar (1/8 in. thickness). Pressure changes within the chamber are measured using a differential pressure transducer with a sensitivity of approximately $\pm$ 2 cm H_2O (Model MP-45-14, Validyne Engineering, Northbridge, CA) and the pressure changes converted to flow rates using a pneumotach port (1 in. diameter opening with six layers of 325 mesh stainless steel wire cloth). The analog flow signal is conditioned using a preamplifier and then sent to a data acquisition and analysis software application (e.g., Life Sciences Suite Po-Ne-Mah Physiology Platform P3 with PCR application, Gould Instrument Systems, Inc., Valley View, OH) for calculation of ventilatory parameters. The values for tidal volume, respiratory rate, and minute volume are determined for each breath and average values calculated for every 0.1 min.

6.6.2 End-Tidal CO_2 Measurement

End-tidal CO_2 (peak expired CO_2) was measured for each breath with a microcapnometer (Microcapnometer, model 0151-003 L, Columbus Instruments, Columbus, OH, USA). This

microcapnometer is uniquely suited for measurement of expired CO_2 in rats and other animals with low minute volumes (200–400 mL/min) since it utilizes relatively low flow rates (5 or 20 cc/min) compared with the standard capnometers that require 150–200 cc/min. This capability is achieved by using a low-pressure, high-velocity principle for analyzing the sampled gas. Airflow to the microcapnometer is maintained at 20 mL/min and is collected through a Teflon catheter (I.D. = 0.76 mm). Carbon dioxide concentrations are measured spectrophotometrically using standard infrared gas sensor technology and the values are expressed as percentage of total dry air volume. Average values for end-tidal CO_2 are calculated and expressed as numerical output every 0.1 min by the microcapnometer. The waveform and numerical data can be acquired by a computer system for storage and analysis. The microcapnometer is calibrated using an analyzed gas mixture containing 5% CO_2 and 95% O_2.

To convert the percentage CO_2 values measured by the microcapnometer (in dry air and at room temperature) to partial pressure values of CO_2 present in the alveoli (P_ACO_2), the following formula is used:

$$P_ACO_2(\text{mmHg}) = \%CO_2 \times [BP(\text{mmHg}) - P_AH_2O(\text{mmHg})]$$

where BP is the barometric pressure measured at room temperature and P_AH_2O is the partial pressure of H_2O in alveolar gas at body temperature (39°C) and saturated with water.

End-tidal CO_2 is monitored in conscious rats by using a mask that is fitted to the snout of the rat. Since rats are obligate nasal breathers, enclosure of the mouth is not necessary. The distal tip of the nasal mask has an opening (I.D. = 3.5 mm) for breathing through and an attachment site for the tube connecting to the microcapnometer. The mask is held in place with a harness that fits over the head of the animal, and air samples are collected from the tip of the mask. To ensure a comfortable and tight seal around the snout, the inner edge of the plastic mask is coated with silicone foam (Life care®, Lafayette, CO, USA). Dead space associated with the mask is approximately 0.06 cc. All animals should be acclimated to the plethysmograph chamber, harness, and mask on at least five occasions prior to end-tidal CO_2 measurements.

7.1 General Considerations

Safety pharmacology is defined as those studies that investigate the potential undesirable pharmacodynamic effects of a substance on physiological functions in relation to exposure in the therapeutic range and above (ICH-guideline S7A 2001). Safety pharmacology in metabolism pharmacology is of secondary importance in comparison to the safety pharmacology of vital functions (safety pharmacology core battery: cardiovascular, respiratory, and central nervous systems) and therefore listed under "Follow-up and Supplemental Safety Pharmacology Studies (ICH-guideline S7A 2001: Sect. 2.8.2)." In this section of the guideline, the subjects of safety pharmacology in metabolism pharmacology are listed under the topics of "gastrointestinal system" (ICH-guideline S7A 2001: Sect. 2.8.2.3) and "other organ systems" (ICH-guideline S7A 2001: Sect. 2.8.2.4).

In this chapter, pharmacological methods are described for the characterization of candidate compounds on their effects on the gastrointestinal functions (gastric acid secretion, bile secretion, exocrine pancreatic secretion, gastrointestinal motility) and their gastrointestinal injury potential. In addition, there are pharmacological methods described with respect to elucidate the undesirable effect potential of compounds on intermediary carbohydrate and lipid metabolism resulting in hypo- or hyperglycemia, hyperlipidemia, and insulin resistance, which could finally provoke life-threatening hypoglycemia or on the long-run diabetes, atherosclerosis, and obesity.

In principle, every pharmacological assay, which is described in detail by Vogel (2008), can be used for the safety pharmacological characterization of a candidate

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_7, © Springer-Verlag Berlin Heidelberg 2013

compound with respect to safety pharmacology in metabolism pharmacology (Vogel (2008): Activity on the gastrointestinal tract (Chapter J), antidiabetic activity (Chapter K), anti-obesity activity (Chapter L), and anti-atherosclerotic activity (Chapter M). Here, in this part of the book, selections of these assays are presented which primarily meet the ICH guideline (ICH-guideline S7A 2001) and which are appropriately adapted to the characterization of candidate compounds with a different primary indication for the assessment of their pharmacological side effect potential on metabolism pharmacology.

7.2 Gastrointestinal System

7.2.1 General Considerations

If a candidate compound with a totally different primary indication causes additionally an inhibition of gastric acid secretion, this finding may be assessed as additionally beneficial and therefore does not represent a safety concern, irrespective whether these pharmacological effects occur in the pharmacological dose range for the primary pharmacological effect or at suprapharmacological doses as usually used for safety pharmacological studies of a candidate compound. The opposite situation that a candidate compound for a different primary indication causes additionally a stimulatory effect on gastric acid secretion represents always a safety concern due to the risk for induction of gastrointestinal ulcers.

On the other hand, an unrealized antisecretory effect on gastric acid secretion, which might occur at suprapharmacological doses as used for toxicity studies, can become obvious during cancerogenicity studies in rats, resulting in the finding of carcinoids (ECL-cell proliferation) due to the long-lasting increase in gastric pH with subsequently elevated gastrin levels, which functionally and tropically control gastrointestinal enterochromaffin-like cells (ECL cells). This connection between gastric pH, gastrin level, ECL-cell proliferation, and gastric carcinoids has first been demonstrated for the proton pump inhibitor omeprazole (Arnold et al. 1986; Creutzfeldt et al. 1986; Ekman et al. 1985).

Table 7.1 Four main gastrointestinal functions investigated by appropriate test methods for detection of the side effect potential of new drug candidates

Function	Assay/test
Gastric secretion	Pylours-ligated rat
Gastric-intestinal injury	Gastrointestinal ulceration in rats
Transit time	Propulsive gut motility in mice or rats (charcoal)
Gastric emptying assay	Stomach emptying in mice or rats (phenol red)

An acute stimulatory effect on gastric acid secretion as well as a direct effect on reduction of gastric mucus or bicarbonate secretion may finally result in gastric ulcers. An ulcerogenic side effect potential is always a safety issue of a candidate compound and should be carefully investigated. Since nearly 100 years, it has well been known that nonsteroidal anti-inflammatory drugs (NSAID) cause gastric ulcerations, but their molecular mode of action, the inhibition of the cyclooxygenase (COX), the key enzyme in prostaglandin (PGG_2, PGH_2) synthesis, has first been proposed since the early 1970s (Vane 1971). In the meanwhile, different isoforms of the COX enzyme have been identified (Smith et al. 1996). The constitutionally expressed isoenzyme COX-1 represents the dominant isoform in gastric mucosa. To get rid of the ulcerogenic side effect potential of NSAIDs, more selective inhibitors for COX-2 have been developed (Kurumbail et al. 1996; Wolfe 1998).

In the following chapters, a selection of pharmacological methods in gastroenterology is presented which primarily meet the ICH guideline (ICH-guideline S7A 2001) and exceed present practice. To date, only four main tests appear to be widely used by pharmacologists to study gastrointestinal functions in safety pharmacology (Table 7.1; Harrison et al. 2004).

7.2.2 Gastric Acid Secretion (Gastric Ph Measurement)

7.2.2.1 Gastric Acid Secretion in Pylorus-Ligated Rats

PURPOSE AND RATIONALE

The secretory potential of a candidate compound might be under safety aspects much more problematic due to its ulcerogenic potential compared to the antisecretory potential of a candidate compound with a different primary indication.

A simple and reliable method for the measurement of gastric acid secretion and production of gastric ulcers in the rat based on ligature of the pylorus has been published by Shay et al. (1945). Gastric acid secretion can be stimulated by histamine, carbachol, or gastrin. Candidate compounds with antisecretory potential inhibit stimulated gastric acid secretion. The secretory potential of a candidate compound can be studied during basal conditions without administration of a secretagogue.

PROCEDURE (MODIFIED AFTER Shay et al. 1945)

This study is performed in conscious rats with a body weight of 150–170 g. Food is withdrawn 16 h before beginning of the study with water available ad libitum. Following pylorus ligation, performed under ether anesthesia, the candidate compound is administered intraperitoneally (i.p.) or intraduodenally (i.d.). Gastric acid secretion is either studied under basal conditions or stimulated by subcutaneous (s.c.) injection of a secretagogue. The secretagogue is injected again 1 h later. Three hours after the beginning of the experiment, the animals are killed, the stomach excised, and the accumulated gastric juice collected. The three different secretagogues employed are histamine (2 × 20 mg/kg s.c.), desglugastrin (2 × 400 μg/kg s.c.), or carbachol (2 × 40 μg/kg s.c.).

EVALUATION

The volume of the collected gastric juice is measured. Acid concentration is measured by titration against 100 mM NaOH to an endpoint of pH 7. Total acid output (mmol H^+/3 h) is calculated, and percent inhibition of the treated rat group is calculated against the control group. Using various doses, dose-response curves can be established for gastric acid secretion. ID_{50} values can be calculated by probit analysis, whereby 0% corresponds to no and 100% to maximal stimulated gastric acid output.

CRITICAL ASSESSMENT OF THE METHOD

The pylorus-ligated rat has been proven to be a valuable method to evaluate the secretory (vs basal secretion) as well as the antisecretory potential (vs stimulation with histamine, gastrin, or carbachol) of a candidate compound with various secretory or antisecretory mechanisms of action.

For the safety pharmacological evaluation, this method allows the administration of necessary high doses by i.d. or i.p. administration probably as suspension (methylcellulose) irrespective of solubility issues of the candidate compound.

7.2.2.2 Gastric Acid Secretion in Anesthetized Stomach-Lumen Perfused Rats

PURPOSE AND RATIONALE

Originally, Gosh and Schild (1958) introduced a method for the continuous recording of gastric acid secretion in the stomach-lumen perfused anesthetized rat. In this model, gastric acid secretion can be stimulated by histamine, carbachol, or gastrin. Candidate compounds can be pharmacologically characterized for their gastric acid antisecretory potential during stimulated gastric acid secretion.

PROCEDURE (MODIFIED AFTER Gosh and Schild 1958)

Gastric acid secretion in anesthetized rats with a body weight of 300–350 g is used. The animals are fasted for 18 h prior to the experiment with free access to water. Anesthesia is induced by ketamine (20 mg/kg) plus pentobarbital (priming bolus 60 mg/kg i.p. plus infusion s.c. at about 20 mg/kg/h for maintaining constant anesthesia). Body temperature is artificially stabilized by means of a rectal thermometer and a heating pad. The trachea is exposed and cannulated for artificial respiration. The jugular veins are then exposed and cannulated with polyethylene tubes beveled at the tip. The abdomen is opened through a midline incision. The esophagus and pylorus are ligated, and a double lumen perfusion cannula is inserted and fixed in the forestomach. The stomach is perfused continuously with warm (37°C) saline at a rate of 1 mL/min. The perfusate is collected at 15-min periods and its acid concentration measured. Histamine (10 mg/kg/h), desglugastrin (100 μg/kg/h), or carbachol (30 μg/kg/h) are administered by i.v. infusion into the jugular vein after a basal period of 45 min. Ninety minutes after the onset of the secretagogue infusion, acid output has reached a stable plateau (Fig. 7.1). As soon as acid secretion has reached a plateau, candidate compound or standard is injected intravenously.

EVALUATION

The perfusate is collected at 15-min periods, and its acid concentration measured by titration against 100 mM NaOH to an endpoint of pH 7 and acid output

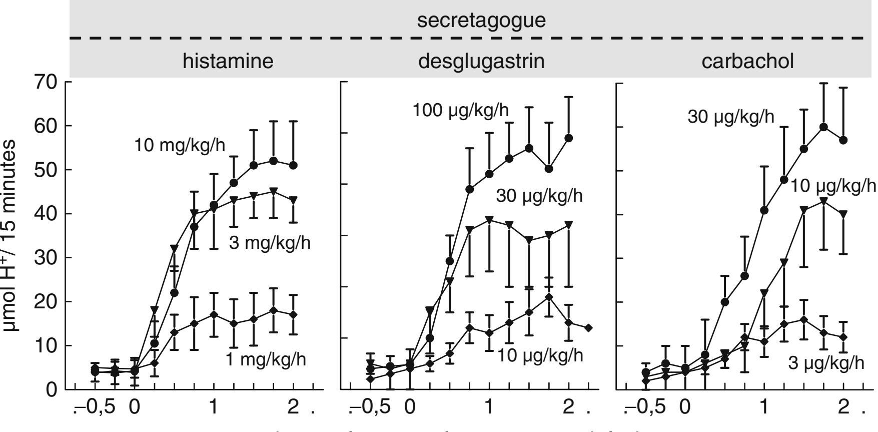

Fig. 7.1 Dose dependency of secretagogue infusion on gastric acid output in stomach-lumen perfused rats. Values are mean ± SEM, $n = 4$–6

(μmol H^+/15 min) are calculated. Using various doses of the candidate compound and of a standard, dose-response curves can be established, and activity ratios with confidence limits can be calculated.

CRITICAL ASSESSMENT OF THE METHOD

For the specific pharmacological assessment of inhibitors of gastric acid secretion, like H_2-blockers, anticholinergics, H^+/K^+-ATPase inhibitors, this method reveals valid results with respect to the antisecretory potential of the candidate compound. Limitations of this methods with respect to safety pharmacological assessment of candidate compounds are (1) only parenteral administration of the candidate compound, preferentially i.v., is feasible and should be preferred and (2) only antisecretory putative side effects can be investigated; this method is of limited relevance to study secretory side effect potential of candidate compounds.

For safety pharmacological assessment of a candidate compound with a totally different inherent primary indication, its antisecretory potential at suprapharmacological doses has to be studied. Therefore, whether this method can be used for the safety evaluation depends on the solubility of the candidate compound for i.v. administration of suprapharmacological doses.

As different pathways of stimulation are exclusively initiated by histamine, gastrin, or carbachol, it is possible to estimate the potential interaction of the candidate compound with the secretory pathways of acid secretion (Herling and Weidmann 1996): Candidate compounds affecting:

1. The H_2-receptor inhibit histamine- and gastrin-stimulated gastric acid secretion.
2. The gastrin receptor inhibit only gastrin-stimulated gastric acid secretion.
3. The muscarinic receptor inhibit only carbachol-stimulated gastric acid secretion.
4. Carboanhydrase activity inhibit gastric acid secretion, irrespective of the kind of stimulation.
5. H^+/K^+-ATPase (gastric proton pump) inhibit gastric acid secretion, irrespective of the kind of stimulation.

MODIFICATIONS OF THE METHOD

Burn et al. (1952) described the evaluation of substances, which affect gastric secretion using perfusion of the stomach in anesthetized cats.

Lawrence and Smith (1974) described the measurement of gastric acid secretion in the rat by conductivity. The stomach of an anesthetized rat is continuously perfused with 2 mL/min of an isotonic (0.308 M) glucose solution at 37°C. The conductance of a solution depends on the total ion concentration and is therefore not specific for hydrogen ions. Since hydrogen ions have an equivalent conductance nearly five times greater than any other ion found in gastric juice and since they are secreted in a far greater concentration than other ions, conductivity measurements can be regarded as a relatively specific measure of hydrogen ions. Using Mullard conductivity cells (type E 791/B) and a commercially available meter (Phillips PW 9501), simultaneous measurements in six rats were performed.

Gallo-Torres et al. (1979) described in detail a method for the bioassay of antisecretory activity in the conscious rat with acute gastric fistula with additional collection of the biliary and pancreatic secretion by means of a catheter in the common bile duct. The gastric secretions are collected by gravity via a cannula in the most gravity-dependent site of the glandular stomach.

Larsson et al. (1983) described studies in the acutely vagotomized rat. Truncal vagotomy is performed under ether anesthesia by cutting the dorsal and ventral branches of nervus vagus just below the diaphragm. The pylorus is then ligated, and a polyethylene catheter (PP 200) is inserted into the duodenum, close to the pylorus. Each animal is placed in a modified Bollman cage and is allowed to recover at least 1 h before the experiment. Gastric juice is collected by free drainage in 30 min samples.

Herling and Bickel (1986) showed that gastric acid secretion in stomach-lumen perfused rats can be stimulated in vivo on the subreceptor level by IBMX (phosphodiesterase inhibitor) and forskolin (nonreceptor activation of the adenylate cyclase). H^+/K^+-ATPase inhibitors and H_2-antagonists show, according to their different modes of action, also a different inhibitory profile in this assay.

Hammer et al. (1992) used anesthetized female Sprague-Dawley rats weighing 200–320 g. After insertion of a tracheal cannula, a 3-mm silicon tubing is placed through the mouth and advanced to the stomach. The tubing is tied to the esophagus at the neck. A 4-mm drainage tube is inserted into the stomach through a laparotomy incision and an incision in the duodenum and ligated in place at the pylorus.

Gastric perfusate (0.9% saline at 37°C) is collected on ice every 5 min for titration to pH 7.0.

7.2.2.3 Gastric Acid Secretion in Conscious Dogs (Chronic Heidenhain-Pouch Fistula in Dogs)

PURPOSE AND RATIONALE

ICH-guideline S7A (2001: Sect. 2) recommended the use of unanesthetized animals for the safety pharmacological assessment of candidate compounds. The preparation of a chronic gastric pouch, as described by Heidenhain in 1878, is one of the classic techniques in experimental surgery. This model has much contributed to the understanding of the physiology and pathology of the stomach and to modern techniques of abdominal surgery in man. The surgical technique has been described again in detail by deVito and Harkins (1957). A preparation of chronic denervated pouches in the rat has been described by Alphin and Lin (1959). Both preparations can be used as pharmacological models for testing antisecretory drugs.

PROCEDURE

The principle technique is demonstrated in Fig. 7.2. Dogs weighing 15–20 kg are fasted 24 h preoperatively. The abdominal surgery is performed during appropriate anesthesia (in former times by, e.g., 30 mg/kg pentobarbital sodium; nowadays, more appropriate by inhalation with halothane or isoflurane). The abdominal part is shaved with electric clippers, then with a razor. The skin is disinfected with a surface disinfectant (e.g., Zephiran®-70% alcohol). Sterile drapes are applied to cover the whole surgical field. A midline linea alba incision from xiphoid to umbilicus provides excellent exposure and ease for closure. As the posterior sheath is divided, the large ventral fat pad present in dogs should be excised completely. A self-retaining retractor is applied, and the stomach is palpated for the absence of food. Then, the spleen is displaced, wrapped in warm, moist pads and laid on the ventral wall below the incision.

The stomach is pulled into the operative field. The greater curvature is held at multiple points so that the stomach is stretched out and the line of incision for the pouch is selected. The pouch should be made from the corpus of the stomach so that true parietal cell juice can be obtained. A line projected from the incisura angularis perpendicular to the proximal lesser curvature will generally fall across the junction between corpus and antrum. Appropriate division of the gastric branches of the right gastroepiploic artery at the lower end of the proposed line of transsection clears the greater curvature for 1–2 cm. The gastroepiploic artery itself should be sectioned at this site and a long rent formed on the adjacent omentum, else the omentum vessels tend to tear during subsequent manipulations.

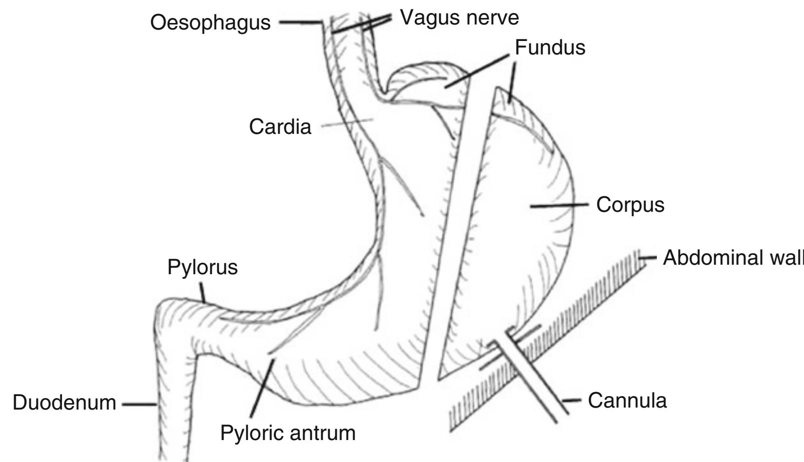

Fig. 7.2 Technique of Heidenhain-pouch fistula in dogs

An index finger is then inserted through this defect dorsal to the stomach to emerge higher on the greater curvature through the gastrosplenic ligament at the upper end of the proposed line of transsection. This portion of the greater curve is cleared for 1–2 cm. Von Petz clamps with their staplings are used to control bleeding and to avoid leakage of gastric content. The stomach should be kept stretched and flattened while the clamps are applied. After division between the staples, any bleeding is controlled, and the cut edges of the main stomach and pouch are then oversewn with continuous sutures of black silk. The suture should be of an inverting type. Surprisingly, leakage or excessive adhesions are not a problem when serosal apposition is neglected.

The pouch so formed is about 30% of the corpus volume and provides adequate secretory volume for further studies (Fig. 7.2). A cannula, made of stainless steel, 7 cm long with a beveled flange threaded at the other end is placed in the most ventral portion of the pouch through a small incision in the anterior wall. A single purse string of silk holds it in place. A double sheet of omentum is then wrapped about the pouch and the cannula before being pulled through the abdominal wall, about 3 cm to the left of the midline subcostally. It is important that the cannula be held snugly by fascia; otherwise, it will readily pull out of the pouch and abdominal wall. The linea alba is closed with a continuous suture of silk and the skin with subcuticular stitches of chromic catgut. On the outside of the cannula, a stainless steel jacket is screwed. The cannula is always open so that secreted gastric juice does not accumulate within but is drained from the pouch.

Before recovery from anesthesia, the dog receives 500 mL 5% glucose in saline intravenously. The same volume is given for 3 days postoperatively together with oral fluid ad libitum. From the fourth day onward, normal food is given. A period of 7–10 days is required for full recovery from the operation. Special care has to be taken for each animal being kept separately in a suitable cage.

For pharmacological studies, food is withdrawn 18 h prior to the experiment with water ad libitum. The animals are placed in Pawlow stands during the experiment of gastric secretion measurement, and a tube is fitted to the cannula to collect the gastric juice from the pouch for measurement of volume and acidity by titration. To test the secretory potential of a candidate compound, which might represent a direct safety concern, the candidate compound is studied under basal (nonstimulated conditions) and administered orally or by i.v. injection or infusion, and the gastric acid secretion from the pouch is measured in intervals of 15 or 30 min. The values are compared to the predrug secretion values and to a respective control group.

For testing the antisecretory potential, gastric acid secretion is stimulated either by i.v. infusions of histamine (0.1 mg/kg/h), carbachol (10 μg/kg/h), or pentagastrin (8 μg/kg/h). When stimulated gastric acid secretion has reached a stable plateau (after 1.5 h), the candidate compound is administered orally or by i.v. injection, and secreted fluid is collected at 15- or 30-min intervals and analyzed for free HCl.

EVALUATION

The secreted volume per time interval is measured. An aliquot is used for the determination of acidity by

titration against 100 mmol/L NaOH, and total acid output per time interval is calculated. The effect on volume and HCl secretion at 15- or 30-min intervals after administration of the test compound is compared with the control values. Mean inhibition of stimulated gastric acid secretion can be calculated according to the formula:

$$\text{Mean inhibition } (\%) = -\left(\left(\left(\frac{-\frac{SAO_{postdrug}}{N_{postdrug}}}{AO_{predrug}}\right) * 100\right) - 100\right)$$

$SAO_{postdrug}$ = sum of acid output per 30 min after compound administration
$N_{postdrug}$ = number of 30 min collection intervals after compound administration
$AO_{predrug}$ = acid output prior compound administration

In addition to the total acidity of the secreted juice also pepsin, total activity can be determined by appropriate enzymatic methods.

MODIFICATIONS OF THE METHOD

Boldyreff (1925) described a simplified method for isolation of a portion of the stomach as compared to the original method of Heidenhain (1878).

Gastric motility can be measured by balloon manometry of the Heidenhain pouch in the conscious dog. The animals are deprived of food for 18 h before the experiment, but water is allowed ad libitum. A latex balloon, connected via a polyethylene catheter to a pressure transducer (Statham P 23 BB), is introduced through the fistula cannula into the accessory stomach. Changes in intragastric pressure are measured on a frequency measurement bridge and are recorded continuously. The number and height of the pressure waves are used as indices of gastric motor activity. Secretin inhibits gastric motility dose dependently. After injection of gastrin or gastrin analogues, a dose-dependent increase of pressure is noted over a wide dose range.

Jacobson et al. (1966, 1967) studied gastric secretion in relation to mucosal blood flow by an antipyrine clearance technique in conscious dogs with vagally denervated gastric fundic (Heidenhain) pouches. A vagally denervated fundic pouch is so constructed that the entire arterial blood supply is delivered by the splenic artery. A noncannulating transducer (electromagnetic flowmeter) and a hydraulic occluder were implanted on the vessel.

The Heidenhain pouch preparation was used by Carter and Grossman (1978) and Kauffman et al. (1980) to study the effect of luminal pH on acid secretion evoked by topical and parenteral stimulants and the effect of topical and intravenous 16,16-dimethyl prostaglandin E_2 on gastric bicarbonate secretion.

Baker (1979) and Roszkowski et al. (1986) developed a modified Heidenhain dog pouch preparation for collecting gastric juice exclusively from the pouch during experimental periods but allowed the pouch to be an integral part of the gastrointestinal tract during nonexperimental periods. The pouch is prepared using conventional techniques, but instead of being fitted with a simple cannula through the abdominal wall, a three-way cannula is used which provides passage between the exterior orifice, the pouch, and the main body of the stomach. By inserting an appropriate adapter, passage is available only to the pouch and not to the main stomach or vice versa.

The Heidenhain pouch technique in dogs has been used for preclinical evaluation of various drugs, such as:

- A histamine H_2 antagonist by Uchida et al. (1993).
- Dual histamine H_2- and gastrin-receptor antagonists by Kawanishi et al. (1997).
- A 5-HT_4-receptor antagonist by Bingham et al. (1995).
- Another 5-HT_4-receptor antagonist by Wardle et al. (1996).
- Inhibition of motilin-induced phase III contractions by pentagastrin by Yamamoto et al. (1994).
- Peptide YY by Zai et al. (1996).
- Reversible K^+-competitive inhibitors of the gastric H^+/K^+-ATPase by Parsons et al. (1995).
- The antiulcer agent SWR-215 by Kataoka et al. (1997).
- A selective gastrin-/CCK-B-receptor antagonist by Yuki et al. (1997).
- Descroix-Vagne et al. (1993) used Heidenhain pouch preparations in cats and rabbits to study the effect of perfusion at pH 5.5 on acid and pepsin secretion.
- For identification of the KCNQ1 protein as the K^+-channel colocalized with the H^+/K^+-ATPase at the

apical membrane of the gastric parietal by studying the gastric acid inhibitory potential of the tool compound 293B (inhibitor of KCNQ1) cell by Grahammer et al. (2001).

CRITICAL ASSESSMENT OF THE METHOD

Due to the surgical procedure, the connections of the autonomic nervous system of the isolated pouch are interrupted from those of the main stomach. Therefore, basal gastric acid secretion from the pouch, which based mainly on the parasympathetic activity, is reduced.

7.2.2.4 Effect of Candidate Compounds with Antisecretory Potential on Serum Gastrin Levels

PURPOSE AND RATIONALE

It is known from long-lasting and potent gastric acid inhibition caused, e.g., by the H^+/K^+-ATPase inhibitor omeprazole that the total acid blockade initiates a gastric antral feedback mechanism resulting in an excessive hypergastrinemia (Arnold et al. 1986; Creutzfeldt et al. 1986; Larsson et al. 1986) which is believed to cause diffuse endocrine cell hyperplasia, characterized as carcinoids, in the gastric corpus after 2 years of treatment (cancerogenicity study) in the rat (Ekman et al. 1985).

PROCEDURE

Groups of 10–15 rats weighing 90–110 g are treated daily for 10 weeks with the candidate compound (omeprazole as standard at doses of 10 or 30 mg/kg p.o.). After treatment for 2, 4, 7, and 10 weeks, blood samples are collected under ether anesthesia by retroorbital puncture. Gastrin is determined by a commercially available radioimmunoassay kit. At the end of the study of 10 weeks, the animals are studied for their gastric acid output using the pylorus ligation (Shay technique).

EVALUATION

Serum gastrin levels are determined as pg/mL. Statistical differences ($p < 0.05$) are calculated using appropriate statistical methods.

MODIFICATIONS OF THE METHOD

Katz et al. (1987) described a 5-day test to predict the long-term effects of gastric antisecretory agents on serum gastrin in rats.

7.2.3 Bile Secretion

7.2.3.1 Bile Secretion in Mice

PURPOSE AND RATIONALE

The effect on bile secretion of a candidate compound can be studied in mice by weighing the gall bladder filled with bile. This simple method was first published by Litvinchuk (1976). With respect to the safety assessment of candidate compounds, a decreased bile secretion (compound-induced cholestasis) predominantly represents a safety issue.

PROCEDURE

Groups of ten mice weighing 15–20 g are used. Food, but not water, is withdrawn 24 h prior to the experiment. The test compound or the control solution is administered subcutaneously or orally. After 1 h, the animals are sacrificed and bled from the carotid artery. Laparotomy is performed, the liver exposed, and a no. 75 silk ligature is tied around the cystic duct, which is detached from the bile ducts and removed from the peritoneal cavity. If a large volume of bile has been accumulated, the full gall bladder is removed together with the bile ducts. The isolated gall bladder is weighed on a suitable balance; after which the contents are removed, the gall bladder walls are washed with distilled water and dried on filter paper, and the organ is weighed again. The difference in weight of the full and the empty gall bladder indicates the quantity of bile secreted during a measured time. The concentration of cholates, bilirubin, and cholesterol in the bile can be determined.

EVALUATION

The average of secreted bile in groups of ten treated mice is compared with the average value of the control group using appropriate statistical methods.

CRITICAL ASSESSMENT OF THE METHOD

The method has the clear advantage of simplicity but does not measure the true bile excretion since the outflow from the bile bladder during the test period is neglected.

MODIFICATIONS OF THE METHOD

Sterczer et al. (1996) studied the effect of cholagogues on the volume of the gallbladder in healthy dogs fasted for 24 h by two-dimensional ultrasonography. The volume was measured immediately before the administration of each test substance and at 10-min intervals for 120 min thereafter.

7.2.3.2 Bile Secretion in Anesthetized Rats

PURPOSE AND RATIONALE

In contrast to other animals, rats do not possess a bile bladder. Therefore, cannulation of the bile duct in rats can be used as a suitable model to measure choleretic (increased bile production) or cholestatic (decreased bile production) side effect potential of drug candidates. If the test compound reduces bile production, it is recommended to investigate a putative hyperlipidemic side effect potential of the drug candidate by its influence on total blood cholesterol and triglycerides in appropriate experimental methods.

In addition, this method of the bile fistula rat can be used for ADME profiling of drug candidates with respect to a hepatobiliary elimination potential (high first-pass effect) (Herling et al. 2002).

PROCEDURE

Bile secretion is studied in anesthetized bile fistula rats, which are anesthetized by an intraperitoneal injection of ketamine (20 mg/kg) plus pentobarbital sodium (60 mg/kg), tracheotomized, and one jugular vein per rat is cannulated for intravenous administration (bolus injection or infusion of the drug candidate). Anesthesia is maintained for up to 7 h by subcutaneous infusion of pentobarbital sodium (adjusted to the anesthetic depth of the individual animal; about 24 mg/kg/h). Body temperature is monitored with a rectal probe thermometer, and temperature is maintained at 37°C by means of a heated surgical plate.

After laparotomy, the common bile duct is cannulated in the upper half with polyethylene tubing, and bile is collected every 30 min up to 7 h. The drug candidate is administered at an appropriate dose by bolus injections intravenously into the jugular vein 1 h after finishing surgery or by intraperitoneal administration of a 1% carboxymethylcellulose suspension, if not adequate soluble for an intravenous formulation. The volume of excreted bile per 30 min is determined gravimetrically (difference between tube weight without and with bile per collection period) with the assumption that 1 g is equivalent to 1 mL of bile. According to our experience, bile flow is stable for up to 3 h (200–300 μL/30 min) and can decline later due to the interruption of the enterohepatic circulation of bile acids; if not, the secreted bile is reinjected into the ileum.

For ADME purposes, the concentration of the parent test compound in the bile is measured by appropriate analytical methods, and total compound excretion is calculated from the secreted volume and the measured concentration of the test compound in the bile of each sampling interval.

For determination of the side effect potential of a candidate compound on choleresis or cholestasis, groups of at least six rats are used for control (vehicle control) and treated groups (rats receiving one dose of the test compound per group). For ADME purposes, smaller groups are sufficient ($n = 3$–4) to determine hepatobiliary elimination of the test compound. Ideally, the analytical method includes the determination of major metabolites appearing in the bile.

EVALUATION

Mean values (μL bile/30 min) for each group are calculated and compared to that of the control group. If bile flow is affected by the test compound detailed analysis of the bile with respect to cholesterol, bile

acids and phospholipids should be performed to elucidate the underlying mechanism.

For ADME purposes, the amount of hepatobiliary-eliminated compound plus metabolites are calculated per collecting interval, and total excreted amount over the whole experiment can be calculated and can be set into relation to the total administered dose per animal.

MODIFICATIONS OF THE METHOD

Several authors tested the choleretic activity of plant extracts and essential oils (De la Puerta et al. 1993; Peana et al. 1994; Trabace et al. 1994) and of synthetic compounds (Grella et al. 1992; Paglietti et al. 1994) in rats.

Tripodi et al. (1993) investigated the anticholelithogenic and choleretic activities of taurohyodeoxycholic acid by measurement of biliary flow and biliary solids content in rats.

Bouchard et al. (1993) induced cholestasis in rats by treatment with 17-α-ethinyl estradiol and studied the influence of oral treatment with ursodeoxycholic and tauroursodeoxycholic acids.

Miki et al. (1993) investigated the metabolism and the choleretic activity of homochenodeoxycholic acid in hamsters with bile fistula.

Pesson et al. (1959) recommended the guinea pig as the best choice among the common laboratory animals to study choleretic agents.

Matsumura et al. (1996) analyzed hypercholeresis in dogs with pigment gallstones after cholate infusion.

CRITICAL ASSESSMENT OF THE METHOD

The method is simple and provides reliable results during terminal anesthetized conditions. Intraduodenal administration of the test compound, which is also reported in the literature, should be avoided due to the fact that intestinal absorption is obviously impaired during the reduced intestinal motility during anesthesia. The interrupted enterohepatic circulation should be taken into account when extrapolating the results (choleretic and cholestatic potential) to the intact organism.

7.2.3.3 Bile Secretion in Conscious Rats (Chronic Bile Fistula Rats)

PURPOSE AND RATIONALE

ICH-guideline S7A (2001: Sect. 2) recommended the use of unanesthetized animals for the safety pharmacological assessment of candidate compounds. Most of the techniques for collection of bile in rats use restrained or anesthetized animals. Such factors as well as the surgical intervention itself may profoundly influence the results. Therefore, Remie

et al. (1990, 1991) developed a technique for a permanent double bile fistula in rats. The procedure is described in detail.

PROCEDURE

Preparation of Cannulae

Cannulae are made of silicon rubber. The proximal bile cannula, which will be inserted into the common bile duct in the direction to the liver, is 18 cm long (e.g., Silastic tubing, Dow Corning, no. 605–135; 0.51 i.d. and 0.94 o.d.) and has one square cut and one beveled end. Two silicon rings are wrapped around the cannula at 7 mm and 50 mm, respectively, from the beveled end.

The distal bile cannula, which will be inserted into the common bile duct in the direction of the gut, is made of the same material, is also 18 cm long and has one square cut and one beveled end. This cannula, however, must have a smaller tip diameter (e.g., Silastic tubing, Dow Corning, no. 605–105: 0.31 i.d. and 0.64 o.d.). To serve this purpose, the square cut end of the cannula is immersed in ether, causing the tubing to dilate. When the tubing is wide enough, a 13-mm piece of small diameter Silastic tubing is inserted. Subsequently, two silicon rings are wrapped around the cannula, one at the joint of the two tubes and the other 5 cm from the tip. The tip is then cut at a 45° angle, 7 mm from the first silicon ring.

The duodenal cannula (Silastic tubing, Dow Corning, no. 605–135) is also 18 cm long and has one square and one beveled end. An additional ring is placed 30 mm from the tip. Before the cannulae are fixed to the skull, they must be connected to a stainless steel needle bent in a 90° angle.

Anesthesia

The animal is anesthetized by inhalation with isoflurane or halothane/N_2O/O_2.

Preparation of the Crown of the Head

The head of the animal is shaved and disinfected. An incision of about 1 cm is made and the bregma exposed. Three stainless steel screws (1.0 × 4.2 mm) are mounted in the crown, two in the left and one on the right side of the bregma. The screws are tightened that approximately 2 mm is left between the skull and the head of the screws.

Double Cannulation of the Bile Duct

The abdominal wall is shaved and disinfected, and the animal is secured on the operation board with adhesive tape. A midline incision is made from the level of the pubic bones to the xiphoid cartilage. The abdomen is then opened by making an incision over the linea alba toward the sternum up to the distal part of the fourth sternebra, thus exposing the xiphoid cartilage.

Then, the intestines are lifted out and are laid next to the animal on moistened gauze. Using jeweler's forceps, the bile duct is stripped off its surrounding tissue and ligated with a 7–0 suture. The duct is placed under tension with an artery forceps for cannulation. With the aid of a microscope, a V-shaped hole is made just cranial of the first ligature with iridectomy scissors. The sterile proximal cannula is inserted into the duct. The second ligature is tied and pulled tight ensuring that the cannula is not obstructed. The bile is now flowing into the cannula. The first ligature is released and the threads are tied behind the silicon ring. The rat is then turned and the ligature reclamped, thereby putting the distal part of the duct under tension. A third ligature is loosely introduced around the duct, distal to the first ligature. Another V-shaped aperture is made between the first and third ligature for insertion of the distal bile cannula. The third ligature is tied and pulled tight. The first ligature is released from the artery forceps and tied around the second cannula behind the silicon ring. All the loose threats are cut close to the knots. The sections of the cannulae, which lie between the silicon rings, are placed kink-free in the abdominal cavity. The cannulae are fixed using 7–0 silk suture to the abdominal muscle near the xiphoid cartilage.

Cannulation of the Duodenum

After location of the place where the bile duct enters the duodenum (sphincter of Oddi), a four fine-stitch purse-string suture (7–0) is made in the wall of the duodenum at the outer border at about 1 cm proximal to the sphincter. Using a 20G needle, an incision is made inside the purse string. The cannula is inserted into the duodenum until the first, smaller silicon ring has entered the lumen, and the purse string is tightened between the first and the second ring. This cannula together with the bile cannula is placed kink-free in the abdominal cavity and anchored to the internal muscle. The abdomen is closed of resorbable sutures leaving 1 cm of the skin unclosed.

Subcutaneous Tunneling and Anchoring of the Cannulae

From the back of the neck, a slender needle holder is pushed subcutaneously through the connective tissue in caudal direction as near as possible to the skin down to the xiphoid cartilage. The cannulae are then grasped and pulled through to emerge at the crown of the head. The abdominal wall is closed completely.

With a 5-cm piece of polyethylene tubing (0.75 × 1.45 mm), the two long ends of the L-shaped stainless steel adapters are connected and the short ends inserted into the respective cannulae. The cannulae together with the tubing are fixed to the skull with acrylic glue flowing under the heads of the screws.

Postoperative Care

The animals are allowed to recover in a warm and quiet place. They reach usually preoperative weight within 2–3 days and display normal feeding and drinking behavior. Supplementation with saline besides the normal tap water may be necessary.

Collection of Bile

The animals are housed in individual metabolic cages. For bile collection, they are attached to long-swiveled PE cannulae (0.75 × 1.45 mm). A stainless steel coil is used to protect the rats from gnawing on the tubing. For continuous collection of bile, the cannula can be connected to a fraction collector.

CRITICAL ASSESSMENT OF THE METHOD

Among other applications, the method is suited to study the enterohepatic circulation of compounds. There should be a close health monitoring of the chronically prepared rats, and only those in a very good health conditions should be used for the study to avoid any misinterpretations of the results.

MODIFICATIONS OF THE METHOD

Castilho et al. (1990) studied the intestinal mucosal cholesterol synthesis in rats using a chronic bile duct-ureter fistula model. Male Wistar rats weighing 300–350 g were anesthetized with 50 mg/kg pentobarbital i.p. and submitted to a bile duct-right ureter fistula utilizing a PE-50 catheter after a right-kidney nephrectomy.

Cohen et al. (1992) reported a study in male black-tailed prairie dogs (*Cynomys ludovicianus*) weighing 1.0 ± 0.2 kg anesthetized with 20 mg/kg xylazine i.m. and 20 min later with 100 mg/kg ketamine i.m. Through an abdominal incision, the cystic duct is ligated, and gallbladder bile is aspirated. A PE-50 polyethylene cannula is inserted into the common bile duct and secured with silk sutures, thereby completely diverting bile flow for collection. The bile duct cannula is externalized, the abdominal incision closed, and the prairie dog placed in a restraining cage with access to food and water.

7.2.3.4 Bile Secretion in Conscious Dogs (Chronic Bile Fistula in Dogs)

PURPOSE AND RATIONALE

ICH-guideline S7A (2001: Sect. 2) recommended the use of unanesthetized animals for the safety pharmacological assessment of candidate compounds. Herrera et al. (1968) described a special cannula, which can be

used to obtain bile or pancreatic juice from a duodenal pouch after appropriate surgical procedures in conscious dogs.

PROCEDURE

Male Beagle dogs weighing 15–20 kg are used. The abdominal surgery is performed during appropriate anesthesia (in former times by, e.g., 30 mg/kg pentobarbital sodium; nowadays, more appropriate by inhalation with halothane or isoflurane). The abdomen is opened through a midline epigastric incision. The duodenum is mobilized at the pyloric and jejunal ends, and a 5-cm duodenal segment containing the common bile duct is isolated. The distal stoma of the duodenum is closed and continuity restored by end-to-side duodenojejunostomy. The duodenal pouch is closed at both ends.

The cannula to be inserted is made of stainless steel and consists of three parts. The main casement measures 10.5 cm in length, with an external diameter of 1.0 cm. The internal end is flanged, and 1.5 cm from this point, there is a short lateral limb, also 1.5 cm in length. The lateral limb is also flanged but, in addition, possesses a small V-shaped defect to facilitate insertion into the pouch. When not in use, the cannula is sealed from the exterior by inserting a threaded plug which allows bile to enter the duodenum in the normal manner. For collection of bile, this plug is removed and a long obturator is inserted. The latter effectively isolates the bile secretion from duodenal contents. A similar hollow obturator is reserved for use when duodenal perfusion is studied, the obturator being connected via a plastic tube to the irrigating fluid.

Through a small antimesenteric incision in the duodenal pouch, the lateral limb of the cannula is inserted; the V-shaped defect in the flange facilitates entry into the pouch. A purse string secures the cannula in position. The defunctioned loop of duodenum is then brought anterior to the pancreas, and the remaining limb of the cannula inserted through a small duodenotomy and secured by a further purse-string suture. The whole system is then generously wrapped in omentum, and the cannula exteriorized through a stab incision toward the flank. An external collar stabilizes the cannula. The cannula is left open to drain blood and secretions for 24 h postoperatively, after which time the plug is inserted. Physiologic saline is administered subcutaneously for a period of 3 days, after which the animals are permitted to drink water. Daily checks of the cannula are advisable to ensure that the plug remains tight. The animals receive normal kennel food and water ad libitum.

The dogs are allowed at least 4 weeks to recover. Eighteen hours prior to the experiment, food is withdrawn but water allowed ad libitum. The long hollow obturator is inserted and bile collected for 15-min periods. After 1 h pretest time, the test compound is given either orally or intravenously.

EVALUATION

Secretion of bile is measured at 15-min intervals, and volume and bile contents are determined from 1-mL samples. The values are compared with pretest data. The remaining bile is reinfused into the duodenum via the hollow obturator.

MODIFICATIONS OF THE METHOD

Boldyreff (1925) described several techniques for fistulae of the gall bladder and also for the fistula of the ductus choledochus in dogs.

An abdominal incision about 10 cm is made on the median line. The duodenum is pulled out, and the orifice of the large (first) pancreatic duct is found. The orifice of the ductus choledochus with the orifice of the small (second) pancreatic duct is situated on the other side of the intestine some 2 or 3 cm nearer the stomach. The ductus choledochus goes straight from the gallbladder to the duodenum; further, it lies parallel its end and is attached to the wall of the duodenum. The small pancreatic duct goes from the gland straight to the duodenum.

At the very beginning of the operation, it is useful to cut the ligamentum that goes from the liver to the duodenum, because this facilitates orientation and operating. It is necessary to cut out a piece of the intestinal wall with the orifice of the ductus choledochus. But before this, one must prepare off a little bit the intestine from the pancreas so as to be able to close conveniently and securely the hole in the intestine and divide between double ligatures the second pancreatic duct.

On the duodenum around the orifice of the ductus choledochus, an incomplete oval figure is now marked with a knife, so that the duct enters this figure through the incomplete part of the oval and has its orifice in the middle of this figure. The length of the oval is about 1.5 cm and its width 1 cm. A suture is then made on the edge of this oval, which is cut out not completely but

leaving a small bridge about 0.5 cm wide between the intestine and the oval; through the bridge, the duct enters the oval. The mucosa of this bridge must be completely destroyed with a knife.

The oval piece of the intestine is now turned with the mucosa up, and its serosa is sutured to the serosa of the intestine. The hole in the intestine is very carefully closed with two layers of sutures. Two heavy threads are then passed underneath the intestine on either side of the place of operation; they are laid through the abdominal wall and tied after the operation is over. They serve as temporary supporting sutures. The oval piece of the intestine is now sutured with the skin of the abdominal wound, and the wound is closed in the usual manner. The supporting sutures must be taken out 1 day or 2 days after the operation.

CRITICAL ASSESSMENT OF THE METHOD

There should be a close health monitoring of the chronically prepared dogs, and only those in a very good health conditions should be used for the study to avoid any misinterpretations of the results.

7.2.4 Exocrine Pancreatic Secretion

7.2.4.1 Exocrine Pancreatic Secretion in Anesthetized Rats

PURPOSE AND RATIONALE

The effect of a candidate compound on pancreas secretion can be measured in rats with acute pancreas fistula. For safety pharmacological assessment of candidate compounds, the decrease of exocrine pancreatic secretion might be problematic due to the potential of induction of pancreatitis.

PROCEDURE

Rats weighing 150–200 g are used. Eighteen hours prior to the experiment, food is withdrawn with free access to water. The appropriate size of the study groups for the control and candidate compound consists of 5–7 animals. Anesthesia is induced by ketamine 20 mg/kg plus pentobarbital (priming bolus 60 mg/kg i.p. plus infusion s.c. at about 20 mg/kg/h). Body temperature is artificially stabilized by means of a rectal thermometer and a heating pad. The trachea is exposed and cannulated for artificial respiration. The abdomen is opened by a midline incision and the pylorus is ligated. The proximal part of the bile duct is ligated near the hepatic porta. The bile is drained via a thin polyethylene tube into the duodenum. The distal part of the bile duct with the orifices of pancreatic ducts is cannulated with another thin polyethylene tube. The pancreatic juice is collected in Eppendorf tubes, and secreted volume is measured gravimetrically or by graduated microsyringes every 15, 30, or 60 min. After a pretest period of 60 min, the test compounds are applied intravenously or intraduodenally.

EVALUATION

The secretion after injection of the test compound is compared with the pretest values. Secretin or cholecystokinin (CCK) increases pancreatic secretion volume in a dose-dependent manner and can be used as a positive standard.

MODIFICATIONS OF THE METHOD

Guan et al. (1990) inserted two separate cannulae for bile and pancreatic juice to rats under methoxyfluorane anesthesia. Both fluids were returned to the intestine. Placing the rats in modified Bollman-type restraint cages, experiments could be performed after a few days in conscious animals.

Ito et al. (1994) studied the inhibition of CCK-8-induced pancreatic amylase secretion by a cholecystokinin type-A-receptor antagonist in rats.

Niederau et al. (1989) compared the effects of CCK-receptor antagonists on rat pancreatic secretion in vivo. Output of amylase in pancreaticobiliary secretion was measured after various doses of cerulein. The effects of high cerulein doses were dose dependently inhibited by CCK antagonists.

Alvarez and Lopez (1989) studied the effect of alloxan diabetes on exocrine pancreatic secretion in the anesthetized rabbit. After a 14–15 h fasting period,

but with free access to water, rabbits weighing about 2.0 kg are anesthetized by intravenous injection of 1.0 g/kg urethane. After tracheotomy, a median laparotomy is performed; the main pancreatic duct is exposed and cannulated near its entrance to the duodenum following ligation of the pylorus and cannulation of the bile duct for deviation of bile to the exterior.

Kim et al. (1993) studied the effect of [(CH_2NH) 4,5] secretin on pancreatic exocrine secretion in guinea pigs and rats using an acute pancreatic fistula preparation.

Niederau et al. (1990) and Tachibana et al. (1996) determined pancreatic exocrine secretion in mice. Because the cannulation of mouse pancreatic duct is not possible for technical reasons, the amount of amylase was determined in vivo. Five minutes after i.v. administration of candidate compounds, mice were sacrificed and a 5 cm-duodenal loop was removed. The duodenal contents were washed out with 1.0 mL ice-cold saline and collected for amylase activity.

7.2.4.2 Exocrine Pancreatic Secretion in Anesthetized Dogs

PURPOSE AND RATIONALE

To collect pancreatic secretion in dogs, three animal models have been developed: pancreatic fistulas, duodenal pouches (which collect the exocrine pancreatic secretion), and duodenal fistulas (through which a thin cannula is inserted into the pancreatic duct). With the exception of acute studies in anesthetized animals, pancreatic fistulas were used mainly during the first half of the twentieth century and have rather historic significance. The latter two methods, duodenal pouches and duodenal fistulas, although originally developed in the 1960s and 1940s, respectively, are still in use today (Niebergall-Roth et al. 1997).

The duct system of the canine pancreas is different from that of the human pancreas. In dogs, the main duct is the accessory pancreatic duct (Ductus pancreaticus minor). The pancreatic duct, which joins the bile duct (Ductus pancreaticus major) and forms the major duodenal papilla in man, is small and not always present in dogs.

Here, the pancreatic fistula technique in anesthetized dogs is described. The effect of exogenous hormones, e.g., secretin or gastrin, or of vagal stimulation, on exocrine pancreatic secretion can be measured in anesthetized dogs with acute pancreatic fistulas.

PROCEDURE

Beagle dogs of either sex weighing 12–20 kg are used. The animals are fasted for a 24-h period and then anesthetized using appropriate anesthetics, e.g., inhalation with isoflurane, i.v. infusion with probufol, or i.v. injection with ketamine plus pentobarbital sodium. After opening the abdomen along the midline, the pyloric sphincter is ligated and the common bile duct cannulated to prevent the entry of acid chyme and bile into the duodenum. The bile is allowed to drain. The pancreas is gently exposed and the major pancreatic duct ligated. A polyethylene tube of 2-mm diameter is inserted into the minor pancreatic duct for collection of the pancreatic juice. The left femoral vein is cannulated for continuous infusion or i.v. injection.

The pancreatic juice is collected in an ice bath in a special tapered tube with fine calibrations for measuring volumes of less than 1 mL.

At the end of each collection period, the volume is recorded, and the bicarbonate content determined titrimetrically. Furthermore, pancreatic enzymes, such as amylase, are determined in the samples. Determination of protein concentrations in the pancreatic juice can be used as endpoint since the total protein concentration is proportional to the individual enzymes (Keller et al. 1958). In a pretest period of 10 min, samples are collected every 2 min. Then, the test compound is injected intravenously and the pancreatic juice is collected every 2 min.

At the end of the animal experiment, the dog is euthanized by an overdose of barbiturate.

EVALUATION

The secretion after injection of the test compound is compared with the pretest values. Secretin increases pancreatic volume and bicarbonate secretion in a dose-dependent manner and can be ideally used as reference secretagogue.

MODIFICATIONS OF THE METHOD

Glad et al. (1996) tested the influence of gastrin-releasing peptide on acid-induced secretin release and pancreatobiliary and duodenal bicarbonate secretion in Danish country strain pigs weighing between 22 and 30 kg. The animals, starved overnight with free access to water, were premedicated with 4 mg/kg i.m azaperone and with 5 mg/kg i.p. metomidate. After 20 min, a cannula was placed in an ear vein, and 5–10 mg/kg metomidate was given i.v. followed by intubation and artificial respiration with 50% O_2 and 50% N_2O. Anesthesia was maintained with an intravenous bolus infusion of 0.53% chloralose.

Both external jugular veins were cannulated for infusion of saline or drugs. A femoral artery was cannulated for withdrawal of blood samples and recording of blood pressure. After laparotomy, the cystic duct was ligated, and the common hepatic duct and the pancreatic duct were catheterized. The duodenal segment was defined as extending from the pylorus to the ligament of Treitz. A Foley catheter was passed through the pylorus into the proximal part of the duodenum and inflated. Distal to the pylorus, the pancreaticoduodenal arteries, veins, and nerves were dissected, and a double ligature was passed under these structures and tied around the duodenum. At the ligament of Treitz, an inflated Foley catheter was placed in the distal part of the duodenum and tied with a suture around the duodenum. A catheter was placed through a splenic branch of the left gastroepiploic vein and advanced through the lienal vein to the portal vein.

The flow of pancreatic juice and bile was tested before and after the experiment by means of an intravenous bolus of 5 pmol/kg secretin. Before the experiment, the duodenum was continuously perfused at a rate of 2 mL/min for 435 min with isotonic saline containing phenol red (10 mg/L) as a marker. After drug treatment (intravenous infusion of gastrin-releasing peptide or duodenal HCl perfusion), pancreatic and hepatic secretions were collected in 15-min periods and the volumes were determined by weighing. Duodenal effluents were collected in 15-min periods and phenol red concentrations determined spectrophotometrically. Blood samples were withdrawn for determination of secretin by radioimmunoassay.

7.2.4.3 Exocrine Pancreatic Secretion in Conscious Dogs (Chronic Duodenal Pouches in Dogs)

PURPOSE AND RATIONALE

ICH-guideline S7A (2001: Sect. 2) recommended the use of unanesthetized animals for the safety pharmacological assessment of candidate compounds. Duodenal pouches and duodenal fistulas (through which

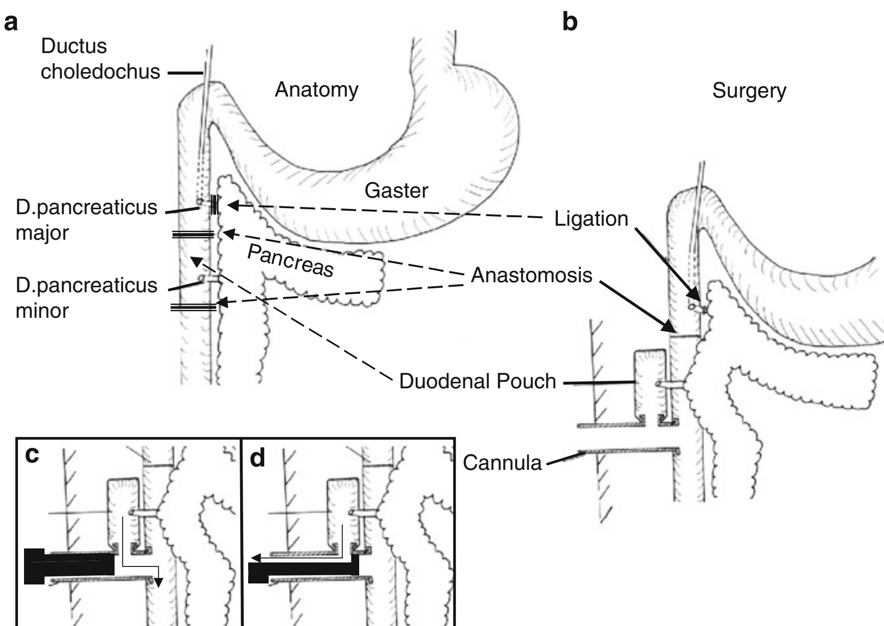

Fig. 7.3 Technique of chronic pancreatic fistula in dogs. Part **a** shows the normal anatomic situation. Part **b**: diagram of the duodenal pouch preparation. Part **c**: demonstration of the normal flow of exocrine pancreatic juice during nonassay condition. Part **d**: demonstration of the flow of exocrine pancreatic juice during study condition

a thin cannula is inserted into the Ductus pancreaticus minor, which represents the main pancreatic duct in dogs), although originally developed in the 1960s and 1940s, respectively, are still in use today (Niebergall-Roth et al. 1997). Here, the duodenal pouch technique is described by using a Herrera cannula. Herrera et al. (1968) described a special cannula, which can be used to obtain pancreatic juice or bile from a duodenal pouch after appropriate surgical procedures (Preshaw and Grossman 1965).

PROCEDURE

The principle technique is demonstrated in Fig. 7.3. Male Beagle dogs weighing 15–20 kg are used. The abdominal surgery is performed during appropriate anesthesia (in former times by, e.g., 30 mg/kg pentobarbital sodium; nowadays, more appropriate by inhalation with halothane or isoflurane). The abdomen is opened through a midline epigastric incision under barbiturate anesthesia. The duodenum is mobilized at the pyloric and jejunal ends, and a 5-cm duodenal segment containing the Ductus pancreaticus minor, which represents the main pancreatic duct in dogs, is isolated. The proximal level of the duodenal section lies immediately distal to the opening of the common bile duct and the distal level of section lies 2.5 cm distal to the main pancreatic duct (Ductus pancreaticus minor). The duodenum integrity is restored by end-to-end duodenojejunostomy. The duodenal pouch is closed at the proximal end.

The cannula to be inserted is made of stainless steel and consists of three parts. The main casement measures 10.5 cm in length, with an external diameter of 1.0 cm. The internal end is flanged, and 1.5 cm from this point, there is a short lateral limb, also 1.5 cm in length. The lateral limb is also flanged but, in addition, possesses a small V-shaped defect to facilitate insertion into the duodenal pouch.

When not in use, the cannula is sealed from the exterior by inserting a threaded plug which allows pancreatic juice to enter the duodenum in the normal manner (Fig. 7.3, part C). For collection of juice, this plug is removed and a long obturator is inserted (Fig. 7.3, part D). The latter effectively isolates the pancreatic secretion from other duodenal contents.

The lateral limb of the cannula is inserted in the distal end of the isolated duodenal segment in which the main pancreatic duct opens. The remaining limb of the cannula inserted through a small duodenotomy and secured further by a purse-string suture. The whole system is then generously wrapped in omentum, and the cannula exteriorized through a stab incision toward the flank. An external collar stabilizes the cannula.

The cannula is left open to drain blood and secretions for 24 h postoperatively, after which time the

plug is inserted. Physiologic saline is administered subcutaneously for a period of 3 days, after which the animals are permitted to drink water. Checking the cannula daily is advisable to ensure that the plug remains tight. The animals receive normal kennel food and water ad libitum.

The dogs are allowed at least 2 weeks to recover. Eighteen hours prior to the experiment, food is withdrawn but water is allowed ad libitum. The long obturator is inserted (Fig. 7.3, part D), and pancreatic juice is collected for 15-min periods. After 1 h pretest time, the candidate compound is given either orally or intravenously.

EVALUATION

Secretion of pancreas juice is measured at 15-min intervals and volume and enzyme content determined. The values are compared with pretest data.

MODIFICATIONS OF THE METHOD

Boldyreff (1925) described details of the technique as recommended by Pavlov (1902) as well as his own modification.

Konturek et al. (1976, 1984) performed experiments with chronic gastric fistulas in cats as well as in dogs to compare the species-specific activities of vasoactive intestinal peptide and secretin in stimulation of pancreatic secretion.

Ninomiya et al. (1998) studied the effects of a cholecystokinin-A-receptor antagonist on pancreatic exocrine secretion stimulated by exogenously administered CCK-8 in conscious dogs with chronic pancreatic fistula.

Garvin et al. (1993) described distal pancreatectomy with autotransplantation and pancreaticocystostomy in dogs.

Kuroda et al. (1995) developed a new technique in dogs for pancreaticogastrointestinal anastomosis that consists of pancreatectomy using the ultrasonic dissector and implantation of the pancreatic duct into the gastrointestinal tract without suturing the pancreatic parenchyma.

7.2.5 Gastrointestinal Injury Potential

7.2.5.1 Gastrointestinal Injury

PURPOSE AND RATIONALE

The gastrointestinal injury potential of a candidate compound is studied in rats after oral administration. Every positive finding represents a serious safety issue for a candidate compound.

Nonsteroidal anti-inflammatory agents (NASID), like indomethacin and acetylsalicylic acid (aspirin), induce gastric lesions in man and in experimental animals by inhibition of gastric cyclooxygenase (COX) resulting in less formation of prostacyclin, the predominant prostanoid produced in the gastric mucosa.

PROCEDURE

After a 24-h starvation period, groups of 8–10 rats weighing 150–200 g are used. The candidate compound is administered orally in 0.1% Tween 80 solution. Six hours later, the rats are sacrificed in CO_2 anesthesia, and their stomachs and intestines are removed. The stomach and gastrointestinal tract are removed. The mucosa is examined with a stereomicroscope and examined and assessed in relation to an ulceration index. The number of ulcers is noted and the severity recorded with the following scores:

0 = No ulcer
1 = Superficial ulcers
2 = Deep ulcers
3 = Perforation

For example, indomethacin 20 mg/kg orally or aspirin 50–100 mg/kg can be used as standard for the induction of ulcers.

EVALUATION

An ulcer index U_I is calculated:

$U_I = U_N + U_S + U_P \times 10^{-1}$

U_N = average of number of ulcers per animal
U_S = average of severity score
U_P = percentage of animals with ulcers

Ulcer index of treated animals is compared with controls. Using various doses, dose-response curves can be established for ulcer formation and gastric acid secretion. ID_{50} values can be calculated by probit analysis, whereby 0% corresponds to no and 100% to maximal stimulated gastric acid output.

Instead of an ulcer index, the area of injured gastrointestinal mucosa can be measured by the following procedure. After removal of the stomach, formol saline (2% v/v) is then injected into the totally ligated stomachs for storage overnight. The next day, the stomachs are opened along the greater curvature, then washed in warm water, and examined under a threefold magnifier. The lengths of the longest diameters of the lesions are measured and summated to give a total lesion score (mm) for each animal, and the total injured area can be estimated, the mean count for each group being calculated.

MODIFICATION OF THE METHOD

Kitajima et al. (1993) studied the role of endothelin and platelet-activating factor in indomethacin-induced gastric mucosal injury in rats. Four hours after subcutaneous injection of 25 mg/kg indomethacin, the rats were sacrificed after ether anesthesia, and the stomach was removed. The stomach was filled with 1.5 mL of 2% buffered formalin for 10 min and then opened along the greater curvature. The total length of the lesions was measured.

Dose and time dependency of the ulcerogenic action of indomethacin were studied by Djahanguiri (1969).

Instead of indomethacin, gastric lesions are induced by intravenous or oral doses of aspirin which can be prevented by exogenous PGE2 or PGI2 (Konturek et al. 1981). Furthermore, reserpine at a dose of 8 mg/kg i.p. or cysteamine hydrochloride at a dose of 400 mg/kg s.c. induces ulcers in rats (Tarutani et al. 1985).

Wallace et al. (1989) studied the ulcerogenic activity of endothelin in indomethacin pretreated rats using an ex vivo gastric chamber.

Scarpignato et al. (1995) evaluated NSAID-induced gastric mucosal damage by continuous measurement and recording gastric potential difference in the rat.

CRITICAL ASSESSMENT OF THE METHOD

Absorptive and secretory changes of the gastrointestinal mucosa and microscopic damage (tight junction/brush borders) are not examined by this method.

7.2.5.2 Gastric Ulcer in Pylorus-Ligated Rats (SHAY Rat)

PURPOSE AND RATIONALE

A simple and reliable method for production of gastric ulceration in the rat based on ligature of the pylorus has been published by Shay et al. (1945). The ulceration is caused by accumulation of acidic gastric juice in the stomach.

PROCEDURE

Rats weighing 150–170 g are starved for 48 h having access to drinking water ad libitum. During this time, they are housed single in cages with raised bottoms of wide wire mesh in order to avoid cannibalism and coprophagy. Ten animals are used per dose and as controls. Under ether anesthesia, a midline abdominal incision is made. The pylorus is ligated, care being exercised that neither damage to the blood supply nor traction on the pylorus occurs. Grasping the stomach with instruments is to be meticulously avoided, else ulceration will invariably develop at such points. The abdominal wall is closed by sutures. The test compounds are given either orally by gavage or injected subcutaneously.

The animals are placed for 19 h in plastic cylinders with an inner diameter of 45 mm being closed on both ends by wire mesh. Afterward, the animals are sacrificed in CO_2 anesthesia. The abdomen is opened and a ligature is placed around the esophagus close to the diaphragm. The stomach is removed, and the contents are drained in a centrifuge tube. Along the greater curvature, the stomach is opened and pinned on a cork plate. The mucosa is examined with a stereomicroscope. In the rat, the upper two fifths of the stomach form the rumen with squamous epithelium and possess little protective mechanisms against the corrosive action of gastric juice. Below a limiting ridge, in the glandular portion of the stomach, the protective mechanisms are better in the mucosa of the medium two fifths of the stomach than in the lowest part, forming the antrum. Therefore, lesions occur mainly in the rumen and in the antrum. The number of ulcers is noted and the severity is recorded with the following scores:

0 = No ulcer
1 = Superficial ulcers
2 = Deep ulcers
3 = Perforation

The volume of the gastric content is measured. After centrifugation, acidity is determined by titration with 100 mmol/L NaOH.

EVALUATION

An ulcer index U_I is calculated:

$U_I = U_N + U_S + U_P \times 10^{-1}$

U_N = average of number of ulcers per animal

U_S = average of severity score

U_P = percentage of animals with ulcers

Ulcer index and acidity of the gastric content of treated animals are compared with controls. Using various doses, dose-response curves can be established for ulcer formation and gastric acid secretion. ID_{50} values can be calculated by probit analysis, whereby 0% corresponds to no and 100% to maximal stimulated gastric acid output.

CRITICAL ASSESSMENT OF THE METHOD

The "Shay rat" has been proven to be a valuable tool to evaluate the ulcerogenic or anti-ulcerogenic potential of a candidate compound independent of its mechanisms of action. However, due to the prolonged distress to the animals, the use of this method should be ethically balanced very carefully against the expected added value of the study outcome.

7.2.6 Gut Motility

7.2.6.1 Ileal Contraction In Vitro

Isolated Ileum (MAGNUS Technique)

PURPOSE AND RATIONALE

During the profiling process of specific and safety pharmacological characterization of a candidate compound in the target-oriented research process, the side effect potential is first estimated from the binding characteristics to a receptor panel in vitro. If there is a binding to a respective receptor identified in the low molar concentration range, which is not associated to the primary mode of action of the drug candidate, there is always the question how relevant is this finding with respect to an undesired side effect potential by receptor agonism or antagonism with respect to the receptor-mediated pharmacological effect. As a first estimate, simple methods are preferred to investigate putative receptor-mediated effects. A wide variety of different receptors appear in the gut; their activation (using the drug candidate itself) or inhibition (using the respective receptor agonist together with the drug candidate) can be studied by isolated gut preparations.

The isolated ileum, as first described by Magnus (1904), is probably the most widely used model in experimental pharmacology. Magnus already studied simultaneously the spontaneous contractions of the longitudinal and circular musculature and the inhibiting effect of atropine. The method has been used for many purposes, such as the study on the effects of epinephrine (adrenaline) on the lower segments causing contraction and on the segments of the upper end causing relaxation by Munro (1951) or the study on the origin of acetylcholine released from guinea-pig intestine and longitudinal muscle strips by Paton and Zar (1968) either retaining or being denervated from Auerbach's plexus. The model is used as a basic screening procedure for spasmolytic activity, whereby an anti-acetylcholine or anticarbachol effect indicates antimuscarinic activity and an anti-$BaCl_2$ effect indicates a musculotropic, papaverine-like effect. In addition to the isolated ileum, other parts of the gut such as the isolated duodenum and colon have been used widely.

PROCEDURE

Guinea pigs of either sex weighing 300–500 g are used. They are sacrificed by stunning and exsanguination. The abdomen is opened with scissors. Just distal to the pylorus, a cord is tied around the intestine, which is then severed above the cord. The intestine is gradually removed, with the mesentery being cut away as necessary. When the colon is reached, the intestine is cut. Below the cord, the intestine is cut halfway through, so that a glass tube can be inserted. Tyrode solution is passed through the tube and the intestine until the effluent is clear. Mesentery is cut away from the intestine that was joined to the colon. Pieces of 2–3-cm length are cut. Preferably, the most distal piece is used being the most sensitive one. This piece is fixed with a tissue clamp and brought into a 15-mL organ bath containing Tyrode solution at 37°C being oxygenated with 95% O_2/5% CO_2. The other end is fixed to an isometric force transducer (UC 2 Gould-Statham, Oxnard, USA). A preload of 1 g is chosen. Responses are recorded on a polygraph. After a preincubation time of 30 min, the experiment is started.

The following agonists and antagonists (standards) are used (concentrations in g/mL bath fluid):

Agonist	Antagonist
Acetylcholine 10^{-7} g/mL	Atropine 10^{-8}–10^{-9} g/mL
	Scopolamine 10^{-8}–10^{-9} g/mL
Carbachol 10^{-7} g/mL	Atropine 10^{-8}–10^{-9} g/mL
Histamine 10^{-6} g/mL	Histamine antagonists, e.g., cimetidine, ranitidine, famotidine
BaCl2 10^{-4} g/mL	Papaverine 10^{-5}–10^{-6} g/mL
Serotonin (5-HT) 10^{-6} g/mL	Serotonin (5-HT) antagonists
PGE2 2×10^{-7} g/mL	PG antagonists

EVALUATION

Several methods for the quantitative evaluation of an antagonistic effect are available. One approach is the determination of pD_2 values according to van Rossum and van den Brink (1963). Acetylcholine or histamine is added in 1/2 $\log_{10}$ concentration increments until a maximum response is obtained. Control curves are recorded at 30-min intervals. After uniform control responses are obtained, the potential antagonist or the

standard is added 5 min before the concentration-response curve is reobtained. The potency of the antagonist is obtained by calculating the pD_2 value which is defined as the negative logarithm of the molar concentration of an antagonist that causes a 50% reduction or the maximal response obtained with an agonist.

MODIFICATIONS OF THE METHOD

Many modifications of the Magnus technique have been described in the literature, mainly with the isolated ileum (e.g., Koelle et al. 1950).

Okwuasaba and Cook (1980) dissected the myenteric plexus and longitudinal muscle free of the underlying circular muscle according to the method of Paton (1957) and Paton and Zar (1968) and stimulated the preparation with trains of supramaximal rectangular pulses of 1.0-ms duration at a frequency of 0.2 Hz.

Kilbinger et al. (1995) studied the influence of 5-HT_4 receptors on [^{3}H]-acetylcholine release from guinea-pig myenteric plexus.

De Graaf et al. (1983) described a fully automated system for in vitro experiments with isolated tissues. The apparatus consists of an organ bath equipped with (a) a gradient pump supplying a logarithmic concentration/time gradient of agonist; (b) pumps and valves for dispensing bath fluid, antagonist solutions, and an oxygenation gas mixture; and (c) a transducer with automatic baseline adjustment. The information coming from the preparation is fed into a minicomputer. The data of various experiments can be accumulated and Schild plots obtained.

Furukuwa et al. (1980) studied the effects of thyrotropin-releasing hormone on the isolated small intestine and taenia coli of the guinea pig.

Paiva et al. (1988) studied the role of sodium ions in angiotensin tachyphylaxis in the guinea-pig ileum and taenia coli.

Barnette et al. (1990) used electrically stimulated strips of circular smooth muscle from the lower esophageal sphincter of dogs to study the inhibition of neuronally induced relaxation by opioid peptides.

Griesbacher and Lembeck (1992) used the isolated guinea-pig ileum for analysis of bradykinin antagonists.

Hew et al. (1990) used field-stimulated (95% of maximum voltage, 0.1 Hz, 0.5 ms) guinea-pig ileum, bathed in physiological salt solution at 37°C in the presence of 1 mM mepyramine for determination of histamine-H_3 bioresponse. Reduction of contractile response by the test substance (>50% relative to control 0.3 mM R-a-methylhistamine) indicates possible histamine-H_3 agonism. At a test concentration where no significant activity is seen, ability to inhibit (>50%) R-α-methylhistamine-induced contractile reduction indicates antagonistic activity.

Feniuk et al. (1993) used the guinea-pig isolated ileum, vas deferens, and right atrium to characterize somatostatin receptors. Transmural electrical stimulation was applied to guinea-pig ileum (0.1 Hz, 0.1 ms continuously) and vas deferens (5 Hz, 0.5 ms for 1.5 s every 30 s) at supramaximal currents (approximately 800 mA) delivered from a Digitimer D330 multistimulator.

Radimirow et al. (1994) investigated opioid effects of short enkephalin fragments containing the Gly-Phe sequence on contractile responses of guinea-pig ileum after addition of 10 nM acetylcholine or after electrical stimulation.

Coupar and Liu (1996) described a simple method for measuring the effects of drugs on intestinal longitudinal and circular muscle in rats. The preparation consists of a segment of rat ileum setup to measure the tension developed in the longitudinal muscle and intraluminal pressure developed in the circular muscle in response to transmural electrical stimulation.

Vassilev et al. (1993) exposed Wistar rats to subtoxic doses of Co^{2+} or Ni^{2+}, receiving $Co(NO_3)_2$ or $NiSO_4$ with drinking water for 30 days, and measured the changes in the contractile responses to carbachol and in the inhibitory effects of verapamil and nitrendipine on isolated smooth muscle preparations of the ileum and the trachea.

Pencheva and Radomirov (1993) and Pencheva et al. (1999) studied the effects of GABA-receptor agonists on the spontaneous activity of the circular layer in the terminal ileum of cats. Segments of the terminal ileum approximately 0.5 cm long were mounted in an organ bath along the axis of the circular layer through a cotton thread with a large knot situated at the inner part of the gut wall.

Similar preparations of cat ileum were used by Kortezova et al. (1994) and Chernaeva and Mizhorkova (1995).

Vassilev and Radomirov (1992) used an isolated preparation of rat rectum. The rectal region, 1–6 cm proximal to the anal sphincter, was removed and a 20-mm-long segment suspended in an organ bath. The influence of prostaglandins and antagonists on spontaneous mechanical activity and electrically stimulated responses was investigated.

7.2.6.2 Transit Time In Vivo (Gut Motility) and Intestinal Secretion

Propulsive Gut Motility in Mice

PURPOSE AND RATIONALE

To study the side effect potential of a candidate compound on gastrointestinal motility, the passage of a charcoal meal through the gastrointestinal tract in mice or rats is a simple, reliable, and widely used method of safety pharmacologists.

PROCEDURE (EXEMPLARILY DESCRIBED FOR THE METHOD IN MICE)

Groups of ten mice weighing 15 g are fed an oat diet for 3 days. Eighteen hours prior to the experiment, food, but not water, is withdrawn. The animals are treated either subcutaneously 15 min or orally 60 min before administration of the charcoal meal (0.2 mL of a 4% suspension of charcoal in 2% carboxymethylcellulose solution). The mice are sacrificed after various time intervals: 5, 10, 15, 30, and 60 min. Ten animals serve as controls for each time interval. The entire intestine is immediately removed and immersed in 5% formalin to halt peristalsis, then washed in running water. The distance the meal has traveled through the intestine as indicated by the charcoal is measured and expressed as percent of the total distance from the pylorus to the cecum.

EVALUATION

The values for the treated groups with the candidate compound for each time point are compared to those for the vehicle control group by using appropriate statistical methods. By using several doses of the candidate compound, a dose-response curve can be established.

CRITICAL ASSESSMENT OF THE METHOD

The charcoal passage test can be used for evaluation of laxative activity as well as for inhibition of intestinal motility.

MODIFICATIONS OF THE METHOD

Instead of charcoal, unsubstituted Hostapermblau (CuPcB) suspended in gummi arabicum mucilage can be used.

Carmine red (15) suspended in a 1% tragacanth solution was used for measurement of small intestine transit in rats (Leng-Peschlow 1986).

Miller et al. (1981) measured the intestinal transit in the rat by the use of radiochromium (^{51}Cr). Female Sprague-Dawley rats weighing approximately 200 g were implanted with indwelling silastic cannulae in the proximal duodenum. Following a 3-day recovery period, the animals were fasted for 18 h and then treated with the test compounds. Thirty minutes later, 0.2 mL of radiochromium (0.5 mCi $Na^{51}CrO_4$) was instilled into the small intestine via the indwelling silastic cannula. Twenty-five minutes after chromium instillation, the animals were sacrificed. The small intestine was carefully removed and divided into ten equal segments. The radioactivity was determined with an automatic gamma counting system. The effect of drugs could be quantified by determining the geometric center of the distribution of chromium through the small intestine.

Shook et al. (1989) used radiolabeled chromium to measure gastrointestinal transit in mice.

Megens et al. (1989) used the charcoal test to study the in vivo dissociation between the antipropulsive and antidiarrheal properties of opioids in rats.

Lish and Peters (1957) recommended an intestinal antipropulsive test in intact insulin-treated rats providing certain advantages over the commonly used charcoal meal test for screening of synthetic antispasmodic and antipropulsive agents.

Stomach Emptying in Rats

PURPOSE AND RATIONALE

Reynell and Spray (1956) described a method for the simultaneous measurements of gastric emptying and

intestinal transit of test substances in the rat using phenol red as marker. This simple method can also be ideally used for safety pharmacological assessment of candidate compounds on their side effect potential on gastrointestinal motility.

PROCEDURE

Rats weighing 200–300 g are starved for 24 h, with free access to water before the experiment. They are treated orally or subcutaneously with the test compound 15 min prior to oral administration by gavage of 1.5 mL 0.07% phenol red in 2% carboxymethylcellulose solution. Fifteen minutes later, the animal is sacrificed and the stomach is immediately removed. The whole stomach including the stomach content is alkalized with 1N NaOH and homogenized. The homogenate is filtered and, after precipitation of the protein with 10% trichloroacetic acid, centrifuged for 15 min at 3,000 rpm. The concentration of phenol red in the supernatant is measured colorimetrically in a photometer at 546 nm.

EVALUATION

Percentage of stomach emptying (S_e) is calculated according to the following formula:

$$S_e = 100 - \left(P_s \times {P_a}^{-1} \times 100\right)$$

P_s = Concentration of phenol red in the stomach (μg/mL)

P_a = Concentration of phenol red in the initial solution after addition of equal volumes of 1 N NaOH and trichloroacetic acid (μg/mL)

MODIFICATIONS OF THE METHOD

Droppleman et al. (1980) described a simplified method for assessing drug effects on gastric emptying in rats. Three milliliters of a semisolid test meal, based on methylcellulose, is given to rats fasted 24 h prior to the experiment. At a specified time following the test meal, the rats are sacrificed and laparotomized and the stomachs removed. The full stomachs are weighed on an analytical balance; they are opened and rinsed. Excess moisture is removed and the empty stomach is weighed again. The difference is subtracted from the weight of 3 mL of the test meal, indicating the quantity emptied from the stomach during the test period. Gastric motor stimulants, e.g., metoclopramide increase, and anticholinergic compounds decrease gastric emptying.

Megens et al. (1990) used phenol red as marker to measure gastrointestinal propulsion after castor oil or paraffin oil challenge in rats.

Hedge et al. (1995) studied 5-HT_4 receptor-mediated stimulation of gastric emptying in rats using a specially prepared semisolid test meal containing charcoal.

Bonnafous et al. (1995) investigated benzodiazepine-withdrawal-induced gastric emptying disturbances in rats. Rats, weighing 200–250 g, fasted for 16 h, received by gavage 2 mL of a test meal containing 1 μCi/mL of ^{51}Cr sodium chromate, 15 min after drug administration. Thirty minutes later, the animals were sacrificed by cervical dislocation. The stomach, small intestine (ten segments), and the colon were excised and placed into tubes. Radioactivity was determined by placing the tubes in a gamma counter. Gastric emptying was calculated as the percentage of total counts found in the small intestine and the colon.

Varga et al. (1995) determined gastric emptying in rats 5 min after a 3-mL intragastric load of 0.9% NaCl using phenol red as marker in order to define which bombesin receptors are involved in the delay of gastric emptying by bombesin-like peptides.

Lasheras et al. (1996) studied gastric emptying in rats. Sixty minutes after oral administration of vehicle or test compounds, the rats received by gavage 40 steel spheroids (1-mm diameter) in 2 mL 3% carboxymethylcellulose. Sixty minutes later, the animals were sacrificed and the spheroids remaining inside the stomach counted.

Yegen et al. (1996) studied the inhibitory effects of gastrin-releasing peptide on gastric emptying in rats using methylcellulose and phenol red as nonabsorbable marker.

Haga et al. (1994) studied gastric emptying in mice. Male mice, weighing 18–22 g, had free access to food and water before the experiment. The test compounds were administered orally in 10 mL/kg 0.5% methylcellulose solution. The mice were deprived of food and water and sacrificed 4 h later by cervical dislocation. The stomachs were removed and opened. The contents of the stomach were mixed with 10% trichloroacetic acid and centrifuged at 3,000 rpm for 30 min. The weight of the sediment was taken as the food remaining in the stomach.

Ding and Håkanson (1996) examined the effect of drugs on a cholecystokinin-A-receptor-mediated response by gastric emptying of a charcoal meal in mice.

Costall et al. (1987) used the guinea pig to study the influence of a 5-HT_3 antagonist on gastric emptying.

Brighton et al. (1987) used scintigraphy following indium-111-labeled meals in Beagle dogs and baboons. Indium-111-labeled polystyrene beads (500 mCi per dog) were mixed into a meal consisting of 50 g of finely crushed commercial dog food and 50 mL of milk. Images of 1-min duration were taken every 5 min for a period of 1 h using a large field of view gamma camera (ON Sigma 410).

Gullikson et al. (1991, 1993) studied gastric emptying of a solid meal in dogs.

Stomach Emptying and Gastrointestinal Transit in Dogs

PURPOSE AND RATIONALE

Using the pharmacokinetic profile of specific and defined marker substances, e.g., paracetamol (acetaminophen), for estimating, the rate of gastric emptying has been used since decades not only in animals but also in humans (Clements et al. 1978). This study principle of the analysis of the pharmacokinetic profile of marker substances has also been used for physiological studies of the influence of different food constituents on gastrointestinal motility (Mizuta et al. 1990). This study principle can be ideally used for safety pharmacological assessment of candidate compounds on their side effect potential on gastrointestinal motility.

PROCEDURE

Groups of six male dogs were used in a crossover design (compound vs vehicle control) with a minimum of 3 days between each session. Animals received a single dose of candidate compound or vehicle. After an appropriate time (depends on known pharmacokinetic data of the candidate compound; T_{max}, C_{max}), the marker compound paracetamol (20–25 mg/kg) was administered into the stomach by gavage using rubber tubing connected to a 30-mL syringe. The tube was rinsed with 15 mL water and 10 mL air immediately after dose administration.

Blood samples of 1–2 mL were collected for pharmacokinetic analysis of paracetamol at multiple time intervals, e.g., at 0, 10, 20, 30, 60, 90 min, 2, 3, 4, 5, 6, and 7 h after administration of the marker.

Blood samples were drawn into vacutainer tubes containing EDTA. Plasma was prepared by centrifugation 1500 × g for 10 min, at 4°C within 30 min after sampling and stored at −70°C until analysis of marker level of paracetamol in the plasma. For the bioanalysis of paracetamol, plasma samples were appropriately prepared for analysis with HPLC/MS/MS.

EVALUATION

The rate of absorption of orally administered paracetamol depends on the rate of gastric emptying and is usually rapid and complete. The mean systemic availability is about 75%. The difference of t_{max} (and c_{max}) of paracetamol between vehicle-treated and candidate-compound-treated group represents a measure of changes in the rate of gastric emptying. For example, atropine delayed gastric emptying during starved and fed conditions.

MODIFICATIONS OF THE METHOD

Sjödin et al. (2011) described an elegant method of combined assessment of the rate of gastric emptying and the intestinal transit time. They used a pharmacokinetic method (double marker method) for the simultaneous measurements of gastric emptying (marker: paracetamol) and intestinal transit (marker: sulfapyridine generated from orally administered sulfasalazine by colonic bacterial flora). They investigated the influence of the nutritional state (fed vs fasting) as well as that of standard substances (atropine, erythromycin) in the dog on gastric emptying and gastrointestinal transit, respectively. Paracetamol and sulfasalazine were administered together as an oral mixture at doses of 24 mg/kg and 20 mg/kg, respectively. The pharmacokinetic profile of paracetamol was used for evaluation of gastric emptying, as mentioned above. Sulfasalazine is poorly absorbed in the stomach and small intestine but is rapidly metabolized by the bacterial flora in the colon; the colonic metabolite sulfapyridine is then absorbed in the colon, and its appearance in the blood served as a marker of gastrointestinal transit time through the small intestine. The time period of blood sampling is about 7 h for paracetamol and about 36 h for sulfapyridine.

Enteropooling Test

PURPOSE AND RATIONALE

The enteropooling assay in rats has been developed by Robert et al. (1976) to test the diarrheogenic property of prostaglandins for prediction of this clinically relevant side effect of several synthetic prostaglandins. This method can also be used for the safety pharmacological assessment of candidate compounds on their side effect potential to induce diarrhea.

PROCEDURE

Rats weighing 190–215 g are used. The animals are fasted overnight having free access to water. The candidate compound is administered orally, and the animals, 10–12 per group, are sacrificed 1 h later. The fluid accumulation occurs in the small intestine which is cut at the pylorus and the ileocecal junction, and its contents, consisting of a thick fluid (in controls) and a very watery fluid (in prostaglandin-treated animals), are collected into a graduated test tube by milking the whole length of the small intestine with the fingers. The volume of fluid is recorded.

EVALUATION

Using various doses, dose-response curves can be established and potency ratios calculated. 16,16-dimethyl PGE_2 was found to be the most active compound and can be used as standard to estimate the diarrheogenic side effect potential of candidate compound.

CRITICAL ASSESSMENT OF THE METHOD

Some other diarrheogenic agents, like $MgSO_4$, castor oil, bile, taurocholate, and taurochenodesoxycholate,

cause enteropooling, whereas mineral oil and tragacanth are ineffective. The anticholinergic agent methylscopolamine partially counteracted the enteropooling. The assay, therefore, can be used to test the laxative or the antidiarrheal activity of drug candidates (Shook et al. 1989).

MODIFICATIONS OF THE METHOD

Beubler and Badhri (1990) used the PGE_2-induced net fluid secretion in the jejunum and colon in the rat to evaluate the antisecretory effects of antidiarrheal drugs. Polyethylene catheters were placed into the jejunum and colon, and Tyrode solution was instilled into the loops. Net fluid transfer rates were determined gravimetrically 30 min after instillation of Tyrode solution.

7.3 Carbohydrate and Lipid Metabolism

7.3.1 General Considerations

If a candidate compound with a totally different primary indication has additionally lipid-lowering potential or causes an insulin sensitization, these findings may be assessed as additionally beneficial and therefore do not represent a safety concern, irrespective whether these pharmacological effects occur in the pharmacological dose range for the primary pharmacological effect or at suprapharmacological doses as usually used for safety pharmacological studies of a candidate compound. In contrast, if a candidate compound causes increases in plasma lipid parameters (free fatty acids, triglycerides, cholesterol), detailed analysis of the these side effects is highly recommended, because increased free fatty acids and triglycerides might induce insulin resistance and increased triglycerides and total cholesterol might be connected to an increased atherogenic risk.

The acute side effect potential on intermediary metabolism resulting in changes in blood glucose and lactate as well as in changes of free fatty acids can be investigated in rodents after single administration of candidate compounds, as these blood parameters physiologically vary quickly. However, changes of triglycerides and predominantly of cholesterol appear physiologically much slower. Therefore, the side effect potential of candidate compounds on these parameters are hardly to be detected in single dose studies as usually performed during initial safety pharmacological characterization. If there are additional hints, e.g., from toxicity studies, demonstrating putative side effects on triglyceride and cholesterol metabolism, additional multiple-dose studies in safety pharmacology in appropriate animal models to detect an atherogenic potential are necessary to characterize the side effect potential of candidate compounds.

Due to the fact that nearly most of initial safety pharmacological studies are performed in small rodents (mainly rats and mice), one has to take carefully into consideration the differences in rat physiology compared to human physiology for characterizing the side effect potential of a candidate compound on intermediary metabolism. A normal rat is night active and takes up food predominantly during the night (8–10 meals per night) and, to a smaller extent, also during the day (3–4 meals per day). Blood glucose and liver glycogen do not vary during 24 h (Gaertner 2001), resulting in a permanent prandial or postprandial state but never in a postabsorptive state. In humans, blood glucose and liver glycogen vary in dependence to meal intake during the day and decrease during the night to fasting values in the morning. In general, carbohydrate and fatty acid metabolism in laboratory animals are much more similar to that of humans compared to cholesterol metabolism. The functions of lipoprotein fractions (predominantly LDL and HDL) differ substantially between rodents and humans. Therefore, total cholesterol in blood is the most reliable marker in rats and mice, and the results from LDL and HDL cholesterol in these rodents should be interpreted very carefully with respect to their role in atherosclerosis known from human pathophysiology. With respect to cholesterol metabolism, the

guinea pig seems to be more closely to the human cholesterol metabolism compared to mice and rats (Fernandez 2001).

Interpretation of changes in blood glucose and free fatty acids should only be performed with the additional knowledge of the corresponding serum insulin levels. This is important not only in single dose studies but also in long-term studies. Candidate compounds, which cause a slight increase in free fatty acids and triglyceride in multiple-dose studies, may induce insulin resistance (normoglycemia in the presence of hyperinsulinemia), which might provoke the progression to diabetes and obesity.

7.3.2 Acute Effects on Metabolic Blood and Tissue Parameters

7.3.2.1 Acute Effects on Metabolic Blood and Tissue Parameters in Anesthetized Rats

PURPOSE AND RATIONALE

Anesthetized rats are used for testing the side effect potential of a candidate compound on intermediary metabolism in liver, muscle, and adipose tissue with subsequent effects on metabolic blood parameters (e.g., glucose, lactate, free fatty acids, triglycerides) and insulin. The use of anesthetized rats represents more a principal assessment of the pharmacological side effect potential since the candidate compound must be administered intravenously or intraperitoneally (enteral/intestinal administration should be avoided due to the anesthesia-induced decrease in intestinal motility with subsequent impairment of enteral absorption), compared to the study in conscious rats in which the candidate compound can be studied after oral administration, which, in most cases, represents the clinical route of administration for small molecular drugs.

PROCEDURE

Metabolic blood parameters are assayed in anesthetized male rats using a modified method of glucose clamp studies in rodents (Terretaz and Jeanrenaud 1983). Four to six rats per group (vehicle control and one dose of the candidate compound) are used. Rats are anesthetized with an intraperitoneal injection of ketamine (20 mg/kg) plus pentobarbital sodium (60 mg/kg) and tracheotomized, and one jugular vein per rat is cannulated for intravenous infusion; the other vein is prepared for collection of blood samples. Anesthesia is maintained for up to 7 h by subcutaneous infusion of pentobarbital sodium (adjusted to the anesthetic depth of the individual animal; about 24 mg/kg/h). Body temperature is monitored with a rectal probe thermometer, and temperature is maintained at 37°C by means of a heated surgical table. Blood samples for glucose analysis (10 μL) are obtained from the tip of the tail every 15 min and for lactate analysis (20 μL) every 30 min. The rats are allowed to stabilize their blood glucose levels after surgery for up to 2 h. Then, the candidate compound is injected or infused intravenously or administered intraperitoneally, respectively. Blood samples (100 μL) for detection of free fatty acids, triglycerides, and insulin are collected from a peripheral vein (e.g., jugular vein) immediately prior and every 1 or 2 h after compound administration.

At the end of the experiment, the abdomen is opened; terminal blood collection is performed from the vena cava caud. or the aorta abdominalis for determination of metabolic blood parameters and insulin. A part of the liver is freeze clamped immediately as well as a part (about 1 gr) of skeletal muscle (e.g., M. gastrocnemius). The frozen tissue is stored in liquid nitrogen for subsequent determinations of intrahepatic and intramuscular concentrations of glycogen, glucose-6-phosphate (G6P), and ATP. In liver samples, hepatic triglycerides can be measured additionally. Standard enzymatic procedures were used to determine glucose, lactate, free fatty acids, triglycerides, glycogen, G6P, and ATP (Bergmeyer 1974); insulin is determined by using a commercially available radioimmunoassay or ELISA kit.

EVALUATION

The differences of the metabolic blood parameters after compound administration are calculated with respect to the predrug values and against a control group, which has received the vehicle only. The

metabolic tissue parameters at the end of the study are assessed between control and treatment group.

Two parallel experiments in normal fed (high glucose, low free fatty acids, high triglycerides, high serum insulin) and overnight starved rats (fasting blood glucose, elevated free fatty acids, low serum insulin) as well as the complete data set of metabolic blood and tissue parameters and serum insulin levels are necessary to assess the acute putative side effect potential and its putative mechanism of the candidate compound on intermediary metabolism.

MODIFICATIONS OF THE METHOD

By using rats, which are starved longer than 16 h before their use in the pharmacological experiment, fasting blood glucose is maintained exclusively by the process of gluconeogenesis, due to the very low glycogen content in the liver. Candidate compounds, which reduce blood glucose during this experimental setup, interfere with the process of endogenous glucose production (hepatic and renal gluconeogenesis) either by direct interference with an enzymatic step of gluconeogenesis or by interference with the energy generation machinery (mitochondrial function, generation of ATP). Additional reasons of a blood glucose reduction during this experimental setup could be an insulin release from the pancreatic β-cell or the interference with the insulin-signaling cascade in the insulin target tissues. Candidate compounds, which decrease free fatty acids, which are physiologically elevated during starvation, interfere with the process of lipolysis (antilipolytic activity) (Schoelch et al. 2004). Compounds, which increase free fatty acids (lipolytic activity), might have, e.g., a stimulatory β-sympathetic potential.

It is recommended to perform a parallel experiment by using normal fed rats. Candidate compounds, which increase blood glucose, might inhibit insulin release or peripheral insulin action or stimulate glycogenolysis. A putative lipolytic activity (increase in free fatty acids) is more pronounced during normal fed conditions, because free fatty acids are physiologically low due to elevated insulin levels. Fed rats can be also used for studying the effect of a candidate compound exclusively on the process of glycogenolysis. During this experimental setup, glycogenolysis is induced by an intravenous bolus injection of glucagon at a dose of 1 mg/rat. It can be assumed that the hyperglycemia induced by the glucagon injection, and which lasts for about 90–120 min, is the result of the glucagon-induced breakdown of hepatic glycogen (Herling et al. 1998, 1999).

CRITICAL ASSESSMENT OF THE METHOD

In general, pharmacological studies during anesthesia should be assessed appropriately due to the possible interaction between the test compound and the used anesthetic as well as due to the reduced tone of the autonomic nervous system. Enteral administration of the candidate compound should be avoided, because enteral absorption of the test compound might be reduced due to the impaired intestinal motility during anesthesia. With respect to the effect of the anesthetic compound itself on intermediary metabolism, the barbiturate pentobarbital sodium is the most inert anesthetic and does not cause alterations of metabolic blood and tissue parameters. In contrast, e.g., urethane (often used in former times for long-term anesthesia) as well as isoflurane (inhalation anesthetic) influences by itself substantially metabolic parameters over time (hours). In our hands, anesthesia with pentobarbital sodium does not influence intermediary metabolism or insulin secretion and is essential for obtaining reliable results during such pharmacological studies lasting for several hours. Most other anesthetics including inhalation anesthetics like isoflurane should not be used due to their inhibitory effect on insulin secretion from pancreatic β-cells and subsequent alterations of metabolic control.

7.3.2.2 Acute Effects on Metabolic Blood and Tissue Parameters in Conscious Rats

PURPOSE AND RATIONALE
Conscious rats are used for testing the side effect potential of a candidate compound on intermediary metabolism in liver, muscle, and adipose tissue with subsequent effects on metabolic blood parameters (e.g., glucose, lactate, free fatty acids, triglycerides) and insulin after oral administration, which represents in most cases the clinical route of administration for small molecular drugs.

PROCEDURE
Rats weighing 180–240 g are kept on standard diet. Groups of eight nonfasted animals are treated orally with various doses of the test compounds suspended in 0.4% starch suspension. One control group receives the vehicle only. Blood is withdrawn from the tip of the tail immediately before and 1, 2, 3, 5, and 24 h after administration of the candidate compound. Blood glucose is determined in 10 μL blood samples collected from the tip of the tail. If pharmacokinetic data for the candidate compound are already available, when performing this test, additional blood samples (100 μL) should be taken at t_{max} by retroorbital bleeding for detection of free fatty acids, triglycerides, and insulin.

At the end of the experiment, the rats are terminally anesthetized, the abdomen is opened, and terminal blood collection is performed from the vena cava caud. or the aorta abdominalis for determination of metabolic blood parameters and insulin. A part of the liver is freeze clamped immediately as well as a part (about 1 gr) of skeletal muscle (e.g., M. gastrocnemius). The frozen tissue is stored in liquid nitrogen for subsequent determinations of intrahepatic and intramuscular concentrations of glycogen, glucose-6-phosphate (G6P), and ATP. In liver samples, hepatic triglycerides can be measured additionally. Standard enzymatic procedures were used to determine glucose, lactate, free fatty acids, triglycerides, glycogen, G6P, and ATP (Bergmeyer 1974); insulin is determined by using a commercially available radioimmunoassay or ELISA.

EVALUATION
The differences of the metabolic blood parameters after compound administration are calculated against a control group, which has received the vehicle only, for the respective time points. The metabolic tissue parameters at the end of the study are assessed between control and treatment group.

Two parallel experiments in normal fed (high glucose, low free fatty acids, high triglycerides, high serum insulin) and overnight starved rats (fasting blood glucose, elevated free fatty acids, low serum insulin) as well as the complete data set of metabolic blood and tissue parameters and serum insulin levels are necessary to assess the acute putative side effect potential and its putative mechanism of the candidate compound on intermediary metabolism.

7.3.2.3 Blood-Glucose-Lowering Activity in Conscious Rabbits

PURPOSE AND RATIONALE
The rabbit has been used since many years for standardization of insulin. Therefore, it has been chosen as primary screening model for screening of blood-glucose-lowering compounds as well as for establishing time-response curves and relative activities (Bänder et al. 1969; Geisen 1988). For the safety pharmacological evaluation of candidate compounds with a different primary indication, the rabbit is not the preferred animal species for first initial studies on metabolism pharmacology.

PROCEDURE
Groups of 4–5 mixed breed rabbits of either sex weighing 3.0–4.5 kg are used. For insulin evaluation, food is withheld overnight. For evaluation of sulfonylureas and other blood-glucose-lowering agents, the animals are on a normal diet prior to the experiment. The animals are gently placed into special restraining boxes allowing free access to the rabbit's ears.

Oral blood-glucose-lowering substances are applied by gavage in 1 mL/kg of 0.4% starch suspension or intravenously in solution. Several doses are given to different groups. One control group receives the vehicle only. By puncture of the ear veins, blood is withdrawn immediately before and 1, 2, 3, 4, 5, 24, 48, and 72 h after treatment. For time-response curves, values are also measured after 8, 12, 16, and 20 h. Blood glucose is determined in 10 μL blood samples.

MODIFICATIONS OF THE METHOD

For special purposes, the effect of blood-glucose-lowering agents is studied in glucose-loaded animals. Rabbits of either sex weighing 3.0–4.5 kg are treated either once (0.5 h after test compound) or twice (0.5 and 2.5 h after test compound) orally with 2 g glucose/kg body weight in 50% solution.

EVALUATION

Averages of the blood glucose values are plotted versus time for each dosage. Besides the original values, percentage data related to the value before the experiment are calculated. Similarly, other metabolic blood parameters (e.g. lactate, insulin) are plotted versus time and compared with control values. Statistical evaluation is performed using appropriate methods.

7.3.2.4 Acute Effects on Metabolic Blood Parameters in Conscious Dogs

PURPOSE AND RATIONALE

Since most safety studies for safety pharmacological evaluation of candidate compounds are performed in rodents, a second nonrodent species should be included to exclude any species differences in the safety pharmacological findings. Dogs are a preferred second animal species in metabolism pharmacology, because their night/day acitivity, their food intake behavior, and therefore their intermediary metabolism are obviously different to that of rodents and resemble more that of humans.

PROCEDURE

Male Beagle dogs weighing 15–20 kg are kept on standard diet. Food is withdrawn 18 h prior to the administration of the candidate compound which is given either orally or intravenously in various doses. Control animals receive the vehicle only. Blood is collected at different time intervals up to 48 h for determination of metabolic blood parameters (e.g., glucose, lactate, free fatty acids, triglycerides) and insulin. Standard enzymatic procedures were used to determine metabolic blood parameters (Bergmeyer 1974); insulin is determined by using a commercially available radioimmunoassay or ELISA kit.

EVALUATION

Averages of the metabolic blood parameters (e.g., glucose, lactate) are plotted versus time for each dosage. Besides the original values, percentage data related to the value before the experiment are calculated. Similarly, plasma insulin levels are plotted versus time and compared with control values. Statistical evaluation is performed using appropriate methods.

MODIFICATIONS OF THE METHOD

Continuous Blood Glucose Monitoring

A device for continuous blood glucose monitoring and infusion in freely mobile dogs was described by Geisen et al. (1981).

7.3.3 Functional Tests

7.3.3.1 Oral Glucose Tolerance Test (oGTT) in Conscious Rats

General Consideration

Oral glucose tolerance test (oGTT) represents a simple method for estimating the effect of a candidate compound either to impair or to improve glucose tolerance. In general, impaired glucose tolerance often represents a condition of some degree of insulin resistance or impaired pancreatic insulin secretion during a glucose load. An impairment of insulin sensitivity (induction of insulin resistance) resulting in impaired glucose tolerance, which can be detected in normal animals (rarely in single dose studies but more likely in multiple-dose studies lasting for 1 or 2 weeks), represents a safety concern, since insulin resistance is associated with hyperinsulinemia and can provoke the progression to overt diabetes (type 2) and obesity. For the assessment of the glucose tolerance, the additional determination of insulin is essential. Since the commercial availability of ELISA kits using only some microliter serum for insulin determination, it has become possible also in rodents to collect appropriate blood samples for insulin determinations in parallel to blood glucose measurements during conscious conditions.

On the other hand, normal animals are insulin sensitive, and further improvement of insulin sensitivity cannot be expected. Therefore, if there are hints from other studies for a candidate compound (reduction in free fatty acids, triglycerides and insulin), to have a putative insulin-sensitizing potential, which does not represent a safety concern, appropriate studies should be performed by using insulin-resistant animal disease models (genetic models: e.g., Zucker-fatty (fa/fa) rat, Zucker Diabetic Fatty (ZDF, fa/fa) rat, diet-induced insulin resistant rats: e.g., high-fat-fed rats, high-fructose-fed rats) (Vogel 2008)

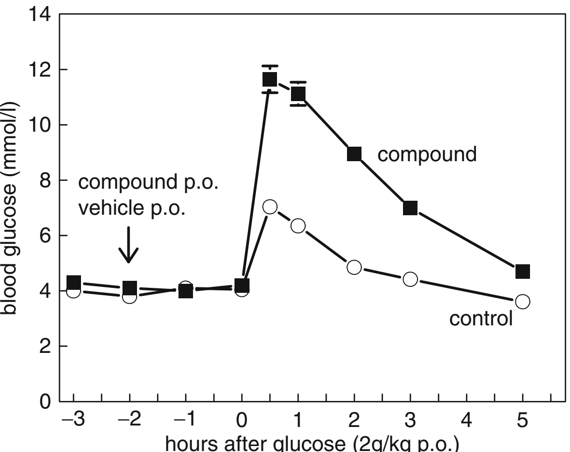

Fig. 7.4 Representative oral glucose tolerance test shown for a candidate compound, which impairs glucose tolerance. Candidate compound and vehicle are administered 2 h before the oral glucose load. Values are mean +/−SEM, $n = 8$ rats

PURPOSE AND RATIONALE

oGTT in conscious rats are used to assess the side effect potential of a candidate compound to impair glucose tolerance (Fig. 7.4).

PROCEDURE

Rats weighing 180–240 g are starved overnight. Groups of eight animals are treated orally with various doses of the candidate compound suspended in 0.5% HEC or Tylose. One control group receives the vehicle only. Based on the pharmacokinetic data (t_{max}), the candidate compound is administered appropriately before the glucose load (e.g., 0.5, 1, or 2 h). Glucose is administered at a dose of 2 g/kg orally. Blood is withdrawn from the tip of the tail immediately before compound administration and immediately before glucose administration and 0.5, 1, 2, 3, and 5 h after administration of glucose. Blood glucose is determined in 10 μL blood samples collected from the tip of the tail. An additional blood sample (80–100 μL, resulting in about 40 μL serum) should be taken for insulin determinations. Standard enzymatic procedures are used to determine blood glucose (Bergmeyer 1974); insulin is determined by using a commercially available ELISA kit.

EVALUATION

Mean values of blood glucose for each time point are calculated, and time course of control and treated groups are compared. Area under the blood glucose curve (AUC) can be calculated and compared for both groups; baseline values of blood glucose should be subtracted for the calculation of glucose AUC.

CRITICAL ASSESSMENT OF THE METHOD

An impairment of glucose tolerance can be the result of peripheral insulin resistance, an impaired insulin

secretion from the pancreatic β-cell, or both. Therefore, blood glucose levels as well as corresponding insulin levels are essential for the assessments of the glucose tolerance results. An improvement of glucose tolerance during an oGTT in normal animals can be caused by candidate compounds, which inhibit gastric emptying and thereby delay the glucose absorption from the gut.

MODIFICATION OF THE METHOD

Many authors used mice instead of rats (Gross et al. 1994; Bailey et al. 1997; Ahren et al. 2000). However, parallel insulin measurements are much more limited in mice than in rats. Also, oGTT in insulin-resistant animal disease models in mice (e.g., genetic: ob/ob, db/db, Ay) are described to assess peripheral insulin resistance (Xiao et al. 2001; Arakawa et al. 2001; Nagakura et al. 2003; Thorkildsen et al. 2003; Minoura et al. 2004). Other routes for glucose administration (e.g., intraperitoneal) are also reported (Xie et al. 2004).

7.3.3.2 Euglycemic-Hyperinsulinemic Glucose Clamp Technique in Anesthetized Rats

PURPOSE AND RATIONALE

The euglycemic glucose clamp technique represents the "gold standard" for measuring peripheral insulin sensitivity in humans and animals. This technique was first described in humans by DeFronzo et al. (1979). In this technique, a variable glucose infusion is delivered to maintain euglycemia during insulin infusion. Whole-body tissue sensitivity to insulin, as determined by net glucose uptake, can be quantitated under conditions of near steady state glucose and insulin levels. Terrettaz and Jeanrenaud (1983) adapted this technique to anesthetized rats; Kraegen et al. (1983, 1985) developed the euglycemic glucose clamp technique for use in conscious rats.

PROCEDURE

The study can be performed as described by Terrettaz and Jeanrenaud (1983). Briefly, overnight-fasted rats are anesthetized with ketamine (20 mg/kg) plus pentobarbital sodium (priming bolus 60 mg/kg i.p. plus infusion s.c. at about 20 mg/kg/h); their temperature is kept at 37.5°C. Through left jugular and femoral vein catheters, glucose and insulin are infused. Studies last 240 min. During a 120-min baseline period, blood glucose is determined every 15 min. Then, insulin is administered as a bolus (48 mU/kg/min) for 5 min, followed by a constant i.v. infusion at 4.8 mU/kg/min for

further 115 min. Blood drawn from the tip of the tail is now measured for glucose every 5 min, and 15% D-glucose infused to maintain euglycemia at about 5 mmol/L. At 120 and at 240 min, additional blood samples are drawn from the right jugular vein and placed in K-EDTA-tubes, which are immediately centrifuged at 6°C at 5,000 rpm followed by determination of plasma FFA within 60 min; plasma aliquots are frozen for insulin determinations.

To differentiate between peripheral (predominantly skeletal muscle) and hepatic insulin sensitivity, tracer techniques can be applied (e.g., U-^{13}C-glucose; Neumann-Haefelin et al. 2004). Additionally, the rats are given a constant infusion of U-^{13}C-glucose (1 mg/kg/min) to estimate rates of glucose production and utilization (Michael et al. 2000). Every 15 min, blood samples are obtained via tail-tip bleeds for determination of glucose enrichment. Enrichments are calculated from the ratio of U-^{13}C-glucose/^{12}C-glucose during the last 30 min of the basal period and during the last 60 min of the clamp (i.e., steady state conditions). This ratio was determined by GC-MS analyses of derivatized glucose from blood samples following literature protocols (Michael et al. 2000).

Blood samples were taken at 30 min for determination of baseline insulin levels and at 180, 210, and 240 min for determination of insulin levels under hyperinsulinemia. At 120 and at 240 min, additional blood samples for determination of free fatty acids are taken. Animals were killed by pentobarbital overdose. Metabolic blood parameters are determined using standard methods (Bergmeyer 1974); insulin measurements are performed using commercially available ELISA kits.

EVALUATION

Whole-body insulin sensitivity is calculated as the mean glucose infusion rate (GIR) during the last 60 min of the clamp study.

During steady state, the total glucose appearance in the circulation (Ra) equals the rate of disappearance of glucose (Rd) and is calculated by dividing the U-^{13}C-glucose infusion rate by the steady state value of glucose enrichment. Endogenous glucose production (EGP) is calculated as follows: EGP equals Rd minus glucose infused (GIR). For each animal, two values of EGP are obtained: one during basal conditions and one during the euglycemic-hyperinsulinemic clamp. The methods for quantification of endogenous glucose production in humans are entirely reviewed by Radziuk and Pye (2002).

MODIFICATIONS OF THE METHOD

Burnol et al. (1983) and Smith et al. (1987) used the euglycemic insulin clamp technique coupled with isotopic measurement of glucose turnover to quantify insulin sensitivity in the anesthetized and conscious rats, respectively.

The effects of counterregulatory hormones on insulin-induced glucose utilization by individual tissues in rats, using the euglycemic-hyperinsulinemic clamp technique combined with an injection of 2-[1-3H]-deoxyglucose, were studied by Marfaing et al. (1991).

Lee et al. (1994) studied the metabolic effects of troglitazone on fructose-induced insulin resistance with the euglycemic-hyperinsulinemic clamp technique in rats.

Hulman et al. (1993) studied insulin resistance in the conscious spontaneously hypertensive rat with the euglycemic-hyperinsulinemic clamp technique.

Cheung and Bryer-Ash (1994) described a modified method for the performance of glucose insulin clamp studies in conscious rats under local anesthesia.

Xie et al. (1996) described an insulin sensitivity test using a modified euglycemic clamp in cats and rats. This test uses the amount of glucose required to be infused to maintain euglycemia over a 30-min period in rats and 60 min in cats following a bolus administration of insulin as the index of insulin sensitivity. Glucose levels are determined a short intervals, and variable glucose infusion is used to hold glucose levels within a few percentage points of the basal pretest glucose level. A new blood sampling technique is described that allows each insulin sensitivity test to be carried out using a total of only 0.5 mL of blood.

CRITICAL ASSESSMENT OF THE METHOD

For the safety, pharmacological assessment of candidate compounds to increase or reduce insulin resistance often long-term pretreatment periods for 1 week or longer is necessary before an effect on insulin sensitivity can be detected. Candidate compounds causing an acute effect on lipolysis or antilipolysis of adipose tissue with subsequent changes in free fatty acids normally causes also a fast effect on peripheral insulin sensitivity, which can be measured after a relatively short (16 h) pretreatment period (Schoelch et al. 2004).

7.3.4 Multiple-Dose Studies

7.3.4.1 Effects on Metabolic Blood and Tissue Parameters in Conscious Rats (Multiple-Dose Study)

PURPOSE AND RATIONALE

For studying the side effect potential of candidate compounds on blood triglycerides and cholesterol as well as on metabolic rate, insulin sensitivity and body weight development multiple-dose studies for at least 1 week are necessary. For transcriptional active compounds like the PPAR agonist (peroxisome proliferators-activated receptor), multiple-dose studies lasting several weeks are necessary to detect the pharmacological activity. The fibrates (e.g., fenofibrate), known since decades as triglyceride-reducing drugs, are agonist of PPARα; thiazolidinediones (or glitazones, e.g., rosiglitazone, pioglitazone) are ligands of PPARγ. These agonists exhibit their full pharmacodynamic profile after they have activated the transcription of whole gene families. Agonists of PPARα predominantly induce gene expression of enzymes involved in lipid catabolism, while agonists of PPARγ predominantly induce genes which are involved in lipid anabolism (adipocytogenesis). PPARα agonists reduce blood lipids (triglyceride, free fatty acids) as well as tissue lipids in muscle and liver by inducing fatty acid oxidation in peroxisomes and mitochondria and thereby improving metabolic blood and tissue parameters. PPARγ agonists induce the permanent formation of new adipocytes in fat tissue and thereby maintain a permanent remodeling of the adipose tissue resulting in a redistribution of fatty acids from ectopic lipid accumulation in liver and muscle as well as reducing blood lipid parameters, however, at the expense of increased total fat mass and increased body weight. Their effects in normal rats are marginal but impressive in animal disease models of insulin resistance, obesity, and hypertriglyceridemia (e.g., Zucker-fatty (fa/fa) rats, Zucker

diabetic fatty (ZDF-fa/fa) rats). Various animal models resembling type 2 diabetes are used for evaluation. Details of these models are described elsewhere (Vogel 2008).

At the end of such multiple-dose studies, the animals are killed in terminal anesthesia, and maximal blood collection is possible. Therefore, not only the target metabolic parameters (e.g., glucose, lactate, free fatty acids, triglycerids, cholesterol) but also other parameters, which reflect intermediary metabolism (e.g., keton bodies, urea, uric acid), as well as safety parameters (e.g., ASAT, ALAT, AP, LDH) can be determined by clinical chemistry.

PROCEDURE

Eight rats per group (lean control, obese control, and obese dose groups) are treated with the candidate compound in various doses for up to 6 weeks. According to the pharmacokinetic profile ($t_{1/2}$), the candidate compound is administered once or twice a day by gavage. If the stability of the compound is sufficient, the candidate compound can also be administered by food admixture. Food and water consumption as well as body weight are measured at least once a week. Blood glucose is determined in 10 μL blood samples as well as for insulin (80 μL blood: 30–40 μL serum) collected from the tip of the tail and by retroorbital bleeding for detection of free fatty acids, triglycerides, and other metabolic (e.g., cholesterol, keton bodies) or safety (e.g., ASAT, ALAT, AP) parameters every 2 weeks.

At the end of the experiment, the rats are terminally anesthetized, the abdomen is opened, and terminal blood collection is performed from the vena cava caud. or the aorta abdominalis for determination of metabolic blood parameters and insulin. A part of the liver is freeze clamped immediately as well as a part (about 1 gr) of skeletal muscle (e.g., M. gastrocnemius). The frozen tissue is stored in liquid nitrogen for subsequent determinations of intrahepatic and intramuscular concentrations of glycogen, glucose-6-phosphate (G6P), and ATP. In liver samples, hepatic triglycerides can be measured additionally. Standard enzymatic procedures were used to determine glucose, lactate, free fatty acids, triglycerides, glycogen, G6P, and ATP (Bergmeyer 1974); insulin is determined by using a commercially available ELISA kits.

EVALUATION

The differences of the metabolic blood parameters of the treated groups are calculated against both control groups (lean and obese), which have received the vehicle only. The metabolic tissue parameters at the end of the study are assessed between the two control and treatment groups.

MODIFICATION OF THE METHOD

For the assessment of the side effect potential of the candidate compound on peripheral insulin sensitivity, multiple oGTTs can be performed during the treatment period or the animal study is finished by a hyperinsulinemic-euglycemic glucose clamp study.

Chang et al. (1983) studied ciglitazone in ob/ob and db/db mice, diabetic Chinese hamsters, and normal and streptozotocin-diabetic rats.

Fujita et al. (1983) investigated the effects of ciglitazone in obese-diabetic yellow KK (KK-Ay) mice and obese Zucker-fatty rats.

Diani et al. (1984) treated C5BL/6J-ob/ob and C57BL/KsJ-db/db mice for several weeks with ciglitazone and studied the morphological effects on pancreatic islets.

Fujiwara et al. (1988) performed studies in KK and ob/ob mice and Zucker-fatty rats.

Moreover, Fujiwara et al. (1991) studied the effects of CS-045 on glycemic control and pancreatic islet structure at a late stage of the diabetes syndrome in C57BL/KsJ-db/db mice.

Ikeda et al. (1990) and Sohda et al. (1990) used insulin-resistant animals (yellow KK mice, Zucker-fatty rats, and obese Beagle dogs with moderate insulin resistance).

Gill and Yen (1991) studied the effects on endogenous plasma islet amyloid polypeptide and insulin sensitivity in obese-diabetic viable yellow mice.

Hofmann et al. (1991, 1992) treated insulin-resistant KKAy mice.

Stevenson et al. (1991) studied the effects of englitazone in nondiabetic rats and found no overt hypoglycemia but an enhancement of insulin action.

Kobayashi et al. (1992) found an increase of insulin sensitivity by activating insulin receptor kinase in genetically obese Wistar fatty rats treated with various doses of pioglitazone.

Sugiyama et al. (1990) found a reduction of glucose intolerance and hypersecretion of insulin in

Wistar fatty rats after treatment with pioglitazone for 10 days.

Tominaga et al. (1993) used the glucose clamp technique in streptozotocin-induced diabetic rats.

Yoshioka et al. (1993) found antihypertensive effects in obese Zucker rats.

Lee et al. (1994) studied the metabolic effects on fructose-induced insulin resistance in rats.

Apweiler et al. (1995) administered BM 13.09143 to lean and obese Zucker rats and performed hyperinsulinemic-euglycemic clamp studies in these animals.

Fujiwara et al. (1995) found a suppression of hepatic gluconeogenesis in long-term troglitazone-treated diabetic KK and C57BL/ksJ-db/db mice.

Lee and Olefsky (1995) studied the effects of troglitazone in normal rats with the euglycemic glucose clamp technique.

CRITICAL ASSESSMENT OF THE METHOD

The results of metabolic tissue parameters in liver and muscle must be interpreted carefully, when a hyperinsulinemic-euglycemic glucose clamp study is performed at the end of the treatment period. Under clamp conditions, these tissue parameters are mainly influenced by the hyperinsulinemic condition during the clamp study than by the compound's effect itself.

7.3.4.2 Cholesterol Diet-Induced Atherosclerosis in Rabbits and Other Species

General Consideration

The additional anti-atherosclerotic potential of a candidate compound with a different primary indication does not represent a safety concern. In contrast, the atherogenic potential of a candidate compound, identified during safety pharmacological evaluation, represents a serious safety issue. Development of atherosclerosis needs time, and therefore, multiple-dose studies are necessary to detect a putative anti-atherosclerotic or atherogenic side effect potential of a candidate compound.

Experimental atherosclerosis was first successfully induced in rabbits by Saltykow (1908) and Ignatowski (1909). During the following years, various scientists found that dietary cholesterol was the responsible stimulus for development of atherosclerosis. Other species are also susceptible to diet-induced atherosclerosis (Reviews by Kritchevsky 1964a, b; Hadjiinky et al. 1991). A unifying hypothesis of the pathogenesis of atherosclerosis has been proposed by Schwartz et al. (1991).

PURPOSE AND RATIONALE

Rabbits are known to be susceptible to hypercholesterolemia and arteriosclerosis after excessive cholesterol feeding (supplemented with 0.3–2% cholesterol in the diet). Therefore, this approach has been chosen by many authors to study the effect of potential anti-arteriosclerotic drugs. For studying the atherogenic potential of a candidate compound, a low cholesterol concentration in the diet (0.1–0.3%) is recommended (proatherogenic).

PROCEDURE

Several modifications of the protocol have been described. Usually, male rabbits from an inbred strain, e.g., white New Zealand, at an age of 8–10 weeks are used. Body weight variation should be as low as possible. At the beginning of the experiment, blood is withdrawn from the marginal ear vein for determination of total cholesterol, total triglycerides, and blood glucose. Groups of ten animals are used for treatment with drugs or as controls. The rabbits are switched from commercial food to a diet supplemented with 0.3–2% cholesterol and kept on this regimen for a period of 10–12 weeks. One group is kept on normal diet. During and at the end of the experiment, blood is taken for analysis. Usually, cholesterol and triglyceride levels increase several fold over the original values.

The animals are sacrificed and the thoracic aorta is removed, cleaned of surrounding tissues, and longitudinally cut and opened for fixation with formaldehyde. The tissue is stained with oil red. The percentage of the intimal surface covered by the oil red positive lesions is calculated with a computerized planimeter. In animals fed a normal diet, the aorta does not show any staining whereas, in cholesterol-fed rabbits, the aorta shows severe atherogenic lesions.

EVALUATION

The areas of the aortic lesions are compared between control and treatment groups. Appropriate statistical evaluation is performed, and percent inhibition (anti-atherogenic effect) or percent increase of areas with lesions (atherogenic effect) can be calculated.

MODIFICATIONS OF THE METHOD

Shore and Shore (1976) studied two different strains of rabbits (New Zealand White and Dutch Belt) as models of hyperlipoproteinemia and atherosclerosis.

Studies of Kritchevsky et al. (1989) on experimental atherosclerosis in rabbits fed cholesterol-free diets revealed a greater influence of animal protein and of partially hydrogenated soybean oil on development of atherosclerosis than plant protein and unsaturated soybean oil.

Cockerels (Tennent et al. 1960) and turkeys (Simpson and Harms 1969) are very susceptible to cholesterol feeding and develop marked hypercholesterolemia in rather short periods. Atherosclerosis could also be induced in cockerels by high doses of estrogen without atherogenic diet (Caldwell and Suydam 1959).

Spontaneous arteriosclerosis in pigeons has been described by Clarkson and Lofland (1961).

The Japanese sea quail (*Coturnix coturnix japonica*) is highly susceptible to the rapid development of severe experimental atherosclerosis (Day et al. 1975, 1977, 1979, 1990; Chapman et al. 1976).

Out of 13 strains of mice, Roberts and Thompson (1976) selected the C57BR/cdJ and the CBA/J strain and used these strains and their hybrids as models for atherosclerosis research.

Paigen et al. (1987) described quantitative assessment of atherosclerotic lesions in mice. After 14 weeks on an atherogenic diet, C57BL/6J female mice had aortic lesions at each of the coronary arteries, at the junction of the aorta to the heart and in scattered areas of the aortic surface. The lesions increased after 9 months of atherogenic diet. Methods of evaluating the number and size of lesions were compared including sizing with a microscope eyepiece grid and computer-assisted planimetry.

Atherosclerosis susceptibility differences among progenitors of recombinant inbred strains of mice were described by Paigen et al. (1990).

Yamaguchi et al. (1993) found that addition of 10% linoleic acid to a high-cholesterol diet enhanced cholesterol deposition in the aorta of male ICR strain mice.

In rats, hypercholesterolemia can be induced by daily administration by gavage of 1 mL/100 g body weight of a cocktail containing in 1 L peanut oil: 100 g cholesterol, 30 g propylthiouracil, and 100 g cholic acid over a period of 7 days. The test compounds are administered simultaneously with the cocktail (Fillios et al. 1956; Lustalot et al. 1961).

Inoue et al. (1990) induced experimental atherosclerosis in the rat carotid artery by balloon de-endothelialization and atherogenic diet. A balloon catheter was introduced into the rat's carotid arteries from the iliac arteries, and the endothelium was denuded.

The hamster is susceptible to atherosclerosis. Nistor et al. (1987) fed male hamsters a hyperlipidemic diet consisting of standard chow supplemented with 3% cholesterol and 15% commercial butter for 12 months. Serum total cholesterol doubled after 3 weeks and attained a 17-fold value after 10 months. Up to 6 months, smooth muscle cells in the intima and media of the aorta as well as endothelial cells began to load with lipids. After 10 months, the affected zones looked like human atherosclerotic plaque with huge cholesterol crystal deposits, calcium deposits, and necrosis.

Especially, the hybrid hamster strain Bioä F1B (Bio Breeders Fitchburg, MA, USA) is more susceptible to dietary-induced atherosclerosis than other strains (Kowala et al. 1991). Early atherosclerotic lesions can be induced within a 3-month feeding of a cholesterol/butter-enriched diet. In these animals, simvastatin dose dependently inhibited the development of hyperlipidemia and the plaque formation by cholesterol synthesis inhibition. The histopathological examination of the aortas showed that the cholesterol-/butter-fed F1B hamster developed atherosclerotic lesions and functional changes in the aorta which are closely related to man (Schäfer et al. 1999).

Soret et al. (1976) studied the diet-induced hypercholesterinemia in the diabetic and nondiabetic Chinese hamster.

Beitz and Mest (1991) used cholesterol-fed guinea pigs to study the antihyperlipemic effects of a potentially anti-atherosclerotic drug.

Malinow et al. (1976) recommended the cynomolgus monkey as a model for therapeutic intervention on established coronary atherosclerosis.

This species was used by Hollander et al. (1978) to study the development atherosclerosis after a cholesterol- and fat-enriched diet.

Beere et al. (1992) described experimental atherosclerosis at the carotid bifurcation of the cynomolgus monkey by a cholesterol-enriched diet.

Eggen et al. (1991) studied the progression and the regression of diet-induced atherosclerotic lesions in aorta and coronary arteries on rhesus monkeys.

Howard (1976) recommended the baboon as model in atherosclerosis research because of the similarity of cholesterol metabolism and composition of the lipoproteins to man.

Kushwaha et al. (1991) determined the effect of estrogen and progesterone on plasma cholesterol concentrations and on arterial lesions in ovarectomized and hysterectomized baboons fed a high-cholesterol/high-saturated-fat diet.

Blaton and Peeters (1976) reported studies on the chimpanzee, the baboon, and the rhesus macacus as models for atherosclerosis.

Ming-Peng et al. (1990) studied high-density lipoproteins and prevention of experimental atherosclerosis in tree shrews (*Tupaia belangeri yunalis*). In contrast to rabbits, no increased lipid deposition in aortic intima after cholesterol feeding was found in tree shrews.

CRITICAL ASSESSMENT OF THE METHOD

Diet-induced hypercholesterolemia is useful only for detection of agents interfering with the adsorption, degradation, and excretion of cholesterol. Agents interfering with cholesterol biosynthesis are less probable to be detected.

The use of normal adult marmosets, a species with a lipoprotein profile similar to that of man, may be an alternative (Crook et al. 1990; Baxter et al. 1992).

7.3.5 Acute Effect on Food Consumption

7.3.5.1 General Considerations

The additional weak anorectic effect of a candidate compound with a different primary indication does not represent a safety concern, if not representing a symptom of weak or starting toxicity. In contrast, an orexigenic potential of a candidate compound, identified during safety pharmacological evaluation, represents a serious safety issue. Compound-mediated increased food consumption (orexigenic effect) might lead to obesity, to insulin resistance, and to overt type 2 diabetes. Food and milk consumption can be measured in acute experiments in mice and rats as well as in multiple-dose studies over weeks in parallel to the measurement of body weight development and changes in body composition.

7.3.5.2 Acute Effect on Milk Consumption in Mice

PURPOSE AND RATIONALE

Milk intake is measured in acute experiments in normal or obese mice after an overnight fast. Milk intake serves as a surrogate for food consumption.

PROCEDURE

According to Bickel et al. (2004), male, fasted (24 h) mice, which are placed individually in cages having free access to sugared milk (1 mL = 3.27 kJ) in a graduated cylinder, are used to monitor the amount of milk consumed by the animals. Milk is offered at time 0 min. Cumulative milk consumption is measured at 2, 4, and 6 h after drug or vehicle administration. The experiments are performed during the light phase. During the experimental session, the animals have no access to solid feed.

EVALUATION

Average milk consumption is recorded per control, and treatment groups and can be expressed as means per time point or cumulative over the whole study period of 6 h.

MODIFICATIONS OF THE METHOD

Yamada et al. (2003) studied the interaction of the leptin-induced suppression of milk consumption with the serotonergic pathway.

Yamada J, Sugimoto Y, Hirose H, Kajiwara Y (2003) Role of serotonergic mechanisms in leptin-induced suppression of milk intake in mice. Neurosci Lett 348:195–197

7.3.5.3 Acute Effect on Food Consumption in Rats

PURPOSE AND RATIONALE

Food intake is measured in acute experiments in normal or obese rats. Additionally, in subchronic and chronic multiple-dose experiments, body weight gain is recorded.

PROCEDURE

Female Zucker (fa/fa) rats weighing 250–350 g are maintained under standard conditions (temperature, light-dark cycle, ground rodent pellet chow, tap water). Measurements of food intake begin on day 2. The food is offered in special dishes to reduce spillage. Food intake and body weight are measured daily between 8:00 and 9:00 a.m. At this time, any spilled food from the collecting paper under the cage is gathered, air-dried if necessary, and weighed. Individual food intakes in grams are recorded. The tests compounds are either administered with the food or injected intraperitoneally. Groups of 8–10 animals are used for control or treatment with various doses of the test compound or the standard. Mazindol, 3 m/kg i.p. or 10 mg/kg p.o., can serve as standard. Treatment is continued for 7 days.

EVALUATION

Average food intake and body weight are recorded for each day. Average values of candidate compounds are compared statistically for each day with the control group. Results after oral administration have to be confirmed by parenteral route in order to exclude errors due to palatability.

MODIFICATIONS OF THE METHOD

Bickel et al. (2004) reported the use of an online-feeding monitoring system. Animals were placed individually in cages (Macrolon-cage (type 4), size: 44′ 26′ 15 cm) equipped with a device for continuous monitoring of feed consumption. This device is a container, filled with feed, and hanging on an electronic balance. The balance transmits the weight changes of the feed container continuously to a central unit; data were stored and processed at the end of the experiment. This system can measure feed consumption up to 3 weeks from >100 feeding sensors simultaneously. The feeding monitoring system and data processing hard- and software (Release V3.07-03/2001) were obtained from TSE, Technical & Scientific Equipment GmbH, Bad Homburg, Germany. Software options: The data are processed from a matrix. The matrix delivers cumulatively or sequentially feed consumption in grams (g) for given time intervals for each individual animal. Cumulative and sequential feed consumption is normalized to g feed/time/100 g body weight (bw). A program for microstructural analysis calculates the parameters for feed consumption over a given time (24 h). Parameters delivered are number of meals (Nm/time), intermeal breaks (IMB) (min), average meal size (g), and average meal duration (min). A meal was defined to be 0.5 g and the IMB 15 min. Details of this method are described by Bickel et al. (2000).

Hull and Maher and Maher and Hull (1990) used male Sprague-Dawley rats placed on a mush diet composed of equal parts of ground rodent chow and of 4% nutrient agar solution. The agar-based chow allows a more accurate measurement of food intake and has been shown to be sufficient for maintaining normal growth in rats. The rats were made hyperphagic by food deprivation for 4 h at the beginning of the dark cycle.

Mennini et al. (1991) and Anelli et al. (1992) studied the anorectic activity of various compounds in different species, such as mice, rats, and guinea pigs.

Bowden et al. (1988) used metabolism cages equipped with automated feeding monitors. Food was provided as 45 mg pellets which were singly delivered

to a feeding trough. A photodetector sensed the removal of the pellet, and the number of pellets delivered over a specified time interval was recorded.

Samanin et al. (1979) described anorexia in rats induced by the central serotonin agonist m-chlorophenylpiperazine.

Blavet et al. (1982) studied food intake in fasted rats after treatment with several typical anorexigenic agents.

Dourish et al. (1985) investigated the effects of the serotonin agonist 8-OH-DPAT on food intake in nondeprived male rats. This effect was prevented by *p*-chlorophenylalanine (Dourish et al. 1986).

The anxiolytics gepirone, buspirone, and ipsapirone increased free feeding in rats and did not inhibit feeding induced by 8-OH-DPAT (Gilbert and Dourish 1987).

Jackson et al. (1997) investigated the mechanisms underlying the hypophagic effects of the 5-HT and noradrenaline reuptake inhibitor, sibutramine, in the rat.

Simansky and Vaidya (1990) tested the anorectic action of a serotonin uptake inhibitor by measuring the volume of milk consumed by food-deprived rats.

Stevens and Edwards (1996) induced anorexia by subcutaneous injection of 5 mg/kg 5-hydroxytryptamine in Wistar rats habituated to a restricted feeding regime and tested the effects of a 5-HT_3 antagonist.

Rouru et al. (1992) investigated in genetically obese male Zucker rats the effect of subchronic metformin treatment on food intake, weight gain and plasma insulin and corticosterone levels, and somatostatin concentrations in the pancreas.

Cooper et al. (1990a, b) used nondeprived rats to study anorectic effects in a test of palatable food consumption and in nocturnal free feeding.

Cooper et al. (1990c) tested not only food consumption but also the frequency of feeding bouts and duration of individual feeding episodes.

Eberle-Wang and Simansky (1992) studied the influence on the anorectic action of CCK and serotonin by measuring the uptake of sweetened mash mixture in rats.

Voigt et al. (1995) studied the involvement of the 5-HT_{1A} receptor in CCK induced satiety by recording food intake during a 2-h test meal in food-deprived and in freely feeding rats.

Influence on postprandial satiety in rats was tested by Rosofsky and Geary (1989). Rats were given pelleted chow and water ad libitum. Near the middle of the bright phase of the light-dark cycle, pellets were removed, the animals treated, and condensed milk presented 30 min later. Milk consumption was measured at 4-min intervals for 40 min.

Rats show a dramatic and reliable reduction of food intake if they are prefed a low-protein basal diet and then offered a diet that is imbalanced in any of the essential amino acids (Leung and Rogers 1969). This anorectic response has been used by Hammer et al. (1990) to test serotonin3-receptor antagonists.

Thurlby and Samanin (1981) studied the effect of anorectic drugs on food-rewarded runway behavior.

Ferrari et al. (1992) studied the effects on anorexia induced by ACTH and immobilization in rats in an X-maze with alternate open and covered arms, each baited with laboratory chow.

Cooper et al. (1993) studied dopamine D1-receptor antagonists in rats with chronic gastric fistula, which were trained to sham feed a 10% sucrose solution in a 60 min test.

In wild rodents, hoarding of food covers the long-term alimentary need. In the laboratory, hoarding behavior does not occur in ad libitum fed rats. On the contrary, rats whose energy balance is threatened by previous food restriction hoard as soon as experimental conditions allow to do so. When such a rat gets free access to a food stock (placed outside its usual territory), it carries food into its shelter and accumulates an amount proportionate to its body weight. Fantino et al. (1980, 1986, 1988) and Nishida et al. (1990) used the reduction of the amount of food hoarded during a period of 3 h as parameter for anorectic activity of drugs.

Caccia et al. (1993) studied the anorectic effect of D-fenfluramine in the marmoset (*Callithrix jacchus*).

8.1 Tolerance of Local Anesthetics

8.1.1 General Considerations

One generally has to distinguish between surface anesthesia, infiltration anesthesia, and conduction anesthesia (Fromherz 1922; Schaumann 1938; Camougis and Takman 1971). Special local tolerance tests have been developed for each of these applications including peridural and intrathecal injections.

8.1.2 Irritancy After Surface Anesthesia

PURPOSE AND RATIONALE

Surface anesthesia is used to anesthetize the cornea and conjunctiva of the eye and the mucous membranes in the mouth. The classical pharmacological test is the blockade of the rabbit corneal reflex as described by Régnier (1923) that has become a standard test method for evaluating local anesthetics (Fußgänger and Schaumann 1931; Ther 1953a; Quevauviller 1971;

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*, DOI 10.1007/978-3-642-25240-2_8, © Springer-Verlag Berlin Heidelberg 2013

Muschaweck et al. 1986). These pharmacological methods are only partially suitable to determine the irritancy potential of local anesthetic on mucous membranes. Luduena et al. (1960) compared the mucous membrane irritancy of mepivacaine and lidocaine by the eye irritation method according to Hoppe et al. (1950) and Draize et al. (1944).

For further description of the method, see Chapters I.N (Chap. 12, "Ocular Safety Tests") and I.P (Chap. 15, "Skin Pharmacology").

PROCEDURE

For the rabbit eye irritation tests, the rabbits are placed in ventilated boxes with only the head free. Solutions of local anesthetics in 0.9% saline are prepared, and a volume of 0.2 ml is instilled into the conjunctival sac of one eye, leaving the other as control. The lower lid is retracted gently and held away from the cornea for 1 min, thus ensuring exposure to the solution.

EVALUATION

The medicated eye is examined in comparison with the control eye at 1, 2, 4, and 8 h after medication and scored according to the method of Draize et al. (1944).

Threshold irritant concentrations are calculated. The threshold irritant concentration is taken as that concentration, expressed in percent, which produces no more than a mild irritation.

According to Draize et al. (1944), injuries to the cornea, conjunctival and palpebral mucosae, and the iris are scored separately. The severity of ocular lesions has been graded in a scale of weighted scores.

8.1.2.1 Cornea

A. Opacity—Degree of density (area which is most dense is taken for reading)

Scattered or diffuse area, details of iris clearly visible	1
Easily discernible translucent areas, details of iris slightly obscured	2
Opalescent areas, no details of iris visible, size of pupil barely discernible	3
Opaque, iris invisible	4

B. Area of cornea involved

One quarter (or less) but not zero	1
Greater than one quarter, but less than one-half	2
Greater than one half, less than three quarters	3
Greater than three quarters, up to the whole area	4

Score equals A × B × 5
Total maximum = 80

8.1.2.2 Iris

Values

Folds above normal, congestion, swelling, circumcorneal injection (any one or all of these or combination of any thereof), iris still reacting to light (sluggish reaction is positive)	1
No reaction to light, hemorrhage, gross destruction (any one or all of these)	2

Score equals A × 5
Total possible maximum = 10

8.1.2.3 Conjunctivae

A. *Redness* (refers to palpebral conjunctivae only)

Vessels definitively injected above normal	1
More diffuse, deeper crimson red, individual vessels not easily discernible	2
Diffuse beefy red	3

B. *Chemosis*

Any swelling above normal (includes nictitating membrane)	1
Obvious swelling with partial eversion of the lids	2
Swelling with lids about half closed	3
Swelling with lids about half closed to completely closed	4

C. *Discharge*

Any amount different from normal (does not include small amount observed in inner canthus of normal animals)	1
Discharge with moistening of the lids and hairs just adjacent to the lids	2
Discharge with moistening of the lids and considerable area around the eye	3

Score (A + B + C) × 2
Total maximum = 20

The *maximum total score* is the sum of all scores obtained from the cornea, iris, and conjunctivae.

CRITICAL ASSESSMENT OF THE METHOD

The Draize ocular irritation test is the accepted standard as part of evaluating chemical substances for eye safety. Justified by an exigency for public protection, the Draize test became a governmentally endorsed method to evaluate the safety of materials meant for the use in or around eyes. Because of discomfort to test animals that may be associated with a positive response, continued use of the Draize test has been criticized and alternative methods proposed (Durham

et al. 1992; Prinsen and Koeter 1993; York and Steiling 1998; Curren and Harbell 1998; Kulkarni et al. 2001; Wilhelmus 2001; Abraham et al. 2003; Perrot et al. 2003). With the development of alternative methods to replace the Draize test, the data generated in the Draize test are still being used as a "gold standard" against which the performance of alternative procedures is measured.

8.1.3 Irritancy After Intradermal Injection

PURPOSE AND RATIONALE

Intradermal tolerance of local anesthetics can be used as a screening selection criterion for finding an optimal local anesthetic. Luduena and Hoppe (1952) and Luduena et al. (1960) determined intradermal irritancy by the trypan blue method according to Hoppe et al. (1950).

PROCEDURE

Albino rabbits of either sex weighing 2–3 kg are fastened securely in a supine position and the hair carefully clipped from the abdominal area with a fine-bladed clipper. The bare abdominal surface is marked off into six to eight areas of approximately 20 cm^2 each by a soft wax pencil. In preparing solutions for injections, the highest concentration is prepared first and subsequent dilutions are made therefrom in ratios of 1/2, 1/4, 1/8, 1/16, etc., in order to find the submaximal irritation range. A volume of 0.3 ml of each dilution is injected intracutaneously into randomly designed areas of the abdominal skin of the rabbit. A dose of 1.0 ml/kg of a 1% solution of trypan blue in normal saline is injected 10–20 min after the last intracutaneous injection of test solutions. The sites of injection are examined at one-half, one, and three hours after injection of trypan blue.

EVALUATION

The intensity of staining by trypan blue at the site of injection is scored as follows:

No color	0
Faint but discernible color	2
Distinct blue color throughout	4
Deep blue color throughout	8
Ischemic central area surrounded by deep blue halo	16

The scores are rated as follows:

Average score rating	
0	None
1–3	Mild
4–7	Moderate
8	Or greater marked

The threshold concentration is taken as that concentration expressed in%, which produces no more than a mild irritation.

MODIFICATION OF THE METHOD

Henn and Brattsand (1966), using the trypan blue test, reported that intradermal irritancy of mepivacaine in rabbits was less than with tetracaine, whether the solution contained adrenaline or not.

Using the trypan blue test, Luduena et al. (1972) found that racemic, (+), and (−) mepivacaine had the same intradermal irritancy.

8.1.4 Irritancy After Subcutaneous Injection

PURPOSE AND RATIONALE

The pharmacological irritancy after subcutaneous injection is determined with the method of Bülbring and Wajda (1945) in guinea pigs and modifications thereof (Ther 1953b).

Irritancy of local anesthetics after subcutaneous injections can be determined by subcutaneous injection into the ears of rabbits (Ulfendahl 1957). This method can be used not only as a screening selection criterion for finding an optimal local anesthetic but also as test method for evaluation of production batches (Hergott 1965).

PROCEDURE

Rabbits of either sex weighing 2.5–3.5 kg are used. A volume of 0.1 ml of the test solution is injected in the outer part of the rabbit's ear avoiding hitting any blood vessels. The same volume of saline is injected into the contralateral ear. A pale discoloration of the skin appears immediately, which disappears within 1 h in the control.

EVALUATION

The injection site is inspected after 2 and 24 h. Reactions are scored as absent, slight, moderate, or marked (necrosis).

MODIFICATION OF THE METHOD

The method has been used for evaluation of several local anesthetics (Ther 1953a; Muschaweck and Rippel 1986).

8.1.5 Irritancy After Intramuscular Injection

PURPOSE AND RATIONALE

Local irritancy after intramuscular injection anesthetics can cause irritation and necrosis in muscular tissue. Most studies are performed in rabbits (Luduena et al. 1960; Baeder et al. 1974).

PROCEDURE

Groups of three rabbits of either sex weighing 2–3.5 kg are injected intramuscularly in the gluteal muscle with 1 ml solution of the local anesthetic with and without vasoconstrictor in various concentrations. Each muscle injection site is used only once. The animals are sacrificed at 1-, 2-, or 7-day intervals. The injection sites are examined macroscopically, fixed in Zenker formalin and embedded in paraffin. Histologic preparations are made in the usual way for microscopic examination.

EVALUATION

The slides are checked for inflammatory signs, such as edema, leukocytic infiltration, or foci of coagulative necrosis.

MODIFICATION OF THE METHOD

Several studies were performed on myotoxicity of local anesthetics.

Basson (1978) and Basson and Carlson (1980) described myotoxicity after single and repeated injections of mepivacaine in the rat. Young rats received single or repeated injections of 2% mepivacaine into the tibialis anterior or extensor digitorum longus muscles. Repeated injections consisted of six injections of the anesthetic (100 μl per injection into the tibialis anterior) on different schedules, at intervals of 2 1/2 h, 24 h, or 4 days. The muscles were examined histologically for evidence of myotoxicity from 0 to 7 and 20 days after the last injection. Single injections showed that mepivacaine is a myotoxic drug, producing a lesion, which ultimately results in a degeneration and subsequent regeneration of large amounts of muscle. A similar picture was seen with repeated injections except that greater tissue destruction was noted. Long-term studies following a single injection of mepivacaine showed restoration of the original muscle structure, whereas after repeated injections, some muscles showed persisting foci of interstitial connective tissue. The damage produced by 2% mepivacaine is restored to a large extent by the regeneration of new muscle fibers.

Benoit and Belt (1972) described effects of local anesthetic agents on skeletal muscle and the correlation between local anesthetic-induced myotoxicity and disturbances of intracellular calcium distribution. The gracilis anticus and posticus muscles of albino rats were exposed to various local anesthetic agents (lidocaine, procaine, bupivacaine, cocaine, mepivacaine, or prilocaine). Clinically used concentrations of most agents appeared to be specifically destructive to skeletal muscle. Muscle regeneration from single myoblasts was found to be rapid and complete by 2 weeks. One experiment (experiment 3) was designed to assess only extent of damage but not sequence of changes. Muscles were removed 1 day after a single injection of local anesthetic. No muscle damage was observed with 0.5% lidocaine, 0.5% mepivacaine, or 2% procaine. After 2% prilocaine and 2% mepivacaine, the muscle damage was more extensive.

In another study (Benoit et al. 1980), the local anesthetic mepivacaine and various other drugs known to perturb sarcoplasmic calcium metabolism and/or sarcolemmal sodium conduction were injected into the gastrocnemius or subcutaneously over the gracilis muscle of rats. After 48 h, all of the agents which are capable of increasing the intracellular concentration of free calcium (mepivacaine HCl, quinidine gluconate, A23187, caffeine, and 2,4-dinitrophenol) produced extensive and qualitatively similar myonecrosis. To assess the influence of a calcium antagonist on local anesthetic-induced myonecrosis, verapamil HCl was administered s.c., both alone and in combination with mepivacaine. Although verapamil itself resulted in some minor surface injury, it almost completely blocked the damage produced by mepivacaine. It was concluded that the myotoxicity of local anesthetics is related to a disturbance of intracellular calcium homeostasis.

Carabot et al. (1988) tried to explain the myotoxicity by effects of mepivacaine on the microcirculation of the skeletal muscle. Mepivacaine was inoculated directly into the anterior tibialis muscle of rats. Capillaries were examined through an electron microscope, and capillary density in the damaged

area was calculated by the alkaline phosphatase technique. Degenerative changes were observed in the capillaries 1 h postinoculation. These changes were more significant at 5 days and were no longer visible after 20 days when the regeneration of the muscle fibers was almost complete. Capillary density was reduced when ultrastructural changes were most intense.

Since local anesthetics are widely used in ophthalmic surgery, several studies on extraocular muscle regeneration after local anesthetic–induced lesions were performed by Carlson and Rainin (1985), Økland et al. (1989) in rats, and by Carlson et al. (1992) in primates. In the first study, rats were given an injection of 50 μl of a local anesthetic (mepivacaine, lidocaine, or bupivacaine) into the retrobulbar space of the left eye and injection of the same volume of sterile saline into the retrobulbar space of the right eye. The point of needle entry was posterior to the eyeball. Rats were sacrificed at 3, 7, and 30 days after treatment. The eyes and orbital content were removed and fixed in Bouin's fluid for paraffin sectioning. Sections were stained with hematoxylin–eosin. All three anesthetics produced massive degeneration of the extraocular muscles. Muscle degeneration is followed by regeneration on the damaged muscle fibers. In addition to muscular damage, severe damage was also seen in Harderian glands. In another study, adult rats were given single retrobulbar injections of 50 μl of 2% mepivacaine, and the lateral rectus muscles were examined ultrastructurally from 15 min to 30 days postinjection. The lateral rectus muscle was massively damaged by exposure to the anesthetic, with membrane lesions seen as early as 15 min after the injection. Intracellular damage was followed by the phagocytic removal of the remnants of the damaged muscle fibers. The activation of satellite cells to myoblasts began during the phase of phagocytosis, and between 3 and 4 days after injection, multinucleated myotubes actively forming sarcomeres appeared. The myotoxic effect of retrobulbarly applied local anesthetics in rats seemed to be much greater than they are in primates.

In a study in rhesus monkeys, retrobulbar administration of local anesthetics resulted in a low incidence of muscle fiber lesions in the extraocular muscles closest to the site of injection. Most lesions resulted in the degeneration and regeneration of muscle fibers on the surface of the muscles, but occasionally, a massive internal lesion was seen.

Hagiwara and Ozawa (1985) investigated toxicity of local anesthetics on chick myogenic cells (mononucleated myoblasts and multinucleated myotubes) in culture. Following treatment with the drugs, myogenic cells showed some morphological changes and finally detached from the culture dishes. The toxic effect was estimated by the amount of cells detached and by the DNA and creatine kinase activity of the cells remaining on the dishes. Dibucaine was more toxic than bupivacaine, mepivacaine, tetracaine, and procaine.

Carlson et al. (1990) studied local anesthetic–induced skeletal muscle fiber degeneration and regeneration in the monkey by light microscopy and Komorowski et al. (1990) by electron microscopy. Intramuscular injections of 0.75% bupivacaine, 2% mepivacaine, or 2% lidocaine + epinephrine were given into the abductor pollicis muscles of rhesus monkeys. The muscles were examined from 2 to 28 days. Severe muscle damage, consisting of breakdown of sarcolemma and myofibrils, was seen as early as 2 h. Phagocyte-mediated fragmentation of the degenerating muscle fibers was at its peak during the third and fourth days. Myoblasts were abundant during the fourth day. Early myotubes appeared on the fifth and sixth days, and they matured during the second week. Satellite cells appeared alongside mature myotubes.

8.1.6 Irritancy After Intraneural and Perineural Injection

PURPOSE AND RATIONALE

Nerve irritancy after intraneural and perineural injection injuries is a well-recognized complication of regional anesthesia (Selander 1993; Borgeat and Ekatodramis 2001). Kalichman et al. (1986, 1988, 1989) studied neurotoxicity of local anesthetics in rat sciatic nerve.

PROCEDURE

Female Sprague Dawley rats (250–400 g) were anesthetized by intraperitoneal injection of a mixture of sodium pentobarbital 50 mg/ml, diazepam 5 mg/ml, and 0.9% saline in volume proportions of 1:1:2. Both sciatic nerves were exposed by lateral incision of the thigh and reflexion of the fascia and underlying muscle. Commercial preparations of low- and high-potency ester and amide local anesthetics (among them 2% mepivacaine) were administered using a 30-gauge needle adjacent to the nerve, but external to the epineurium. The wounds were closed and the rats allowed to recover. After 48 h, nerves were excised after anesthesia and prepared for light and electron microscopy. They were fixed by immersion in 2.5% glutaraldehyde in 0.1 M phosphate buffer at a pH of 7.4. After glutaraldehyde fixation for 24 h, nerves were rinsed in buffer and postfixed for 3 h in 1% osmium tetroxide. The tissue was subsequently dehydrated in serial alcohol solutions and later in propylene oxide prior to infiltration with araldite. Blocks were sectioned for light microscopy and stained with either paraphenylenediamine or methylene blue azure II. Electron microscopy was performed on selected bocks after preparation of ultrathin sections stained with uranyl acetate and bismuth subnitrate. Sections were examined in Siemens 1001 ultramicroscope operation at 80 kV.

EVALUATION

Concentration dependence of nerve injury was tested using a subjective scoring system of 0, 1, or 2. Maximum severity was assigned a score of 2, a score of 0 indicated no injury, and moderate or equivocal injury was indicated by a score of 1. The three measures of interest were edema ("structureless space"), nerve fiber injury (degeneration and demyelinization), and lipid droplets (osmophilic inclusions in epineural, perineural, and endoneural cells).

MODIFICATION OF THE METHOD

Henn and Brattsand (1966) tested tissue irritancy after intraneural and perineural injection in rabbits. The test solution—0.25 ml intraneural and 1.0 ml perineural, respectively – was injected into/around the exposed N. ischiadicus of adult-mixed bred rabbits anesthetized with thiopental sodium. Four and eight days after the operation, tissue specimens were excised. The nerve tissues were treated by two different methods – according to the Marchi technique and according to the hematoxylin–eosin staining procedure after fixation in Bouin's solution. At all injection sites, some connective tissue proliferation was found, and after intraneural injection, some loosening-up of neurofibrils was observed. These reactions were also seen among the controls with NaCl and were therefore due to the trauma caused by the operation and injection. In no case were there pathological findings in the axons of the nerves. On the other hand, at high concentrations, some moderate degenerative effects upon the myelin sheaths were observed. At concentrations of 0.5–3% mepivacaine used clinically, no such signs were found.

Knox et al. (1961) studied nervous tissue toxicity in anesthetized rabbits. Using a sterile technique, the right and left sciatic nerves were exposed. In one series of 15 animals, 0.25 ml of lidocaine and mepivacaine in concentrations of 0.5, 1.0, 1.5, and 2% were injected directly into the right and left sciatic nerves. In a second series, three animals received 0.25 ml

mepivacaine 4% directly into both nerves. Controls received 0.25 ml normal saline. In a fourth series of five animals, 1.0 ml of test drugs was deposited around the nerve utilizing the same concentrations. All animals except the controls had a satisfactory sciatic nerve block as evidenced by hind limb paresis on recovery from the ether anesthesia. The rabbits were sacrificed on the second, fourth, and eighth day following injections, and the sciatic nerves were excised and prepared for histologic examination utilizing hematoxylin and eosin, Luxol fast blue, and Masson's trichrome staining techniques. In none of the microscopic sections of sciatic nerves which were exposed to the 0.5 through the 2.0% concentrations of drugs was there evidence of nerve damage (myelin and/or axon degeneration). No demonstrable difference was noted between nerves blocked with lidocaine and those blocked with mepivacaine. The usual reaction seen in these sections was a connective tissue proliferation which was believed to be caused by the trauma of surgery or the injection and which did not differ markedly from control. Nerve degeneration was seen in the right sciatic nerves of two of the three rabbits that received mepivacaine 4% in both sciatic nerves. This reaction was noted in the rabbits sacrificed on the fourth and eighth days.

Gentili et al. (1980) performed a light and electron microscopic, fluorescent microscopic, and horseradish peroxidase study in rats on nerve injection injury with local anesthetic agents: the sciatic nerve of pentobarbital-anesthetized adult Wistar rats was exposed in the upper thigh with the aid of an operating microscope; care was taken to avoid damage to the vascular supply. Using a 30-gauge needle, the nerve was injected at a standard location 1 cm distal to its exit from under the piriform muscle. The agents were injected either directly into the nerve fascicle or applied to the surrounding epineural tissues (extrafascicular). The nerve was examined at 1–2 h and 9–12 days after injection. Extrafascicular injections did not result in any significant nerve injury or disturbance of the blood-nerve barrier. After intrafascicular injection, the degree of injury varied significantly depending on the specific agent injected. Minimal damage was seen after the injection of 1% mepivacaine and 0.5% bupivacaine. The most severe injury with widespread axonal and myelin degeneration was seen after the injection of 2% procaine and 1% tetracaine.

8.1.7 Irritancy After Epidural Anesthesia

PURPOSE AND RATIONALE

Activity irritancy after epidural anesthesia and tolerability of new local anesthetics after intrathecal injection have to be studied in various animal species in order to predict both parameters for spinal (subarachnoid) anesthesia in patients. Myers and Sommer (1993) published a survey on methodology for spinal neurotoxicity studies. Studies in rats were reported by Blomberg and Rickstein (1988); in guinea pigs by Siems and Soehring (1952) and Åkerman et al. (1988b); rabbits by Hughes et al. (1993) and Chernyakova et al. (1994); dogs by Defalque and Stoelting (1966), Feldman and Covino (1988), Raner et al. (1994), and Kamibayachi et al. (1995); cats by Ide et al. (2001); laboratory pigs by Richer et al. (1998); and sheep by Lebeaux (1975) and Feldman et al. (1997). Kief and Bähr (1970) described epidural tolerance of local anesthetics in dogs.

PROCEDURE

Epidural tolerance of articaine with and without addition of Suprarenin was studied in beagle dogs weighing 9–12 kg. For preoperative sedation, the dogs received

0.03 ml/kg Combelen (propionylpromazine) intravenously. The fur of the lumbosacral area was shaved and the skin disinfected. A single dose of 5 ml of a 2% articaine solution was administered epidurally under sterile conditions. All dogs showed the typical symptoms of spinal anesthesia, which subsided after a few hours. The dogs were sacrificed after 1 or 3 days. The portion of the vertebral column with the site of injection in the middle was removed and placed in 8% buffered formalin. When semifixed, the vertebral arches were opened, and the spinal cord, as well as the roots of the spinal nerves with the adipose tissue of the epidural space, was removed. After embedding in gelatin and Paraplast, the serial sections from the area of injection were stained with fast red 7B, hematoxylin–eosin, and myelin sheath staining according to Olivecrona was performed. Furthermore, the PAS and iron reaction was performed in one section.

EVALUATION

The presence or absence of nerve damage and of inflammation was noted.

8.1.8 Irritancy After Intrathecal (Spinal) Injection

PURPOSE AND RATIONALE

Transient irritancy after intrathecal (spinal) injection neurological symptoms have been observed in patients after spinal anesthesia (Hampl et al. 1995). Activity and tolerability of new local anesthetics after intrathecal injection were studied in various animal species in order to predict both parameters for spinal (subarachnoid) anesthesia in patients.

Myers and Sommer (1993) published a survey on methodology for spinal neurotoxicity studies. Studies in rats were performed by Yaksh and Rudy (1976), Hylden and Wilcox (1980), Bahar et al. (1984a), Åkerman (1985), Ossipov et al. (1988), Cole et al. (1990), Wang et al. (1991), Dirksen et al. (1992), Mestre et al. (1994), Omote et al. (1995), Chanimov et al. (1997), Grouls et al. (1997), and De la Calle and Palíno (2002); in mice by Hylden and Wilcox (1980), Åkerman (1985), Åkerman et al. (1988a,b), and Langerman et al. (1994); in rabbits by Bieter et al. (1936a, b), Luduena et al. (1960), and Langerman et al. (1991); in dogs by Wagner et al. (1940), Feldman and Covino (1981), Kozody et al. (1985), and Dohi et al. (1987); in marmosets by Bahar et al. (1984b); in rhesus monkeys by Denson et al. (1981); in sheep by Lebeaux (1975) and Kyles et al. (1992).

For Detailed Description of the Pharmacological Effects, See Chap. 11 "Blood Constituents and Safety Pharmacology."

Kirihara et al. (2003) compared neurotoxicity of intrathecal and epidural lidocaine in rats.

PROCEDURE

Kirihara et al. (2003) compared neurotoxicity of intrathecal and epidural lidocaine in rats. Male Sprague Dawley rats were anesthetized with sodium pentobarbital (30 mg/kg i.p.) and 1.5% halothane. A catheter of stretched polyethylene tubing PE-10 was introduced into the subarachnoid or epidural space using an aseptic technique. Catheters were passed through the L4–L5 intervertebral space and advanced 1.3 cm in the caudal direction. Rats were allowed 4 days to rest for recovery from the operation.

To measure the response to noxious heat stimulus, a tail flick test was performed. A 100-W projector lamp was focused on the distal segment of the tail approximately 5 cm from the tip. The time at which rats withdrew the tail was defined as the tail flick latency. A cutoff time of 10 s was used to avoid damage of the tail.

To measure the response of legs to noxious mechanical stimulus, a paw pressure test was applied to the dorsal surface of both hind paws using a device capable of progressively increasing the pressure at a rate of 15 g/s. The pressure at which the rat withdrew the paw from the device was defined as the paw pressure threshold, and the mean of both paws was used for analysis. A cutoff pressure of 400 g was used to prevent damage to the paws.

Motor function in the lower limbs was assessed by grading: 0 = none, 1 = partially blocked, and 2 = completely blocked.

Various concentrations of local anesthetic or saline are injected intrathecally in a volume of 20 μl or epidurally in a volume of 100 μl followed by 10 μl saline to flush the catheter. Tail flick test, paw pressure test, and motor function were performed 10, 20, 30, 60, 120, 180, and 240 min after injection and continued daily for 4 days.

After the last experiments, the rats are euthanized by injection of an overdose of pentobarbital and then perfused intracardially with a phosphate-buffered 2.0% paraformaldehyde—2.5% glutaraldehyde fixative. Methyl green solution was injected to confirm the location of the catheter after the perfusion. The spinal cord and nerve roots were dissected out and immersed in the same fixative for 4 h. Two specimens (10 mm rostral and caudal to the conus medullaris) from each rat were postfixed with cacodylate-buffered 1% osmium tetroxide dehydrated in a series of graded alcohol solutions and embedded in epoxy resin. From the embedded tissue, 1-μm transverse sections were obtained and stained with toluidine blue dyes. Sections obtained from 10 mm rostral to the conus (caudal spinal cord) were used for qualitative evaluation. Quantitative analysis of nerve injury was performed using the sections obtained from 10 mm caudal to the conus. Each fascicle present in the cross section was assigned to an injury score 0–3. The injury score for each cross section was then calculated as the average score of all fascicles present in the cross section.

EVALUATION

Data are presented as mean ± SEM. Tail flick latencies and paw pressure thresholds were converted to the percentage of maximal possible effect. The area under the time-effect curve was calculated by accumulating the effect measured at discrete time intervals using the trapezoidal integration method. The results were analyzed by ANOVA with repeated measures followed by Scheffe and Dunnett tests. The injury score for each technique and each solution was compared using two-way ANOVA followed by the Scheffe test. The frequency (i.e., the number of rats with lesions) in each group was analyzed by chi-square test.

MODIFICATION OF THE METHOD

Wakamatsu et al. (1999), Ohtake et al. (2000), and Oka et al. (2001) studied the effects of intrathecally administered local anesthetics on glutamate release and neuronal injury in rabbits. New Zealand white rabbits were anesthetized with isoflurane. With the rabbits in prone position, midline skin and subcutaneous fascia were incised between the third lumbar and the first sacral spinous process after infiltration with 0.25% bupivacaine. Muscles were dissected; the third to seventh processes, ligamentum flavum, and epidural fat were sequentially removed; and the underlying dura was exposed. Using an operating microscope, a small slit was made in the dura and arachnoid membrane at the L3–4 interlaminar space. A loop-type dialysis probe was then implanted. A PE-10 catheter for the administration of saline or the local anesthetic to be tested was implanted intrathecally through the slit made at the L6–7 interlaminar space so that the tip of the catheter was located at the level of the cauda equina. The implanted dialysis probe was perfused with artificial cerebrospinal fluid bubbled with 95% oxygen and 5% CO_2 at pH 7.2. Samples were collected

before and after administration of test substance and analyzed for glutamate.

After collecting the last sample (90 min after intrathecal administration of test substance), the catheters were removed, and all incisions were sutured. Isoflurane was discontinued, and the lungs were ventilated with 100% oxygen. Extubation of the trachea was performed when adequate spontaneous ventilation occurred. The animals were allowed to recover with infusion of Ringer's solution and antibiotic treatment.

The animals were neurologically assessed daily until 1 week after test drug administration by an observer unaware of the treatment group. Sensory function was evaluated by seeking an aversive response to pinprick stimulation with a 23-gauge needle, progressing from sacral to thoracic dermatomes. The score of the sensory function was assessed by a three-point grading scale. The hind-limb motor function was assessed by a five-point grading scale.

After completion of the neurologic function scoring at 1 week, the animals were reanesthetized, and transcardiac perfusion and fixation were performed. The spinal cord was removed and refrigerated in phosphate-buffered formalin 10% for 48 h. After dehydration in graded concentrations of ethanol and butanol, the spinal cord was embedded in paraffin. The coronal sections of the spinal cord at L3, L4, and L5 levels were cut at a thickness of 8 μm and stained with hematoxylin and eosin. The degree of the spinal cord damage was assessed for the vacuolation of the dorsal funiculus with a four-point grading scale and the chromatolytic changes of the motor neuron. The neurons with chromatolytic appearance were identified by round-shaped cytoplasm with loss of Nissl substance from the central part of the cell and eccentric nuclei. The motor neurons with chromatolytic appearance were counted in two sections for each animal and averaged.

Parametric data were presented as mean $\pm$ SD. To determine differences in glutamate concentrations, a repeated measures analysis of variance was performed. The cutaneous sensation, hind-limb motor function, and morphological changes of the spinal cord were analyzed with a nonparametric method (Kruskal–Wallis test) followed by the Mann–Whitney *U*-test.

Muschaweck et al. (1971) performed comparative intrathecal tolerance studies in dogs. Beagle dogs weighing 8–12 kg were anesthetized with 30 mg/kg sodium pentobarbital intravenously. The animals were intubated and submitted to artificial respiration. The fur on the neck was shaved and the skin disinfected. All further procedures were carried out under sterile conditions. The spinal canal was punctured through the foramen magnum at the atlanto-occipital joint. Successful entry of the spinal cervical canal was checked by withdrawal of cerebrospinal fluid. Five milli liter of cerebrospinal fluid was withdrawn and used as solvent for the tested local anesthetics. The same volume was injected intrathecally either as solution of local anesthetics in concentrations used in therapy or as control (saline solution). Artificial respiration was continued until spontaneous breathing resumed. Motor performance was checked during 24 h. Two days later, the animals were sacrificed under anesthesia. Dissection included the cerebellum, medulla oblongata, and sections from the cervical, thoracic, and lumbar cord, carefully observing that always the same segments were taken including the injection site. Segments were semifixed in 8% buffered formaldehyde for 2 days. When semifixed, the vertebral arches were opened and the spinal cord, as well as the roots of the spinal nerves, was removed and completely fixed. After embedding in gelatin and Paraplast, a fat red 7B and myelin sheath staining according to Olivecrona were performed on serial sections from the site of injection as well as from cervical, thoracic, and lumbar marrow. Hematoxylin–eosin staining, as well as PAS and iron reaction, was performed in one section. The presence or absence of nerve damage and of inflammation was noted.

Yaksh et al. (1995) studied the safety of chronically administered neostigmine methylsulfate in rats and dogs. Adult beagle dogs weighing 13–17 kg were adapted for 5 days to experimental protocols and placement of a nylon vest. For placement of the spinal catheter, the dogs were sedated (atropine 0.04 mg/kg and xylazine "Rompun" 1–2 mg/kg i.m.) given an i.m. injection of penicillin G and procaine and brought an anesthetic depth by mask administration of halothane (3–5%), and then the trachea was intubated. The dog was maintained under spontaneous ventilation with 1–2% halothane and 50% N_2/50% O_2. Surgical areas on the back of the neck and head were shaved and prepared with alcohol and a povidone iodine scrub, and the dog was placed in a stereotaxic head holder.

After draping and using sterile technique, the cisterna magna was exposed, and a small incision (10–2 mm) was made. The intrathecal catheter (polyethylene rubbing PE-50 stretched by 30%, making the nominal diameter 0.6 mm) was inserted and passed caudally at a distance of 40 cm, to a level corresponding approximately to the L3–L4 segment. Presence of the catheter in the intrathecal space was confirmed by free withdrawal of cerebrospinal fluid. A small stainless steel screw was placed in the skull and the catheter fixed to the screw. The catheter was tunneled subcutaneously and caudally to exit on the upper left back at the level of the scapula. The incision was closed by sutures, the halothane turned off, and the animal allowed to recover. An analgesic was administered for postoperative pain medication. At this time, the catheter was connected to the infusion pump placed into a vest side pocket, and an infusion of sterile saline (2 ml/day) was started.

For a 28-day infusion study, dogs were randomly assigned to receive saline or neostigmine (4 mg/4 ml). After 28 days of infusion, the dogs were sacrificed. After induction of a deep anesthesia, the animal was manually ventilated to maintain adequate oxygenation. A percutaneous puncture of the cisterna magna was performed and cerebrospinal fluid withdrawn for analysis. The chest was opened and a large-bore cannula placed in the aortic arch through which was perfused saline followed be 10% formalin. After fixation, the dura was exposed by an extensive laminectomy of the spinal canal and the lower brainstem, being careful to leave the catheter and the dura undisturbed. Dye was injected through the catheter to determine its integrity, visualize the position of the intrathecal catheter, and determine the spread of dye around the catheter; the spinal cord was removed in four blocks (cervical, thoracic, caudal, and rostral from the catheter tip), taking care to keep the dura intact, and placed in formalin. After fixation, tissue blocks were embedded in paraffin and then decalcified overnight, embedded in paraffin, sectioned at a thickness of 6–7 μm, and stained with hematoxylin and eosin. Particular attention was given to the presence or absence of fibrosis and other reactions around the catheter, dural thickening or other reaction; inflammation in the epidural space, leptomeninges/subarachnoid space, or spinal cord parenchyma, microglial nodules, demyelinization, or gliosis. The degree of chronic and/or acute inflammation was graded as normal, mild, moderate, or severe.

8.1.9 Studies on Porphyrogenicity

PURPOSE AND RATIONALE

Acute porphyrogenicity hereditary porphyrias are disorders of heme synthesis in which overproduction of heme precursors is often accompanied by severe clinical manifestations. Most of the time, these diseases remain clinically latent and only occasionally result in acute abdominal and neuropsychiatric symptoms. Occurrence of the symptoms often follows exposure to drugs, such as barbiturates, sulfonamides, estrogens, and some local anesthetics (Blanloeil et al. 1989).

De Verneuil et al. (1983), Deybach et al. (1987), and Blanloeil et al. (1989) studied according to the method of Anderson (1978) the propensity of various drugs to induce hepatic porphyria. A situation analogous to the latent stage of human hepatic porphyria could be produced in chick embryos by injecting an inhibitor of ferrochelatase (the last enzyme in the heme biosynthesis pathway). The simultaneous injection of a porphyrinogenic drug (e.g., barbiturate) results in a strong increase of the porphyrin levels in the chick embryo. This method is used for drug screening: drugs that are found porphyrinogenic in this test were considered to be potentially dangerous to patients with hepatic porphyria.

PROCEDURE

Fertilized 16-day-old chick embryos are kept in an incubator at 37°C with 70% humidity. Drugs are dissolved in a small volume (0.1–0.3 ml) of 0.15 M NaCl. According to Anderson (1978), a small dose of DDC (1,4-dihydro-3,5-dicarbethoxycollidine) is added that leads to the formation of N-methylprotoporphyrin, which is the inhibitor of ferrochelatase, the last enzyme in heme biosynthesis. Sterile injections are made when the eggs are 18 days old. After 24 h, the embryos are killed by decapitation and the livers removed, separated from the gall bladder, and rinsed with saline prior to homogenization with 3 vol of 0.25 M sucrose/0.02 M Tris buffer, pH 7.4. At least six embryo livers are pooled for each determination.

For determination of porphyrins, the livers are extracted from the whole homogenate with 1 N perchloric acid:methanol (1:1 v/v). The type and the concentrations of porphyrins are studied with a spectrofluorimeter (Grandchamp et al. 1980). The type of accumulated porphyrins is confirmed by

high-pressure liquid gas chromatography (de Verneuil et al. 1978).

For enzyme assays, the homogenates are centrifuged at 800 g for 15 min, and the supernatant is sonicated three times for 15 s. Activity of δ-aminolevulinate synthase (ALA-S) is measured following the radiochemical method of Strand et al. (1972) with [^{14}C]succinic acid and a succinyl-CoA-generating system. Enzyme activity is expressed as pmoles δ-aminolevulinic acid per 30 min per mg of protein. Ferrochelatase activity is measured using a modified radiochemical method (Bonkowsky et al. 1975; Deybach et al. 1981).

To measure cytochrome P-450, 10 ml of the 800 g supernatant is centrifuged at 12,000 g for 15 min; 5 ml of the supernatant is then centrifuged at 105,000 g for 30 min; after washing twice, microsomes (pellet) are resuspended in phosphate buffer and the protein concentration adjusted to 2 mg/ml. The level of cytochrome P-450 is measured in the microsomal fraction using the method of Omura and Sato (1964).

EVALUATION

The tests allow judgment of the propensity of local anesthetics to induce symptoms of hepatic porphyria. The local anesthetics lidocaine, bupivacaine, etidocaine, mepivacaine, prilocaine, and procaine belong to this group, but procaine, butacaine, oxybuprocaine, proxymethacaine, and tetracaine had no (or very slight) porphyrinogenic effect.

MODIFICATION OF THE METHOD

Schütz and Fuchs (1985a, b) studied the porphyrinogenic potential of the local anesthetic articaine (Ultracain). Rats and dogs were given 25–30 intravenous and intramuscular injections of ultracaine without a vasoconstrictor in sublethal or maximum tolerated doses. No signs of any hepatotoxic effect were observed. Rabbits found to have porphyrinuria following administration of allyl-isopropyl-acetyl-carbamide (Apronal) were injected, the local anesthetic intramuscularly on five successive days in a dosage (50 mg/kg) which caused cramps without resulting in urinary porphyrin secretion or hepatic damage.

Bayar and Sümer (1995) investigated the effect of some local anesthetics on methemoglobin levels and erythrocyte enzymes.

8.2 Tolerance of Neuromuscular Blocking Agents

8.2.1 General Considerations

Neuromuscular tolerance of neuromuscular blocking agents transmission is mediated by nicotinic acetylcholine receptors, for which various subtypes are described (Sargent 1993; McGehee and Role 1995; Karlin and Akabas 1995; Alexander et al. 2001).

Neuromuscular blocking agents are distinguished by whether or not they cause depolarization of the motor end plate. They are classified either as competitive (stabilizing) agents, of which **d**-tubocurarine is the classical example, or as depolarizing, desensitizing agents such as succinylcholine.

For safety evaluation, the absence of cardiovascular side effects is important (Vizi et al. 2003).

8.2.2 Evaluation of Autonomic Margins of Safety

PURPOSE AND RATIONALE

Savarese (1979) determined not only the potencies of metocurine and **d**-tubocurarine but also the autonomic margins of safety in anesthetized cats.

PROCEDURE

Adult cats of either sex are anesthetized with α-chloralose, 80 mg/kg, and pentobarbital 7 mg/kg, given intraperitoneally. Cannulas are placed in the left femoral vein and artery for drug injection and recording blood pressure and heart rate. The lungs are mechanically ventilated through a tracheostomy and a small animal ventilator set to deliver 15 ml/kg tidal volume and 20 breaths/min.

The right vagus nerve and the right sympathetic trunk are exposed and divided in the neck. The distal ends are placed on the same shielded platinum wire electrode to permit preganglionic stimulation of both nerve trunks. The left sympathetic trunk is also dissected along its postganglionic portion at the base of the skull and cut distal to the superior cervical ganglion to permit postganglionic stimulation through another electrode. Trains of square wave pulses (20 Hz for 10 s) are delivered at supramaximal voltage every 4 min simultaneously to all three autonomic nerve trunks. The resulting bradycardia and hypotension (the vagal response) are measured. Contractions of both nictitating membranes, one (the right) elicited preganglionically and the other (the left) elicited postganglionically, are recorded. The maximal vagal response (i.e., cardiac arrest for 10 s) is achieved by stimulation of the right vagus nerve or of both vagus nerves.

Twitches of the right tibialis anterior muscle are elicited at 0.15 Hz via the peroneal branch of the right sciatic nerve, to which square-wave shocks of 0.2 ms are applied at supramaximal voltage. Twitch recording is done via a transducer. All nerves and tendons are kept moist in small pools of mineral oil or in cotton pledges soaked in mineral oil. Tibialis anterior and esophageal muscle temperatures are monitored and kept between 35°C and 38°C by heat lamps.

Simultaneous recordings of heart rate, arterial pressure, pre- and postganglionic-elicited contractions of the nictitating membrane, and twitches of the tibialis anterior muscle are made on a polygraph. Cumulative dose–response curves for inhibition of neuromuscular, vagal (parasympathetic), and sympathetic functions are determined simultaneously for each animal. The mechanism of vagal inhibition is localized at parasympathetic ganglia or cardiac muscarinic receptors by determining whether the bradycardic response to methacholine (20 μg/kg) is blocked as well as the neurally elicited bradycardia.

A single-bolus dose of the neuromuscular relaxants producing the delayed depressor response plus tachycardia (Paton 1957) is determined in each animal. This response being pathognomonic for histamine release is defined as sudden hypotension to less than 80% of the control arterial pressure within 2 min of relaxant injection and with tachycardia to more than 25% above the baseline value.

Test drugs are given intravenously.

EVALUATION

Data analysis is done by the method of Litchfield and Wilcoxon. Mean dose–response curves are plotted on

log-probit paper. Best fit to straight lines on these scales is determined by computerized regression. The cumulative ED_{50} values for vagal and sympathetic inhibition and the cumulative ED_{95} values for neuromuscular blockade are determined from the lines, and 95% confidence limits are calculated. Differences in potency are considered significant when $P < 0.05$.

The occurrence of histamine release is also treated as an all-or-none response to permit log-probit plotting. The delayed depressor response plus tachycardia is judged to have or have not occurred after each single-bolus injection of the drugs. The percentage of animals responding at each dose level is then determined and the data handled by the Litchfield–Wilcoxon method.

The autonomic margins of safety of the test drugs are calculated as the ratios of cumulative doses producing 50% block (ED_{50}) of vagal (parasympathetic) and sympathetic transmission and the ED_{50} for histamine release, each divided by the ED_{50} of neuromuscular blockade.

MODIFICATION OF THE METHOD

Clutton et al. (1992) studied the autonomic and cardiovascular effects of neuromuscular blockade antagonism in the dog. Neuromuscular blockade was antagonized with various anticholinesterase–antimuscarinic drug combinations including atropine, neostigmine, and glycopyrrolate.

9.1 Determination of Safety of Intravenous Anesthetics

9.1.1 General Considerations

PURPOSE AND RATIONALE

The determination of safety of intravenous anesthetics first agents used as intravenous anesthetics were *barbiturates*. Barbiturates with a duration of action appropriate to the requirements of surgery became available with the introduction of hexobarbital and thiopental (Volwiler and Tabern 1930; Miller et al. 1936). The studies with barbiturates were extended (Butler and Bush 1942; Christensen and Lee 1973). Intravenous anesthetics from other chemical groups were developed, such as *acetamidoeugenol* (Estil, Domenjoz 1959), steroid derivatives (Presuren = *hydroxydione sodium*, Laubach et al. 1955), *alfaxolone* (CT1341, Child et al. 1971), *propanidid* (Epontol, Goldenthal 1971), *ketamine* (CI-581, Chen et al. 1966; Reich and Silvay 1989), *etomidate* (Janssen et al. 1975), *propofol* (ICI 35868, Glenn 1980), and *midazolam* (Pieri 1983; Reilly and Nimmo 1987).

9.1.2 Tests for Safety of Intravenous Anesthetics

PURPOSE AND RATIONALE

Besides determination of the ratio between anesthetic and lethal dose, intravenous anesthetics have to be tested for their influence on the cardiovascular and pulmonary system. Borkowski et al. (1990) described a method to compare intravenous anesthetics in rabbits.

PROCEDURE

Adult New Zealand white rabbits with a mean weight of 4.5 kg are used. To provide access for direct blood pressure measurement and arterial blood samples, an 18-gauge catheter is implanted into the left carotid artery under halothane anesthesia. Following a minimum 24-h recovery period, the rabbit is placed in a sling and a pneumograph is fitted around the rabbit's caudal thorax at the level of the 10th to 12th rib to monitor respiratory rate and pattern. From the arterial catheter, blood is withdrawn for blood gas analysis. Then the catheter is connected to a blood pressure transducer. A 10-min acclimatization period is allowed before control measurements are recorded. Each rabbit serves as its own control in that cardiopulmonary parameters and responses to noxious stimuli are determined before anesthesia is induced. The right marginal ear vein is catheterized with a 22-gauge catheter, which is secured with adhesive tape, flushed with physiologic sterile saline, and used for the administration of the anesthetic agents.

One third of the dose of the anesthetic to be tested is injected manually over a 1-min period. When the rabbit is relaxed, it is removed from the sling and is placed in left lateral recumbence on a heating blanket. The degree of muscle tension and reaction to noxious stimuli are determined while the rabbit is in the sling and at 15-min intervals following anesthesia. The assessments performed include those of jaw tone, leg muscle tone, palpebral reflex, corneal reflex, ear pinch reflex, and pedal withdrawal reflex. Jaw tone is evaluated subjectively by pulling the lower jaw open by an index finger. Leg muscle tone is evaluated by flexion and extension of the right rear leg according to subjective scores. The corneal reflex is tested by placing a moistened cotton swab on the cornea. The palpebral reflex is tested by touching the medial canthus with a dry cotton swab. Assessment of the ear pinch reflex is performed by applying a compression force with an alligator clip. The pedal withdrawal reflex is determined by applying the same clip on the right rear fifth digit at the distal phalanx.

Cardiopulmonary parameters and rectal body temperature are determined while the rabbit is in the sling and also at 15-min intervals following induction of anesthesia with the rabbit in lateral recumbency. Heart rate, mean arterial blood pressure, respiratory rate, and respiratory pattern are calculated from tracings from the physiological recorder. Arterial blood pH, partial pressure of oxygen (PaO_2), and partial pressure of carbon dioxide ($PaCO_2$) are determined from arterial blood samples.

EVALUATION

The heart rate, mean arterial blood pressure, respiratory rate, pH, PaO_2, and $PaCO_2$ are analyzed using a two-factor analysis on repeated measures. The control values are treated as covariate to allow standardization of the inherent variation between rabbits.

The single *t*-test for paired differences is used to compare control values to data obtained during the later testing intervals. The standard error of the mean (SEM) is calculated for each variable at each time interval. Data for muscle tone and responses to noxious stimuli are calculated as frequency percentages. The Fisher's exact test is used to compare between treatments. For all of the statistical analyses, a p value of less than 0.05 is considered significant.

MODIFICATIONS OF THE METHOD

Details of anesthesia in the rabbit were also described by Murdock (1969).

Peeters et al. (1988) performed a comparative study of four methods for general anesthesia in rabbits.

Glenn (1980) examined the anesthetic activity of propofol (ICI 35868) in mice, rats, rabbits, cats, pigs, and monkeys, including cardiovascular and respiratory parameters and EEG studies.

Korkmaz and Wahlström (1997) developed the electroencephalographic (EEG) threshold test in rats to determine the central nervous sensitivity to several depressant drugs, mainly intravenous anesthetic drugs. The test drugs were administered by continuous intravenous infusion until a defined EEG criterion indicating deep anesthesia was reached. The criterion was a burst suppression which lasted 1 s or more, the "silent second" (SS). The dose of the drug needed to induce the SS, the threshold dose, was the dependent variable. In the intact animal, it is influenced by the potency of the drug and the dose administration rate of the infusion. With the method, it is possible under in vivo conditions to monitor continuously the electrical changes in the CNS.

9.2 Determination of Safety of Inhalation Anesthetics

9.2.1 General Considerations

PURPOSE AND RATIONALE

The determination of safety of inhalation anesthetics efficacy and safety of new inhalation anesthetics has to be evaluated in pharmacological experiments. Robbins (1946) defined the anesthetic AD_{50} as the concentration of anesthetic at which 50% of mice failed to right themselves for 15 s when placed in a rotating bottle with a known concentration of anesthetic. The concentration of the anesthetic that caused apnea in 50% of the mice in 10 min was defined as the LD_{50}, and the ratio LD_{50}/AD_{50} as an index of safety.

Wolfson et al. (1972) recommended brain anesthetic concentration for construction of anesthetic indices.

9.2.2 Safety Margin of Inhalation Anesthetics

PURPOSE AND RATIONALE

To assess the safety margin of an inhalation anesthetic, not only should the ED_{50} values but also the maximally effective dose and the dose with a minimal danger of fatal outcome be determined. In particular, *cardiovascular parameters* are observed (Kissin et al. 1983).

PROCEDURE

Male Sprague Dawley rats weighing 300–350 g are placed into a clear chamber with the tail protruding from a special opening. An anesthetic-oxygen nonhumidified mixture is directed into the chamber at a rate of 4 l/min. The inhalation anesthetics, e.g., halothane or isoflurane, are vaporized in Draeger vaporizers, and the level in the chamber is monitored

with a gas analyzer which is calibrated with a mass spectrometer. Rectal temperature is monitored and maintained at 37°C with a heating pad. Each rat is exposed to only one predetermined concentration of anesthetic for 30 min, at which time the presence or absence of the end point of anesthesia is determined. For the lethal endpoint, rats are tracheotomized and ventilated at 60 strokes/min through an endotracheal catheter. Tidal volume is adjusted to maintain Pa_{CO_2} at 40 ± 5 mmHg.

Endpoints of anesthesia used:

1. Loss of righting reflex. The test is regarded as positive if the animal fails to right itself with all 4 ft on the floor within 15 s after being placed in a side position.
2. Prevention of purposeful movements response to a noxious stimulus. The animals are stimulated for 60 s by placement of a 1-kg weight on the middle of the tail. Only the purposeful movement of the head or legs is considered to be a response.
3. Prevention of the heart rate increase to a noxious stimulus (ECG signals). An increase in heart rate of greater than 1% is regarded as a positive response.
4. The endpoint for the lethal effect is 7 mmHg in the femoral artery with artificial respiration.

With each of the anesthetics, four series of experiments are performed: to determine the righting reflex, purposeful movement response, heart rate response, and lethal effect. The concentrations of the test compounds and the standard are spaced equally between the above-mentioned doses.

After determination of the heart rate effect and the lethal effect, the rats are sacrificed for determinations of brain tissue concentrations. The whole brain is removed, and tissue anesthetic concentration is determined by gas chromatography.

EVALUATION

For calculation of the dose-effect curves, the probit method of statistical analysis is used.

For the assessment of anesthetic safety, not only the therapeutic ratio (LD_{50}/ED_{50}) but also the standard safety margin

$$SSM = (LD_5 - ED_{95})/ED_{95} \times 100$$

is used. This represents the percentage by which the ED_{95} has to be increased before LD_5 is reached.

CRITICAL ASSESSMENT OF THE METHOD

The standard safety margin has definitive advantages over therapeutic ratio. In contrast to the LD_{50}/ED_{50} index, the standard safety margin is influenced not only by the distance between central points of the anesthetic and lethal dose-effect curves but also by the slope of these curves.

MODIFICATIONS OF THE METHOD

A similar concept, based on response to tail clamping, respiratory arrest, and cardiovascular failure in the *rat*, was published as an anesthetic index by Wolfson et al. (1973).

Another attempt to determine anesthetic requirements in rats was published by White et al. (1974).

Kissin et al. (1984) studied the morphine-halothane interaction in rats.

Fukuda et al. (1996) investigated the effects of sevoflurane and isoflurane on bupivacaine-induced arrhythmias and seizures in rats.

Kanaya et al. (1998) compared myocardial depression by sevoflurane, isoflurane, or halothane in *cultured neonatal rat ventricular myocytes*. Changes in beating rate and amplitude during exposure to the anesthetics were measured.

Chaves et al. (2003) used noninvasive electrocardiography in *mice* to study the effects of intravenous and inhalation anesthetics and of age.

Krantz et al. (1941, 1953) described an anesthetic index between surgical anesthesia (cornea and wink reflexes abolished) and respiratory failure in *dogs*.

Van Poznak and Artusio (1960a, b) determined the anesthetic properties of fluorinated compounds in dogs using a face mask for the induction of anesthesia and a cuffed endotracheal tube later on. ECG (lead II) and EEG were monitored.

Steffey and Howland (1978) determined the potency of enflurane in dogs in comparison with halothane and isoflurane.

Johnson et al. (1998) compared isoflurane with sevoflurane for anesthesia induction and recovery in adult dogs.

Salmempera et al. (1992) studied in dogs the potency of remifentanil, a short-acting opioid analgesic, which is used as anesthetic adjunct by variable-rate infusion. Enflurane minimal alveolar concentration was measured by the tail-clamp method in dogs before and after sequential infusion of various doses of

remifentanil. The plasma concentration causing a 50% reduction of enflurane minimal alveolar concentration was determined.

Kataoka et al. (1994) studied the negative inotropic effects of sevoflurane, isoflurane, enflurane, and halothane in canine blood-perfused papillary muscles.

Hirano et al. (1995) compared the coronary hemodynamics during isoflurane and sevoflurane anesthesia in dogs.

Mutoh et al. (1997) compared the cardiopulmonary effects of sevoflurane with those of halothane, enflurane, and isoflurane in dogs.

Hashimoto et al. (1994) examined the effects of sevoflurane and halothane on the effective refractory period and ventricular activation in a canine myocardial infarction model.

The effects of desflurane, sevoflurane, and halothane on postinfarction spontaneous dysrhythmias in dogs were examined by Novalija et al. (1998).

Cardiopulmonary effects in *cats* were studied for desflurane by McMurphy and Hodgson (1996) and for sevoflurane by Hisaka et al. (1997).

Saeki et al. (1996) determined the effects of sevoflurane, enflurane, and isoflurane on baroreceptor-sympathetic reflex in *rabbits*.

Hanagata et al. (1995) found that isoflurane and sevoflurane produce a dose-dependent reduction in the shivering threshold in rabbits.

Antognini and Eisele (1993) determined anesthetic potency and cardiopulmonary effects of enflurane, halothane, and isoflurane in *goats*.

The effects of multiple administrations of sevoflurane to *cynomolgus monkeys* were evaluated by Soma et al. (1995).

The effect of inhalation anesthetics on the *respiratory system* was investigated in several studies:

Mazzeo et al. (1996) compared the relaxing effects of desflurane and halothane at various *MAC*s on isolated proximal and distal airways of dogs precontracted with acetylcholine.

Hashimoto et al. (1996) compared the bronchodilating effect of sevoflurane, enflurane, and halothane in dogs using a superfine fiber-optic bronchoscope. The dogs were anesthetized with pentobarbital, paralyzed with pancuronium, and the lungs were mechanically ventilated. The endotracheal tube had an additional lumen to insert the superfine fiber-optic bronchoscope (outer diameter 2.2 mm) which was located between a second and third bronchial bifurcation to monitor continuously the bronchial cross-sectional area of third or fourth generation bronchi. Bronchoconstriction was produced by histamine injection and infusion. The bronchial cross-sectional area was printed out by a video printer at the end of expiration and was calculated on a computer using an image program after various *MAC*s of the different inhalation anesthetics.

Mitsuhata et al. (1994) induced systemic anaphylaxis in dogs sensitized to *Ascaris suum* by intravenous injection of the antigen and measured pulmonary resistance and dynamic pulmonary compliance. Sevoflurane was as effective as isoflurane in attenuating bronchoconstriction associated with anaphylaxis in dogs.

Cervin and Lindberg (1998) examined the short-term effects of halothane, isoflurane, and desflurane on mucociliary activity in the rabbit maxillary sinus in vivo.

9.2.3 Determination of Minimal Alveolar Anesthetic Concentration (*MAC*)

PURPOSE AND RATIONALE

The determination of minimal alveolar anesthetic concentration (MAC) term "minimum alveolar anesthetic concentration" (*MAC*) was coined by Merkel and Eger (1963) as an index to compare various anesthetic agents.

The use of *MAC* which represents the partial anesthetic pressure in the brain has gained wide acceptance (Eger et al. 1965; Quasha et al. 1980).

For *man*, Saidman and Eger (1964) defined *MAC* as the point at which 50% of the patients moved in response to a surgical incision.

A method for determining minimum alveolar concentration of anesthetic in the *rat* was published by Waizer et al. (1973). Kashimoto et al. (1997) determined the minimum alveolar concentration of sevoflurane in rats. Eger et al. (1999) studied minimum alveolar anesthetic concentration of fluorinated alkanols in rats and discussed the relevance to theories of narcosis. Eger et al. (2003) studied additive minimum alveolar concentration effects of halothane and isoflurane in rats.

Issues in the design and interpretation of minimum alveolar anesthetic concentration studies were discussed by Sonner (2002).

PROCEDURE

Minimum alveolar anesthetic concentrations are determined in Sprague Dawley rats weighing 300–450 g. Each rat is placed in an individual gas-tight plastic cylinder closed at both ends by rubber stoppers. The stoppers are pierced with holes for various purposes. A rectal temperature probe (temperature maintained between 36°C and 38.5°C) and the rat's tail are drawn separately through holes in the rubber stopper closing the distal end of the cylinder. Delivered gases at an average inflow rate of 1 L/min to each rat enter through ports at the head (proximal) end of the cylinder and exit at the tail (distal end), a flow to minimize rebreathing (inspired $CO_2 < 10$ mmHg). Exiting gases are scavenged.

The anesthetics are introduced from conventional vaporizers. For the determination of *MAC*, an initial concentration is used that permits movement of the rats in response to noxious stimulation. A tail clamp is applied for 1 min or until the animal moves, and the anesthetic partial pressure is measured by gas chromatography. If the animal moves, the partial pressure

is increased by 0.2% or 0.3% atmospheres. After equilibration for 30 min, the tail clamp is applied again and the anesthetic partial pressure measured by gas chromatography. This procedure is repeated until the partial pressures bracketing movement-nonmovement are determined for each rat.

EVALUATION

MAC is defined as the average of the partial pressures that just prevented movement in response to clamping of the tail. Differences between anesthetics are accepted at $P < 0.05$.

MODIFICATIONS OF THE METHOD

Fang et al. (1997) found that maturation decreases ethanol minimum alveolar anesthetic concentration more than desflurane *MAC* in rats.

Gong et al. (1998) assessed the effect of rat strain on susceptibility to anesthesia and convulsions produced by inhaled compounds in five different rat strains. Strain minimally influenced anesthetic and convulsant requirements of inhaled compounds in *rats*.

Doquier et al. (2003) studied the minimum alveolar anesthetic concentration of volatile anesthetics in rats as tools to assess antinociception in animals.

Davis et al.'s (1975) determination of the minimal alveolar concentration of halothane in the white New Zealand *rabbit* was published.

Determination of an anesthetic index (Apnea/*MAC*) in experiments in dogs has been proposed by Regan and Eger (1967).

Murphy and Hug (1982), Hall et al. (1987) used the reduction of enflurane *MAC* values in dogs as parameter for the anesthetic potency of fentanyl or sufentanil, respectively.

Seifen et al. (1987) used *MAC* values for comparison of cardiac effects of enflurane, isoflurane, and halothane in the dog *heart-lung preparation*.

Ide et al. (1998) used airway occlusion in *cats* as a noxious respiratory stimulus that induces a visceral sensation of choking for determination of minimum alveolar anesthetic concentrations during halothane, isoflurane, and sevoflurane anesthesia. These values were compared with *MAC* values for somatic noxious stimuli such as toe pinch or tetanic stimulus. The authors recommended this method as a new concept for *MAC* determination.

Eger et al. (1988) determined minimum alveolar concentration of fluorinated anesthetics in *pigs*.

10.1 Drug Addiction and Drug Dependency

10.1.1 General Considerations

Drug abuse is a complex phenomenon, and many factors (e.g., availability, cost) contribute to whether a particular drug will be abused by a particular individual. Nevertheless, many drugs that are abused have common neurobiological and behavioral effects. Consequently, some of the properties of drugs that contribute to abuse can be examined systematically in animals using well-established and validated behavioral procedures. A major strength of this area of research is that the effects of drugs in these procedures (i.e., in nonhuman species) are highly predictive of the effects of the same drugs in humans; thus, behavioral assessments are used both to study the underlying biological and behavioral phenomena associated with drug abuse (e.g., drug reinforcement, physical dependence) and to assess whether new chemical entities have properties in animals that would indicate a likelihood of abuse in humans. Preclinical abuse and dependence liability studies typically comprise the following approaches and procedures:

- Physical dependence
- Tolerance
- Drug discrimination
- Self-administration
- Conditioned place preference

No single procedure or any set of procedures can exactly predict whether a drug is likely to be abused. However, when considered within the context of other known properties of the drug (e.g., receptor binding, pharmacokinetic profile), results of behavioral studies

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_10, © Springer-Verlag Berlin Heidelberg 2013

can be very useful in estimating the likelihood that new chemical entities will be abused, largely by comparing (in standardized assays) those new entities to reference compounds and known drugs of abuse.

10.1.2 Physical Dependence Studies

PURPOSE AND RATIONALE

Withdrawal phenomena, either after abrupt cessation of chronic treatment or after administration of a pharmacologic antagonist (e.g., naltrexone), can be observed in a variety of nonhuman species. Importantly, the withdrawal that emerges in some nonhumans topographically resembles important features of withdrawal in humans. On this basis, tests for drug dependence and withdrawal have been developed for monkeys (Seevers 1936; Seevers and Deneau 1963; Aceto 1990; Woods et al. 1993), dogs (Martin et al. 1974, 1976), rats (Buckett 1964; Cowan et al. 1988), and mice (Way et al. 1969; VonVoigtlander and Lewis 1983). Two general approaches are used to evaluate physical dependence potential: primary physical dependence and single-dose substitution. In the former, a test substance is administered repeatedly over days, and the assessment of dependence (i.e., by the emergence of withdrawal) occurs either after discontinuation of drug treatment or by administration of a pharmacologic antagonist. Precipitated withdrawal studies are warranted only when the mechanism or site of action of the test substance is known and when an appropriate pharmacologic antagonist is available. In a single-dose substitution study, a reference substance (e.g., morphine) is administered repeatedly over a sufficient number of days to produce dependence; after discontinuation of treatment with the reference substance, and when reliable withdrawal signs have emerged, the test substance is assessed for its ability to attenuate withdrawal signs. In this type of study, the test substance can be administered just once to assess its acute withdrawal-reversing effects or can be administered repeated over days (i.e., replace the reference substance) and subsequently discontinued followed by assessment of withdrawal signs.

A well-established in vitro procedure has also been used to test for opioid dependence (i.e., antagonist-precipitated withdrawal) in opioid-treated guinea pig ileum (Villarreal et al. 1977; Rodríguez et al. 1978; Collier et al. 1981; Cruz et al. 1991).

PROCEDURES

10.1.2.1 Opioid Withdrawal Responses in the Guinea Pig Ileum Made Dependent In Vitro

A 40-cm-long segment of the small intestine of male guinea pigs weighing 600–900 g is removed and placed in a low-magnesium Krebs solution. The terminal section of the guinea pig ileum is used after discarding the portion of 10 cm closest to the ileocecal junction. The ileum is cut in eight 3-cm-long segments. The intestinal content is gently removed with the aid of a glass rod. To produce opioid dependence, segments are incubated in 500-ml Erlenmeyer flasks containing 480 nM morphine in 250 ml Krebs solution saturated with a 95% O_2/5% CO_2 gas mixture at a temperature ranging between 4°C and 6°C for 1–48 h. One hour before completion of the incubation time, the segments are removed, placed in glass chambers with 50 ml Krebs solution bubbled with 95% O_2/5% CO_2 gas mixture at 36°C, and mounted on a vertical electrode with one edge fixed to the chamber plug and the opposite fixed to an isometrical force transducer (Grass FT 03) connected to a polygraph for recording the contractile activity of the longitudinal muscle. The ilea are set up with an initial tension of 1 g and left for a period of 30 min for stabilization. Thereafter, all segments are electrically stimulated with supramaximal rectangular pulses (10–40 V) of 0.5-ms duration at a frequency of 0.1 H.

Five minutes before naloxone administration, the electrical stimulation is suspended. The response to naloxone is recorded by administration of up to 100 nM. The response to the antagonist is recorded for 20 min, and thereafter the electrical stimulation is reinitiated and maintained for 10 min.

Thirty-five minutes after naloxone administration, various doses of nicotine are administered to provide a positive control. For comparison, a concentration-response curve for nicotine (1, 1.78, 3.2, 5.6, 10, 17.8, 32, and 56 μM) is obtained in untreated ilea. Moreover, the concentration-response curve for nicotine is obtained in ilea that are treated as follows: (1) exposed to 10 nM naloxone for 20 min, (2) exposed to 480 nM of morphine for 1 h, or (3) pretreated for 10 min with 3 or 10 nM of naloxone and exposed to 480 nM of morphine for 1 h. The response to nicotine is attenuated after pretreatment with morphine, and this attenuation is dose dependently antagonized by naloxone.

A correlation between the response to supramaximal electrical stimulation and the withdrawal response (contraction) precipitated with 100 nM naloxone as well as a correlation between withdrawal and nicotine response after long-term exposure (12–48 h) with 480 nM morphine is used to determine whether physical dependence developed and, therefore, whether the naloxone-induced contraction indicates withdrawal.

10.1.2.2 Test for Physical Dependence in Rats

Male albino rats receive either morphine or saline i.p. twice daily. The starting dose of morphine is 20 mg/kg and is increased by 40 mg/kg increments daily until, by day 11, the dose is 400 mg/kg. Maintenance at 400 mg/kg is continued through day 20. The test compound is similarly administered to groups of ten rats each, typically in ascending doses and a maximally tolerated dose. The daily increments have to be adjusted to a maximum level that is not lethal for the duration of the experiment.

Primary physical dependence capacity is measured on days 11 and 17 when all animals receive an injection of 10 mg/kg of naltrexone or naloxone i.p. in the morning. Signs of withdrawal are recorded during a 30- to 60-min period. Rats are scored for the presence or absence of withdrawal signs (e.g., diarrhea, wet-dog-type shaking) using standardized scoring.

A single-dose substitution study substitutes either a single dose or multiple doses (from day 20 through day 23) of the test substance in morphine-dependent rats; scoring for suppression of withdrawal occurs on days 20–23 and after discontinuation of the test substance.

10.1.2.3 Test for Physical Dependence in Monkeys

Groups of 3–4 rhesus monkeys (3–6 kg body weight) receive morphine four times daily (s.c. or i.m.) beginning with a dose of 1.0 mg/kg. Progressively, the unit dose is increased to a final dose of 3.2 mg/kg/6 h. The test substance is similarly administered to groups of 3–4 monkeys. For the test compound, the daily increments in drug administration are adjusted to a maximally tolerated (nontoxic) dose and frequency of injection. Both groups of monkeys are then maintained at their appropriate dose levels for a minimum of 112 days. On days 35, 60, and 91, 1 mg/kg of naltrexone or naloxone is administered (s.c. or i.m.) in the morning. On days 50 and 112, all doses are omitted for 24 h. Signs of withdrawal are recorded during a 30- to 60-min period using standardized scoring (e.g., Katz 1986; Becker et al. 2008; Brandt and France 1998).

CRITICAL ASSESSMENT OF THE METHOD

The emergence of withdrawal signs after discontinuation of drug treatment is dependent of the duration of action of the treatment compound. Thus, after discontinuation of morphine treatment, withdrawal reliably emerges within 12–24 h. For drugs with an unusually long duration of action (e.g., buprenorphine), observations for withdrawal signs need to occur over longer periods of time (e.g., several days); for drugs with an exceptionally long duration of action, the gradual and prolonged offset of drug action might preclude emergence of significant withdrawal, despite development of dependence. Opioid antagonists will precipitate withdrawal in animals treated with opioid agonists. If a test substance has actions at non-opioid receptors, a negative result with naltrexone or naloxone in a precipitated withdrawal study might not provide useful information regarding dependence potential. Thus, both precipitated withdrawal and treatment discontinuation-induced withdrawal need to be studied for test compounds.

Rhesus monkeys have been used extensively for assessing physical dependence potential of opioid receptor agonists. An excellent correlation between humans and rhesus monkeys has been shown regarding the physical dependence liability of opioids, although there are some compounds for which the relative potency between humans and monkeys is not what is predicted from other data.

Nonhuman species can also be used to assess physical dependence potential of other classes of drugs, including sedative/hypnotics such as benzodiazepines and barbiturates. Physical dependence potential alone cannot be assumed to predict abuse liability because some drugs that are not abused (e.g., kappa opioid receptor agonists) can produce marked physical dependence (Gmerek et al. 1987) and discontinuation of some widely used therapeutic drugs (selective serotonin reuptake inhibitors) can result in a discontinuation syndrome that does not appear to promote drug taking (Black et al. 2000; Hosenbocus and Chahal 2011).

MODIFICATIONS OF THE METHODS

Mouse jumping as a simple screening method to estimate the physical dependence capacity of opioid agonists has been recommended by Saelens et al. (1971). Mice receive seven i.p. injections over 2 days. The test compound is given at doses increasing in multiples of two until a maximally tolerated dose is reached. Two hours after the last injection, the animals receive an i.p. injection of 100 mg/kg naloxone and are placed individually into glass cylinders. The number of jumps is recorded during 10 min.

Rothwell et al. (2011) used acoustic startle reflex and conditioned place aversion to examine long-lasting changes in behavior caused by a single injection of naloxone at different times after a single injection of morphine.

Opioid-receptor agonist-induced dependence can be studied by measuring withdrawal in the guinea pig ileum made dependent in vitro (Cruz et al. 1991).

Kest et al. (2002) compared naloxone-precipitated withdrawal jumping in several strains of mice after acute or multiple injections of morphine or after chronic infusion of morphine with osmotic minipumps.

Becker et al. (2010) used Pavlovian conditioning to demonstrate the ability of environmental stimuli that are paired with the administration of naloxone to elicit withdrawal in morphine-dependent rats.

Yoshimura et al. (1993) studied physical dependence on morphine induced in dogs via the use of osmotic minipumps. Naloxone-precipitated withdrawal signs were recorded such as hyperactivity, biting, digging, tremors, nausea, hyperthermia, increased wakefulness, and by EEG activation in the amygdala and hippocampus, followed by a dissociation of the EEG in the cortex (fast wave) from that in the limbic (slow wave) system, increased heart rate and raised blood pressure. Withdrawal signs were more severe in animals with osmotic minipumps than in those receiving the same dose by syringe injections.

Pierce and Raper (1995) studied the effects of laboratory handling procedures on naloxone-precipitated withdrawal behavior in morphine-dependent rats, and Gellert and Holtzman (1978) used access to drug in drinking solutions to study morphine dependence and withdrawal in rats.

Pierce et al. (1996) used slow release emulsion formulations of methadone to induce dependence in rats. Withdrawal was induced following i.p. challenge with either naloxone or saline, and dependence was assessed in terms of the presence or absence of characteristic withdrawal signs.

Antagonist-precipitated and discontinuation-induced withdrawal in morphine-dependent rhesus monkeys was studied by Becker et al. (2008) using several behavioral procedures as well as telemetry. Changes in heart rate and body temperature persisted for much longer (several weeks) than other directly observable indices of withdrawal or discriminative stimulus effects.

Korkmaz and Wahlström (1999) used EEG threshold and sensitivity to hexobarbital to compare withdrawal in rats treated for different durations with benzodiazepines such as diazepam and lorazepam.

Gallaher et al. (1986) used directly observable changes in behavior to characterize withdrawal in mice that consumed diazepam for 53 days (as much as 1,000 mg/kg/day) in laboratory chow.

McMahon et al. (2007) compared directly observable behavioral effects, rate of operant responding, discriminative stimulus effects, and serum drug concentration to characterize withdrawal after discontinuation of chronic treatment with diazepam in rhesus monkeys.

Stewart and McMahon (2010) compared directly observable behavioral effects and discriminative stimulus effects to withdrawal-like behavior produced by administration of the cannabinoid receptor antagonist rimonabant in rhesus monkeys treated chronically with the cannabinoid receptor agonist delta-9-tetrahydrocannabinol.

Weerts et al. (2005) demonstrated dependence to gamma hydroxybutyrate, and Goodwin et al. (2006) demonstrated dependence to gamma-butyrolactone in baboons using directly observable behavioral effects after administration of an antagonist and after discontinuation of chronic drug treatment.

10.1.3 Tolerance Studies

PURPOSE AND RATIONALE

Repeated treatment with some drugs can decrease sensitivity to the effects of the same drugs (tolerance) and to the effects of pharmacologically related drugs (cross-tolerance). The development of tolerance can limit the effectiveness of drugs (e.g., analgesics), thereby necessitating an increase in the dose for recovery of the desired effect. The radiant heat or the hot plate method for testing antinociceptive activity of opioid receptor agonists in mice is adapted to measure drug-induced changes in the sensitivity to a noxious stimulus.

PROCEDURE

Male mice (10–12 per condition) with an initial weight of 18–20 g are used. They are placed in restraining cages. A noxious stimulus is produced by an intense light beam directed to the proximal part of the tail. The subject can respond to this stimulus by flicking its tail. The reaction time, the interval between stimulus onset and response, is measured automatically with commercially available equipment or manually with a stopwatch. A maximum time of exposure to the stimulus (e.g., 12-s cutoff time) prevents tissue damage. Prior to drug administration, two control measures of reaction time are obtained for each animal. After administration of the drug, the test is repeated 15, 30, and 60 min after s.c. injection or 30, 60, and 120 min after oral administration. In this way, time of peak activity can be determined. Mice showing a reaction time of the average control value plus two times the standard deviation in the control experiment are regarded as positive. Complete dose–response curves are determined, and ED_{50} values are calculated. Subsequently, the animals are treated for 5 days once every day with a dose which is four times higher than the ED_{50} in the first experiment. On the following day, dose–response curves are determined using at least three doses and the ED_{50} is calculated again. Frequency and duration of drug administration should be adjusted to insure adequate exposure for assessing tolerance. Cross-tolerance can be assessed in the same animals shown to be tolerant to one drug by determining a dose–response curve for a second drug.

EVALUATION

Reduced effectiveness of a fixed dose and/or the need for larger doses to obtain a constant response indicates the development of tolerance. ED_{50} values obtained before and after repeated daily treatment are compared to assess the magnitude of tolerance. Similarly, comparison of ED_{50} values for one drug, obtained in untreated animals and in animals treated with (and shown to be tolerant to) a second drug, is used to determine cross-tolerance.

CRITICAL ASSESSMENT OF THE TEST

Tolerance is observed with a variety of drugs including opioid receptor agonists, barbiturates, benzodiazepines, and ethanol. The measurement of antinociception after single and repeated administration, therefore, has to be regarded as a primary test. Moreover, a decrease in the potency of a drug after daily drug treatment, while providing evidence for tolerance, does not give insight to the mechanism by which tolerance has developed (i.e., pharmacodynamic, pharmacokinetic, behavioral). Demonstration that the antinociceptive effects of a new drug do not decrease after repeated daily treatment with high doses indicates that it is not necessary to escalate dose in order to maintain effectiveness and represents the first step for establishing the absence of tolerance liability. For drugs that do not have antinociceptive actions, other tests need to be employed using a similar dosing strategy for assessing tolerance and cross-tolerance.

MODIFICATIONS OF THE METHOD

Other authors (e.g., Glassman 1971) injected the dose which induced a full antinociceptive effect in mice twice daily for a period of 21 days and evaluated the stepwise decay of effectiveness. After 21 days, the effect of 10 mg/kg morphine or 30 mg/kg meperidine i.p. decreased to approximately 50% of the value of the first day.

Boisse et al. (1986, 1990) demonstrated tolerance and dependence to both short-acting (midazolam) and long-acting (chlordiazepoxide) benzodiazepines in rats.

Langerman et al. (1995) evaluated the acute tolerance to continuous morphine infusion up to 8 h in the

rat with various doses using the hot plate and the tail flick assay. Tolerance was observed with the hot plate assay but not with the tail flick assay suggesting tolerance development at a supraspinal site.

Smith et al. (2003) used twice-daily injections of morphine and implantation of morphine-containing pellets to study mechanisms of opioid tolerance in mice.

Riba et al. (2002) showed that the role of mu opioid receptors in modifying the antinociceptive effects of delta opioid receptor agonists changes during morphine tolerance.

Schwandt et al. (2008) report rapid tolerance to the motor impairing effects of ethanol in adolescent rhesus monkeys.

Eppilito and Gerak (2010) treated rats daily with the neuroactive steroid pregnenolone and showed tolerance to some, but not all, effects on operant responding for food.

10.1.4 Tests for Abuse Liability

10.1.4.1 General Considerations

Drug abuse often occurs in the absence of physical dependence. The term “psychological dependence” is often used to describe abuse-related phenomena that are not specifically related to physical dependence (Deneau 1964), and laboratory procedures have been developed in animals, not physically dependent on drugs, which are predictive of abuse-related effects in humans. For example, drug discrimination procedures are frequently used to complement other assays of abuse liability; discrimination procedures have the advantage of having a high degree of pharmacologic selectivity which can be used to identify mechanism of action (e.g., receptor type) or to compare mechanism of action between a reference substance and a test substance. Importantly, drug discrimination procedures are predictive of the subjective effects of drugs in humans (Holtzman 1983, 1990; Brady et al. 1987; Colpaert 1987; Overton 1987; Hoffmeister 1988). Self-administration procedures are used to study the reinforcing effects of drugs and are the procedures used most often for predicting abuse liability of new chemical entities (Deneau et al. 1969; Hoffmeister 1979; Littmann et al. 1979; Woolverton and Schuster 1983; Bozarth 1987; Meisch and Carroll 1987; Weeks and Collins 1987; Yokel 1987; Woolverton and Nader 1990). More recently, and in a more limited context, conditioned place preference procedures have been used to examine drug effects that might be predictive of abuse. Finally, based on the early observations of Olds and colleagues (Olds et al. 1956; Olds 1979) on intracranial self-stimulation, procedures have also been developed for studying drug-induced changes in brain-stimulation reward (Kornetsky and Bain 1990), although this methodology has not been used systematically with a sufficiently wide range of drugs for it to be included in a standard abuse liability assessment.

10.1.4.2 Drug Discrimination Studies

PURPOSE AND RATIONALE

Many laboratories use two-choice discrimination procedures to investigate the mechanism or site of action

of test substances by examining compounds in animals trained to discriminate a reference substance and known drug of abuse (Shannon and Holtzman 1976, 1986; Holtzman 1983, 1990; Brady et al. 1987; Colpaert 1987; Overton 1987; Hoffmeister 1988; Carboni et al. 1989). Because of the pharmacologic selectivity of this procedure, test substances might need to be assessed in different groups of animals trained to discriminate different reference substances (e.g., cocaine or heroin). Less common are studies in which animals are trained to discriminate a test substance (presumably with a mechanism[s] of action that is not fully known) and reference substances are examined for their ability to produce discriminative stimulus effects like the test substance.

PROCEDURE

Rats are trained to press one of two choice levers either to receive a food pellet or to avoid/escape electric foot shock which is delivered intermittently beginning 5 s after the start of the trial. The occurrence of a trial is signaled by the illumination of a light in the operant chamber. In some procedures, a third (observing) lever is mounted in the wall of the chamber opposite the two-choice levers and must be pressed before the choice response is made. This contingency prevents the rat from persevering on a single response lever; thus, the choice response in each trial is relatively independent of the consequences of choice responses in the preceding trials of the session. The rats are tested in 20-trial sessions. Animals are trained to discriminate a prototype of the drug of interest. Morphine and fentanyl have served well as training drugs for exploring the discriminative effects of prototypic mu opioid receptor agonists; however, many drugs from a variety of pharmacologic classes have been used as training stimuli in drug discrimination studies (see Glennon and Young 2011). Training often occurs more rapidly when the dose of the training drug is the largest dose that does not disrupt behavior. For discrimination training, the animal is placed in the operant chamber and trained to perform the required response, initially under a schedule of continuous reinforcement where a single response on either lever delivers a food pellet or postpones/terminates electric shock. As performance improves, the response requirement is increased progressively across days (e.g., to a maximum of 10 [fixed-ratio 10]), and discrimination training commences whereby responding on just one of the levers is reinforced in each session. In two-choice procedures, the left choice lever and the right choice lever are designated for drug and vehicle training sessions, respectively, for half of the animals in a group; the lever designation is reversed for the other half of the animals. Acquisition of the discrimination is a function of the drug, training dose, and the number of training sessions. Training continues until the subject reaches predetermined performance criteria, which typically could be the following: at least 80% of the total session responses on the injection (drug or vehicle) appropriate lever and less than one fixed-ratio value (e.g., 10) of responses on the injection-inappropriate lever prior to delivery of the first reinforcer (i.e., food pellet delivery or first postponement/termination of shock) for six consecutive training sessions. A morphine discrimination can be established in rats, according to these criteria, in 6–12 weeks. Once stable discrimination performance is achieved; tests of generalization to test substances can be interposed among the training sessions. During test sessions, the reinforcer is available after completion of the response requirement on either lever. Complete dose–response curves for the training drug and the test drug are obtained. In cases where the test drug does not produce responding on the training drug-appropriate lever, the test drug should be evaluated up to doses that decrease rates of lever pressing or until other behavioral effects are observed, in order to insure that the substance is evaluated up to behaviorally active doses. Drugs from a wide variety of classes have been used as training stimuli in these types of procedures and in a variety of species.

EVALUATION

Results of the stimulus-generalization test usually are evaluated with the quantitative or graded method, whereby the amount of responding on the training drug-associated lever is expressed as a percentage of the total number of responses during a test (i.e., responding on the drug-appropriate lever plus responding on the vehicle-appropriate lever). This percentage is compared with the percentage of drug-appropriate responses normally engendered by the training dose of the training drug (reference standard). The discriminative stimulus effects of the test drug substitute for those of the training drug if the maximal percentages of drug-appropriate responding are not significantly different from each other. When stimulus control of behavior transfers from one drug to another,

it can be inferred that the test drug produced discriminative stimulus effects that are similar to those of the training drug. Advantages of this procedure are that it is pharmacologically very selective and that the discriminative stimulus effects of drugs are related to and predictive of subjective effects in humans. When appropriate pharmacological tools (e.g., antagonists acting at the same receptor as the training drug) are available, the mechanism(s) mediating the discriminative stimulus effects of a drug can be confirmed by combining drugs (agonists with antagonists).

CRITICAL ASSESSMENT OF THE METHOD

Drug discrimination procedures display a high degree of pharmacologic selectivity. Test drugs that dose dependently occasion responding on the drug-appropriate lever likely share a mechanism of action with the training drug; drugs that do not occasion responding on the drug-appropriate lever likely are pharmacologically dissimilar to the training drug (in terms of site of action and/or in terms of efficacy) and will typically cause responding predominantly if not exclusively on the lever that is appropriate for the drug vehicle, up to behaviorally active doses. The pharmacologic selectivity of these procedures permits differentiation not only among compounds acting on different receptors or neurochemical systems (e.g., dopamine receptors vs. opioid receptors) but also among compounds acting on different subtypes of receptors within the same receptor class (e.g., mu vs. kappa opioid receptor agonists). Because of the importance of pharmacokinetic factors to the overall abuse liability of drugs, and because drug discrimination procedures are relatively insensitive to pharmacokinetic factors (as compared to self-administration procedures), positive results from a drug discrimination study are not in themselves sufficient to predict abuse liability. Along with other measures of drug action, results of drug discrimination studies are used to predict the likelihood of new compounds having abuse liability. Typically, self-administration data are used along with drug discrimination data, since these two assays are sensitive to different, though related aspects of drug activity. A negative effect with a test compound in a drug discrimination procedure indicates that the test substance, at the doses and pretreatment times studied, does not share discriminative stimulus effects with the training drug; it does not indicate that the test substance is devoid of discriminative stimulus effects or that the test substance is not likely to be abused. Thus, the high pharmacological selectivity of drug discrimination procedures is both an asset and a limitation.

MODIFICATIONS OF THE METHOD

Drug discrimination studies are performed in a variety of species including squirrel monkeys, rhesus monkeys, pigeons, gerbils, and mice (Hein et al. 1981; Herling and Woods 1981; Bertalmio and Woods 1987; Bertalmio et al. 1982; Dykstra et al. 1987, 1988; France and Woods 1993; France et al. 1994, 1995; Jarbe and Swedberg 1998; Shelton et al. 2004; Stolerman et al. 2004). Operant responding can be maintained with different reinforcers, including food, liquids, and aversive stimuli (e.g., electric shock). While the percentage of the total responses made on the drug-appropriate lever (averaged among subjects) is commonly used to express and analyze drug effects, some investigators express and analyze data in terms of the percentage of animals emitting some predetermined minimum (e.g., 90%) percentage of responses on the drug-appropriate lever.

The pharmacologic selectivity of drug discrimination procedures is particularly evident with opioid receptor agonists that bind selectively to different receptor subtypes. For example, monkeys trained to discriminate injections of a mu opioid receptor agonist (codeine, etorphine, or alfentanil) generalize to other mu opioid receptor agonists and not to non-opioid drugs, not to opioid receptor antagonists, and not to opioid receptor agonists acting at other (e.g., kappa) opioid receptors. Conversely, monkeys trained to discriminate a kappa opioid receptor agonist such as ethylketocyclazocine or U-50,488 generalize to other kappa receptor agonists and not to mu receptor agonists, antagonists, or to non-opioids (Woods et al. 1993; France et al. 1994).

Meert et al. (1989) used drug discrimination studies to characterize risperidone as an antagonist of the discriminative stimulus effects of LSD.

Meert and Janssen (1989) and Meert et al. (1990) showed differences between ritanserin and chlordiazepoxide in drug discrimination procedures.

Discrimination procedures have also been used to examine stimulus conditions that are believed to reflect drug withdrawal. Some of those procedures involve Pavlovian conditioning of aversive stimuli (Davis et al. 2009) whereas others involve operant procedures in which pharmacological antagonists are the training

stimuli in animals treated chronically with an agonist (Becker et al. 2008; Stewart and McMahon 2010).

Delta-9-tetrahydrocannabinol discrimination in rats was proposed as model for cannabis intoxication in humans (Balster and Prescott 1990).

The drug discrimination method has also been applied to study anxiolytic drugs using pentylenetetrazol at subconvulsive doses (Sherman and Lal 1979, 1980; Sherman et al. 1979; Lal and Sherman 1980).

The conditioned taste aversion procedure has been described as a more rapid alternative to two-lever operant procedures in drug discrimination research (Garcia et al. 1955; van Heest et al. 1992).

Others have studied combinations of drugs in animals trained to discriminate one or more drugs alone or in combination (McMillan et al. 2009; Stolerman et al. 1999).

10.1.4.3 Self-Administration Studies

PURPOSE AND RATIONALE

Drug self-administration is studied under a variety of conditions that can involve free or limited access. Some procedures (e.g., two-bottle choice for alcohol drinking in rodents) provide conditions that promote voluntary drug intake without particular attention to patterns of drug taking whereas other procedures (e.g., operant self-administration) permit detailed examination of specific aspects of drug taking. Operant procedures involving i.v. drug administration are the most widely used procedures for assessing abuse liability, and these procedures have a high degree of predictive validity for drugs that are abused by humans. The goal of self-administration procedures is often to compare self-administration of a test substance to self-administration of a standard reference substance and known drug of abuse (e.g., heroin). Alternatively, other procedures test whether drug naïve animals will initiate and maintain self-administration of a test substance.

PROCEDURE

Self-administration procedures in rodents commonly use the i.v. route of drug administration as this route maximizes the likelihood of detecting positive reinforcing effects because of the rapid onset of drug action after i.v. administration. Unlike drug discrimination and conditioned place preference procedures, where onset and duration of drug action are not critical factors so long as drugs are studied at times (and doses) that have activity, pharmacokinetics are critically important for self-administration studies. Even drugs that otherwise are very effective, positive reinforcers can be less effective or ineffective when their administration is delayed after a response. Self-administration procedures also are available for oral, intragastric, parenteral, and inhalation routes of administration.

Male Sprague–Dawley rats weighing 250–300 g are used for these studies. The apparatus consists of commercially available operant chambers equipped with levers, lights, a food hopper, and a mechanism for i.v. drug delivery (e.g., syringe pump).

Food-restricted rats are first trained to press levers for food prior to catheter implantation; the useful period of the catheter is extended when rats are trained to press levers for food before surgery. In daily sessions, a single response on either lever delivers a food pellet. After a single session in which 50 pellets are received under the continuous reinforcement schedule, one of the levers is designated (randomly or systematically balanced across subjects in a group) the active lever for the remainder of the study. The response requirement is increased over days, so long as rats receive the maximum of 50 pellets in a session, to a maximum of 5 (fixed-ratio [FR] 5). Once responding is reliable under the FR 5 schedule (e.g., 50 pellets delivered per session for three consecutive sessions), food training is suspended and the rats receive a chronic indwelling catheter.

Surgery is conducted under isoflurane anesthesia with the catheter (3 French) implanted in the jugular or femoral vein. The catheter is tunneled s.c., exteriorized in the midscapular region, and connected to an access port that is mounted in a jacket. For daily 90-min sessions, a Huber point needle connected to a syringe pump by sterile tubing delivers drug or vehicle to the access port and catheter. The port and catheter are filled with heparinized saline after each session. The beginning of the self-administration session is signaled by illumination of lights over the active lever; five responses on the active lever deliver drug or vehicle with each injection followed by a 3-min timeout when the chamber is dark and lever presses have no programmed consequence.

Stable self-administration responding is established with a reference compound (e.g., 0.32 mg/kg/injection, cocaine, i.v.), defined by three consecutive sessions when the number of injections received per session is greater than 20 and the number of injections in each session does not vary by more than $\pm 20\%$ of the mean number of injections for those sessions. Next, saline is substituted for the reference compound in order to extinguish responding and, thereby, to confirm the positive reinforcing effects of the reference compound under these conditions. Extinction is defined as three consecutive sessions when the number of saline injections received per session is less than eight. Once these criteria are satisfied, a dose of test substance is substituted to see if it maintains self-administration responding. The test substance is studied for a minimum of five and a maximum of ten sessions or until stable responding is observed, as defined by three consecutive sessions when the number of injections received per session does not vary by more than $\pm 20\%$ of the mean number of injections for those sessions. Following the test substance, saline is

available for self-administration for a minimum of five sessions and until the number of saline injections received is less than eight for three consecutive sessions. Finally, a retest with the reference substance (e.g., cocaine) confirms the sensitivity of the assay (and the subject) to positive reinforcing effects of a known drug of abuse. Different doses of a test substance are studied in different groups (n = 8/group) of rats that are initially trained to self-administer a reference substance.

EVALUATION

Self-administration of a test substance is compared to self-administration of vehicle and self-administration of the reference substance. Data are expressed either as the number of injections (mean ± SEM) received per session or as the response rate on the active lever. A range of doses of the test substance must be examined in order to insure that sufficient exposure occurred to test whether that substance has positive reinforcing effects.

CRITICAL ASSESSMENT OF THE METHOD

Self-administration procedures are, generally, not pharmacologically specific insofar as animals with a history of self-administering a drug from one pharmacological class (e.g., cocaine-like stimulant) will readily self-administer a drug from a different pharmacological class (e.g., heroin-like opioid), although there are examples where specific drug and behavioral history can facilitate subsequent drug self-administration (Collins and Woods 2009). While the predicative validity of self-administration studies in nonhumans is quite high for abuse liability in humans, it is not unanimous insofar as some drugs that are abused by humans (e.g., lysergic acid dimethylamide) are not readily self-administered by nonhumans. Conversely, some drugs that are self-administered by nonhumans do not appear to have high-abuse liability in humans (e.g., modafinil). Nevertheless, i.v. self-administration procedures remain the "gold standard" in preclinical studies for assessing and predicting abuse liability.

MODIFICATIONS OF THE METHOD

In addition to fixed-ratio schedules, a variety of different schedules of reinforcement have been used to study drug reinforcement including second-order schedules (Howell et al. 2007), multiple schedules (Ginsburg and Lamb 2006), and progressive ratio schedules (Carroll et al. 2011).

Winsauer et al. (2000) examined the effects of self-administered cocaine on acquisition and performance of response sequences for food using a multiple schedule in monkeys.

Henry and Howell (2009) studied reinstatement of responding by non-contingent i.v. cocaine injections in monkeys with a history of i.v. cocaine self-administration under a second-order schedule.

Wang and Woolverton (2007) used progressive ratio schedules to compare reinforcing effects of the isomers of MDMA and of methamphetamine in monkeys.

Modification by amphetamine of the reinforcing effects of cocaine under a progressive ratio schedule was studied in rats (Chiodo et al. 2008) and rhesus monkeys (Czoty et al. 2010).

Responding that has been extinguished (by responding in the absence of drug or the absence of drug and drug-paired stimuli) can be reinstated by presenting various stimuli, including drugs, non-drug stimuli that were paired with contingent drug administration, or by stress. Such reinstatement procedures are used to examine, in the preclinical laboratory (Bossert et al. 2007; Holtz et al. 2011), some of the factors that might contribute to reinitiation of drug taking in abstinent individuals.

Extending the period of drug access in self-administration procedures increases drug intake more than the proportional increase in session length (Ahmed et al. 2000) and can modify sensitivity to drugs (Morgan and Roberts 2004) as well as increase the likelihood of dependence developing (O'Dell et al. 2007).

10.1.4.4 Conditioned Place Preference Studies

PURPOSE AND RATIONALE

Conditioned place preference procedures have been used to examine behavioral actions that are thought to be related to positive reinforcing effects as measured by other procedures, such as self-administration (van der Kooy 1987; Hoffman 1998; Tzschenke 1998; Self and Stein 1992). Particular environmental stimuli are paired with the presence or absence of a presumed reinforcer (e.g., drug or food), and later, in the absence of that reinforcer, animals are tested for their preference for either environment.

PROCEDURE

To induce place preference with food, a food-restricted animal is exposed to an experimental chamber that consists of two compartments (which differ in floor texture and/or wall color) and that are separated by a removable barrier. In some iterations of this procedure, the two compartments are joined by a small tunnel or a third (neutral) compartment. On alternate days, the animal is confined to one or the other compartment, with food available in only one of the compartments. Thus, food is selectively paired with one of the distinctive environments. After several (e.g., four in each compartment for a total of eight) conditioning sessions, the animal is placed in the same chamber without the barrier in place (for procedures that use a third [neutral] compartment, the animal is placed in that compartment and otherwise in the middle of the chamber). In the absence of the reinforcer (e.g., food), animals demonstrate a relative increase in the amount of time spent in the environment that was paired with the reinforcer (e.g., food) as compared to the compartment that was not paired with the reinforcer. Place conditioning with drugs is conceptually similar and involves the differential pairing of drug effect with one compartment and the absence of drug effect (vehicle) with the other. Drugs can be administered by various different routes (Amalric et al. 1987, Bals-Kubik et al. 1990; Iwamoto 1988; Shippenberg and Herz 1987), and usually animals are placed in the chamber immediately after drug administration for a 40-min conditioning session.

Male Sprague–Dawley rats weighing 250–300 g are typically used for these studies. Drugs are usually administered i.p. or s.c. When drugs are to be administered intracerebroventricularly, rats are anesthetized with 60 mg/kg i.p. sodium hexobarbital and 23-gauge guide cannulae aimed at the lateral ventricle ($AP = -0.9$ mm, $L = +\ 1.5$ mm, $DV = 3.5$ mm) (Paxinos and Watson 1982) are stereotaxically implanted; conditioning commences 1 week later.

The apparatus consists of 30 × 60 × 30-cm Plexiglas boxes. For conditioning sessions, each box is divided into two equal-sized compartments by means of a removable sliding wall. One compartment is white with a textured floor, the other black with a smooth floor. For testing, the central wall is raised 12 cm above the floor to allow passage from one compartment to the other.

Conditioning sessions are conducted once a day for 8 days and consist of administering drug or its vehicle

on alternate days. The rats are immediately confined to one compartment of the box following drug injection and to the other compartment following vehicle injection. Conditioning sessions last 40 min although, for drugs with delayed onset or very short duration of action, the temporal conditions need to be adjusted to insure that conditioning occurs at a time of biological activity. Test sessions are carried out 1 day after the last training session and in the absence of drug. The rats are placed in a neutral position (either in the center or in the neutral compartment) of the test box and allowed free access to both sides of the box for 15 min. A video camera with integrated stopwatch is used for data recording. Alternatively, photocells mounted along the sides of each compartment can be used to electronically monitor the location of the subject in the apparatus. The time spent in each compartment is assessed by visual analysis of the recorded videotape or by data collected through photocell beam breaks.

For intracerebroventricular injections, a 30-gauge injection needle is attached to a microsyringe via polyethylene tubing. The drug solutions are administered over a 60-s period, and the injection needles are left in place for an additional 30 s to ensure complete delivery of the solution. For antagonism tests, groups of rats receive an intracerebroventricularly injection of the antagonist (naltrexone or naloxone) or vehicle 10 min before the microinjection of the conditioning drug. At the end of the experiments, the rats are anesthetized and sacrificed by decapitation. The brains are removed and sectioned in a cryostat to verify the location of the cannulae. Alternatively, antagonists can be administered systemically.

EVALUATION

Conditioning scores represent the time spent in the drug-paired place minus the time spent in the vehicle-paired place and are expressed as means ± SEM. In cases where animals show a bias toward one compartment prior to conditioning, drug conditioning can be established with the non-preferred compartment, thereby increasing the confidence that preference for that compartment is specifically related to drug administration. A range of doses should be studied since the dose–response curve for conditioned place preference can be biphasic such that smaller doses produce preference whereas larger doses have no effect or produce an aversion.

CRITICAL ASSESSMENT OF THE METHOD

Conditioned place preference procedures are not pharmacologically selective in the manner that drug discrimination studies are insofar as drugs from several different classes (e.g., opioids, ethanol, and stimulants) can generate positive results. Generally, there is a strong positive correlation between drugs that can be used to establish conditioned place preference and those that are positive reinforcers by other measures (e.g., i.v. self-administration); however, one of the most effective reinforcers in self-administration studies, that is also widely abused by humans, does not unanimously generate strong conditioned place preference in nonhumans—cocaine. Thus, results from conditioned place preference studies should be used in concert with results from other measures of reinforcing effects (e.g., self-administration) in order to determine the likelihood that a drug exerts a profile of behavioral effects that would indicate its abuse. For the purpose of opioids, in general, mu opioid receptor agonists are effective for establishing place preference whereas kappa receptor agonists are not. In fact, kappa receptor agonists can generate place aversion (e.g., Sante et al. 2000).

MODIFICATIONS OF THE METHOD

In order to distinguish place preference and place aversion, place-conditioning behavior can be expressed by a difference in the time spent in the preferred and the non-preferred sides in the postconditioning and preconditioning tests, respectively. Positive values indicate preference and negative values aversion (Kitaichi et al. 1996). For non-biased procedures, where animals do not show an inherent preference for either compartment, results are presented simply as a difference score (i.e., time spent in the drug-paired compartment minus time spent in the vehicle-paired compartment).

In addition to place preference, others (Mucha and Herz 1985; Broadbent et al. 2002) used taste preference conditioning.

Foltin and Evans (1997) established place preference for cocaine in rhesus monkeys, and Wang et al. (2011) established a preference with morphine in monkeys.

Cunningham (Bormann and Cunningham 1998; Gabriel et al. 2004) and others (Sevak et al. 2007, 2008a, b) use the same chamber for training and testing with the exception that only floor texture varies

according to treatment condition. Thus, drug and vehicle are paired with different floor textures, and during test sessions, the time spent on each section of a floor comprising the two different textures (half of the floor with each) is used as an index of preference or aversion. This procedure has the advantage that the size of the test chamber is not different from the size of the training chamber.

Perks and Clifton (1997) used sucrose solution to generate a place preference which was subsequently devalued using a LiCl taste aversion procedure.

Brockwell et al. (1996) described a computerized system for the simultaneous monitoring of place conditioning and locomotor activity in rats consisting of four independent conditioning boxes, each equipped with six pairs of photosensors connected to an Experiment Controller, an electronic board containing a microprocessor, a programmable timer, and 16 K of RAM used to store both instructions and data.

Steinpreis et al. (1996) investigated place preference in Sprague–Dawley rats treated with graded i.p. doses of methadone. Place preference for methadone peaked at 4 mg/kg, and aversion was produced at 10 mg/kg.

Using the conditioned place preference paradigm, Mamoon et al. (1995) assessed the rewarding properties of butorphanol in comparison to morphine after unilateral microinjections into the ventral tegmental area of male Lewis rats.

Gaiardi et al. (1997) assessed rewarding and aversive effects of buprenorphine by place preference and taste aversion conditioning. After s.c. administration of doses ranging from 0.025 to 0.1 mg/kg, buprenorphine caused a significant increase in the amount of time spent on the drug-paired compartment but no significant decrease of saccharin consumption. Rewarding and aversive effects did not occur within a similar dose range.

Contarino et al. (1997) found no tolerance to the rewarding properties of morphine, after repeated i.p. injections of morphine, in prolonged conditioned place preference trials.

Tsuji et al. (1996) studied the effect of microinjections of GABA receptor agonists and antagonists into the ventral tegmental area of Sprague Dawley rats on morphine-induced place preference.

Sufka (1994) recommended the conditioned place preference paradigm as a novel approach for assessing effects of opioids in chronic pain induced in rats by unilateral injections of Freund's adjuvant into the hind paw.

Conditioned place avoidance by naloxone was attenuated by clonidine (Kosten 1994).

In addition to morphine and other mu opioid receptor agonists, other drugs with known or putative abuse liability were tested in the place-conditioning paradigm including the following: cocaine (Lepore et al. 1995; Suzuki and Misawa 1995; Calcagnetti et al. 1996; Martin-Iverson and Reimer 1996; Martin-Iverson et al. 1997), caffeine (Brockwell et al. 1991; Brockwell and Beninger 1996), cannabinoids (Lepore et al. 1995; Sañudo-Peña et al. 1997), LSD (Parker 1996), methamphetamine (Suzuki and Misawa 1995), amphetamine (Hoffman and Donovan 1995; Turenne et al. 1996), methylphenidate (Gatley et al. 1996) and fenfluramine (Davies and Parker 1993), 7-OH-DPAT (Khroyan et al. 1995; Chaperon and Thiébot 1996), gamma-hydroxybutyric acid (Martellotta et al. 1997), propofol (Pain et al. 1997), alcohol (Kennedy et al. 2011; Voorhees and Cunningham 2011; Zarrindast et al. 2010), methylenedioxymethamphetamine (Daza-Losada et al. 2011), and NMDA receptor antagonists (Steinpreis et al. 1995; Papp et al. 1996).

Furthermore, 5-HT_3 receptor antagonists (Acquas et al. 1990), 5-HT_3 receptor agonists (Higgins et al. 1993), dopamine release inhibitors (Schechter and Meehan 1994), dopamine D1 receptor antagonists (Acquas and Di Chiara 1994), dopamine D3 receptor agonists (Khroyan et al. 1997), and antiemetic agents (Frisch et al. 1995) were studied in the place-conditioning paradigm.

Suzuki et al. (1991, 1993) and del Poso et al. (1996) studied opioid-induced place preference in mice, and Bechtholt et al. (2004) studied the effects of handling on conditioned place aversion and conditioned place preference by ethanol in mice.

11.1 In Vitro Tests

11.1.1 Blood Coagulation Tests

PURPOSE AND RATIONALE

The coagulation cascade consists of a complex network of interactions resulting in thrombin-mediated conversion of fibrinogen to fibrin, which is one major component of a thrombus. The coagulation cascade can be initiated either by the "exogenous pathway," the release of thromboplastin (tissue factor) leading to activation of factor VII to the tissue factor/factor VIIa complex, or by the "endogenous pathway," so-called contact activation leading via factors XII, XI, and IX to the assembly of the tenase complex consisting of activated factors VIII and IX and Ca^{2+} on a phospholipid surface. Both complexes can activate factor X, which induces the formation of the prothrombinase complex consisting of factor Xa, factor Va, and Ca^{2+} on a phospholipid's surface. The latter leads to the activation of thrombin, which in turn cleaves fibrinogen to fibrin. The three coagulation tests (PT, APTT, and TT) allow differentiating between effects on the exogenous or endogenous pathway or on fibrin formation. The influence of compounds on the plasmatic blood coagulation is determined by measuring the coagulation parameters prothrombin time (PT), activated partial thromboplastin time (APTT), and thrombin time (TT) ex vivo.

PROCEDURE

Male Sprague–Dawley rats weighing 200–220 g receive the test compound or the vehicle (controls) by oral, intraperitoneal, or intravenous administration. After the end of the absorption time, they are anesthetized by intravenous injection of 60 mg/kg sodium pentobarbital. The caudal caval vein is exposed by a midline incision, and 1.8 ml blood is collected into a plastic syringe containing 0.2 ml 100 mM citrate buffer pH 4.5 (Behring Werke, Marburg, Germany). The sample is immediately agitated and centrifuged in a plastic tube at 1,500 g for 10 min. Plasma is transferred to another plastic tube, and the coagulation tests for the determination of thrombin time (TT), thromboplastin time (PT), and activated partial thromboplastin time (APTT) are performed within 3 h.

In general, citrated plasma is coagulated by the addition of the respective compounds (see below), and the time to clot formation is determined in the coagulometer (=coagulation time). For detailed laboratory diagnosis of bleeding disorders and assessment of blood coagulation, see Palmer (1984) and Nilsson (1987).

11.1.1.1 Prothrombin Time (PT)

An aliquot of 0.1 ml of citrated plasma is incubated for 1 min at 37°C. Then, 0.2 ml of human thromboplastin (Thromborel®, Behring Werke, Marburg) is added, and the coagulometer (Schnittger+Gross coagulometer, Amelung, Brake) is started. The time to clot formation is determined. The PT measures effects on the exogenous pathway of coagulation.

11.1.1.2 Activated Partial Thromboplastin Time (APTT)

To 0.1 ml of citrated plasma, 0.1 ml of human placenta lipid extract (Pathrombin®, Behring Werke, Marburg) is added, and the mixture is incubated for 2 min at 37°C. The coagulation process is initiated by the addition of 0.1 ml 25 mM calcium chloride when the coagulometer is started, and the time to clot formation is determined. The APTT measures effects on the endogenous pathway of coagulation.

11.1.1.3 Thrombin Time (TT)

To 0.1 ml of citrated plasma, 0.1 ml of diethyl barbiturate-citrate buffer pH 7.6 (Behring Werke, Marburg) is added, and the mixture is incubated for 1 min at 37°C. Then, 0.1 ml of bovine test thrombin (30 IU/ml, Behring Werke, Marburg) is added, and the coagulometer is started. The time to clot formation is determined. The TT measures effects on fibrin formation.

EVALUATION

Mean values of TT, PT, and PTT are calculated in dosage groups and vehicle controls. Statistical evaluation is performed by means of the unpaired Student's *t*-test.

11.1.2 Thrombelastography

PURPOSE AND RATIONALE

Thrombelastography (TEG) was developed first by Hartert (1948). The thrombelastograph (Haemoscope Corp., Skokie, Illinois, USA) is a device that provides a continuous recording of the process of blood coagulation and subsequent clot retraction. The blood samples are transferred to cuvettes and maintained at 37°C. The cuvettes are set in motion around their vertical axes. Originally, a torsion-wire suspended mirror in the plasma remains immobile as long as the plasma is fluid. The cuvette and the mirror become dynamically related as fibrin forms, resulting in transmission of cuvette motion to the mirror. The mirror then oscillates with an amplitude governed by the specific mechanical properties of the clot and reflects its light to a thermo paper. The modern thrombelastograph transfers the analogous recording to a digital signal that is evaluated by a computer program.

PROCEDURE

Thrombelastography can be performed in either whole blood or in citrated platelet-rich or platelet-poor plasma after recalcification. Blood samples are obtained from Beagle dogs, weighing 12–20 kg, from rabbits, weighing 1.7–2.5 kg, from Wistar rats weighing 150–300 g, or from humans. The test subjects receive the compound by intravenous, subcutaneous, or by oral administration. Ten or 20-min postdosing (i.v., s.c. administration) or 60, 90, or 180-min postdosing (oral administration) blood is collected. The blood samples are mixed with 3.8% trisodium citrate solution (one-part citrate solution to nine-part blood) as anticoagulant. The citrated whole blood is recalcified by adding 0.4 ml isotonic calcium chloride solution. An aliquot of 0.36 ml of the recalcified whole blood is transferred to the prewarmed cup of the thrombelastograph. After the apparatus has been correctly adjusted and the samples sealed with liquid paraffin to prevent drying, the time for the whole procedure is noted. The thrombelastogram is recorded for 2 h.

EVALUATION

The following measurements are the standard variables of TEG:

- *Reaction time* (*r*): the time from sample placement in the cup until onset of clotting (defined as amplitude of 1 mm). This represents the rate of initial fibrin formation.
- *Clot formation time (k)*: the difference from the 1-mm *r* to 20-mm amplitude. *k* represents the time taken for a fixed degree of viscoelasticity achieved by the forming clot caused by fibrin build up and cross-linking.
- *Alpha angle (α)*: angle formed by the slope of the TEG tracing from the *r* to *k* value. It denotes speed at which solid clot forms.
- *Maximum amplitude (MA)*: greatest amplitude on the TEG trace. *MA* represents the absolute strength of the fibrin clot and is a direct function of the maximum dynamic strength of fibrin and platelets.
- *Clot strength (G in dynes per square centimeter)*: defined by $G = (5{,}000\ MA)/(96\text{–}MA)$. In a tissue-factor-modified TEG (Khurana et al. 1997), clot strength is clearly a function of platelet concentration.
- *Lysis 30, lysis 60 (Ly30, Ly60)*: reduction of amplitude relative to maximum amplitude at 30 and 60 min after time of maximum amplitude. These parameters represent the influence of clot retraction and fibrinolysis.

Effect of various stimuli on platelet/fibrin clot dynamics as shown by Mousa et al. (2000)

TEG parameters	TF (25 ng)	LPS (0.63 ug)	Xa (0.25 nM)	Thrombin (0.3 mU)
	Mean±SEM			
R (minutes)	29.7±2.3	23.4±1.4	15.6±2.9	3.4±0.6
K (minutes)	5.8±1.0	7.6±0.9	4.8±0.5	5.5±0.8c
α (angle)	45.0±2.6	47.8±3.2	61.5±2.1	57.8±2.9
MA (mm)	58.2±1.7	50.0±2.0	65.0±0.8	50.1±2.4

Citrated human whole blood plus 2.5 mM calcium. Data represent mean for n = 6±SEM

MODIFICATIONS OF THE METHOD

Bhargava et al. (1980) compared the anticoagulant effect of a new potent heparin preparation with a commercially available heparin by thrombelastography in vitro using citrated dog and human blood. Barabas et al. (1993) used fibrin plate assay and thrombelastography to assess the antifibrinolytic effects of synthetic thrombin inhibitors. Scherer et al. (1995) described a short-time, endotoxin-induced rabbit model of hypercoagulability for the study of the coagulation cascade and the therapeutic effects of coagulation inhibitors using various parameters including thrombelastography.

Khurana et al. (1997) introduced tissue-factor-modified TEG to study platelet glycoprotein IIb/IIIa function and to establish a quantitative assay of platelet function. With this modification, Mousa et al. (2000) found two classes of glycoprotein IIb/IIIa antagonists, one with high binding affinity for resting and activated platelets and slow platelet dissociation rates (class I) demonstrating potent inhibition of platelet function, in contrast to those with fast platelet dissociation rates (class II). Additionally, Mousa et al. (2005) utilized the TEG in phase II clinical trial in monitoring the efficacy of oral platelet GPIIb/IIIa antagonist on platelet/fibrin clot dynamics.

CRITICAL ASSESSMENT OF THE METHOD

Zuckerman et al. (1981) compared thrombelastography with other common coagulation tests (fibrinogen, prothrombin time, activated thromboplastin time, platelet count, and fibrin split products) and found that there is a strong relationship between the thrombelastographic variables and these common laboratory tests. Moreover, TEG has an increased sensitivity for detecting blood clotting anomalies; it contains additional information on the hemostatic process. This is due to the following: (1) the fact that most laboratory measurements end with the formation of the first fibrin strands while TEG measures the coagulation process on whole blood from initiation of clotting to the final stages of clot lysis and retraction and (2) the possibility of TEG to use whole non-anticoagulated blood without influence of citrate or other anticoagulants.

11.1.3 Chandler Loop

PURPOSE AND RATIONALE

The Chandler loop technique allows producing in vitro thrombi in a moving column of blood (Chandler 1958). The thrombi generated in the Chandler device show morphology very similar to human thrombi formed in vivo (Robbie et al. 1997) with platelet-rich upstream sections ("white heads") that are relatively resistant to t-PA-mediated thrombolysis in contrast to the red blood-cell-rich downstream parts ("red tails") (Stringer et al. 1994).

PROCEDURE

One millimeter of non-anticoagulated whole blood is drawn directly into a polyvinyl tube with a length of 25 cm and an internal diameter of 0.375 cm (1 mm = 9.9 cm tubing). The two ends of the tube are then brought together and closed by an outside plastic collar. The circular tube is placed and centered on a turntable, tilted to an angle of 23°, and rotated at 17 rpm. When the developing thrombus inside the tube becomes large enough to occlude the lumen; the blood column becomes static and moves around in the direction of rotation of the tube.

EVALUATION

Time to thrombus occlusion establishes a definite end point in this system.

MODIFICATIONS OF THE METHOD

Stringer et al. (1994) used this method to determine the influence of an anti-PAI-1 antibody (CLB-2 C8) on the t-PA-induced lysis of Chandler thrombi in vitro.

They used citrated blood and supplemented it with 5.8 μM [^{125}I]–labeled fibrinogen prior to recalcification. After generation in the Chandler loop, the thrombi were washed with isotonic saline and then cut transversally into an upstream (head) and a downstream part (tail). The radioactivity of both parts was determined in a gamma counter (prevalue). The head and the tail were then subjected to thrombolysis by adding 300 μl phosphate-buffered saline containing plasminogen (2 μM) and t-PA (0.9 nM). During the observation time of 240 min aliquots of 10 μl were taken at 30, 60, 120, 180, and 240 min, and the radioactivity was determined. The relation of the measured radioactivity to the prevalue was expressed as percentage of clot lysis.

Van Giezen et al. (1998) used this method to differentiate the effect of an anti-PAI-1 polyclonal antibody (PRAP-1) on human or rat thrombi.

11.1.4 Platelet Aggregation and Disaggregation in Platelet-Rich Plasma or Washed Platelets (Born Method)

PURPOSE AND RATIONALE

Platelets play a crucial role in primary hemostasis by forming hemostatic plugs at sites of vascular injury. Moreover, they contribute to intravascular thrombus formation mostly upon rupture of an atherosclerotic plaque. The contact of nonactivated platelets to exposed subendothelial tissue leads to adhesion via two main mechanisms: binding of subendothelial von Willebrand factor (vWF) to the platelet GPIb-IX-V-complex at high shear rates and binding of collagen to two receptors, integrin α2β1 and GPVI. Platelet adhesion initiates the reactions of shape change, secretion, and activation of GPIIb-IIIa-ligand binding sites. These reactions result in the formation of platelet aggregates. Activation of GPIIb-IIIa is also achieved through signaling by a number of agonists that bind to G-protein-coupled receptors. Consequently, for the measurement of platelet aggregation, platelets are activated by the addition of one of the following agonists to platelet-rich plasma (PRP) or washed platelets: ADP, arachidonic acid (forming thromboxane A2) or U 46619, collagen, thrombin or TRAP, serotonin, epinephrine, and PAF. The formation of platelet aggregates with stirring leads to changes in optical density that are monitored photometrically, usually for 4 min. The test was developed originally by Born (1962a, b) and is used to evaluate quantitatively the effect of compounds on induced platelet aggregation in vitro or ex vivo. For in vitro studies, human PRP is preferred.

PROCEDURE

11.1.4.1 Materials and Solutions

Anticoagulating substances:	
Hirudin (Sigma)	200 μg/ml
Trisodium citrate	0.11 M
Acid-citrate-dextrose (ACD) solution:	
Citric acid	38 mM
Sodium citrate	75 mM
Glucose	124 mM
Platelet aggregating substances (final concentrations in the test):	
ADP: for reversible or biphasic aggregation	0.1–5 μM
ADP: for irreversible aggregation (Sigma)	3–10 μM
Sodium arachidonate (Biodata)	0.3–1 mM
Calcium ionophore A 23187 (Calbiochem)	10 μM
Collagen (Hormonchemie)	3 μg/ml
PAF-acether (C 16-PAF, Bachem)	0.1 μM
Thrombin (Sigma)	0.02–0.05 IU/ml
TRAP (SFLLRNP, Bachem)	1–10 μM
U 46619 (ICN)	1–10 μM
Ristocetin	0.1–1 mg/ml
GPRP (fibrin antipolymerant, Bachem)	0.5 mM
Four-channel aggregometer (PAP 4, BioData)	

The test is carried out either ex vivo or in vitro

For ex vivo assays, mice, rats, or guinea pigs from either sex receive the test compound or the vehicle (for controls) by oral, intraperitoneal, or intravenous administration. At the end of the absorption time, blood is collected by caval venipuncture under pentobarbital sodium anesthesia and xylazine (8 mg/kg i.m.) premedication.

From rabbits (Chinchilla strain, weighing 3 kg), blood is withdrawn by cardiopuncture under xylazine (20 mg/kg i.m.) sedation. The first blood sample (control) is collected before administration of the test compound, the second sample at the end of the absorption time of the test agent.

For in vitro assays, human blood is collected from the antecubital vein of adult volunteers who had not received any medication for the last 2 weeks.

11.1.4.2 Preparation of PRP, PPP, and WP

The entire procedure is performed in plastic (polystyrene) tubes and carried out at room temperature. Freshly collected venous blood is anticoagulated with hirudin (1 volume + 9 volumes of animal blood) or ACD solution (1 volume + 9 volumes of human blood) and centrifuged at 170 g for 15 min to obtain platelet-rich plasma (PRP). The PRP supernatant is carefully removed, and the rest is further centrifuged at 1,500 g for 10 min to obtain platelet poor plasma (PPP). PRP is diluted with PPP to a platelet count of 3×10^8/ml before use in the aggregation assays. To obtain washed platelets (WP), 8.5 volumes of human blood are collected into 1.5 volumes of ACD and centrifuged as for PRP. PRP is acidified to a pH of 6.5 by addition of approximately 1 ml ACD to 10 ml PRP. Acidified PRP is centrifuged for 20 min at 430 g. The pellet is resuspended in the original volume with Tyrode solution (mM: NaCl 120, KCl 2.6, $NaHCO_3$ 12, NaH_2PO_4 0.39, HEPES 10, glucose 5.5, albumin 0.35%) and set to platelet count of 3×10^8/ml. Studies should be completed within 3 h after blood withdrawal.

For ex vivo assays, duplicate samples of 320 µl PRP from drug-treated and vehicle control subjects (for rabbits: control samples before drug administration) are inserted into the aggregometer at 37°C under continuous magnetic stirring at 1,000 rpm. After the addition of 40 µl physiological saline and 40 µl aggregating agent, changes in optical density are monitored continuously at 697 nm.

For in vitro assays, 40 µl of the test solution are added to samples of 320 µl PRP or WP from untreated subjects. The samples are inserted into the aggregometer and incubated at 37°C for 2 min under continuous magnetic stirring at 1,000 rpm. After the addition of 40 µl aggregating agent, changes in optical density are monitored continuously at 697 nm either for 4 min or until constant values for aggregation are achieved. In cases of thrombin activation of PRP, glycine-proline-aspartate-proline (GPRP) is added in order to avoid fibrin formation. In order to measure disaggregation, experimental compounds are added to stimulated PRP at 70% or 100% of control aggregation, and monitoring is performed for further 10 min. Deaggregation is measured by the decrease of light transmission (see Haskel and Abendschein 1989).

EVALUATION

The transmission maximum serves as a scale for platelet aggregation (0% = transmission of PRP, 100% = transmission of PPP).

For in vitro assays:

1. Percent inhibition of platelet aggregation is determined in concentration groups relative to vehicle controls.
   Statistical significance is evaluated by means of the unpaired Student's *t*-test.
2. IC_{50} values are determined from the nonlinear curve fitting of concentration-effect relationships. IC_{50} is defined as the concentration of test drug for half maximal inhibition of aggregation.
3. Percent disaggregation is determined at 10 min after addition of compound; IC_{50} is calculated from the concentration-effect relationship.

For ex vivo assays:

1. Mean values for aggregation in dosage groups are compared to the vehicle control groups (for rabbits: control values before drug administration).
   Statistical significance is evaluated by means of the Student's *t*-test (paired for rabbits, unpaired for others).
2. *ED*50 values are determined from the dose–response curves. *ED*50 is defined as the dose of drug leading to 50% inhibition of aggregation in the animals.

CRITICAL ASSESSMENT OF THE METHOD

The assay, introduced by Born (1962a, b), has become a standard method in clinical diagnosis of platelet function disorders and of aspirin intake. Furthermore, the method is used in the discovery of antiplatelet drugs with the advantage of rapid measurement of

a functional parameter in intact human platelets. However, processing of platelets during the preparation of PRP, washed or filtered platelets from whole blood, results in platelet activation and separation of large-size platelets.

MODIFICATIONS OF THE METHOD

Several authors described modifications of the assay procedure. Breddin (1975) described spontaneous aggregation of platelets from vascular patients in a rotating cuvette. Klose et al. (1975) measured platelet aggregation under laminar flow conditions using a thermostated cone-plate streaming chamber in which shear rates are continuously augmented and platelet aggregation is measured from light transmission through a transilluminating system. Marguerie et al. (1979, 1980) developed a method measuring two phases of platelet aggregation after gel filtration of a platelet suspension (see below). Lumley and Humphrey (1981) described a method to measure platelet aggregation in whole blood (see below). Fratantoni and Poindexter (1990) performed aggregation measurements using a microtiter plate reader with specific modification of the agitation of samples. Comparison of the 96-well microtiter plate method with conventional aggregometry showed similar dose–response curves for thrombin, ADP, and arachidonic acid.

Ammit and O'Neill (1991) used a quantitative bioassay of platelet aggregation for rapid and selective measurement of platelet-activating factor.

11.1.5 Platelet Aggregation After Gel Filtration

PURPOSE AND RATIONALE

Triggering of platelet activation by low concentrations of ADP, epinephrine, or serotonin—so-called weak platelet agonists—in plasma- and fibrinogen-free platelet suspensions does not result in platelet aggregation unless exogenous fibrinogen is added. As opposed to this, platelet aggregation induced by thrombin, collagen, or prostaglandin endoperoxide—so-called strong agonists—is independent of exogenous fibrinogen because these substances lead to the secretion of intracellular platelet ADP and fibrinogen. Studies of platelet aggregation in gel-filtered platelets are performed in cases where the adhesive ligand fibrinogen or vWF is needed in a defined concentration or where plasma proteins could negatively interfere with the effect of compounds. The assay is mostly used to evaluate the influence of compounds on platelet GPIIb-IIIa or other integrins or on GPIb-IX–V.

PROCEDURE

11.1.5.1 Materials and Solutions

Acid-citrate-dextrose (ACD) solution:	
Citric acid	0.8%
Sodium citrate	2.2%
Glucose	2.45%
Hirudin	0.6 U/ml
Tyrode solution:	
NaCl	137 mM
KCl	2.7 mM
$MgCl_2$	5.5 mM
NaH_2PO_4	3.0 mM
HEPES	3.5 mM
Glucose	5.5 mM

(*continued*)

Albumin	0.2%
Hirudin	0.06 U/ml
Apyrase	40 μg/ml
pH	7.2
ADP	10 μM
Thrombin	0.02–0.05 U/ml
$CaCl_2$	0.5 mM
Fibrinogen (American Diagnostca)	1 mg/ml
von Willebrand factor	10 μg/ml
Sepharose CL 2B (Pharmacia)	
Acrylic glass column (Reichelt Chemietechnik, 3-cm inner diameter, 18-cm length)	
Aggregometer (PAP 4, Biodata)	

11.1.5.2 Preparation of Gel-Filtered Platelets

The entire procedure is performed in plastic (polystyrene) tubes at room temperature according to Marguerie et al. (1979).

Blood is drawn from healthy adult volunteers who had no medication for the last 2 weeks. Venous blood (8.4 ml) is collected into 1.4 ml ACD solution and centrifuged for 10 min at 120 g. The platelet-rich plasma (PRP) is carefully removed, the pH adjusted to 6.5 with ACD solution and centrifuged at 285 g for 20 min. The resulting pellet is resuspended in Tyrode buffer (approximately 500 μl buffer/10 ml PRP). The platelet suspension is applied immediately to a Sepharose CL 2B column; equilibration and elution at 2 ml/min flow rate is done with Tyrode buffer without hirudin and apyrase. Platelets are recovered in the void volume. Final platelet suspension is adjusted to 4×10^8/ml. Gel-filtered platelets (GFP) are kept at room temperature for 1 h until the test is started.

11.1.5.3 Experimental Course

For the aggregation studies, GFP in Tyrode buffer is incubated with $CaCl_2$ (final concentration 0.5 mM) with or without fibrinogen (final concentration 1 mg/ml) in polystyrene tubes. After 1 min, 20 μl of the test compound or the vehicle (controls) are added, and the samples are incubated for another 2 min. After the addition of 20 μl platelet agonist, changes in light transmission are recorded. The whole procedure is done under continuous magnetic stirring at 37°C (1,000 rpm) in the aggregometer. Samples with added $CaCl_2$ but without fibrinogen identify proper exclusion of plasma proteins if neither spontaneous aggregation occurs nor aggregation in the presence of weak agonists. Full aggregation response of GFP to 10 μM ADP shows intact platelets (with only minor preactivation with gel filtration).

EVALUATION

The transmission maximum serves as a scale for platelet aggregation. Each test compound is assayed with at least two different donor GFP; in the case of an antiaggregating effect, the test is performed with 4–6 GFPs.

Mean values of the dosage groups are compared to the controls. Statistical significance is evaluated by means of the Student's *t*-test.

The percent inhibition of platelet aggregation in the dosage groups is calculated relative to the vehicle controls. IC_{50} values (50% inhibition of aggregation) are determined from the concentration-effect curves.

For detailed methodology and evaluation of different agents, see Marguerie et al. (1979, 1980) and Markell et al. (1993).

11.1.6 Platelet Aggregation in Whole Blood

PURPOSE AND RATIONALE

The method uses a whole blood platelet counter that counts single platelets and does not require their separation from other blood cell types. Platelet aggregation is induced in anticoagulated human whole blood samples by the addition of the aggregating agent's arachidonic acid or collagen. The number of platelets is determined in drug-treated and vehicle control samples; the percentage of inhibition of aggregation and IC_{50} values are calculated in dosage groups. The effect of compounds on other blood cells that secondarily can

influence platelet aggregation is included in this test system. The method has been described by Lumley and Humphrey (1981) and Cardinal and Flower (1980).

PROCEDURE

11.1.6.1 Materials and Solutions

Anticoagulant: sodium citrate to induce platelet aggregation	3.8%
Sodium arachidonate (Bio/Data)	3.6×10^{-4} M
Collagen (Hormonchemie)	10 µg/ml
Serono Hematology System 9000 or Sysmex Microcell counter F 800	

The entire procedure is performed in plastic (polystyrene) tubes and carried out at room temperature. Blood is drawn from healthy adult volunteers who had not received medication for the last 2 weeks. Nine milliliters of venous blood is anticoagulated with 1 ml of sodium citrate and kept in a closed tube at room temperature for 30 min until the start of the test.

For the aggregation studies, 10 µl test substance or vehicle (control) are added to 480 µl citrated blood. Samples in closed tubes are preincubated for 5 min in a 37°C water shaker bath at 75 strokes/min. Ten microliters aggregating agent are added and samples are incubated for another 10 min. The number of platelets (platelet count) is determined in 10 µl samples immediately before and 10 min after the addition of the aggregating agent ("initial platelet count," "10-min-platelet count") in a hematology cell counter. The following samples for the determination of the platelet count are prepared in duplicate:

- Control aggregation = spontaneous aggregation (without aggregating agent): 480 µl blood + 20 µl vehicle. Blood samples with >20% spontaneous aggregation are not used to test for induced aggregation.
- Maximal aggregation: 480 µl blood + 10 µl vehicle + 10 µl aggregating agent.
  Values represent the maximal induced aggregation rate of the blood sample.
- Test substance aggregation: 480 µl blood + 10 µl test substance + 10 µl aggregating agent.

EVALUATION

1. From the samples for maximal aggregation (vehicle), the percentage of maximal aggregation is calculated according to the following formula:

$$\%\ \text{maximal aggregation} = 100 - \frac{\text{10-min-platelet count} \times 100}{\text{initial platelet count}}$$

[*This value for maximal aggregation is taken as* 100%].

2. From the samples for test substance–induced aggregation, the percentage of aggregation in dosage groups is calculated according to the following formula:

$$\%\ \text{aggregation} = \frac{\text{10-min-platelet count} \times 100}{\text{initial platelet count}}$$

3. IC_{50} values (50% inhibition of aggregation) are determined from the dose–response curves (log concentration test substance versus % inhibition of aggregation).

11.1.7 Platelet Micro- and Macroaggregation Using Laser Scattering

Purpose and Rationale

- A new highly sensitive method to study platelet aggregation based on the measurement of mean radius or particle size makes it possible to record kinetics of formation of micro- and macroaggregates in real time.
- Sensitivity in measurements of spontaneous aggregation is higher than in routine light transmittance.

A new platelet aggregometer (AG-10; Kowa, Japan) that uses a laser-light-scattering beam was introduced (Tohgi et al. 1996). Platelet aggregates, the size of which can be measured as total voltage of light-scatter intensity at 1.0-s intervals for a 10-min period, can be divided into three ranges: small aggregates (diameter 9–25 µm), medium (26–50 µm), and large (>50 µm). Using laser-scatter aggregation, it was found that young smokers had an increased number of

small platelet aggregates, which cannot be detected with a conventional aggregometer based on the turbidometric method (Matsuo et al. 1997). This device detects platelet aggregation in the small-aggregate size range by the addition of unfractionated heparin (UFH), and the aggregates are disaggregable in incubation with protamine sulfate. When platelet aggregation induced by UFH at a final concentration of 0.5 U/ml was observed in 36 normal subjects with no history of heparin exposure, 13 had a positive response in excess of 0.5 V of light intensity in the small-aggregate size range. In chronic hemodialysis patients in whom heparin had been used regularly for many years, a positive response with heparin-induced aggregates was noted in 37 of 59 patients, which was increased compared with that of normal subjects. The light intensity in the small-aggregate size range was enhanced during heparinized dialysis. In patients with a positive heparin response, the intensity of aggregates after heparin was significantly increased compared with that in nonresponders to heparin. The findings of enhanced platelet aggregation during heparin infusion could be directly obtained without the addition of ADP or TRAP using laser aggregometry (Xiao and Théroux 1998).

11.1.7.1 Limitations

This technique cannot be applied in whole blood yet but can be used with PRP, washed platelet, or GFP.

11.1.8 Fibrinogen Receptor Binding

PURPOSE AND RATIONALE

The assay is used to evaluate the binding characteristics of drugs at the fibrinogen receptor. A constant concentration of the radioligand ^{125}I-fibrinogen (30–50 nM) is incubated with increasing concentrations of a nonlabeled test drug (0.1 nM–1 mM) in the presence of gel-filtered human platelets. If the test drug exhibits any affinity to fibrinogen receptors, it is able to compete with the radioligand for receptor binding sites. Thus, the lower the concentration range of the test drug, in which the competition reaction occurs, the more potent the test drug. Platelets are activated with 10 mmol/l ADP to stimulate the ^{125}I-fibrinogen binding at the GPIIb/IIIa receptor.

PROCEDURE

11.1.8.1 Preparation of Gel-Filtered Platelets

From a healthy volunteer, 200 ml blood is collected. An aliquot of 8.4 ml blood is mixed with 1.4 ml ACD buffer in polystyrol tubes and centrifuged at 1,000 rpm for 15 min. The resulting platelet-rich plasma (PRP) is collected, and an aliquot is taken for platelet counting. Ten milliliters of PRP is mixed with 1 ml ACD buffer (ACD-PRP, pH~6.5); 5 ml portions of ACD-PRP are transferred to plastic tubes and centrifuged at 1,600 rpm for 20 min. The resulting supernatant is decanted, and each pellet is resuspended in 500 μl Tyrode buffer C. An aliquot is taken for platelet counting to calculate the loss of platelets. The platelet suspension is then transferred to the Sepharose-packed column that has been eluted with approximately 100 ml degassed Tyrode buffer B (2 ml/min). The column is closed and eluted with degassed Tyrode buffer B (2 ml/min). The first platelets appear after 18–20 min and are then collected for 10 min in a closed plastic cup. Gel-filtered platelets (GFP) are set to 4×10^8 platelets/ml with Tyrode buffer B and kept at room temperature until the start of the test.

11.1.8.2 Experimental Course

For each concentration, samples are tested in triplicate (test tubes No. 72708, Sarstedt). The total volume of each incubation sample is 500 μl. The concentration of ^{125}I-fibrinogen is constant for all samples (10 μg/500 μl).

11.1.8.3 Competition Experiments

The competition reaction is characterized by one buffer value (bidistilled water) and various concentrations of nonlabeled fibrinogen or test compound.

- 100 μl ^{125}I-fibrinogen
- 100 μl nonlabeled fibrinogen or test drug (various concentrations, 10^{-10}–10^{-3} M)
- 50 μl ADP

Nonspecific binding: The nonspecific binding of ^{125}I-fibrinogen is defined as the radioligand binding in the presence of 10^{-5} M of nonlabeled fibrinogen. The binding reaction is started by adding 250 μl GFP (4×10^{8} platelets/ml). The samples are incubated for 30 min at room temperature. Subsequently, a 100 μl aliquot of the incubation sample is transferred to a Microtainer tube containing 400 μl glucose solution. The tubes are centrifuged at 11,750 rpm for 2 min to separate ^{125}I-fibrinogen bound at the platelet glycoprotein IIb–IIIa receptor from free radioligand. The supernatant is carefully decanted and is allowed to run off for approximately 30 min. Radioactivity of the platelet pellets is counted for 1 min in a gamma counter with an efficiency of 65.3%.

11.1.8.4 Materials and Solutions

Solutions for platelet preparation		
Stock solution I	Citrate	0.8%
	Sodium citrate	2.2%
Stock solution II	NaCl	120 mM
	KCl	2.8 mM
	NaH_2PO_4	10.0 mM
	HEPES	10.0 mM
ACD buffer	Stock solution	
	+ Glucose	2.45%
	+ Hirudin	0.06 U/ml
Tyrode buffer A	Stock solution II	
	+ $NaHCO_3$	12.0 mM
Tyrode buffer B	Stock solution II	
	+ $NaHCO_3$	12 mM
	+ Glucose	5.5 mM
	+ Bovine albumin	0.35%
Tyrode buffers A and B are degassed by aspiration for approximately 1 h after setting the pH to 7.2		
Tyrode buffer C	Tyrode buffer B	
	(degassed)	
	+ Apyrase	40 μg/ml
	+ Hirudin	0.06 U/ml
Chromatography column	Acryl glass column (200×170 mm, 30-mm diameter), closed with three perlon filters, pore sizes 63, 90, and 230 μm, and gauze 50 μm filled with degassed Sepharose CL2B suspension (Pharmacia LKB); equilibrated with 500 ml degassed Tyrode buffer A (2 ml/min)	
Incubation buffer		
Stock solution	NaCl	120 mM
	KCl	2.6 mM
	NaH_2PO_4	0.3 mM
	HEPES	10.0 mM
	$CaCl_2$	0.5 mM
Incubation buffer, pH 7.2	Stock solution	
	+ $NaHCO_3$	12 mM
	+ Glucose	5.5 mM
	+ Human albumin	0.35%
Glucose solution (in incubation buffer)		
Radioligand	^{125}I-fibrinogen specific activity 3.7 Mbq/mg fibrinogen (100 μCi/mg fibrinogen) (Amersham), 1 mg radiolabeled fibrinogen is dissolved in 10 ml incubation buffer	
Nonlabeled fibrinogen (mw 340,000, grade L, Sigma; in bidistilled water)		10^{-10}–10^{-3} M
ADP (in incubation buffer)		10 μM
Gamma counter (1282 Compugamma CS, LKB)		

(*continued*)

EVALUATION

The quantity of the specific ^{125}I-fibrinogen binding results from the difference between the total and the nonspecific binding.

Platelet glycoprotein IIb-IIIa receptor binding is given as fmol ^{125}I-fibrinogen/10^{8} platelets or ^{125}I-fibrinogen molecules bound per platelet.

The dissociation constant (*K*i) of the test drug is determined from the competition experiment of ^{125}I-fibrinogen versus nonlabeled drug by a computer-supported analysis of the binding data:

$$K = \frac{K_D{}^{125}I \times IC_{50}}{K_D{}^{125}I + [^{125}I]},$$

where IC_{50} = concentration of the test drug, which displaces 50% of the specifically glycoprotein IIb-IIIa receptor bound ^{125}I-fibrinogen in the competition experiment.

$[^{125}I]$ = concentration of ^{125}I-fibrinogen in the competition experiment.

$KD^{125}I$ = dissociation constant of ^{125}I-fibrinogen, determined from the saturation experiment.

The K_i value of the test drug is the concentration, at which 50% of the fibrinogen receptors are occupied by the test drug.

For detailed methodology and evaluations of various mechanisms and agents, see the following selected references: Bennett and Vilaire (1979); Marguerie et al. (1979, 1980); and Mendelsohn et al. (1990).

11.1.9 Euglobulin Clot Lysis Time

PURPOSE AND RATIONALE

The euglobulin lysis time is used as an indicator for the influence of compounds on the fibrinolytic activity in rat blood according to Gallimore et al. (1971). The euglobulin fraction of plasma is separated from inhibitors of fibrinolysis by acid precipitation and centrifugation. Euglobulin predominantly consists of plasmin, plasminogen, plasminogen activator, and fibrinogen. By addition of thrombin to this fraction, fibrin clots are formed. The lysis time of these clots is determined as a measurement of the activity of activators of fibrinolysis (e.g., plasminogen activators). Thus, compounds can be detected that stimulate the release of tissue-type plasminogen activator from the vessel wall.

PROCEDURE

Rats are anesthetized by intraperitoneal injection of 60 mg/kg pentobarbital sodium and placed on a heating pad (37°C). At the same time, the test solution or the vehicle (controls) is administered intravenously or intraperitoneally. Twenty-five minutes later, the animals receive another intraperitoneal injection of 12 mg/kg sodium pentobarbital to keep them in deep narcosis for 45 min.

11.1.9.1 Plasma Preparation

After the test compound is absorbed, blood is withdrawn from the inferior caval vein exposed by a midline excision. Blood (1.8 ml) is removed with a plastic syringe containing 0.2 ml 3.8% sodium citrate solution. The sample is thoroughly mixed, transferred to a plastic tube, and immediately immersed in ice. Plasma is prepared by centrifugation at 2,000 g for 10 min at 2°C.

11.1.9.2 Euglobulin Preparation

A 0.5 ml portion of plasma is added to 9.5 ml of ice-cold distilled water; the pH is brought to 5.3 by the addition of 0.13 ml of 1% acetic acid. The diluted plasma is kept on ice for 10 min, and the precipitated euglobulin fraction is collected by centrifugation at 2,000 g for 10 min at 2°C. The supernatant is discharged, and the remaining fluid is removed by drying the tube on a filter paper for 1 min. The euglobulin precipitate is dissolved in 1 ml of 0.12 M sodium acetate solution.

11.1.9.3 Euglobulin Lysis Assay

Aliquots (0.45 ml) of the euglobulin solution are transferred to test tubes, and 0.05 ml thrombin (Test Thrombin, Behring Werke) (25 U/ml) are added. The tubes are transferred to a water bath at 37°C. The time interval between the addition of thrombin and the complete lysis of the clots is measured.

EVALUATION

The lysis time [min] is determined. ELT is shortened when activators of fibrinolysis are increased.

Percent lysis time is calculated in dosage groups as compared to controls.

Statistical evaluation is performed by means of the Student's *t*-test.

11.1.10 Flow Behavior of Erythrocytes

PURPOSE AND RATIONALE

The deformation of erythrocytes is an important rheological phenomenon in blood circulation according to Teitel (1977). It allows the passage of normal red cells

through capillaries with diameters smaller than that of the discoid cells and reduces the bulk viscosity of blood flowing in large vessels. In the following test, the initial flow of filtration is taken as a criterion for erythrocyte deformability. A prolonged time of filtration can be due to two basic pathologic phenomena: an increased rigidity of the individual red cells or an increased tendency of the cells to aggregate. To simulate decreased red blood cell deformability, the erythrocytes are artificially modified by one (or by the combination) of the following stress factors:

- Addition of calcium ions (increase in erythrocyte rigidity)
- Addition of lactic acid (decrease in pH value)
- Addition of 350–400 mmol NaCl (hyperosmolarity)
- Storing the sample for at least 4 h (cellular aging, depletion of ADP)

The following procedure can be used to evaluate the effect of test compounds on the flow behavior of erythrocytes.

PROCEDURE

11.1.10.1 Apparatus

Erythrocyte filtrometer MF 4 (Fa. Myrenne, 52159 Roetgen, Germany)

Membrane filter (Nuclepore Corp.) pore diameter: 5–10 μm, pore density: 4×10^5 pores/cm^2

11.1.10.2 Ex Vivo

Blood is collected from Beagle dogs, weighing 12–20 kg; from rabbits, weighing 1.2–2.5 kg; or from Wistar rats, weighing 150–300 g. The test subjects receive the test compound by oral, subcutaneous, or intravenous administration 15, 60, 90, or 180 min before the withdrawal of blood.

11.1.10.3 In Vitro

Following addition of the test compound, blood is incubated at 37°C for 5 or 30 min.

Freshly collected venous blood is anticoagulated with K-EDTA, (1 mg/ml blood) or heparin (5 IU/ml heparin sodium) and centrifuged at 3,000 rpm for 7 min. The supernatant (plasma) and the buffy coat are removed and discarded. The packed erythrocytes are resuspended in autologous plasma containing 0.25% human albumin, and the hematocrit value is fixed at 10%. The red blood cells are altered by one or several of the stress factors mentioned above. A sample of 2 ml of the stressed suspension is applied to the filtrometer, and the initial flow rate is determined. The filtration curve is plotted automatically.

EVALUATION

The cumulative volume of the filtered suspension is recorded per time unit (10 min).

The slope of the curve is determined at different time intervals.

The initial flow rate (10% of the cell suspension having passed the filter) is recorded.

11.1.10.4 Statistics

Data of each set are first tested for normal distribution using the Kolmogorov-Smirnov test. The normal distribution hypothesis is eliminated if the data having a significance level of 5% are not normally distributed. In case that both data sets to be compared are normally distributed, the F-test is applied. The hypothesis of homogeneity of variance of both test series is eliminated when the significance level for homogeneity of variance is 5%. The *t*-test for paired and nonpaired data is performed when homogeneity of variance is present. In any case, a paired difference test (for paired data) or the *U*-test (for non-paired data) is likewise carried out (paired of difference test = Wilcoxon test; *U*-test = Wilcoxon–Mann–Whitney or Mann–Whitney test, respectively).

11.1.11 Filterability of Erythrocytes

PURPOSE AND RATIONALE

The single erythrocyte rigidometer (SER) allows the measurement of deformability of individual red blood cells by determining their passage time through a pore under constant shear stress. In this test, the passage times of single erythrocytes through one pore in a synthetic membrane are determined according to Kiesewetter et al. (1982a), Roggenkamp et al. (1983), and Seiffge and Behr (1986). The pore in the membrane practically represents a capillary with defined diameter and length. The driving pressure is

produced by the constant shear stress. The passage of the red blood cells is measured with the help of an electrical device. A constant current of 50–200 nA is applied. When an erythrocyte passes through the pore, the current is interrupted. The test is used to detect compounds that improve filterability of erythrocytes. To simulate decreased red blood cell deformability, the erythrocytes are artificially modified either by one or by a combination of the following stress factors:

- Addition of calcium ions (increase in erythrocyte rigidity)
- Addition of lactic acid (decrease in pH value)
- Addition of 350–400 mmol NaCl (hyperosmolarity)
- Storing the sample for at least 4 h (cellular aging, depletion of ADP)

PROCEDURE

11.1.11.1 Apparatus

Single erythrocyte rigidometer (Myrenne, 52159 Roetgen, Germany)

Data

Driving pressure: $dp = 70$ Pa (dog, rabbit, rat), $dp = 100$ Pa (man)

Wall shear stress: $\tau = 3$ Pa

Single pore membrane: length: 30 μm, Diameter: 3.5 μm (rat), 4.0 μm (rabbit, dog), 4.5 μm (man)

11.1.11.2 Ex Vivo

Blood is collected from Beagle dogs, weighing 12–20 kg; from rabbits, weighing 1.2–2.5 kg; from Wistar rats, weighing 150–300 g; or from man. The test subjects receive the test compound by oral, subcutaneous, or intravenous administration 15, 60, 90, or 180 min before the withdrawal of blood.

11.1.11.3 In Vitro

Following addition of the test compound, the blood samples are incubated at 37°C for 5 or 30 min. The blood samples are mixed with K-EDTA (1 mg/ml blood) or heparin (5 IE/ml heparin sodium) to prevent clotting. The blood is centrifuged at 3,000 rpm for 7 min. The plasma and the buffy coat are removed and discarded. The packed erythrocytes are resuspended in filtrated HEPES-buffer containing 0.25% human albumin, and the hematocrit value is fixed to $<1\%$. The red blood cells are altered by one or several stress factors mentioned above. A sample of 2 ml of the stressed suspension is applied to the measuring device, and the passage time of a population of 250 erythrocytes (tm) is determined. Cells remaining in the pore for more than 100 ms (tm >100 ms) lead to a rheological occlusion. Untreated red blood cell suspensions serve as control.

EVALUATION

The mean passage time of 250 single erythrocytes and the number of rheological occlusions/250 erythrocytes are determined.

11.1.11.4 Statistics

The statistical significance is evaluated according to the procedure described for flow behavior of erythrocytes described above.

11.1.12 Erythrocyte Aggregation

PURPOSE AND RATIONALE

The aggregation of red blood cells into rouleaux and from rouleaux into three-dimensional cell networks is a rheological parameter that decisively influences the flow behavior of blood especially in disturbed microcirculation. In the following procedure, an apparatus (erythrocyte aggregometer) is used to measure erythrocyte aggregation. The transparent measuring chamber (cone/plate configuration) is transilluminated by light of a defined wavelength. The intensity of the transmitted light, which is modified by the aggregation process, is recorded. The method can be used to determine the effect of test compounds on erythrocyte aggregation according to Kiesewetter et al. (1982b) and Schmid-Schoenbein et al. (1973).

PROCEDURE

11.1.12.1 Apparatus

Selective erythrocyte rigidometer (Fa. Myrenne, 52159 Roetgen, Germany)

11.1.12.2 Ex Vivo

Blood is collected from Beagle dogs, weighing 12–20 kg; from rabbits, weighing 1.2–2.5 kg; or from Wistar rats, weighing 150–300 g. The test subjects receive the test compound by oral, subcutaneous, or intravenous administration 15, 60, 90, or 180 min before the withdrawal of blood.

11.1.12.3 In Vitro

Following addition of the test compound, the blood sample is incubated at 37°C for 5 or 30 min. Blood is obtained from the test subjects by venipuncture and mixed with K-EDTA (1 mg/ml) or heparin (5 IU/ml heparin sodium) to prevent clotting. Erythrocyte aggregation is determined in whole blood of 40% hematocrit. A sample of 40 µl blood is transferred to the measuring device. The red cells are dispersed at a shear rate of 600/s. After 20 s, flow is switched to stasis, and the extent of erythrocyte aggregation is determined photometrically.

EVALUATION

11.1.12.4 Statistics

The statistical significance is evaluated according to the procedure for flow behavior of erythrocytes described above.

11.1.13 Determination of Plasma Viscosity

PURPOSE AND RATIONALE

One of the principal methods for measuring viscosity is based on the rate of flow of a liquid through an orifice according to Harkness (1971). In this test, a defined volume of plasma is transferred into a capillary viscometer, and the efflux time required for the plasma to flow from the upper to the lower mark is measured. Using this procedure, the effect of test compounds on the viscosity of blood plasma can be determined. The test can be carried out either ex vivo or in vitro.

PROCEDURE

11.1.13.1 Ex Vivo

Beagle dogs weighing 12–20 kg, rabbits weighing 2.0–3.0 kg, or Wistar rats weighing 150–300 kg of either sex are used as test animals. Likewise, the test procedure can be performed in man. The test subjects receive the test compound by oral, subcutaneous, or intravenous administration 15, 60, 90, or 180 min before the withdrawal of blood.

11.1.13.2 In Vitro

Following addition of the test compound, plasma (obtained as described below) is incubated at 37°C for 5 or 30 min.

Freshly collected venous blood is anticoagulated with 1 mg/ml blood K^+−EDTA or heparin sodium (5 IU/ml blood) and centrifuged at 3,000 rpm for 5 min. The supernatant (plasma) is removed, and a sample of 0.9 ml plasma is transferred into a capillary viscometer (Coulter Harkness, Coulter Electr. LTD, England) provided with a glass capillary of 0.5-mm inside diameter. The temperature during measurement is 37°C. The flow time t, required for the plasma to flow through the capillary, is measured. Untreated plasma serves as control.

EVALUATION

The viscosity of each sample can be determined using the following formula:

$$\eta = K \times t \times \rho,$$

where

η = viscosity of plasma

K = calibration constant of viscometer

t = flow time of 0.9 ml plasma
ρ = density of plasma.

The change in viscosity relative to the control group is determined.

Statistical evaluation is carried out using the Student's t-test.

11.2 In Vitro Models of Thrombosis

PURPOSE AND RATIONALE

There is abundant evidence suggesting that platelets play a pivotal role in the pathogenesis of arterial thrombotic disorders, including unstable angina (UA), myocardial infarction (MI), and stroke. The underlying pathophysiological mechanism of these processes has been recognized as the disruption or erosion of a vulnerable atherosclerotic plaque leading to local platelet adhesion and subsequent formation of partially or completely occlusive platelet thrombi.

The specific platelet surface receptors that support these initial adhesive interactions are determined by the local fluid dynamic conditions of the vasculature and the extracellular matrix constituents exposed at the sites of vascular injury. Konstantopoulos et al. (1998) and Alevriadou et al. (1993) demonstrated that under high shear conditions, the adhesion of platelets to exposed subendothelial surfaces of atherosclerotic or injured vessels presenting collagen and von Willebrand factor (vWF) is primarily mediated by the platelet glycoprotein (GP)Ib/IX/V complex. This primary adhesion to the matrix activates platelets, leading ultimately to platelet aggregation mediated predominantly by the binding of adhesive proteins such as fibrinogen and vWF to GPIIb/IIIa. In addition, direct platelet aggregation in the bulk phase under conditions of abnormally elevated fluid shear stresses, analogous to those occurring in atherosclerotic or constricted arterial vessels as shown by Turitto (1982), may be important. Shear-induced platelet aggregation is dependent upon the availability of vWF and the presence of both GPIb/IX and GPIIb/IIIa on the platelet membrane. It has been postulated that at high shear stress conditions, the interaction of vWF with the GPIb/IX complex is the initial event leading to platelet activation that also triggers the binding of vWF to GPIIb/IIIa to induce platelet aggregate formation.

A variety of methods have been utilized to assess the ex vivo and/or in vitro efficacy of platelet antagonists, including photometric aggregometry, whole blood electrical aggregometry, and particle counter methods as described in the above segments. In photometric aggregometry, a sample is placed in a stirred cuvette in the optical light path between a light source and a light detector. Aggregate formation is monitored by a decrease in turbidity, and the extent of aggregation is measured as percent of maximal light transmission. The major disadvantage of this technique is that it cannot be applied in whole blood since the presence of erythrocytes interferes with the optical responses. Furthermore, it is insensitive to the formation of small aggregates. Particle counters are used to quantitate the size and the number of particles suspended in an electrolyte solution by monitoring the electrical current between two electrodes immersed in the solution. Aggregation in this system is quantitated by counting the platelets before and after stimulation and is usually expressed as a percentage of the initial count as shown by Jen and McIntire (1984). However, the disadvantage of this technique is that it cannot distinguish platelets and platelet aggregates from other blood cells of the same size. Thus, one is limited to counting only a fraction of single platelets, as well as aggregates that are much larger than erythrocytes and leukocytes. The technique of electrical aggregometry allows the detection of platelet aggregates as they attach to electrodes immersed in a stirred cuvette of whole blood or platelet suspensions. Such an attachment results in a decrease in conductance between the two electrodes that can be quantitated in units of electrical resistance. However, a disadvantage of this method is that it is not sensitive in the detection of small aggregates as demonstrated by Sweeney et al. (1989).

This segment discusses two complementary in vitro flow models of thrombosis that can be used to accurately quantify platelet aggregation in anticoagulated whole blood specimens and evaluate the inhibitory efficacy of platelet antagonists. (1) A viscometric-flow cytometric assay to measure direct shear-induced platelet aggregation in the bulk phase as demonstrated by Konstantopoulos et al. (1995) and (2) a parallel-plate

perfusion chamber coupled with a computerized videomicroscopy system to quantify the adhesion and subsequent aggregation of human platelets in anticoagulated whole blood flowing over an immobilized substrate (e.g., collagen I) as shown by Konstantopoulos et al. (1995) and Mousa et al. (2002). Furthermore, Mousa et al. (2002) demonstrated a third in vitro flow assay in which surface-anchored platelets are preincubated with a GPIIb/IIIa antagonist, and unbound drug is washed away prior to the perfusion of THP-1 monocytic cells, thereby enabling us to distinguish agents with markedly distinct affinities and receptor-bound lifetimes.

PROCEDURES

11.2.1 Isolation of Human Platelets

The steps described in the next subheading outline the procedure for isolation and purification of platelets from whole blood obtained by venipuncture from human volunteers. Obtain blood sample by venipuncture from an antecubital vein into polypropylene syringes containing either sodium citrate (0.38% final concentration) or heparin (10 U/ml final concentration). Centrifuge anticoagulated whole blood at 160 g for 15 min to prepare platelet-rich plasma (PRP).

11.2.2 Isolation of Washed Platelets

PRP specimens are subjected to a further centrifugation (1,100 g for 15 min) in the presence of 2 μM PGE_1 (Evangelista et al. 1996).

1. The platelet pellet is resuspended in HEPES-Tyrode buffer containing 5 mM EGTA and 2 μM PGE_1.
2. Platelets are then washed via centrifugation (1,100 g for 10 min), resuspended at 2×10^8/ml in HEPES-Tyrode buffer, and kept at room temperature for no longer than 4 h before use in aggregation/adhesion assays.

11.2.3 Materials

1. Anticoagulant solution (sodium citrate, porcine heparin, PPACK, etc.)
2. Fluorescently labeled platelet-specific antibody
3. Dulbecco phosphate-buffered saline (D-PBS) (with and without Ca^{2+}/Mg^{2+})
4. Formaldehyde
5. Type I collagen, from bovine Achilles tendon
6. 0.5 mol/L glacial acetic acid in water
7. Glass coverslips (24×50 mm; Corning; Corning, NY)
8. Silicone sheeting (gasket) (0.005-in or 0.010-in thickness; Specialty Manufacturing Inc; Saginaw, MI)
9. Quinacrine dihydrochloride
10. Prostaglandin E_1 (PGE_1) and EGTA
11. Thrombin
12. Bovine serum albumin
13. HEPES-Tyrode buffer (129 mM NaCl, 9.9 mM $NaHCO_3$, 2.8 mM KCl, 0.8 mM K_2PO_4, 0.8 mM $MgCl_2{\bullet}6H_2O$, 1 mM $CaCl_2$, 10 mM HEPES, 5.6 mM dextrose)
14. 3-Aminopropyltriethoxysilane (APES)
15. Acetone
16. 70% nitric acid in water
17. THP-1 monocytic cells
18. Platelet antagonists such as abciximab

EVALUATIONS

The methods described below outline three dynamic adhesion/aggregation assays used to assess the in vitro and/or ex vivo efficacy of platelet antagonists: (1) a viscometric-flow cytometric assay to measure shear-induced platelet-platelet aggregation in the bulk phase and (2) a perfusion chamber coupled with a computerized videomicroscopy system to visualize in real time and quantify (a) the adhesion and subsequent aggregation of platelets flowing over an immobilized substrate (e.g., extracellular matrix protein) and (b) free-flowing monocytic cell adhesion to immobilized platelets.

11.2.4 Cone-and-Plate Viscometry Under Shear Flow Cytometry

PURPOSE AND RATIONALE

The cone-and-plate viscometer is an in vitro flow model used to investigate the effects of bulk fluid shear stress on suspended cells. Anticoagulated whole blood specimens (or isolated cell suspensions) are placed between the two platens (both of stainless steel) of the viscometer. Rotation of the upper conical platen causes a well-defined and uniform shearing stress to be applied to the entire fluid medium as described by Konstantopoulos et al. (1998). The shear rate (γ) in this system can be readily calculated from the cone angle and the speed of the cone using the formula:

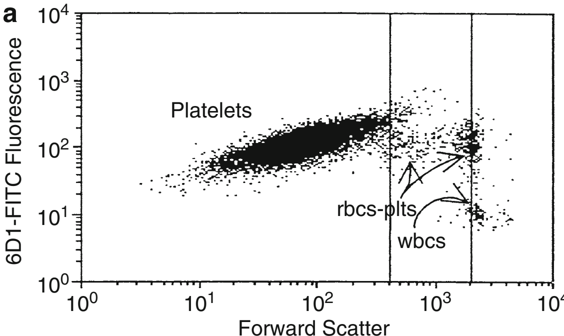
$$\gamma = \left(\frac{2\pi\omega}{60\theta_{cp}}\right)$$

where γ is the shear rate in sec^{-1}, ω is the cone rotational rate in revolutions per minute (rev/min), and θ_{cp} is the cone angle in radians. The latter is typically in the range of 0.3–1.0. The shear stress, τ, is proportional to shear rate, γ, as shown by: $\tau = \mu \cdot \gamma$, where μ is the viscosity of the cell suspension (the viscosity of anticoagulated whole blood is ~0.04 cp at 37°C). This type of rotational viscometer is capable of generating shear stresses from ~2 dyn/cm^2 (venous level) to greater than 200 dyn/cm^2 (stenotic arteries).

PROCEDURES

Single platelets and platelet aggregates generated upon shear exposure of blood specimens are differentiated from other blood cells on the basis of their characteristic forward scatter and fluorescence (by the use of fluorophore-conjugated platelet-specific antibodies) profiles by flow cytometry as described by Konstantopoulos et al. (1995). This technique requires no washing or centrifugation steps that may induce art factual platelet activation and allows the study of platelet function in the presence of other blood elements. Konstantopoulos et al. (1995) described the procedure used to quantify platelet aggregation induced by shear stress as follows: *Incubate anticoagulated whole blood with platelet antagonist or vehicle (control) at 37 °C for 10 min.*

1. Place a blood specimen (typically ~500 μl) on the stationary platen of a cone-and-plate viscometer maintained at 37°C.
2. Take a small aliquot (~3 μl) from the presheared blood sample, fix it with 1% formaldehyde in D-PBS (~30 μl), and process it as outlined in steps 6–8.
3. Expose the blood specimen, in the presence or absence of a platelet antagonist, to well-defined shear levels (typically 4,000 s^{-1} to induce significant platelet aggregation in the absence of a platelet antagonist) for prescribed periods of time (typically 30–60 s).
4. Take a small aliquot (~3 μl) from the sheared blood specimen and immediately fix it with 1% formaldehyde in D-PBS (~30 μl).
5. Incubate the fixed blood samples with a saturating concentration of a fluorescently labeled platelet-specific antibody, such as anti-GPIb(6D1)-FITC, for 30 min in the dark.
6. Dilute specimens with 2 ml of 1% formaldehyde and analyze them by flow cytometry.
7. Flow cytometric analysis is used to distinguish platelets from other blood cells on the basis of their characteristic forward scatter and fluorescence profiles, as shown in Fig. 11.1. Data acquisition is then carried out on each sample for a set period (usually 100 s), thereby allowing equal volumes for both the presheared and sheared specimens to



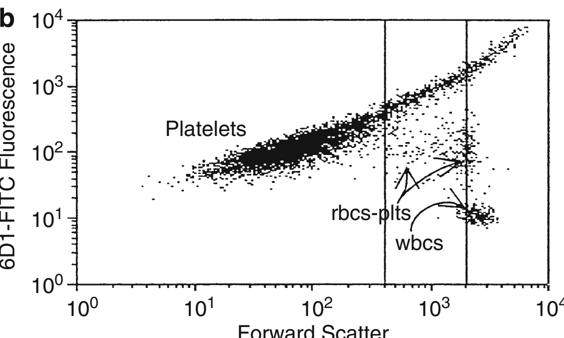


Fig. 11.1 Quantification of shear-induced platelet aggregation by flow cytometry. Panel a corresponds to an unsheared blood specimen. Panel b corresponds to a blood specimen that has been subjected to a pathologically high level of shear stress for 30 s. As can be seen in the figure, there are three distinct cell populations. The upper population consists of platelets and platelet aggregates. The "rbcs-plts" population corresponds to platelets associated with erythrocytes and leukocytes. The "wbcs" population consists of some leukocytes that have elevated levels of FITC autofluorescence. The left vertical line separates single platelets ($\leq$4.5 μm in diameter) from platelet aggregates, whereas the right vertical line separates "small" from "large" platelet aggregates. The latter were defined to be larger than 10 μm in equivalent sphere diameter

be achieved. As a result, the percent platelet aggregation can be determined by the disappearance of single platelets into the platelet aggregate region using the formula:

% Platelet aggregation = (1−Ns/Nc×100), where Ns represents the single platelet population of the sheared specimen and Nc represents the single platelet population of the presheared specimen. By comparing the extents of platelet aggregation in the presence and absence of a platelet antagonist, its antiplatelet efficacy can be readily determined.

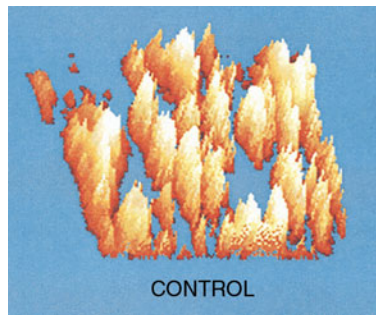
11.2.5 Platelet Adhesion and Aggregation Under Dynamic Shear

PURPOSE AND RATIONALE

The steps described and outlined an in vitro flow model of platelet thrombus formation, which can be used to evaluate the ex vivo and/or in vitro efficacy of platelet antagonists. Thrombus formation may be initiated by platelet adhesion from rapidly flowing blood onto exposed subendothelial surfaces of injured vessels containing collagen and vWF, with subsequent platelet activation and aggregation. Konstantopoulos et al. (1995) described the use of a parallel-plate flow chamber that provides a controlled and well-defined flow environment based on the chamber geometry and the flow rate through the chamber. The wall shear stress, τ_w, assuming a Newtonian and incompressible fluid, can be calculated using the formula:

$$\tau_w = \frac{6\mu Q}{wh^2}$$

where Q is the volumetric flow rate, μ is the viscosity of the flowing fluid, h is the channel height, and w is the channel width. A flow chamber typically consists of a transparent polycarbonate block, a gasket whose thickness determines the channel depth, and a glass coverslip coated with an extracellular matrix protein such as type I fibrillar collagen. The apparatus is held together by vacuum. Shear stress is generated by flowing fluid (e.g., anticoagulated whole blood or isolated cell suspensions) through the chamber over the immobilized substrate under controlled kinematic conditions using a syringe pump. Mousa et al. (2002) combined the parallel-plate flow chamber with a computerized epifluorescence videomicroscopy system, enabling us to visualize in real time and separately



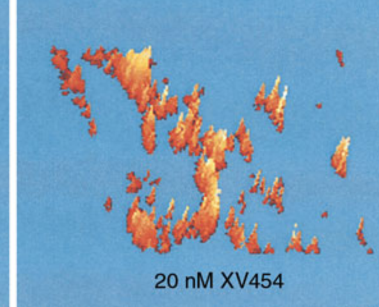


Fig. 11.2 Three-dimensional computer-generated representation of platelet adhesion and subsequent aggregation on collagen I/von Willebrand factor from normal heparinized blood perfused in the absence (control) or presence of a GPIIb/IIIa antagonist (XV454) at 37°C for 1 min at 1,500 s^{-1}

quantify the adhesion and subsequent aggregation of human platelets in anticoagulated whole blood (or isolated platelet suspensions) flowing over an immobilized substrate.

PROCEDURES

Preparation of collagen-coated surfaces (Folie et al. 1988)

1. Dissolve 500 mg collagen type I from bovine Achilles tendon into 200 ml of 0.5 mol/L acetic acid in water, pH 2.8.
2. Homogenize for 3 h.
3. Centrifuge the homogenate at 200 g for 10 min, collect supernatant, and measure collagen concentration by a modified Lowry analysis.
4. Coat glass coverslips with 200 µl of fibrillar collagen I suspension on all but first 10 mm of the slide length (coated area = 12.7×23) and place in a humid environment at 37°C for 45 min.
5. Rinse excess collagen with 10 ml of D-PBS maintained at 37°C before assembly into the flow chamber.

Platelet Perfusion Studies

1. Add the fluorescent dye quinacrine dihydrochloride to anticoagulated whole blood samples at a final concentration of 10 µM immediately after blood collection.
2. Prior to the perfusion experiment, incubate blood with either a platelet antagonist or vehicle (control) at 37°C for 10 min.

Perfuse anticoagulated whole blood through the flow chamber for 1 min at wall shear rates ranging from 100 s^{-1} (typical of venous circulation) to 1,500 s^{-1} (mimicking partially constricted arteries) for prescribed periods of time (e.g., 1 min). Platelet-substrate interactions are monitored in real time using an inverted microscope equipped with an epifluorescent illumination attachment and silicon-intensified target video camera and recorded on videotape. The microscope stage and flow chamber are maintained at 37°C by an incubator heating module and incubator enclosure during the experiment.

3. Videotaped images are digitized and computer analyzed at 5, 15, and 60 s for each perfusion experiment. The number of adherent individual platelets in the microscopic field of view during the initial 15 s of flow is determined by image processing and used as the measurement of platelet adhesion that initiates platelet thrombus formation. The number of platelets in each individual thrombus is calculated as the total thrombus intensity (area×fluorescence intensity) divided by the average intensity of single platelets determined in the 5-s images. By comparing the extents of platelet aggregation in the presence and absence of a platelet antagonist, its antiplatelet efficacy can be determined (Fig. 11.2). Along these lines, any potential inhibitory effects of a platelet antagonist on platelet adhesion can be readily assessed.

11.2.6 Cell Adhesion to Immobilized Platelets: Parallel-Plate Flow Chamber

PURPOSE AND RATIONALE

In this assay, immobilized platelets are pretreated with a GPIIb/IIIa antagonist, and any unbound drug is washed away before the perfusion of monocytic THP-1 cells. Agents with slow platelet off-rates such as XV454 ($t_{1/2}$ of dissociation = 110 min; K_d = 1 nM) and abciximab ($t_{1/2}$ of dissociation = 40 min; K_d = 9.0 nM) that are distributed predominantly as receptor-bound entities with little unbound in the plasma can effectively block these heterotypic interactions as shown by Abulencia et al. (2001) and by Mousa et al. (2002). In contrast, agents with relatively fast platelet dissociation rates such as orbofiban ($t_{1/2}$ of dissociation = 0.2 min; K_d >110 nM), whose antiplatelet efficacy depend on the plasma concentration of the active drug, do not exhibit any inhibitory effects as described by Mousa et al. (2002).

PROCEDURES

Preparation of 3-aminopropyltriethoxysilane Treated Glass Slides

1. Soak glass coverslips overnight in 70% nitric acid.
2. Wash coverslips with tap water for 4 h.
3. Dry coverslips by washing once with acetone followed by immersion in a 4% solution of APES in acetone for 2 min.
4. Repeat step 3 followed by a final rinse of the glass coverslips with acetone.
5. Wash coverslips three times with water and allow them to dry overnight.

Immobilization of Platelets on 3-aminopropyltriethoxy-silane Treated Glass Slides

1. Layer washed platelets or PRP (2×10^8 cells/ml) on the surface of a coverslip at ~30 µl/cm^2.
2. Allow platelets to bind to APES-treated cover slip in a humid environment at 37°C for 30 min.

Monocytic THP-1 Cell-Platelet Adhesion Assay

1. Assemble the platelet-coated cover slip on a parallel-plate flow chamber that is then mounted on the stage of an inverted microscope equipped with a CCD camera connected to a VCR and TV monitor.
2. Perfuse the antiplatelet antagonist at the desirable concentration or vehicle (control) over surface-bound platelets and incubate for 10 min. The extent of platelet activation can be further modulated by the presence of chemical agonists such as thrombin (0.02–2 U/ml) during the 10-min incubation. The microscope stage and flow chamber are maintained at 37°C by an incubator heating module and incubator enclosure during the experiment.
3. In some experiments, unbound platelet antagonist is removed by a brief washing step (4 min) prior to the perfusion of the cells of interest over the platelet layer. In others, the desirable concentration of the platelet antagonist is continuously maintained in the perfusion buffer during the entire course of the experiment.
4. Perfuse cells (e.g., THP-1 monocytic cells, leukocytes, tumor cells, protein-coated beads, etc.) over surface-bound platelets, either in the presence or absence of a platelet antagonist (see above), at the desirable flow rate for prescribed periods of time. THP-1 cell binding to immobilized platelets is monitored in real time and recorded on videotape.
5. Determine the extent of THP-1 cell tethering, rolling, and stationary adhesion to immobilized platelets as well as the average velocity of rolling THP-1 cells. By comparing the corresponding extents of THP-1 cell tethering, rolling, and stationary adhesion to immobilized platelets in the presence and absence of a platelet antagonist (Fig. 11.3), its antiplatelet efficacy can be determined.

EVALUATIONS

1. Low-speed centrifugation results in the separation of platelets (top layer) from larger and denser cells such as leukocytes and erythrocytes (bottom layer). To minimize leukocyte contamination in PRP specimens, slowly aspirate the uppermost 2/3 of the platelet layer. Furthermore, certain rare platelet disorders, such as Bernard-Soulier Syndrome (BSS), are characterized by larger than normal platelets that must therefore be isolated by allowing whole blood to gravity separate for 2-h post venipuncture.
2. The mechanical force most relevant to platelet-mediated thrombosis is shear stress. The normal time-averaged levels of venous and arterial shear stresses range between 1–5 and 6–40 dyn/cm^2, respectively. However, fluid shear stress may reach levels well over 200 dyn/cm^2 in small arteries and arterioles partially obstructed by atherosclerosis or vascular spasm. The cone-and-plate viscometer and

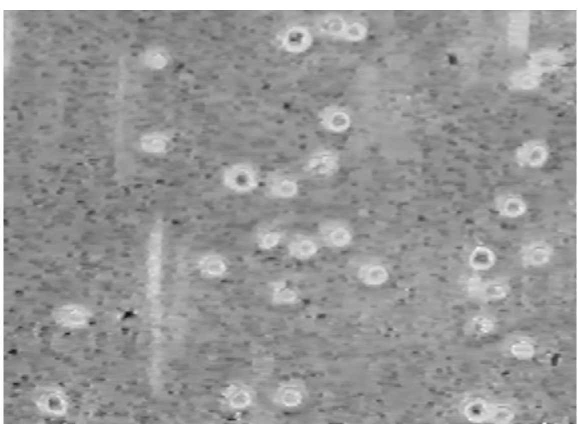

Fig. 11.3 Phase-contrast photomicrograph of THP-1 cells (phase bright objects) attached to a layer of thrombin-treated platelets (phase dark objects) after THP-1 cell perfusion for 3 min at a shear stress level of 1.5 dyn/cm^2

parallel-plate flow chamber are two of the most common devices used to simulate fluid mechanical shearing stress conditions in blood vessels.

3. Due to the large concentration of platelets and erythrocytes in whole blood, small aliquots (∼3 μl) of presheared and postsheared specimens must be obtained and processed prior to the flow cytometric analysis. This will minimize an artifact produced as a platelet and an erythrocyte pass through the light beam of a flow cytometer at the same time.
4. The "rbcs-plts" population represents 3–5% of the displayed cells. A small fraction (∼5%) of this population seems to be leukocyte-platelet aggregates as evidenced by the use of an anti-CD45 monoclonal antibody. The remaining events correspond to erythrocytes associated with platelets. However, it appears that the majority of the latter population is an artifact generated by the simultaneous passage of a platelet and an erythrocyte through the beam of a flow cytometer. This concept is corroborated by the fact that further dilution of presheared and sheared blood specimens and/or reduction of the sample flow rate during the flow cytometric analysis results in a dramatic relative decrease of the "rbcs-plts" population.
5. The collagen density remaining on glass coverslips after D-PBS rinsing can be measured by the difference in weight of 20 clean uncoated slides versus 20 collagen-treated slides.
6. Experiments are optimally monitored ∼100–200 μm downstream from the collagen/glass interface using a 60×FLUOR objective and 1× projection lens, which gives a 3.2×10^4 μm^2 field of view. A field of view closer to the interface may lead to nonreproducible results due to variations in the collagen layering in that region. In contrast, positions farther downstream are avoided in order to minimize the effects of upstream platelet adhesion and subsequent aggregation on both the fluid dynamic environment as well as bulk platelet concentration.
7. The digitization of a background image (at the onset of perfusion prior to platelet adhesion to the collagen I surface) and its subtraction from a subsequent image acquired 5 s after an initial platelet adhesion event allows the determination of the fluorescence intensity emitted by a single platelet. The intensity level of each single platelet is measured as a mean gray level between 0 (black) and 255 (white) through the use of an image processing software (e.g., OPTIMAS; Agris-Schoen Vision Systems, Alexandria, VA) and is multiplied by its corresponding area (total number of pixels covered by each single platelet). The aforementioned products are then averaged for all single platelet events detected at the 5-s time point, thus enabling us to calculate the average intensity of single platelets.
8. A single field of view (10 × 0.55 mm^2) is monitored during the 3-min period of the experiment, and at the end, five additional fields of view (0.55 mm^2) are monitored for 15 s each. The following parameters can be quantified: (a) the number of total interacting cells per mm^2 during the entire 3-min perfusion experiment, (b) the number of stationary interacting cells per mm^2 after 3 min of shear flow, (c) the percentage of total interacting cells that are stationary after 3 min of shear flow, and (d) the average rolling velocity (μm/s) of interacting cells. The number of interacting cells per mm^2 is determined manually by reviewing the videotapes. Stationary interacting cells per mm^2 are considered as those that move <1-cell radius within 10 s at the end of the 3-min attachment assay. To quantify their number, images can be digitized from a videotape recorder using an imaging software package

(e.g., OPTIMAS). Rolling velocities can be computed as the distance traveled by the centroid of the rolling THP-1 cell divided by the time interval using image processing.

11.3 In Vivo or Ex Vivo Models

PURPOSE AND RATIONALE

The general understanding of the pathophysiology of thrombosis is based on the observations of Virchow in 1856. He proposed three factors responsible for thrombogenesis: obstruction of blood flow, changes in the properties of blood constituents (hypercoagulability), and vessel wall injury. Experimental models of thrombosis focus on one, two, or all three factors of the Virchow triad. Therefore, they differ with respect to the prothrombotic challenge—either stenosis, stasis, vessel wall injury (mechanical, electrical, chemical, photochemical, laser light), insertion of foreign surface, or injection of a prothrombotic factor—with respect to the vessel type and with respect to the animal species.

Roughly, two types of models can be differentiated (Didisheim 1972): (1) models in which thrombi are produced in veins by stasis and/or injection of a procoagulant factor resulting in fibrin-rich "red" venous type thrombi and (2) models in which thrombi are produced in arteries by vessel wall injury and/or stenosis resulting in platelet rich "white" mural thrombi. But the differentiation is not strict because platelets and coagulation system influence each other. Drugs preventing fibrin formation may well act in arterial models and vice versa. Thrombosis models are usually performed in healthy animals. The underlying chronic diseases in humans namely, atherosclerosis or thrombophilias are not included in the models. Thus, any model is limited regarding its clinical relevance. The pharmacological effectiveness of a new antithrombotic drug should be studied in more than one animal model. Despite these limitations, animal models predict clinical effectiveness of drugs for the treatment and prevention of thrombotic diseases fairly well. A list of such drugs is presented in a recent review by Leadley et al. (2000). Furthermore, the clinical usefulness of an antithrombotic drug is determined by its safety/efficacy ratio regarding the bleeding risk. Assessment of a parameter of the hemostatic system should therefore be included in the models if possible.

The development of antithrombotic agents requires preclinical assessment of the biochemical and pharmacologic effects of these drugs. It is important to note that the second- and third-generation antithrombotic drugs are devoid of in vitro anticoagulant effects, yet in vivo, by virtue of endogenous interactions, these drugs produce potent antithrombotic actions. The initial belief that an antithrombotic drug must exhibit in vitro anticoagulant activity is no longer valid. This important scientific observation has been possible only because of the availability of animal models.

Several animal models utilizing species such as rats, rabbits, dogs, pigs, and monkeys have been made available for routine use. Other animal species such as the hamster, mouse, cat, and guinea pig have also been utilized. Species variations are an important consideration in selecting a model and interpreting the results as these variations can result in different antithrombotic effects. Rats and rabbits are the most commonly used species in which both arterial and venous thrombosis have been investigated. Both pharmacologic and mechanical means have been used to produce a thrombogenic effect in these models. Both rat and rabbit models for studying bleeding effects of drugs have also been developed. The rabbit ear blood loss model is most commonly used to test the hemorrhagic effect of drugs. The rat tail bleeding models have also been utilized for the study of several antithrombotic drugs.

These animal models have been well established and can be used for the development of antithrombotic drugs. It is also possible to use the standardized bleeding and thrombosis models to predict the safety and efficacy of drugs. Thus, in addition to the evaluation of in vitro potency, the endogenous effect of antithrombotic drugs can also be investigated. Such standardized methods can be recommended for inclusion in pharmacopoeial screening procedures. Numerous models have now been developed to mimic a variety of clinical conditions where antiplatelet and antithrombotic drugs are used including myocardial infarction, stroke, cardiopulmonary bypass, trauma, peripheral vascular diseases, and restenosis. While dog and primate models are relatively expensive, they have also provided useful information on the pharmacokinetics and pharmacodynamics of antithrombotic drugs. The primate models in particular have been extremely useful, as the hemostatic pathways in these species are comparable to those in humans. The development of such agents as the specific glycoprotein IIb/IIIa inhibitor antibodies relies largely on these models. These models are, however, of pivotal value in the development of antithrombotic drugs and provide extremely useful data on the safety and efficacy of new drugs developed for human usage.

PROCEDURES

11.3.1 Animal Models of Thrombosis

In most animal models of thrombosis, healthy animals are challenged with thrombogenic (pathophysiological) stimuli and/or physical stimuli to produce thrombotic or occlusive conditions. These models are useful for the screening of antithrombotic drugs.

1. *Stasis-Thrombosis Model*. Since its introduction by Wessler et al. (1959), the rabbit model of jugular stasis thrombosis has been extensively used for the pharmacologic screening of antithrombotic agents. This model has also been adapted for use in rats (Meuleman et al. 1991). In the *stasis thrombosis model*, a hypercoagulable state is mimicked by administration of one of a number of thrombogenic challenges including human serum (Carrie et al. 1994), thromboplastin (Walenga et al. 1986), activated prothrombin complex concentrates (Vlasuk et al. 1991), factor Xa (Millet et al. 1994), and recombinant relipidated tissue factor (Callas et al. 1995). This administration serves to produce a hypercoagulable state. Diminution of blood flow achieved by ligating the ends of the vessel segments serves to augment the prothrombotic environment. The thrombogenic environment produced in this model simulates venous thrombosis where both blood flow and the activation of coagulation play a role in the development of a thrombus.
2. *Models Based On Vessel Wall Damage*. The formation of a thrombus is not solely induced by a plasmatic hypercoagulable state. In the normal vasculature, the intact endothelium provides a nonthrombogenic surface over which the blood flows. Disruption of the endothelium not only limits the beneficial effects enumerated above but also exposes subendothelial tissue factor and collagen that serve to activate the coagulation and platelet aggregation processes, respectively. Endothelial damage can be induced experimentally by physical means (clamping, catheter), chemical means (FITC, Rose Bengal, ferrous chloride), thermal injury, or electrolytic injury.

EVALUATIONS

Each setting in the design of an animal model can answer specific question in relation to certain thrombotic disorders in human. However, the ultimate model of human thrombosis is in human.

11.3.2 Stenosis- and Mechanical-Injury-Induced Coronary Thrombosis (Folts Model)

PURPOSE AND RATIONALE

Thrombosis in stenosed human coronary arteries is one of the most common thrombotic diseases leading to unstable angina, acute myocardial infarction, or sudden death. Treatment with angioplasty, thrombolysis, or bypass grafts can expose new thrombogenic surfaces, and rethrombosis may occur. The mechanisms responsible for this process include interactions of platelets with the damaged arterial wall and platelet aggregation.

In order to study new drugs for their antithrombotic potential in coronary arteries, Folts and Rowe (1974) developed the model of periodic acute platelet thrombosis and cyclic flow reductions (CFRs) in stenosed canine coronary arteries. Uchida described a similar model in 1975. The model includes various aspects of unstable angina pectoris, i.e., critical stenosis, vascular damage, and downstream vasospasm induced by vasoconstrictors released or generated by platelets. The cyclic variations in coronary blood flow are a result of acute platelet thrombi that may occlude the vessel but that either embolize spontaneously or can easily be embolized by shaking the constricting plastic cylinder. They are not a result of vasospasm (Folts et al. 1982). Clinically, aspirin can reduce the morbidity and mortality of coronary thrombotic diseases, but its effect is limited. Similarly, CFRs in the Folts model are abolished by aspirin, but the effect can be reversed by increases in catecholamines and shear forces (Folts and Rowe 1988). As part of an expert meeting on animal models of thrombosis, a review of the Folts model has been published (Folts 1991).

Five different protocols are described in the following section for the induction of coronary thrombosis.

11.3.2.1 Coronary Thrombosis Induced by Stenosis

The described preparations are characterized by episodic, spontaneous decreases in coronary blood flow interrupted by restorations of blood flow. These alterations in coronary blood flow, called cyclic flow reductions (CFR), are associated with transient platelet aggregation at the site of the coronary constriction and abrupt increase in blood flow after embolization of platelet-rich thrombi.

Damage of the vessel wall is produced by placing a hemostatic clamp on the coronary artery; a fixed amount of stenosis is produced by an externally applied obstructive plastic cylinder upon the damaged part of the vessel. In dogs, the stenosis is critical, i.e., the reactive hyperemic response to a 10-s occlusion is abolished (protocol 1); in pigs, the stenosis is subcritical, i.e., there is a partial reactive hyperemia left (Just et al. 1991; protocol 2).

For some animals, especially for young dogs, damage of the vessel wall and stenosis are not sufficient to induce thrombotic cyclic flow variations. In these cases, an additional activation of platelets by infusion of epinephrine (protocol 3) is required leading to the formation of measurable thrombi. In another preparation (protocol 4), thrombus formation is induced by subcritical stenosis without prior clamping of the artery and infusion of platelet activating factor (PAF) according to the model described by Apprill et al. (1985). In addition to these protocols, coronary spasms induced by released platelet components can influence coronary blood flow. Therefore, this model includes the main pathological factors of unstable angina pectoris.

11.3.2.2 Coronary Thrombosis Induced by Electrical Stimulation

In this preparation, coronary thrombosis is induced by delivery of low amperage electrical current to the intimal surface of the artery according to the method described by Romson et al. (1980a). In contrast to the stenosis protocols, an occluding thrombosis is formed gradually without embolism after some hours (protocol 5). As a consequence of this time course, the thrombi formed are of the mixed type and contain more fibrin than the platelet thrombi with critical stenosis.

PROCEDURE

11.3.2.3 Coronary Thrombosis Induced by Stenosis

Protocol 1: Critical Stenosis

Dogs of either sex weighing 15–40 kg, at least 8 months of age, are anesthetized with pentobarbital sodium (bolus of 30–40 mg/kg and continuous infusion of approximately 0.1 mg/kg/min); respiration is maintained through a tracheal tube using a positive pressure respirator. The heart is exposed through a left thoracotomy at the fourth or fifth intercostal space, the pericard is opened and the left circumflex coronary artery (LCX) is exposed. An electromagnetic or Doppler flow probe is placed on the proximal part of the LCX to measure coronary blood flow. Distal to the flow probe, the vessel is squeezed with a 2-mm hemostatic clamp for 5 s. A small cylindrical plastic constrictor, 2–4 mm in length and with an internal diameter of 1.2–1.8 mm (depending on the size of the LCX), is then placed around the artery at the site of the damage. Usually, the constrictor has to be changed several times (2–5 times) until the appropriate narrowing of the vessel is achieved, and cyclic flow variations are observed. In case of an occlusion of the artery without spontaneous embolization of the formed thrombus, reflow is induced by shortly lifting the vessel with a thread placed beneath the stenotic site. Only dogs with regularly repeated cyclic flow reductions (CFRs) of similar intensity within a pretreatment phase of 60 min are used in these experiments. The test substance is then administered by intravenous bolus injection or continuous infusion, or by intraduodenal application. CFRs are registered for 2–4×60 min and compared to pretreatment values. Prior to testing, preparations for additional hemodynamic measurements are performed (see below).

Protocol 2: Subcritical Stenosis

Male castrated pigs (German landrace, weighing (20–40 kg)) are anesthetized with ketamine (2 mg/kg i.m.), metomidate (10 mg/kg i.p.), and xylazine (1–2 mg/kg i.m.). In order to maintain the stage of surgical anesthesia, animals receive a continuous i.v. infusion of 0.1–0.2 mg/kg/min pentobarbital sodium. Respiration is maintained through a tracheal tube using a positive pressure respirator. The heart is exposed through a left thoracotomy at the fourth and fifth intercostal space, the pericard is opened and the left descending coronary artery (LAD) is exposed. An electromagnetic or Doppler flow probe is placed on the proximal part of the LAD to measure coronary blood flow. Distal to the flow probe, the vessel is squeezed with a 1-mm hemostatic clamp for 5 s. A small cylindrical plastic constrictor, 2 mm in length, is then placed around the artery at the site of the damage. Usually, the constrictor has to be changed several times until the appropriate narrowing of the vessel is achieved, which produces cyclic flow reductions. CFRs are similar to those in dogs; pigs, however, show a reactive hyperemic response. If embolization does not occur spontaneously, the formed thrombus is released at reduction of blood flow by shortly lifting the vessel with forceps. Only pigs with regularly repeated CFRs of similar intensity within a pretreatment phase of 60 min are used in these experiments.

The test substance is then administered by intravenous bolus injection or continuous infusion, or by intraduodenal application. CFRs are registered for 2×60 min and compared to pretreatment values.

Protocol 3: Stenosis+Epinephrine Infusion

If protocol 1 does not lead to CFRs, additionally epinephrine (0.2 μg/kg/min) is infused into a peripheral vein for 2×60 min (60 min before and 60 min following drug administration). CFRs are registered and compared in the 60-min postdrug phase to the 60-min predrug phase.

Protocol 4: Stenosis+PAF Infusion

The LCX is stenosed without prior mechanical wall injury. This preparation does not lead to thrombus

formation (subcritical stenosis). For the induction of CFRs, in addition, PAF (C 16-PAF, Bachem) (0.2 nmol/kg/min) is infused into one cannulated lateral branch of the coronary artery.

After 30 min, PAF infusion is terminated and blood flow returns to its normal, continuous course. Thirty minutes later, concomitantly, the test substance is administered and a second PAF infusion is started for 30 min.

CFRs are registered and compared in the drug treated, second PAF phase, to the pre-drug, first PAF phase.

11.3.2.4 Coronary Thrombosis Induced by Electrical Stimulation

Protocol 5

The LCX is punctuated distal to the flow probe with a chrome-vanadium-steel electrode (3-mm length, 1-mm diameter). The electrode (anode) is placed in the vessel in contact with the intimal lining and connected over a Teflon-coated wire to a 9-V battery, a potentiometer, and an amperemeter. A disc electrode (cathode) is secured to a subcutaneous thoracic muscle layer to complete the electrical circuit. The intima is stimulated with 150 μA for 6 h. During this time, gradually, an occluding thrombosis is formed.

The test substance or the vehicle (control) is administered either at the start of the electrical stimulation or 30 min following the start.

The time interval until the thrombotic occlusion of the vessel occurs and the thrombus size (wet weight measured immediately after removal at the end of the experiment) is determined.

Prior to testing, preparations for additional hemodynamic measurements are performed (see below).

For all protocols, the following preparations and measurements are performed:

- To measure peripheral arterial blood pressure (BP) [mm Hg], the right femoral artery is cannulated and connected to a Statham pressure transducer.
- Left ventricular pressure (LVP) (mm Hg) is determined by inserting a microtip catheter via the carotid artery retrogradely.
- Left ventricular end diastolic pressure (LVEDP) (mm Hg) is evaluated through sensitive amplification of the LVP.
- Contractility (LV *dp*/*dt* max) (mm Hg/s) is determined from the initial slope of the LVP curve.
- Heart rate (min^{-1}) is determined from the pulsatile blood pressure curve.
- The ECG is recorded in lead II.
- Arterial pH and concentrations of blood gases are kept at physiological levels by adjusting respiration and infusion of sodium bicarbonate.
- Blood hematocrit values (37–40%) and number of erythrocytes are kept constant by infusion of oxypolygelatine in dogs and electrolyte solution in pigs.
- Body temperature is monitored with a rectal thermistor probe and kept constant by placing the animals on a heated metal pad with automatic regulation of temperature.
- Template buckle mucosal bleeding time is carried out using the Simplate® device.

At the end of the test, animals are sacrificed by an overdose of pentobarbital sodium (Fig. 11.4).

EVALUATION

For all protocols, the mean maximal reduction of blood pressure (systolic/diastolic) [mm Hg] is determined.

Protocol 1–4

The following parameters are determined to quantify stenosis-induced coronary thrombosis:

- Frequency of cyclic flow reductions = cycle number per time
- Magnitude of cyclic flow reductions = cycle area (mm^2) (total area of all CVRs per time measured by planimetry)

Percent change in cycle number and cycle area after drug treatment is calculated compared to pretreatment controls.

Statistical significance is assessed by the paired Student's *t*-test.

Protocol 5

The following parameters are determined to quantify electrically induced coronary thrombosis:

- Occlusion time (min) = time to zero blood flow
- Thrombus size (mg) = wet weight of the thrombus immediately after removal, percent change in mean values for occlusion time, and thrombus size in drug-treated groups are compared to the control group.

Statistical significance is assessed by the nonpaired Student's *t*-test.

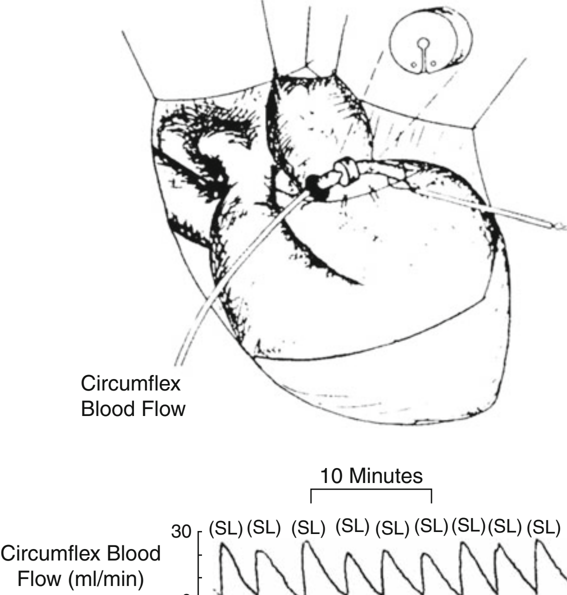

Fig. 11.4 Technique for monitoring platelet aggregation in the partially obstructed left circumflex coronary artery of the dog. Electromagnetic flow probes measure blood flow. Partial obstruction of the coronary artery with a plastic Lexan cylinder results in episodic cyclical reductions in coronary blood flow that are due to platelet-dependent thrombus formation. Every 2–3 mm, the thrombus must he mechanically shaken loose to restore blood. For detailed application of the Folts model, see Folts (1991); Folts and Rowe (1974, 1988); and Folts et al. (1976, 1982)

Standard data

Standard	Dose	% Decrease in CFVs		Protocol	Species
		Number	Area		
Acetylsalicylic acid	1 mg/kg, i.v.	56	80	1	dog
	20 mg/kg, i.d.	87	95	1	dog
	30 mg/kg, i.v.	56	77	2	pig

CRITICAL ASSESSMENT

Both, the stenosis (Folts) and the electrical (Romson/Lucchesi) models of coronary thrombosis are widely used to study the role of mediators in the thrombotic process and the effect of new antithrombotic drugs. Bush and Patrick (1986) reviewed the role of the endothelium in arterial thrombosis and the effect of some inhibitors and mediators in the Folts model, e.g., thromboxane, prostacyclin, cyclooxigenase, serotonin, NO donors, and other vasodilators. The effect of an NO donor could be reversed by the NO scavenger oxyhemoglobin indication that indeed NO was responsible for the antithrombotic action (Just and Schönafinger 1991). Recent mechanisms of antithrombotic drug action that have been studied in either of the two coronary thrombosis models are the oral GPIIb/IIIa antagonist DMP 728 (Mousa et al. 1996), the LMWH enoxaparin (Leadley et al. 1998) that inhibited CFRs in contrast to unfractionated heparin, the thrombin-inhibitors PEG-hirudin (Ruebsamen and Kirchengast 1998) and melagatran (Mehta et al. 1998), an anti-P-selectin antibody (Ikeda et al. 1999), and an activated protein C (Jackson et al. 2000).

The clinical relevance of studies in the Folts model has been questioned because the model is very sensitive to antithrombotic compounds. However, the lack of a reversal of the effect by epinephrine or increase in degree of stenosis differentiates any new drug from aspirin. Electrical coronary thrombosis is less sensitive, e.g., aspirin has no effect, and with some drugs higher dose levels are required; but in principle, most drug mechanisms act in both models if at all.

MODIFICATIONS OF THE METHOD

Romson et al. (1980b) described a simple technique for the induction of coronary artery thrombosis in the conscious dog by delivery of low amperage electric current to the intimal surface of the artery.

Benedict et al. (1986) modified the electrical induction of thrombosis by use of two Doppler flow probes proximal and distal to the needle electrode in order to measure changes in blood flow velocity. The electrical current was stopped at 50% increase in flow velocity, and thrombosis then occurred spontaneously. The important role of serotonin was demonstrated by increases in coronary sinus serotonin levels just prior to occlusion. Warltier et al. (1987) described a canine model of thrombin-induced coronary artery thrombosis and the effects of intracoronary streptokinase on regional myocardial blood flow, contractile function, and infarct size. Al-Wathiqui et al. (1988) described the induction of cyclic flow reduction in the coronary, carotid, and femoral arteries of conscious chronically instrumented dogs.

The method of Folts thrombosis has also been applied to carotid arteries in monkeys. Coller et al. (1989) induced CFRs in carotid arteries of anesthetized cynomologus monkeys and showed abolition by the GPIIb/IIIa antibody abciximab.

11.3.3 Stenosis- and Mechanical-Injury-Induced Arterial and Venous Thrombosis: Harbauer Model

PURPOSE AND RATIONALE

Harbauer (1984) first described a venous model of thrombosis induced by mechanical injury and stenosis of the jugular vein. In a modification, both arterial and venous thrombosis is produced in rabbits by stenosis of the carotid artery and the jugular vein with

simultaneous mechanical damage of the endothelium. This activates platelets and the coagulation system and leads to changes in the bloodstream pattern. As a consequence, occluding thrombi are formed as detected by blood flow measurement. The dominant role of platelets in this model is shown by the inhibitory effect of an antiplatelet serum in both types of vessels (Just 1986). The test is used to evaluate the antithrombotic capacity of compounds in an in vivo model of arterial and venous thrombosis where thrombus formation is highly dependent on platelet activation.

PROCEDURE

Male Chinchilla rabbits weighing 3–4 kg receive the test compound or the vehicle (controls) by oral, intravenous, or intraperitoneal administration. The first ligature (vein, preparation see below) is performed at the end of absorption (i.p. approximately 30 min, p.o. approximately 60 min, i.v. variable).

Sixty-five minutes before stenosis, the animals are sedated by intramuscular injection of 8 mg/kg xylazine (Rompun®) and anesthetized by intravenous injection of 30–40 mg/kg pentobarbital sodium 5 min later. During the course of the test, anesthesia is maintained by continuous infusion of pentobarbital sodium (30–40 mg/kg/h) into one femoral vein.

A Statham pressure transducer is placed into the right femoral artery for continuous measurement of blood pressure. Spontaneous respiration is maintained through a tracheal tube. One jugular vein and one carotid artery are exposed on opposite sides. Small branches of the vein are clamped to avoid blood flow in spite of vessel occlusion.

Electromagnetic or Doppler flow probes are placed on the vein (directly central to the vein branching) and on the artery (as far central as possible). Blood flow (ml/min) is measured continuously.

After reaching steady state (approximately 15–30 min), a metal rod with a diameter of 1.3 mm is placed on the jugular vein (2 cm central to the vein branching), and a ligature is tightened. After 1 min, the rod is removed from the ligature. Immediately thereafter (approximately 1.5 min), the carotid artery is damaged by briefly squeezing it with forceps. Then, a small plastic constricting cylinder with 1.2-mm diameter and 2-mm length is placed around the site of the endothelial damage. Registration of parameters is terminated after 30 min. In addition, the template bleeding time is measured at various time intervals before and after drug treatment (depending on the route of administration) in the shaved inner ear using the Simplate® device. Care is taken to select parts of the skin without larger vessels.

EVALUATION

Percent thrombus formation (= thrombosis incidence) is judged by determination of the number of occluded vessels (blood flow = 0).

Percent inhibition of thrombosis incidence is calculated in dosed groups as compared to vehicle controls.

Thrombosis incidence is always 100% in vehicle controls.

Statistical significance is assessed by means of the Fisher exact test.

If initial values for blood flow do not significantly differ in dosage and control groups, the area below the blood flow curves is measured by planimetry in addition, and mean values in dosed groups are compared to controls by means of the unpaired Student's *t*-test.

Mean values of occlusion times [min] in dosage and control groups are calculated and compared by means of the *t*-test.

The maximal change in systolic and diastolic blood pressure during the time period of stenosis as compared to the initial values before drug administration is determined. There is no standardized assessment score. As an example, a reduction of systolic blood pressure by 30 mm Hg and of diastolic blood pressure by 20 mm Hg is quoted as a strong reduction in blood pressure.

CRITICAL ASSESSMENT OF THE METHOD

Two main factors of arterial thrombosis in men are essential in this model: high-grade stenosis and vessel wall damage. In the absence of either, no thrombus is found. The occlusive thrombus is formed fast and in a highly reproducible manner. In both vessels, thrombus formation is equally dependent on platelet function as shown by antiplatelet serum. Therefore, the jugular vein thrombosis in this model differs from stasis-induced deep vein thrombosis with predominant fibrin formation. On the other hand, these occlusive thrombi are more stable than the pure platelet thrombi in the Folts model (see 11.4.2) since carotid blood flow cannot be restored by shaking the constrictor. The following antithrombotic drugs are effective: (1) antiplatelet drugs like ticlopidine, prostacyclin/iloprost, NO donors (SNP, molsidomine) but not aspirin, and thromboxane

synthase inhibitors; (2) anticoagulants like hirudin, high-dose heparin, and warfarin; and (3) streptokinase/t-PA (Bevilacqua et al. 1991; Just 1986 and unpublished). In contrast, drugs that only lower blood pressure such as hydralazine, clonidine, and prazosin have no effect on thrombus formation in this model.

MODIFICATIONS OF THE METHOD

Bevilacqua et al. (1991) performed the same model in rabbit carotid arteries but compared the procedure in one artery before drug treatment with the contralateral artery after drug treatment. Heparin, the synthetic thrombin inhibitor FPRCH2Cl; iloprost; and t-PA inhibited carotid occlusion in this model but not aspirin.

Spokas and Wun (1992) produced venous thrombosis in the vena cava of rabbits by vascular damage and stasis. The vascular wall was damaged by crushing with hemostat clamps. A segment of the vena cava was looped with two ligatures, 2.5 cm apart. At 2 h after ligation, the isolated venous sac was dissected, and the clot was removed for determination of dry weight.

Lyle et al. (1995) searched for an animal model mimicking the thrombotic reocclusion and restenosis occurring in several cases after successful coronary angioplasty in man. The authors developed a model of angioplasty-induced injury in atherosclerotic rabbit femoral arteries. Acute ^{111}indium-labeled platelet deposition and thrombosis were assessed 4 h after balloon injury in arteries subjected to prior endothelial damage (air desiccation) and cholesterol supplementation (1 month). The effects of inhibitors of factor X_a or platelet adhesion, heparin, and aspirin on platelet deposition were studied.

11.3.3.1 Thrombosis Induced by Supercooling

Meng (1975), Meng and Seuter (1977), and Seuter et al. (1979) described a method to induce arterial thrombosis in rats by chilling of the carotid artery. Rats were anesthetized and the left carotid artery was exposed and occluded proximal by means of a small clamp. The artery was placed for 2 min into a metal groove that was cooled to −15°C. The vessel was compressed by a weight of 200 g. In addition, a silver clip was fixed to the vessel distally from the injured area to produce a disturbed and slow blood flow. After 4 min, the proximal clamp was removed, and the blood flow reestablished in the injured artery. In the rabbit, slightly different conditions were used: the chilling temperature was −12°C for a period of 5 min, and the compressing weight was 500 g. The wound was closed, and the animal was allowed to recover from anesthesia. Antithrombotic compounds were administered in various doses at different time intervals before surgery. After 4 h, the animals received heparin and were reanesthetized. The lesioned carotid artery was removed and thrombus wet weight was immediately measured.

11.3.4 Electrical-Induced Thrombosis

PURPOSE AND RATIONALE

The use of electrical current to induce thrombosis in hamster and dog has been described in the early 1950s by Lutz et al. (1951) and Sawyer and Pate (1953a, b).

In general, two different approaches exist. One method produces electrical damage by means of two externally applied hook-like electrodes (Hladovec 1973; Philp et al. 1978). The other method uses a needle electrode which is advanced through the walls of the blood vessels and positioned in their lumen, the second electrode is placed into a subcutaneous site completing the circuit (Salazar 1961; Romson et al. 1980b; Benedict et al. 1986).

PROCEDURE

Anesthetized rats weighing 200–300 g are intubated, and a femoral artery is cannulated for administration of drugs. One carotid artery is isolated from surrounding tissues over a distance of 10–15 mm. A pair of rigid stainless-steel wire hook-like electrodes with a distance of 4 mm are adjusted to the artery by means of a rack and pinion gear manipulator. The artery is raised slightly away from the surrounding tissue. Isolation of the electrodes is achieved by the insertion of a small piece of parafilm under the artery. Blood flow is measured with an ultrasonic Doppler flow meter (Transonic, Ithaca NY, USA); the flow probe (1RB) is placed proximal to the damaged area.

Thrombus formation is induced in the carotid arteries by the application of an electrical current (350 V, DC, 2 mA) delivered by an electrical stimulator (Stoelting Co, Chicago, Cat. No 58040) for 5 min to the exterior surface of the artery.

EVALUATION

- Blood flow before and after induction of thrombus for 60 min
- Time to occlusion (min): the time between onset of the electrical current and the time at which blood flow decreases under 0.3 ml/min
- Patency of the blood vessel over 30 min

CRITICAL ASSESSMENT OF THE METHOD

The electrical-induced thrombus is composed of densely packed platelets with some red cells. Moreover, the electrical injury causes extensive damage to intimal and subintimal layers. The endothelium is completely destroyed, and this damage extends to subendothelial structures including smooth muscle cells. The deep damage could reduce the possibility of discrimination between drugs on the basis of their antithrombotic activity. However, Philp et al. (1978) could show that unfractionated heparin completely blocked thrombus formation, whereas other antiplatelet agents displayed differentiated antithrombotic action. He concluded that this relatively simple model of arterial thrombosis might prove a useful screening test for drugs with antithrombotic potential.

MODIFICATIONS OF THE METHOD

The technique described by Salazar (1961) uses a stainless steel electrode that is inserted into a coronary artery in the dog and that delivers anodal current to the intravascular lumen. The electrode is positioned under fluoroscopic control, which complicates the method. The technique was modified by Romson et al. (1980b). They placed the electrode directly into the coronary artery of open-chest anesthetized dogs (Fig. 11.5).

Rote et al. (1993, 1994) used a carotid thrombosis model in dogs. A calibrated electromagnetic flow meter was placed on each common carotid artery proximal to both the point of insertion of an intravascular electrode and a mechanical constrictor. The external constrictor was adjusted with a screw until the pulsatile flow pattern decreased by 25% without altering the mean blood flow. Electrolytic injury to the intimal surface was accomplished with the use of an intravascular electrode composed of a Teflon-insulated silver-coated copper wire connected to the positive pole of a 9-V nickel-cadmium battery in series with a 250,000-Ω variable resistor. The cathode was connected to a subcutaneous site. Injury was initiated in the right carotid artery by application of a 150-μA continuous pulse anodal direct current to the intimal surface of the vessel for a maximum duration of 3 h or for 30 min beyond the time of complete vessel occlusion as determined by the blood flow recording. Upon completion of the study on the right carotid, the procedure for induction of vessel wall injury was repeated on the left carotid artery after administration of the test drug.

Benedict et al. (1986) introduced a procedure in which anodal current is discontinued when mean distal coronary flow velocity increased by approximately 50%, reflecting disruption of normal flow by the growing thrombus. Occlusive thrombosis occurred within 1 h after stopping the electrical current. It was observed that the final phase of thrombosis occurred independently of electrical injury.

A ferret model of acute arterial thrombosis was developed by Schumacher et al. (1996b). A 10-min

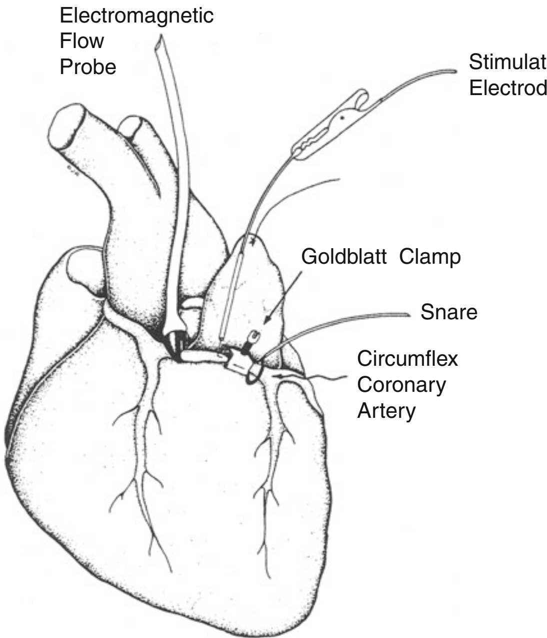

Fig. 11.5 Model of coronary artery thrombosis in the dog. Electrical injury to the intimal surface of the artery leads to occlusive thrombosis formation. The thrombosis is formed in the presence of a flow-limiting stenosis induced by a Goldblatt clamp. Upon spontaneous occlusion, heparin is administered, and the clot is aged for 1 h before initiating the t-PA infusion

anodal electrical stimulation of 1 mA was delivered to the external surface of the carotid artery while measuring carotid blood flow. This produced an occlusive thrombus in all vehicle treated ferrets within 41 ± 3 min with an average weight of 8 ± 1 mg. Thrombus weight was reduced by aspirin or a thromboxan receptor antagonist.

Guarini (1996) produced a completely occlusive thrombus in the common carotid artery of rats by applying an electrical current to the arterial wall (2 mA for 5 min) while simultaneously constricting the artery with a hemostatic clamp placed immediately downstream from the electrodes.

11.3.5 $FeCl_3$-Induced Thrombosis

PURPOSE AND RATIONALE

A variety of chemical agents has been used to induce thrombosis in animals. Topical $FeCl_3$ was described by Reimann-Hunziger (1944) as thrombogenic stimulus in veins. Kurz et al. (1990) showed that the thrombus produced with this method in the carotid arteries of rats is composed of platelets and red blood cells enmeshed in a fibrin network. This model is used as a simple and reproducible test for evaluation of antithrombotic (Broersma et al. 1991) and profibrinolytic test compounds (van Giezen et al. 1997).

PROCEDURE

Rats weighing between 250 and 300 g are anesthetized with Inactin (100 mg/kg), and a polyethylene catheter (PE-205) is inserted into the trachea via a tracheotomy to facilitate breathing. Catheters are also placed in the femoral artery for blood samples and measurement of arterial blood pressure and in the jugular vein for

administration of test agents. The right carotid artery is isolated, and an ultrasonic Doppler flow probe (probe 1RB, Transonic, Ithaca NY, USA) is placed on the vessel to measure blood flow. A small piece of Parafilm "M" (American Can Co., Greenwich, CT) is placed under the vessel to isolate it from surrounding tissues throughout the experiment.

The test agent is administered by gavage or as an intravenous injection at a defined time prior to initiation of thrombus formation. Thrombus formation is induced by the application of filter paper (2×5 mm), saturated with 25% $FeCl_3$ solution, to the carotid artery. The paper is allowed to remain on the vessel 10 min before removal. The experiment is continued for 60 min after the induction of thrombosis. At that time, the thrombus is removed and weighed.

EVALUATION

- Blood flow before and after induction of thrombus for 60 min
- Time to occlusion (min): the time between $FeCl_3$ application and the time at which blood flow decreases under 0.3 ml/min
- Thrombus weight after blotting the thrombus on filter paper

11.4 Thrombin-Induced Clot Formation in Canine Coronary Artery

PURPOSE AND RATIONALE

A canine model of thrombin-induced clot formation was developed by Gold et al. (1984) in which localized coronary thrombosis was produced in the LAD. This is a variation of the technique described by Collen et al. (1983) who used radioactively labeled fibrinogen to monitor the occurrence and extent of thrombolysis of rabbit jugular veins clots. The vessel was intentionally de-endothelialized by external compression with blunt forceps. Snare occluders were then placed proximal and distal to the damaged site, and thrombin (10 U) was injected into the isolated LAD segment in a small volume via a previously isolated side branch. Autologous blood (0.3–0.4 ml) mixed with calcium chloride (0.05 M) also was injected into the isolated LAD segment, producing a stasis-type red clot superimposed on an injured blood vessel. The snares were released 2–5 min later, and total occlusion was confirmed by selective coronary angiography. This model of coronary artery thrombosis relies on the conversion of fibrinogen to fibrin by thrombin. The fibrin-rich thrombus contains platelets, but at no greater concentration than in a similar volume of whole blood. Once the thrombus is formed, it is allowed to age for 1–2 h, after which a thrombolytic agent can be administered to lyse the thrombus and restore blood flow.

PROCEDURES

In the initial study described by Gold et al. (1984), recombinant t-PA was characterized for its ability to lyse 2-h-old thrombi. Tissue plasminogen activator was infused at doses of 4.3, 10, and 25 μg/kg/min i.v. and resulted in reperfusion times of 40, 31, and 13 min, respectively. Thus, in this model of canine coronary thrombosis, t-PA exhibited dose-dependent coronary thrombolysis. Furthermore, it is possible to study the effect of different doses of t-PA on parameters of systemic fibrinolytic activation, such as fibrinogen, plasminogen, and a_2-antiplasmin, as well as to assess myocardial infarct size. For example, Kopia et al. (1988) demonstrated that SK elicited dose-dependent thrombolysis in this model. Subsequently, Gold et al. (1986, 1988) modified the model to study not only reperfusion but also acute reocclusion. Clinically, reocclusion is a persistent problem after effective coronary thrombolysis, which is reported to occur in 15–45% of patients (Goldberg et al. 1985). Thus, an animal model of coronary reperfusion and reocclusion would be important from the standpoint of evaluating adjunctive therapies to t-PA to hasten and/or increase the response rate to thrombolysis as well as prevent acute reocclusion.

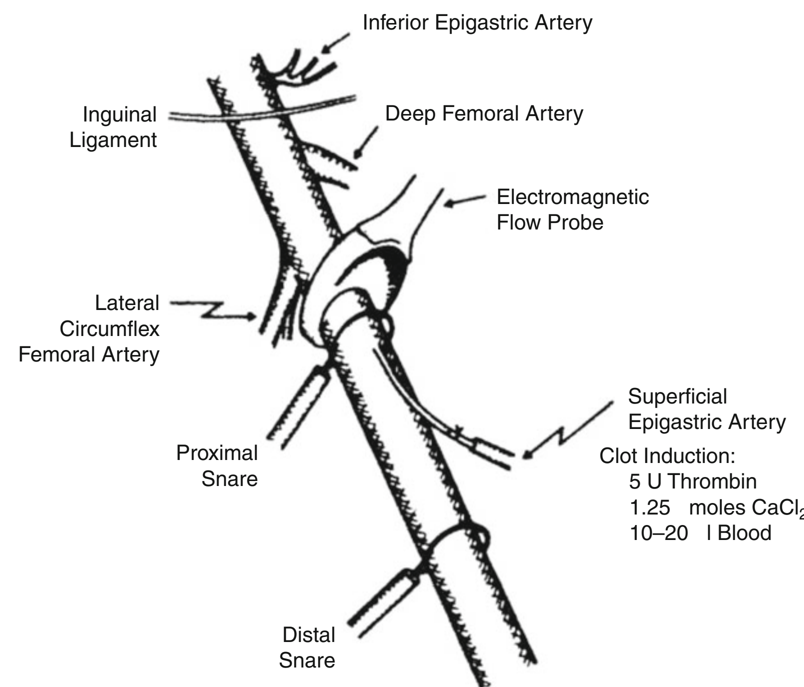

Fig. 11.6 Rabbit model of femoral arterial thrombosis. A clot is introduced into an isolated segment of femoral artery by injection of thrombin, $CaC1_2$, and whole blood. After aging for 1 h, t-PA is infused. Reperfusion is assessed by restoration of blood flow

11.4.1 Thrombin-Induced Rabbit Femoral Artery Thrombosis

Localized thrombosis can also be produced in rabbit peripheral blood vessels such as the femoral artery by injection of thrombin, calcium chloride, and fresh blood via a side branch (Shebuski et al. 1988).

Either femoral artery is isolated distal to the inguinal ligament and traumatized distally from the lateral circumflex artery by rubbing the artery with the jaws of forceps. An electromagnetic flow probe is placed distal to the lateral circumflex artery to monitor femoral artery blood flow (FABF). The superficial epigastric artery is cannulated for induction of the thrombus and subsequent infusion of thrombolytic agents. Localized thrombi distal to the lateral circumflex artery with snares approximately 1 cm apart are induced by the sequential injection of thrombin, $CaCl_2$ (1.25 μmoles), and a volume of blood sufficient to distend the artery. After 30 min, the snares are released, and FABF is monitored for 30 mm to confirm total obstruction of flow by the thrombus. See Fig. 11.6 above.

EVALUATIONS

The model of thrombin-induced clot formation in the canine coronary artery was modified such that a controlled high-grade stenosis was produced with an external constrictor. Blood flow was monitored with an electromagnetic flow probe. In this model of clot formation with superimposed stenosis, reperfusion in response to t-PA occurs with subsequent reocclusion. The monoclonal antibody against the human GPIIb/IIIa receptor developed by Coller et al. (1983) and tested in combination with t-PA in the canine thrombosis model hastened t-PA-induced thrombolysis and prevented acute reocclusion (Yasuda et al. 1988). These actions in vivo were accompanied by abolition of ADP-induced platelet aggregation and markedly prolonged bleeding time.

11.4.2 Laser-Induced Thrombosis

Purpose and Rationale

Thrombus formation in rat or rabbit mesenteric arterioles or venules is induced by laser beams. The test can be performed in normal or pretreated (induction of arteriosclerosis or adjuvant arthritis) animals. The mediators for thrombus formation in this method are platelet adhesion to the injured endothelial vessel wall on one hand and ADP-induced platelet aggregation on the other. Most probably, ADP is primarily released by laser beam–lysed erythrocytes due to the fact that erythrocyte hemoglobin exerts strong adsorbability to frequencies emitted by laser beams. There is a further, secondary, aggregation stimulus following the release reaction induced by the platelets themselves.

PROCEDURE

11.4.2.1 Apparatus

4 W Argon laser (Spectra Physics, Darmstadt, FRG) wavelength, 5,145 nm; energy below the objective, 15 mW; duration of exposure, 1/30 or 1/15 s

- Microscope ICM 405, LD-Epipland 40/0.60 (Zeiss, Oberkochen, FRG)
- Video camera (Sony, Trinicon tube)
- Recorder (Sony, U-matic 3/4")
- Videoanalyzer and correlator to determine blood flow velocity

11.4.2.2 In Vivo Experiment

Male Sprague–Dawley or spontaneously hypertensive stroke prone Wistar or Lewis rats with adjuvant induced arthritis weighing 150–300 g or New Zealand rabbits with arteriosclerosis induced by cholesterol feeding for 3 months are used. The animals receive the test compound by oral, intravenous, intraperitoneal, or subcutaneous administration. Control animals are treated with vehicle alone. Prior to thrombus induction, the animals are pretreated by s.c. injection of 0.1 mg/kg atropine sulfate solution and anesthetized by intraperitoneal administration of 100 mg/kg ketamine hydrochloride and 4 mg/kg xylazine.

Thrombus formation is induced 15, 30, 60, or 90 min postdosing. Investigations are performed in arterioles or venules of 13 ± 1 μm in diameter of the fat-free ileocecal portion of the mesentery. During the test procedure, the mesenterium is superfused with physiological saline solution or degassed paraffin liquid (37°C). The ray of the argon laser is led into the inverted ray path of the microscope by means of a ray adaptation and adjusting device. The frequency of injuries is 1 per 2 min. The exposure time for a single laser shot is 1/30 or 1/15 s. The number of injuries necessary to induce a defined thrombus is determined. All thrombi formed during the observation period with a minimum length of 13 μm or an area of at least 25 μm^2 are evaluated. All measuring procedures are photographed by a video system.

Standard compounds

- Acetylsalicylic acid (10 mg/kg, per os)
- Pentoxifylline (10 mg/kg, per os)

For detailed description and evaluation of various agents and mechanisms, see the following references: Arfors et al. (1968); Herrmann (1983); Seiffge and Kremer (1984, 1986); Seiffge and Weithmann (1987); and Weichert et al. (1983).

EVALUATION

The number of laser shots required to produce a defined thrombus is determined. Mean values and SEM are calculated. Results are shown graphically.

For statistical evaluation, the χ^2-test is used.

11.4.3 Photochemical-Induced Thrombosis

PURPOSE AND RATIONALE

In 1977, Rosenblum and El-Sabban reported that ultraviolet light can produce platelet aggregation in cerebral microvessels of the mouse after intravascular administration of sodium fluorescein. They found that in contrast to heparin, both aspirin and indomethacin prolonged the time to first platelet aggregate. Herrmann (1983) provided a detailed study in which he showed that scavengers of singlet oxygen, not of hydroxyl radicals, inhibited platelet aggregation induced by the photochemical reaction. He postulated that by exciting the intravascularly administrated fluorescein, singlet oxygen damages endothelial cells, which subsequently leads to platelet adhesion and aggregation.

PROCEDURE

Studies are performed in mesenteric arteries of 15–30-μm diameter in anesthetized rats. After intravenous injection of fluorescein isothiocyanate–dextran 70 (FITC-dextran, Sigma, 10%, 0.3 ml), the FITC-dextran in arterioles is exposed to ultraviolet light (wavelength of excitation 490 nm, wavelength of emission 510 nm).

EVALUATION

Thrombus formation is quantitated by determining the time between onset of excitation and appearance of the first platelet aggregate adhering to the vessel wall.

CRITICAL ASSESSMENT OF THE METHOD

In contrast to other thrombosis induction methods, photochemically induced thrombosis can be easily used in smaller animals. Thrombi are composed primarily of platelets; however, the primary target of the photochemical insult is the endothelial cells by means of an oxygen radical damage.

MODIFICATIONS OF THE METHOD

Matsuno et al. (1991) reported a method to induce thrombosis in the rat femoral artery by means of a photochemical reaction after injection of a fluorescent dye (rose Bengal, 10 mg/kg i.v.) and transillumination with a filtered xenon lamp (wavelength: 540 nm). Blood flow is monitored by a pulsed Doppler flow meter. Occlusion is achieved after approximately 5–6 min. Pretreatment with heparin dose dependently prolongs the time required to interrupt the blood flow. The model also enables to study thrombolytic mechanisms, which had been evaluated with t-PA. A comparative data for hirudin in various models was carried out by Just et al. (1991).

11.4.4 Foreign-Surface-Induced Thrombosis

The presence of foreign materials in the circulation produces activation of the coagulation and the platelet system. Various prothrombotic surfaces have been used to develop experimental animal models. In contrast to many other thrombosis models, the thrombosis induced by foreign surfaces does not presuppose endothelial damage.

11.4.4.1 Wire-Coil-Induced Thrombosis

PURPOSE AND RATIONALE

A classical method to produce thrombosis is based on the insertion of wire coils into the lumen of blood vessels. The model was first described by Stone and Lord (1951) in aorta of dogs and was further modified to be used in arterial coronary vessels of opened-chest dogs. The use in venous vessels was described by Kumada et al. (1980).

The formation of thrombotic material around the coil is reproducible and can be easily standardized to study pharmacological agents (Just and Schönafinger 1991; Mellot et al. 1993; Rübsamen and Hornberger 1996).

Venous thrombosis is produced in rats by insertion of a stainless steel wire coil into the inferior caval vein. Platelets as well as plasmatic coagulation are activated on the wire coil. Thrombus formation onto the wire is quantitated by measuring the protein content of the thrombotic material isolated. The kinetics of thrombus formation show an increase in weight and protein content within the first 30 min followed by a steady state between thrombus formation and endogenous thrombolysis leading to a constant protein content of thrombi between 1 and up to 48 h following implantation of the wire coil. Thrombosis incidence in untreated control animals in this model is 100%. The test is used to evaluate antithrombotic and thrombolytic properties of compounds in an in vivo model of venous thrombosis in rats.

PROCEDURE

Male Sprague–Dawley rats weighing 260–300 g receive the test compound or the vehicle (controls) by oral, intravenous, or intraperitoneal administration. At the end of absorption (i.v. 1 min, i.p. 30 min, p.o. 60 min), the animals are anesthetized by intraperitoneal injection of 1.3 g/kg urethane. Through a midline incision, the caudal caval vein is exposed and a stainless-steel wire coil (a dental pate carrier, Zipperer® size 40(st), Zdarsky Erler KG, München) is inserted into the lumen of the vein just below the left renal vein branching by gently twisting of the wire toward the iliac vein. The handle of the carrier is cut off so as to hold the back end of the wire at the vein wall. The incision is sutured, and the animal is placed on its back on a heating pad (37°C). The wound is reopened after 2 h, the wire coil is carefully removed together with the thrombus on it and rinsed with 0.9% saline. The thrombotic material is dissolved in 2 ml alkaline sodium carbonate solution (2% Na_2CO_3 in 0.1 N NaOH) in a boiling water bath for 3 min. The protein content is determined in 100 µl aliquots by the colorimetric method of Lowry. See Fig. 11.7 below.

11.4.4.2 Thrombolysis

In addition to the described preparation, for continuous infusion of a thrombolytic test solution, a polyethylene catheter is inserted in the jugular vein. One and a half hours after implantation of the wire coil, the test compound or the vehicle (controls) is infused for up to 2.5 h. The wire coil is then removed, and the protein content of thrombi is determined (see above). Bernat et al. (1986) demonstrated the fibrinolytic activity of urokinase and streptokinase-human plasminogen complex in this model.

EVALUATION

Thrombosis incidence (=number of animals with thrombi in dosage groups as compared to vehicle controls) is assessed.

The mean protein content (mg) of the thrombotic material in dosage groups and vehicle controls is determined. Percent change in protein content is calculated in dosage groups as compared to controls.

Statistical significance is assessed by means of the unpaired Student's *t*-test.

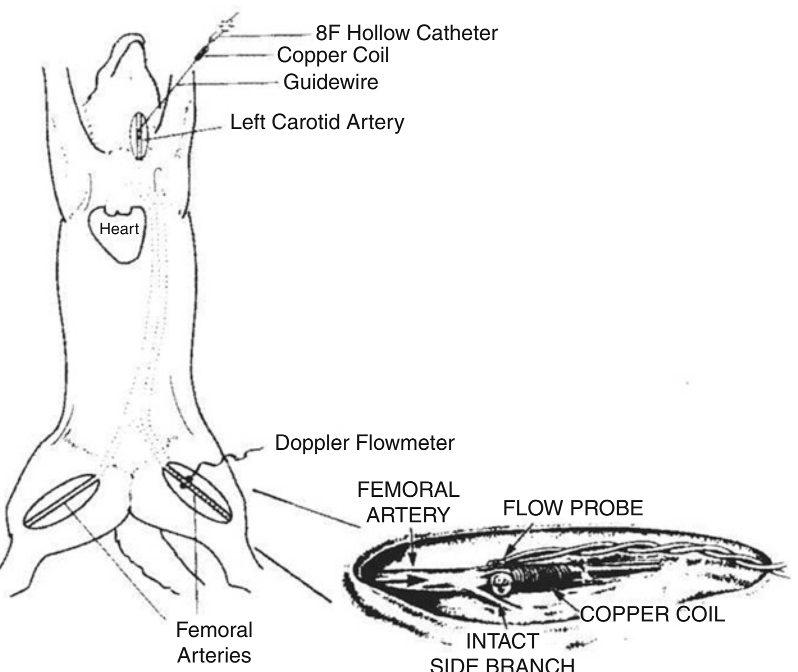

Fig. 11.7 Schematic diagram of the canine femoral artery copper coil model of thrombolysis. A thrombogenic copper coil is advanced to either femoral artery via the left carotid artery. By virtue of the favorable anatomical angles of attachment, a hollow polyurethane catheter advanced down the left carotid artery nearly always enters the descending aorta, and with further advancement, into either femoral artery without fluoroscopic guidance. A flexible, Teflon-coated guide wire is then inserted through the hollow catheter and the latter is removed. A copper coil is then slipped over the guide wire and advanced to the femoral artery (see inset). Femoral artery flow velocity is measured directly and continuously with a Doppler flow probe placed just proximal to the thrombogenic coil and distal to a prominent side branch, which is left patent to dissipate any dead space between the coil and the next proximal side branch. Femoral artery blood flow declines progressively to total occlusion over the next 10–12 mm after coil insertion

11.4.4.3 Eversion-Graft-Induced Thrombosis

PURPOSE AND RATIONALE

The eversion graft model for producing thrombosis in the rabbit artery was first described by Hergrueter et al. (1988) and later modified by Jang et al. (1989, 1990) and Gold et al. (1991). A 4- to 6-mm segment of the rabbit femoral or the dog left circumflex artery is excised, everted, and then reimplanted into the vessel by end-to-end anastomoses. After restoration of the blood flow, a platelet-rich occlusive thrombus forms rapidly leading to complete occlusion of the vessel. This model mimics a deep arterial injury since the adventitial surface is a nonendothelial tissue containing tissue factor and collagen. The rabbit model described here uses a carotid graft inserted into the femoral graft to avoid vasoconstriction often occurring in the inverted femoral segments.

PROCEDURE

In anesthetized New Zealand white rabbits, the right A. carotid is exposed. After double ligation, a 3-mm segment of the artery is excised, everted, and immersed in prewarmed (37°C) isotonic saline. Thereafter, the right femoral artery is exposed and occluded by means of a double occluder (2-cm distance). The femoral artery is transected and the everted graft from the carotid artery is inserted by end-to-end anastomosis using 12 sutures with 9–0 nylon (Prolene, Ethicon, Norderstedt, Germany) under a surgical microscope (Wild M650, Leitz, Heerbrugg, Switzerland). Perfusion of the graft is measured by means of an ultrasonic flow meter (Model T106, Transonic, Ithaca NY, USA). The flow probe is positioned 2 cm distal from the graft. After a stabilization period of 15 min, the test substance is given intravenously through the catheterized right V. jugulars. Ten minutes after substance administration,

the vessel clamps are released, and the blood flow is monitored by the flow meter for 120 min.

Arterial blood is collected from the left carotid artery at baseline (immediately before substance administration), 10, 60, and 120 min after substance administration.

EVALUATION

- Time until occlusion (time after restoring of vessel blood flow until occlusion of the vessel indicated by a flow less than 3.0 ml/min)
- Patency (time during which perfusion of graft is measured related to an observation period of 120 min after administration of test compounds)

11.4.4.4 Statistical Analysis

Time until occlusion and patency are expressed as median and the interquartile range/2 (IQR/2). Significant differences ($p<0.05$) are calculated by the nonparametric Kruskal-Wallis test.

CRITICAL ASSESSMENT OF THE METHOD

The eversion graft is very thrombogenic, although technically difficult and time-consuming. The deep occlusive thrombi can be prevented only by intra-arterial administered thrombolytic or aggressive antithrombotic treatments such as recombinant hirudin at high dosages or PEG-hirudin. The adventitial surface is a nonendothelial tissue containing tissue factor and collagen. Thus, both the coagulation system and blood platelets are activated.

MODIFICATIONS OF THE METHOD

Gold et al. (1991) modified the model to be used in thoracotomized dogs in partial-obstructed left-circumflexed coronary arteries. The combination of reduced blood flow due to the constrictor, along with an abnormal nonendothelial surface, produces total thrombotic occlusion within 5 min.

11.4.4.5 Arteriovenous Shunt Thrombosis

PURPOSE AND RATIONALE

A method for the direct observation of extracorporal thrombus formation has been introduced by Rowntree and Shionoya (1927). These first studies could provide evidence that anticoagulants like heparin and hirudin do inhibit thrombus development in arteriovenous shunts. The AV shunt thrombosis models have been often used to evaluate the antithrombotic potential of new compounds in different species including rabbits (Knabb et al. 1992), rats (Hara et al. 1995), pigs (Scott et al. 1994), dogs and cats (Best et al. 1938), and nonhuman primates (Yokoyama et al. 1995).

PROCEDURE

Rats are anesthetized and fixed in supine position on a temperature-controlled heating plate to maintain body temperature. The left carotid artery and the right jugular vein are catheterized with short polyethylene catheters. The catheters are filled with isotonic saline solution and clamped. The two ends of the catheters are connected with a 2-cm glass capillary with an internal diameter of 1 mm. This glass capillary provides the thrombogenic surface. At a defined time after administration of the test compound, the clamps that are occluding the AV shunt are opened.

The measurement of the patency of the shunt is performed indirectly with a NiCr-Ni thermocouple that is fixed distal to the glass capillary. If blood is flowing, the temperature rises from room temperature to body temperature. In contrast, decreases in temperature indicate the formation of an occluding thrombus. The temperature is measured continuously over 30 min after opening of the shunt.

CRITICAL ASSESSMENT OF THE METHOD

It has been shown by Best et al. (1938) that the thrombi formed in the AV shunt are to a greater part white

arterial thrombi. This might be due to the high pressure and shear rate inside the shunts, the thrombi tend to be more arterial in character (Chi et al. 1999).

11.4.4.6 Thread-Induced Venous Thrombosis

PURPOSE AND RATIONALE

Compared to the arterial system, it seems to be more difficult to develop a thrombosis model in venous blood vessels with respect to reproducibility and variability (Chi et al. 1999). Complete stasis together with a thrombogenic stimulus (Wessler type) is used by numerous investigators to evaluate the effect of compounds on venous thrombosis. Hollenbach et al. (1994) developed a rabbit model of venous thrombosis by inducing cotton threads into the abdominal vena cava of rabbits. The cotton threads serve as a thrombogenic surface, and a thrombus forms around it growing to a maximum mass after 2–3 h. The prolonged nonocclusive character of thrombogenesis in this model focuses on progression of thrombus formation rather than initiation. Therefore, the conditions more closely resemble pathophysiology in humans because blood continues to flow throughout the experiment (Chi et al. 1999).

PROCEDURE

Rabbits weighing between 2.5 and 3.5 kg are anesthetized with isofluorane inhalation anesthesia, and a polyethylene catheter is inserted into the left carotid artery. A polyethylene tube (PE 240, inner diameter 1.67 mm) of 14-cm length is filled with isotonic saline, and a copper wire with five fixed cotton threads (length 6 cm) is inserted into the tube (after determination of the net weight of the cotton threads). A laparotomy is performed and the V. cava and V. iliaca are dissected free from surrounded tissue. The test agent is administered by a rabbit intragastric tube 60 min (depending on the ex vivo study) prior to initiation of thrombus formation. Blood samples will be measured at 60, 90, 120, 150, and 210 min after oral administration of the test compound.

Thrombus formation is induced by the inserting the thrombosis catheter into the caval vein via the V. iliaca (7 cm). Then, the copper wire is pushed forward 3 cm to liberate the cotton threads into the vessel lumen. One hundred fifty minutes after thrombus initiation, the caval segment containing the cotton threads and the developed thrombus will be removed, longitudinally opened, and the content blotted on filter paper. After weighing the cotton thread with the thrombus, the net thread weight will be subtracted to determine the corrected thrombus weight.

EVALUATION

- Corrected thrombus weight after blotting the thrombus on filter paper and subtraction of the net weight of the cotton thread
- Mean arterial blood pressure (MAP)
- APTT, HepTest, antiFIIa and antiFXa activities

CRITICAL ASSESSMENT OF THE METHOD

The composition of the cotton threaded thrombus shows a composition of fibrin together with tightly aggregated and distorted erythrocytes thus being in accordance with human deep vein thrombosis structure. Nonocclusive thrombus formation has been successfully inhibited by heparins, prothrombinase complex inhibitors, and thrombin inhibitors (Hollenbach et al. 1994, 1995).

MODIFICATIONS OF THE METHOD

In addition to the originally described method, it is possible to measure blood flow by means of an ultrasonic flow probe, attached distally to the position of the cotton threads on the vein.

11.4.4.7 Thrombus Formation on Superfused Tendon

PURPOSE AND RATIONALE

In all models that include vessel wall damage, blood gets in contact with adhesive proteins of the subendothelial matrix, i.e., von Willebrand factor, collagens, fibronectin, laminin, and others. Gryglewski et al. (1978) described an in vivo method where blood of an unanesthetized animal is in contact ex vivo with a foreign surface consisting mainly of collagen. The foreign surface is produced out of the tendon of another animal species. After superfusion of the tendon, blood is recirculated to the unanesthetized animal. The method aims at the quantitation of the antiplatelet potency of drugs based on the formation of platelet thrombi onto the surface of the tendons or of aortic strips from atherosclerotic rabbits.

PROCEDURE

Blood was withdrawn from the carotid artery of anesthetized and heparinized cats by a roller pump at a speed of 6 ml/min. After a passage through a warmed jacket (37°C), blood was separated into two streams, each flowing at a speed of 3 ml/min superfusing in parallel two twin strips of the central part of longitudinally cut rabbit Achilles tendon (30×3 mm). The blood superfusing the strips dripped into collectors and by its gravity was returned to the venous system of the animals through the left jugular vein. The tissue strips were freely suspended in air, and the upper end was tied to an auxotonic lever of a smooth muscle/heart Harvard transducer, while the lower end was loaded with a weight (1–2 g) to keep the lever with its counterweight in a neutral position. When superfused with blood, the strips were successively covered with clots changing the weight of the strips. The weight changes were continuously recorded. After a control period of 30 min, the formed thrombi were gently removed and fixed in formalin for histological examination. Then, the strips were superfused with Tyrode solution and the animals injected with the antithrombotic drug. After 10 min, blood superfusion was renewed for another 30 min.

EVALUATION

The ratio of an increase in weight of the strips after the drug treatment to the increase in weight before drug treatment was considered as an index of antiaggregatory activity.

11.4.5 Stasis-Induced Thrombosis (Wessler Model)

PURPOSE AND RATIONALE

The "Wessler model" is a classical method of inducing venous thrombosis in animals. Wessler (1952; 1953, 1955a, 1957; Wessler et al. 1959) combined local venous stasis with hypercoagulability produced by injection of human or dog serum into the systemic circulation of dogs or rabbits. The jugular vein of these animals is occluded by clamps 1 min after the injection of the procoagulatory stimulus into the circulation. Within a few minutes after clamping, a red clot is formed in the isolated venous segment. Fareed et al. (1985) summarized a variety of substances which can

be used as procoagulatory stimuli. Aronson and Thomas (1985) found an inverse correlation between the duration of stasis and the amount of the hypercoagulating agents to produce the clot.

PROCEDURE

Anesthetized rabbits are fixed in supine position on a temperature-controlled (37°C) heating table. Following cannulation of both carotid arteries (the left in cranial direction) and the right V. femoral, segments of 2-cm length of the two external jugular veins are exposed and isolated between two loose sutures. 0.3 ml/kg calcium thromboplastin (SIGMA, Deisenhofen, Germany, FRG) is administered via the left carotid artery. Meticulous care is taken to maintain a standard injection time of 30 s followed by injection of 0.5 ml physiological saline within 15 s. Forty-five seconds later, both jugular vein segments are occluded by distal and proximal sutures. Stasis is maintained for 30 min. Blood samples are taken immediately before occlusion and 30 s before end of stasis. After excision, the occluded vessel segments are placed on a soaked sponge and opened by a longitudinal incision.

EVALUATION

The size of the clots is assessed using a score system: (0, blood only; 1, very small clot piece(s), filling out at most 1/4 of the vessel; 2, larger clot piece(s), filling out at most 1/2 of the vessel; 3, very large clot(s), filling out at most 3/4 of the vessel; 4, one large clot, filling out the whole vessel). The scores of the left and the right jugular vein are added forming the thrombus size value of one animal. Additionally, the thrombus weight is measured after blotting the thrombus on filter paper.

Thrombus score is expressed as median (minimum–maximum). Thrombus weight is given as mean±SEM. For the statistical evaluation of the antithrombotic effect, the nonparametric *U*-test of Mann and Whitney (thrombus score) or Student's *t*-test for unpaired samples (thrombus weight) is used. Significance is expressed as $p<0.05$.

CRITICAL ASSESSMENT OF THE METHOD

Breddin (1989) described the Wessler model because of its static character as the retransformation of an in vitro experiment into a very artificial test situation. One of the major drawbacks is the relative independence of platelet function and hemodynamic changes that largely influence thrombus formation in vivo. However, the model has been shown to be very useful for evaluation of the antithrombotic effect of compounds like heparin and hirudin.

MODIFICATIONS OF THE METHOD

There are a number of different procoagulant agents that had been used to induce thrombosis in this model, such as human serum, Russel viper venom, thromboplastin, thrombin, activated prothrombin complex concentrates, and factor X_a. (Aronson and Thomas 1985; Fareed et al. 1985). The sensitivity and accuracy of the model can be improved by injecting iodinated fibrinogen into the animals before injecting the thrombogenic agent and then measuring the specific radioactivity in the clot.

The general drawback of the Wessler model is the static nature of the venous thrombus development. To overcome this problem, some investigators have developed more dynamic models with reperfusion of the occluded vessel segments after clot development. Depending on the time of test compound administration (pre- or postthrombus initiation), the effect on thrombus growth and fibrinolysis can be evaluated. Levi et al. (1992) have used this model to assess the effects of a murine monoclonal antihuman PAI-1 antibody, and Biemond et al. (1996) compared the effect of thrombin and factor X_a inhibitors with a low-molecular-weight heparin.

11.4.5.1 Venous Reperfusion Model

New Zealand white rabbits weighing 2.5 kg are anesthetized with 0.1 ml atropine, 1.0 mg/kg diazepam, and 0.3 ml Hypnorm (Duphar, 10 mg/ml fluanisone and 0.2 ml fentanyl). Further anesthesia is maintained with 4 mg/kg i.v. thiopental. The carotid artery is cannulated after exposition through an incision in the neck. The jugular vein is dissected free from tissue, and small side branches are ligated over a distance of 2 cm. The vein is clamped proximally and distally to isolate the vein segment. Citrated rabbit blood (from another rabbit) is mixed with ^{131}I-radiolabeled fibrinogen (final radioactivity,

approximately 25 mCi/ml). One hundred fifty microliters of this blood is then aspirated in a 1-ml syringe containing 25 μl thrombin (3.75 IU) and 45 μl 0.25 mol $CaCl_2$, and 200 μl of the clotting blood is immediately injected into the isolated segment. Thirty minutes after clot injection, the vessel clamps are removed and blood flow is restored. ^{125}I-radiolabeled fibrinogen (approximately 5 μCi) is injected through the cannula in the carotid artery (in case of the fibrinolysis studies, immediately followed by 0.5 mg/kg recombinant tissue-type plasminogen activator). For each dosage group, four thrombi are analyzed. The extent of thrombolysis is assessed by measurement of the remaining ^{131}I-fibrinogen in the clot and compared with the initial clot radioactivity. The comparison between blood and thrombus ^{125}I-radioactivity reveals the extent of thrombus growth (blood volume accreted to the blood). The thrombus lysis and extension are monitored 60 or 120 min after thrombus formation and are expressed as percentage of the initial thrombus volume. Statistics is performed as variance analysis and the Newman-Keuls test. Statistical significance is expressed at the level of $p<0.05$.

11.4.6 Disseminated Intravascular Coagulation (DIC) Model

PURPOSE AND RATIONALE

Another model that is also used widely in rats and mice is a model of systemic thrombosis or disseminated intravascular coagulation (DIC) that is induced by tissue factor, endotoxin (lipopolysaccharide), or FXa (Herbert et al. 1996; Yamazaki et al. 1994; Sato et al. 1998). After systemic administration of the thrombogenic stimulus, this model can be performed with or without mechanical vena caval stasis. When stasis is used, the major parameter is the thrombus mass, but when stasis is not used, the readouts are fibrin degradation products, fibrinogen, platelet count, PT, and APTT, among others. As shown by the many and varied parameters, when used without stenosis, the postexperimental analysis can be time-consuming and technically demanding. Although rodents are useful as a primary efficacy model, limitations such as the ability to withdraw multiple blood samples over the course of the experiment and the difference in activity of at least some FXa inhibitors in human compared to rat plasma in vitro require that compounds be characterized further in more advanced in vivo models of thrombosis.

11.4.7 Microvascular Thrombosis in Trauma Models

PURPOSE AND RATIONALE

Successful replantation of amputated extremities is dependent in large degree on maintaining the microcirculation. A number of models have been developed in which blood vessels are subjected to crush injury with or without vascular avulsion and subsequent anastomosis (Fu et al. 1997; Korompilias et al. 1997; Stockmans et al. 1997). In the model of Stockmans (1997), both femoral veins are dissected from the surrounding tissue. A trauma clamp, which has been adjusted to produce a pressure of 1,500 g/mm^2, is positioned parallel to the long axis of the vein. The anterior wall of the vessel is grasped between the walls of the trauma clamp and the two endothelial surfaces are rubbed together for a period of 30 s as the clamp is rotated. Formation and dissolution of platelet-rich mural thrombi are monitored over a period of 35 m by transillumination of the vessel. By using both femoral veins, the effect of drug therapy can be compared to control in the same animal, minimizing intra-animal variations.

The models of Korompilias (1997) and Fu (1997) examine the formation of arterial thrombosis in rats and rabbits, respectively. In these models, either the rat femoral artery or the rabbit central ear artery is subjected to a standardized crush injury. The vessels are subsequently divided at the midpoint of the crushed area and then anastomosed. Vessel patency is evaluated by milking the vessel at various time points postanastomosis. These models have been used to demonstrate the effectiveness of topical administration of LMWH in preventing thrombotic occlusion of the vessels. Such models, while effectively mimicking the clinical situation, are limited by the necessity of a high degree of surgical skill to effectively anastomose the crushed arteries.

11.4.8 Cardiopulmonary Bypass Models

PURPOSE AND RATIONALE

Cardiopulmonary bypass (CPB) models have been described in baboons (Van Wyk et al. 1998), swine (Dewanjee et al. 1996), and dogs (Henny et al. 1985). In each model, the variables that can affect the hemostatic system such as anesthesia, shear stresses caused by the CPB pumps and the exposure of plasma components and blood cells to foreign surfaces (catheters, oxygenators, etc.) are comparable to that observed with human patients. With these models, it is possible to examine the potential usefulness of novel anticoagulants in preventing thrombosis under relatively harsh conditions where both coagulation and platelet function are altered. The effectiveness of direct thrombin inhibitors (Van Wyk, et al. 1998), LMWHs (Murray 1985), and heparinoids (Henny et al. 1985) has been compared to standard heparin. Endpoints have included the measurement of plasmatic anticoagulant levels, the histological determination of microthrombi deposition in various organs, the formation of blood clots in the components of the extracorporeal circuit, and the deposition of radiolabeled platelets in various organs and on the components of the extracorporeal circuit. These models, therefore, can be used to assess the antithrombotic potential of new agents for use in CPB surgery and also to assess the biocompatibility of components used to maintain extracorporeal circulation. For detailed protocols and evaluations, see Callas et al. (1995), Carrie et al. (1994), Fu et al. (1997), Korompilias et al. (1997), Meuleman et al. (1991), Millet et al. (1994), Stockmans et al. (1997), Vlasuk et al. (1991), Walenga et al. (1987), and Wessler et al. (1959).

11.4.9 Extracorporeal Thrombosis Models

PURPOSE AND RATIONALE

These models employ passing blood over a section of damaged vessel (or other selected substrates) and recording the thrombus accumulation on the damaged vessel histologically or by scintigraphic detection of radiolabeled platelets or fibrin (Badimon and Badimon 1989). This model is interesting because the results can be directly compared to the in vivo deep arterial injury model (Wysokinski et al. 1996) results and to results from a similar extracorporeal model used in humans (Dangas et al. 1998; Ørvim et al. 1995). Dangas et al. (1998) used this model to characterize the antithrombotic efficacy of abciximab, a monoclonal antibody-based platelet glycoprotein IIb/IIIa inhibitor, after administration to patients undergoing percutaneous coronary intervention. They demonstrated that abciximab reduces both the platelet and fibrin components of the thrombus, thereby providing further insight into the unique long-term effectiveness of short-term administration of this drug. Ørvim et al. (1995) also used this model in humans to evaluate the antithrombotic efficacy of rTAP, but instead of evaluating the compound after administration of rTAP to the patient, the drug was mixed with the blood immediately as it flowed into the extracorporeal circuit prior to flowing over the thrombogenic surface. By changing the thrombogenic surface, they were able to determine that rTAP was more effective at inhibiting thrombus formation on a tissue-factor-coated surface compared to a collagen-coated surface. These results suggest that optimal antithrombotic efficacy requires an antiplatelet approach along with an anticoagulant. Although this model does not completely represent pathological intravascular thrombus formation, the use of this "human model" of thrombosis may be very useful in developing new drugs because it directly evaluates the ex vivo antithrombotic effect of a drug in flowing human blood.

11.4.10 Experimental Thrombocytopenia or Leukocytopenia

PURPOSE AND RATIONALE

Intravenous administration of collagen, arachidonic acid, ADP, PAF (platelet-activating factor), or thrombin activates thrombocytes leading to a maximal thrombocytopenia within a few minutes. The effect is reinforced by additional injections of epinephrine. Activation of platelets leads to intravessel aggregation and temporary sequestration of aggregates in the lungs and other organs. Depending on the dose of agonist, this experimentally induced reduction of the number of circulating platelets is reversible within 60 min after induction. Following administration of PAF, a leukocytopenia is induced in addition. The assay is used to test the inhibitory capacity of drugs against thrombocytopenia or leukocytopenia as a consequence of in vivo platelet or leukocyte stimulation.

PROCEDURE

11.4.10.1 Materials and Solutions

Substances used to induce thrombocytopenia/leukocytopenia (intravenous administration)	
In rabbits: Arachidonic acid (Sigma)	1 mg/kg
Collagen (Hormonchemie)	30 μg/ml
In mice: Collagen + adrenaline (Hormonchemie)	90 μg/kg +20 μg/kg
In hamsters: Collagen +adrenaline	50 μg/kg +10 μg/kg
In guinea pigs: PAF (Paf-acether, Bachem)	0.03–0.04 μg/kg
Thrombin (Hoffman-LaRoche)	60 U/kg
Anesthetics: Pentobarbital sodium (i.p.)	30 mg/kg
Xylazine (i.m.)	8 mg/kg
Urethane (i.p.)	1.5 g/kg
Platelet analyzer: Sysmex microcellcounter F-800	

Male guinea pigs (Pirbright White) weighing 300–600 g, male NMRI mice (25–36 g), or Chinchilla rabbits of either sex weighing 2–3 kg are used. Animals receive the test compound or the vehicle (controls) by oral, intraperitoneal, or intravenous administration. After the end of the absorption time (p.o. 60 min, i.p. 30 min, i.v. variable), the marginal vein of the ear of rabbits is cannulated, and the thrombocytopenia-inducing substances collagen or arachidonic acid are injected slowly. Blood is collected from the ear artery.

Guinea pigs, hamsters, or mice are anesthetized with pentobarbital sodium (i.p.) and Rompun® (i.m.) and placed on an electrically warmed table at 37°C. The carotid artery is cannulated for blood withdrawal, and the jugular vein is cannulated to administer the thrombocytopenia-inducing substances collagen +adrenaline (injection of the mixture of both within 10 s) or PAF or thrombin. In mice, collagen+adrenaline are injected into a tail vein.

Approximately 50–100 μl blood is collected into potassium-EDTA-coated tubes at times −1, 1, and 2 min (guinea pigs and mice) or 5, 10, and 15 min (rabbits) following the injection of the inducer. The number of platelets and leukocytes is determined within 1 h after withdrawal in 10 μl samples of whole blood using a microcell counter suitable for blood of various animal species.

EVALUATION

The percentage of thrombocytes (or leukocytes) is determined in vehicle control and dosage groups at the different times following injection of the inducer relative to the initial value of control or dosage group, respectively. Calculated percent values of controls are taken as 100%.

Percent inhibition of thrombocytopenia (or leukocytopenia) is calculated in dosage groups relative to controls.

Statistical significance is evaluated by means of the unpaired Student's *t*-test.

CRITICAL ASSESSMENT OF THE METHOD

The method of collagen+epinephrine–induced thrombocytopenia is presently widely used to study the phenotype of mice knocked out for a specific gene with suspected role in hemostasis/thrombosis. A recent example is the Gas6 −/− mouse (Angelillo-Scherrer et al. 2001) and mice lacking the gene for the G protein G(z) (Yang et al. 2000b). The advantage of the method for this purpose is the simple experimental procedure and the small volume of blood necessary. In general, application of the method in small animals (mice,

hamsters) needs only small amounts of drug substance. The model is a useful first step of in vivo antithrombotic efficacy of antiplatelet drugs.

11.4.11 Collagenase-Induced Thrombocytopenia

Purpose and Rationale

Intravenous administration of the proteolytic enzyme collagenase leads to formation of endothelial gaps and to exposure of deeper layers of the vessel wall. This vascular endothelial injury is mainly involved in triggering thrombus formation by activation of platelets through contact with the basal lamina. As a consequence, thrombocytopenia is induced, which is maximal within 5–10 min following collagenase injection and reversible within 30 min after induction. The model is used to test the inhibitory capacity of compounds against thrombocytopenia in a model of collagenase-induced thrombocytopenia in rats as an alternative to the model described before.

PROCEDURE

11.4.11.1 Materials and Solutions

Anesthetic: pentobarbital sodium (i.p.)	60 mg/kg
Heparin (Liquemin®) (i.v.)	500 U/kg
To induce thrombocytopenia (intravenous administration): Collagenase (E.C. 3.4.24.3), (Boehringer, Mannheim)	10 mg/ml/kg
Platelet analyzer:Sysmex microcellcounter F-800	

Male Sprague–Dawley rats weighing 260–300 g are used. The animals receive the test compound or the vehicle (controls) by oral, intraperitoneal, or intravenous administration. After the end of the absorption time (i.p. 30 min, p.o. 60 min, i.v. variable), rats are anesthetized with pentobarbital sodium (i.p.). One carotid artery is cannulated for blood withdrawal, and one jugular vein is cannulated for inducer injection. The animals receive an intravenous injection of heparin, and 20 min later, approximately 100 μl blood is collected (initial value). Ten minutes later, the thrombocytopenia-inducing substance collagenase is administered intravenously.

At times 5, 10, 20, and 30 min following the injection of collagenase, samples of approximately 100 μl blood is collected into potassium-EDTA-coated tubes. The number of platelets is determined in 10 μl samples of whole blood within 1 h after blood withdrawal using a microcell counter. See Völkl and Dierichs (1986) for details.

EVALUATION

1. The percentage of platelets is determined in vehicle control and dosage groups at the different times following injection of collagenase relative to the initial value of control or dosage group, respectively. Calculated percent values of controls are set 100%.
2. Percent inhibition of thrombocytopenia is calculated in treated relative to controls.

Statistical significance is evaluated by means of the unpaired Student's *t*-test.

11.4.12 Reversible Intravital Aggregation of Platelets

PURPOSE AND RATIONALE

Isotopic labeling of platelets can be employed to monitor platelet aggregation and desegregation in vivo. ADP, (adenosine diphosphate), PAF (platelet activating factor), arachidonic acid, thrombin, and collagen are known to induce platelet aggregation. In the following procedure, labeled platelets are

continuously monitored in the thoracic (A) and abdominal (B) region of test animals. Administration of aggregation promoting agents produces an increase in counts in A and a fall in counts in B. This observation implies that platelets are being aggregated within the vascular system and accumulate in the pulmonary microvasculature. The in vivo method can be used to evaluate platelet antiaggregatory properties of test compounds.

PROCEDURE

11.4.12.1 Preparation of Labeled Platelets

Blood is obtained from rats by cardiopuncture. After centrifugation at 240 g for 10 min, the platelet-rich plasma (PRP) is transferred into a tube and suspended in calcium-free Tyrode solution containing 250 ng/ml PGE_1. The suspension is centrifuged at 640 g for 10 min. The supernatant is discarded and the sediment is suspended by gentle shaking with calcium-free Tyrode solution containing 250 ng/ml PGE_1. 51Cr is added to 1 ml of the platelet suspension. Following a 20-min incubation period at 37°C, the suspension is again centrifuged at 640 g for 10 min. The supernatant is removed and the labeled platelets are finally resuspended in 1 ml calcium-free Tyrode solution containing 250 ng/ml PGE_1.

11.4.12.2 In Vivo Experiment

Male Sprague–Dawley or stroke-prone spontaneously hypertensive rats weighing 150–300 g are used. The animals are anesthetized with pentobarbital sodium (30 mg/kg i.p.). Following tracheotomy, the vena femoralis is exposed and cannulated. The labeled platelets are administered via the cannula. The circulating platelets are monitored continuously in the thoracic (A) and abdominal (B) region. The counts are collected using a dual channel gamma spectrometer (Nuclear Enterprise 4681) incorporating a microcomputer (AM 9080A). One hour after administration of labeled platelets (when counts in A and B have stabilized), the aggregation promoting agent (ADP, PAF, arachidonic acid, thrombin, or collagen) is administered twice by intravenous injection. One hour is allowed to elapse between each i.v. injection.

The test compound is administered 2 h after platelet injection concurrently with the fourth administration of the aggregating agent. Thirty minutes (ADP, PAF, arachidonic acid, thrombin) or 1 h (collagen) after compound administration, another control injection of the aggregating agent is given. This injection is either used as an additional control or it may reveal long-term efficacy of a test compound.

Standard compound

- PGI_2 (prostacyclin)

EVALUATION

The microcomputer continuously reveals information about aggregation and desegregation of labeled platelets.

The following parameters are recorded:

- A = counts over thorax
- B = counts over abdomen
- Difference: $A-B$
- Ratio: A/B.

The time course of response is shown in a curve. The area under the curve is calculated by a computer program.

Statistical significance is calculated using the Student's *t*-test.

MODIFICATION OF THE METHOD

Oyekan and Botting (1986) described a method for monitoring platelet aggregation in vivo in rats using platelets labeled with indium^{3+} oxine and recording the increase in radioactivity count in the lung after injection of adenosine diphosphate or collagen.

Smith et al. (1989) monitored continuously the intrathoracic content of intravenously injected ^{111}indium-labeled platelets in anesthetized guinea pigs using a microcomputer-based system.

11.4.13 Microfluidic Devices for Studies of Shear-Dependent Platelet Adhesion

Combination of in vivo models and ex vivo flow chambers allow for manipulation of shear stresses (1–3), controlled addition of platelet stimuli (4, 5),

and evaluation of various pharmacological agents (6). Flow chambers for studying platelet rolling, adhesion, and aggregation over immobilized ligands have been critical in understanding shear-dependent receptor-ligand dynamics (7–9). However, most parallel-plate and annular flow chambers require milliliters of fluid to perform experiments over a relevant time scale. This volume of blood is easily obtained from human subjects but requires pooling or dilution of murine whole blood owing to the relatively low total blood volume of a single animal (~1 ml) (10, 11). The cost of pooling is difficult when using genetically modified mice to obtain data for a single experimental condition in a parallel-plate flow chamber. Thus, current flow chamber designs are poorly suited for research with murine blood. Studies of dynamic platelet adhesion assays in microfluidic devices reduce the blood volume requirements to less than 0.1 ml per assay, making the assays compatible with samples of whole blood obtained from a single mouse. Certain devices have an array of eight flow chambers with shear stress varying by a factor of about two between adjacent chambers, covering a 100-fold range from low venous to arterial. Other devices allow for simultaneous high-resolution fluorescence imaging of dynamic adhesion of platelets from two different blood samples. Adhesion of platelets in the devices to EC monolayer or common ECM substrate coatings can be carried out. These microfluidic systems, with the requirement of small blood volume, allow for investigating blood from wild-type mice and from different genetically modified mouse strains under different shear, which might also allow for adhesion tests in clinical settings with blood from neonates and children.

11.4.13.1 Experimental Protocol

Platelets were visualized by adding 2 μM mepacrine to whole blood to label dense granules where at this concentration no effect on either platelet or leukocyte functions (12, 13). Test compounds are added 15–30 min prior to onset of blood flow through the device. To coat the glass substrata of the microfluidic devices with physiological matrices, the microchannels were filled with 10–20 μg/ml fibrinogen, 100–300 μg/ml acid-soluble type I collagen, or 3–10 μg/ml vWF and incubated for 1 h at room temperature. Subsequently, the devices are rinsed with 20 mM Hepes, pH 7.4 and then blocked with 1–3% serum albumin for 30 min. The flow through the device can be stopped by clamping the Tygon tubing. Use 100–200 μl of human or mouse blood into a 1-cc plastic syringe through a Tygon tubing line, which is then connected to the device inlet.

11.4.13.2 Image Acquisition and Analysis

The microfluidic device is mounted on a mechanical stage of inverted fluorescence microscope. Fluorescence microscopy with light source and a GFP filter set (Ex470/Em525) and the images of the platelets are acquired. The stage could be programmed to move in periodic scanning loops between test chambers 1–8, with eight stops to take a fluorescence image of each chamber.

The microfluidic device could also be used to study platelet-leukocyte or other heterotypic cell interactions.

11.5 Bleeding Models

11.5.1 Subaqueous Tail Bleeding Time in Rodents

PURPOSE AND RATIONALE

The damage of a blood vessel results in the formation of a hemostatic plug, which is achieved by several different mechanisms including vascular spasm, formation of a platelet plug, blood coagulation, and growth of fibrous tissue into the blood clot.

A diagnostic parameter for specific defects of the hemostatic system and for the influence of drugs affecting hemostasis is the length of time that it takes for bleeding to stop from a standard incision, the so-called bleeding time.

Bleeding-time measurements in animals are used to evaluate the hemorrhagic properties of antithrombotic drugs. The transection of the tail of a rodent was first established by Döttl and Ripke (1936) and is commonly used in experimental pharmacology.

PROCEDURE

Anesthetized rats are fixed in supine position on a temperature-controlled (37°C) heating table. Following catheterization of a carotid artery (for measurement of blood pressure) and a jugular vein, the test compound is administered. After a defined latency period, the tail of the rat is transected with a razor blade mounted on a self-constructed device at a distance of 4 mm from the tip of the tail. Immediately after transection, the tail is immersed into a bath filled with isotonic saline solution (37°C).

EVALUATION

The time until bleeding stops is determined within a maximum observation time of 600 s.

CRITICAL ASSESSMENT OF THE METHOD

There are numerous variables that can influence rodents' bleeding time measurements as discussed by Dejana et al. (1979): position of the tail (horizontal or vertical), the environment (air or saline), temperature, anesthesia, and procedure of injury (Simplate method, transsection). All these variables are responsible for the different results reported in literature on compounds like aspirin and heparin under different assay conditions (Stella et al. 1975; Minsker and Kling 1977).

Furthermore, it is impossible to transect exactly one blood vessel because the transected tail region consists of a few major arteries and veins with mutual interaction between one another.

11.5.2 Arterial Bleeding Time in Mesentery

PURPOSE AND RATIONALE

Arterial bleeding is induced by micropuncture of small arteries in the area supplied by the mesenteric artery. Bleeding is arrested in living blood vessels by the formation of a hemostatic plug due to the aggregation of platelets and to fibrin formation. In this test, compounds are evaluated that inhibit thrombus formation thus prolonging arterial bleeding time. The test is used to detect agents that interfere with primary hemostasis in small arteries.

PROCEDURE

Male Sprague–Dawley rats weighing 180–240 g receive the test compound or the vehicle (controls) by oral, intraperitoneal, or intravenous administration. After the end of the absorption time (i.p. 30 min, p.o. 60 min, i.v. variable), the animals are anesthetized by intraperitoneal injection of 60 mg/kg pentobarbital sodium. Rats are placed on an electrically warmed table at 37°C.

The abdomen is opened by a midline incision, and the mesentery is lifted to display the mesenteric

arteries. The mesentery is draped over a plastic plate and superfused continuously with Tyrode solution maintained at 37°C. Bleeding times are determined with small mesenteric arteries (125–250 μm external diameter) at the junction of mesentery with intestines. Adipose tissue surrounding the vessels is carefully cut with a surgical blade.

Arteries are punctured with a hypodermic needle (25 gauge: 16×5/10 mm). The bleeding time of the mesenteric blood vessels is observed through a microscope at a magnification of 40×. The time in seconds is determined from the puncturing until the bleeding is arrested by a hemostatic plug.

EVALUATION

1. Mean values of bleeding times [s] are determined for each dosage group (4–6 animals, 4–6 punctures each) and compared to the controls.
2. The significance of the results is assessed with the unpaired Student's *t*-test.
3. The percent prolongation of bleeding time in dosage groups relative to the vehicle controls is calculated.

For further details on methods and evaluations of various mechanisms or agents, see the following: Butler et al. (1982), Dejana et al. (1979), and Zawilska et al. (1982).

11.5.3 Template Bleeding Time Method

PURPOSE AND RATIONALE

The template bleeding time method is used to produce a standardized linear incision into the skin of humans to detect abnormalities of primary hemostasis due to deficiencies in the platelet or coagulation system. The method has been modified with the development of a spring-loaded cassette with two disposable blades (Simplate II, Organon Teknika, Durham, NC). These template devices ensure reproducibility of length and depth of dermal incisions. Forsythe and Willis (1989) described a method that enables the Simplate technique as a method to analyze the bleeding time in the oral mucosa of dogs.

PROCEDURE

The dog is positioned in sternal or lateral recumbency. A strip of gauze is tied around both the mandible and maxilla as a muzzle. The template device is placed evenly against the buckle mucosa, parallel to the lip margin, and triggered. Simultaneously, a stopwatch is started. Blood flow from the incision is blotted using circular filter paper (Whatman No. 1, Fisher Scientific Co., Clifton, NJ) held directly below, but not touching the wounds. The position of the filter paper is changed every 15 s. The endpoint for each bleeding is determined when the filter paper no longer develops a red crescent.

EVALUATION

The time from triggering the device until blood no longer appears on the paper is recorded as the bleeding time. The normal range lies between 2 and 4 min.

CRITICAL ASSESSMENT OF THE METHOD

The template bleeding time varies considerably between laboratories as well as between species and strains. Therefore, it is important to perform the incisions and the blotting in an identical fashion. Prolonged bleeding times in dogs have been recognized with thrombocytopenia, von Willebrand disease, uremia, treatment with aspirin, anticoagulants, and dextran (Forsythe and Willis 1989; Klement et al. 1998). Brassard and Meyers (1991) describe the buckle mucosa bleeding time as a test that is sensitive to platelet adhesion and aggregation deficits. Generally, results of antithrombotic drugs in bleeding time models in animals do not exactly predict bleeding risks in clinical situations. But the models allow comparison between drugs with different actions (Dejana et al. 1979; Lind 1991).

MODIFICATIONS OF THE METHOD

The Simplate device can also be used to perform incisions at the shaved inner ear of rabbits taking care to avoid major vessels. The normal range of bleeding

time in anesthetized rabbits is approximately 100 s (77 ± 4 s, $n = 20$) in our own laboratory.

Klement et al. (1998) described another ear bleeding model in anesthetized rabbits. The shaved ear was immersed in a beaker containing saline at 37°C. Five full-thickness cuts were made with a no. 11 Bard-Parker scalpel blade avoiding major vessels, and the ear was immediately reimmersed in saline. At different times thereafter (5–30 min), aliquots of the saline solution were removed, red cells were sedimented and lysed, and cyanohemoglobin was determined as a measure of blood loss. In this study, hirudin produced more bleeding than standard heparin.

A cuticle bleeding time (toenail bleeding time) measurement in dogs has been described by Giles et al. (1982). A guillotine-type toenail clipper is used to sever the apex of the nail cuticle. A clean transection of the nail is made just into the quick to produce a free flow of blood. The nail is left to bleed freely. The time until bleeding stops is recorded as the bleeding time. Several nails can be cut at one time to ensure appropriate technique. The normal range lies between 2 and 8 min.

11.6 Genetic Models of Hemostasis and Thrombosis

PURPOSE AND RATIONALE

Recent advances in genetic molecular biology have provided tools allowing scientists to design genetically altered animals that are deficient in certain proteins involved in thrombosis and hemostasis (so-called knockouts, or "nulls") (Carmeliet and Collen 1999; Pearson and Ginsburg 1999). These animals have been extremely useful for identifying and validating novel targets for therapeutic intervention. That is, by examining the phenotype (e.g., spontaneous bleeding, platelet defect, prolonged bleeding after surgical incision, etc.) of a specific knockout strain, scientists can identify the role of the knocked out protein. Then, if the phenotype is favorable (e.g., not lethal), pharmacological agents can be designed to mimic the knockout. More recently, novel gene medicine approaches have also benefited greatly from the availability of these models, as discussed below. The following section briefly summarizes some of the major findings in thrombosis and hemostasis using genetically altered mice and concludes with an example of how these models have been used in the drug discovery process. The majority of these gene knockouts result in mice that develop normally, are born in the expected Mendelian ratios, and are viable as defined by the ability to survive to adulthood. Although seemingly normal, these knockout mice display alterations in hemostatic regulation, especially when challenged. Deletion of FVIII, FIX, vWF, and β_3 integrin (Bi et al. 1996; Denis et al. 1998; Hodivala-Dilke et al. 1999; Wang et al. 1997) results in mice that bleed upon surgical challenge, and despite some minor differences in bleeding susceptibility, these mouse knockout models mirror the human disease states quite well (hemophilia A, hemophilia B, von Willebrand disease, and Glanzmann thrombasthenia, respectively). In addition, deletion of some hemostatic factors results in fragile mice with severe deficiencies in their ability to regulate blood loss. Prenatally, these mice appear to develop normally but are unable to survive the perinatal period due to severe hemorrhage, in most cases due to the trauma of birth.

Genetic knockouts have also been useful in dissecting the role of individual signaling proteins in platelet activation. Deletion of the β_3 integrin (Hodivala-Dilke et al. 1999) or of $G_{\alpha q}$ (Offermanns et al. 1997) results in dramatic impairment of agonist-induced platelet aggregation. Alteration of the protein-coding region in the β_3 integrin carboxy tail, β_3-DiY, at sites that are thought to be phosphorylated upon platelet activation also results in unstable platelet aggregation (Law et al. 1999). Deletion of various receptors

such as thromboxane A_2, P-selectin, P2Y1, and PAR-3 demonstrates diminished responses to some agonists while other platelet responses are intact (Thomas et al. 1998; Subramaniam et al. 1996; Leon et al. 1999; Kahn et al. 1998). Deletion of PAR-3, another thrombin receptor in mice, has little effect on hemostasis. This indicated the presence of yet another thrombin receptor in platelets and led to the identification of PAR-4 (Kahn et al. 1998).

Given that knockouts of prothrombotic factors yield mice with bleeding tendencies, it follows that deletion of factors in the fibrinolytic pathway results in increased thrombotic susceptibility in mice. Plasminogen (Bugge et al. 1995; Ploplis et al. 1995), tissue plasminogen activator (t-PA), urokinase-type plasminogen activator (u-PA), and combined t-PA/u-PA knockout (Carmeliet et al. 1994) result in mice that demonstrate impaired fibrinolysis, susceptibility for thrombosis, vascular occlusion, and tissue damage due to fibrin deposition. Interestingly, due to fibrin formation in the heart, these mice may provide a good model of myocardial infarction and heart failure caused by thrombosis (Christie et al. 1999). Intriguingly, mice deficient in PAI-1, the primary inhibitor of plasminogen activator, demonstrate no spontaneous bleeding and a greater resistance to venous thrombosis due to a mild fibrinolytic state (Carmeliet et al. 1993), suggesting that inhibition of PAI-1 might be a promising approach for novel antithrombotic agents.

In addition to their role in the regulation of hemostasis, several of these genes are important in embryonic development. For example, deletion of tissue factor (Bugge et al. 1996a; Toomey et al. 1996; Carmeliet et al. 1996), tissue factor pathway inhibitor (Huang et al. 1997), or thrombomodulin (Healy et al. 1995) results in an embryonic lethal phenotype. These and other (Connolly et al. 1996; Cui et al. 1996) hemostatic factors also appear to contribute to vascular integrity in the developing embryo. These data suggest that initiation of coagulation and generation of thrombin is important at a critical stage of embryonic development, yet other factors must contribute since some of these embryos are able to progress and survive to birth.

Clearly, genetically altered mice have provided valuable insight into the roles of specific hemostatic factors in physiology and pathophysiology. Results of these studies have provided rationale and impetus for attacking certain targets pharmacologically. These types of models have also provided excellent model systems for studying novel treatments for human diseases. For example, these models provided exceptional systems for studying gene therapy for hemophilia. Specifically, deletion of FIX, generated by specific deletions in the FIX gene and its promoter, results in mice that mimic the human phenotype of hemophilia B (Lin et al. 1997). When these mice are treated with adenoviral-mediated transfer of human FIX, the bleeding diathesis is fully corrected (Kung et al. 1998). Similarly, selectively bred dogs that have a characteristic point mutation in the sequence encoding the catalytic domain of FIX also have a severe hemophilia B that is phenotypically similar to the human disease (Evans et al. 1989). When adeno-associated virus-mediated canine FIX gene was administered to these dogs intramuscularly, therapeutic levels of FIX were measured for up to 17 months (Herzog et al. 1999). Clinically relevant partial recovery of whole blood clotting time and APTT was also observed over this prolonged period. These data provided support for initiating the first study of adeno-associated virus-mediated FIX gene transfer in humans (Kay et al. 2000). Preliminary results from this clinical study provided evidence for expression of FIX in the three hemophilia patients studied and also provided favorable safety data to substantiate studying this therapy at higher doses. Although it is likely that there are differences between the human disease and animal models of hemophilia (or other diseases), it is clear that these experiments have provided pharmacological, pharmacokinetic, and safety data that were extremely useful in developing this approach and designing safe clinical trials.

Gene therapy approaches to rescuing patients with bleeding diatheses are further advanced than gene therapy for thrombotic indications. However, promising preclinical data indicate that local overexpression of thrombomodulin (Waugh et al. 1999a) or tissue plasminogen activator (Waugh et al. 1999b) inhibits thrombus formation in a rabbit model of arterial thrombosis. Similarly, local gene transfer of tissue factor pathway inhibitor prevented thrombus formation in balloon-injured porcine carotid arteries (Zoldhelyi et al. 2000). These and other studies (Vassalli and Dichek 1997) suggest that novel gene therapy approaches will also be effective for thrombotic indications, but these treatments will need to be carefully

optimized for pharmacokinetics, safety, and efficacy in laboratory animal studies prior to administration to humans.

11.6.1 Genetically Modified Animals

Development and application of animal models of thrombosis has played a crucial role in discovering and validating novel drug targets, selecting new agents for clinical evaluation, and providing dosing and safety information for clinical trials. In addition, these models have provided valuable information regarding the mechanisms of these new agents and the interactions between antithrombotic agents that work by different mechanisms. The development and application of small and large animal models of thrombosis to the discovery and development of novel antithrombotic agents is described in this review. The methods and major issues regarding the use of animal models of thrombosis, such as positive controls, appropriate pharmacodynamic markers of activity, safety evaluation, species specificity, and pharmacokinetics, are highlighted. Finally, the use of genetic models of thrombosis/hemostasis is presented using gene therapy for hemophilia as an example of how animal models have aided in the development of therapies that are presently being evaluated clinically.

11.6.2 Knockout Mice

PURPOSE AND RATIONALE

Genetically modified animals, in particular knockout mice, help to understand the role of various factors in blood clotting, thrombolysis, and platelet function. They are useful to verify the mode of action of new drugs.

11.6.2.1 Factor I (Fibrinogen)

Phenotype

Born in normal appearance, ~10% die shortly after birth and another 40% around 1–2 months after birth due to bleeding, failure of pregnancy, blood samples fail to clot, or support platelet aggregation in vitro (Suh et al. 1995).

References and Further Reading

11.6.2.2 Factor II (Prothrombin)

Phenotype

Partial embryonic lethality: 50% between embryonic day (E) 9.5–11.5; at least 1/4 survive to term, but fatal hemorrhage few days after birth; factor II is important in maintaining vascular integrity during development as well as postnatal life (Sun et al. 1998; Xu et al. 1998).

11.6.3 Factor V

Phenotype

Half of the embryos die at E9–10, possibly as a result of abnormal yolk sac vasculature; the remaining 50% progress normally to term but die from massive hemorrhage within 2 h of birth, more severe in mouse than in human (Cui et al. 1996; Yang et al. 2000a).

11.6.3.1 Factor VII

Phenotype

Develop normally but suffer fatal perinatal bleeding (Rosen et al. 1997).

References and Further Reading

Rosen ED, Chan JCY, Idusogie E, Clotman F, Vlasuk G, Luther T, Jalbert LR, Albrecht S, Zhong L, Lissens A, Schoonjans L, Moons L, Collen D, Castellino FJ, Carmeliet P (1997) Mice lacking factor VII develop normally but suffer fatal perinatal bleeding. Nature 390:290–294

11.6.3.2 Factor VIII

Phenotype

Mild phenotype compared with severe hemophilia A in humans; no spontaneous bleeding, illness, or reduced activity during the first year of life; have residual clotting activity (APTT) as shown by Bi et al. (1995).

References and Further Reading

Bi L, Lawler AM, Antonarakis SE, High KA, Gearhart JD, Kazaazian HH (1995) Targeted disruption of the mouse factor VIII gene produces a model of haemophilia A. Nat Genet 10:119–121

11.6.3.3 Factor IX

Phenotype

Factor IX coagulant activities (APTT): +/+ 92%, +/− 53%, −/− <5%; bleeding disorder (extensive bleeding after clipping a portion of the tail, bleeding to death if not cauterized (Kundu et al. 1998; Wang et al. 1997).

References and Further Reading

11.6.3.4 Factor X

Phenotype

Partial embryonic lethality (1/3 died on E11.5–12.5); fatal neonatal bleeding between postnatal day (P) 5–20 as shown by Dewerchin et al. (2000).

References and Further Reading

Dewerchin M, Liang Z, Moons L, Carmeliet P, Castellino FJ, Collen D, Rosen ED (2000) Blood coagulation factor X deficiency causes partial embryonic lethality and fatal neonatal bleeding in mice. Thromb Haemost 83:185–190

11.6.3.5 Factor XI

Phenotype

APTT prolonged in −/− (158–200 s) compared with +/+ (25–34 s) and +/− (40–61 s); no factor XI activity and antigen did not result in intrauterine death, −/− similar bleeding as +/+ with a tendency to prolongation (Gailani et al. 1997).

References and Further Reading

Gailani D, Lasky NM, Broze GJ (1997) A murine model of factor XI deficiency. Blood Coagul Fibrinolysis 8:134–144

11.6.3.6 TF (Tissue Factor)

Phenotype

Abnormal circulation from yolk sac to embryo∼E8.5 leading to embryo wasting and death; TF has a role in blood vessel development (Bugge et al. 1996a; Carmeliet et al. 1996; Toomey et al. 1996, 1997).

11.6.3.7 TFPI (Tissue Factor Pathway Inhibitor)

Phenotype

None survive the neonatal period; 60% die between E9.5 and 11.5 with signs of yolk sac hemorrhage (Huang et al. 1997).

References and Further Reading

Huang ZF, Higuchi D, Lasky N, Broze GJ (1997) Tissue factor pathway inhibitor gene disruption produces intrauterine lethality in mice. Blood 90:944–951

11.6.3.8 Thrombin Receptor

Phenotype

Fifty percent die at E9–10; 50% survive and become grossly normal adult mice with no bleeding diathesis; −/− platelets strongly respond to thrombin; −/− fibroblast lose their ability to respond to thrombin→second TR must exist as shown by Connolly et al. (1996) and by Darrow et al. (1996).

References and Further Reading

11.6.3.9 Thrombomodulin

Phenotype

Embryonic lethality before development of a functional cardiovascular system; die before E9.5 due to retardation of growth; TM+/− mice develop normal without thrombotic complications (Christie et al. 1999; Healy et al. 1995, 1998; Weiler-Guettler et al. 1998).

11.6.3.10 Protein C

Phenotype

KO mice appeared to develop normally macroscopically but possessed obvious signs of bleeding and thrombosis; did not survive beyond 24 h after delivery; microvascular thrombosis in the brain and necrosis in the liver; plasma clottable fibrinogen was not detectable suggesting fibrinogen depletion and secondary consumptive coagulopathy (Jalbert et al. 1998).

References and Further Reading

Jalbert LR, Rosen ED, Moons L, Chan JCY, Carmeliet P (1998) Inactivation of the gene for anticoagulant protein C causes lethal perinatal consumptive coagulopathy in mice. J Clin Invest 102:1481–1488

11.6.3.11 Plasminogen

Phenotype

Severe spontaneous thrombosis; reduced ovulation and fertility; cachexia and shorter survival; severe glomerulonephritis; impaired skin healing; reduced macrophage and keratinocyte migration (Bugge et al. 1995; Ploplis et al. 1995).

References and Further Reading

Bugge TH, Flick MJ, Daugherty CC, Degen JL (1995) Plasminogen deficiency causes severe thrombosis but is compatible with development and reproduction. Genes Dev 9:794–807

11.6.3.12 Alpha$_2$-Antiplasmin

Phenotype

Normal fertility, viability, and development; no bleeding disorder; spontaneous lysis of injected clots→enhanced fibrinolytic potential; significant reduction of renal fibrin deposition after LPS (Lijnen et al. 1999).

References and Further Reading

Lijnen HR, Okada K, Matsuo O Collen D, Dewerchin M (1999) alpha$_2$-antiplasmin gene deficiency in mice is associated with enhanced fibrinolytic potential without overt bleeding. Blood 93:2274–2281

11.6.3.13 T-PA (Tissue-Type Plasminogen Activator)

Phenotype

Extensive spontaneous fibrin deposition; severe spontaneous thrombosis; impaired neointima formation; reduced ovulation and fertility; cachexia and shorter survival; severe glomerulonephritis; abnormal tissue remodelling (Carmeliet et al. 1998; Christie et al. 1999).

References and Further Reading

11.6.3.14 PAI-1 (Plasminogen Activator Inhibitor 1)

Phenotype

Reduced thrombotic incidence; no bleeding; accelerated neointima formation; reduced lung inflammation; reduced atherosclerosis. Detailed studies on PAI-1 are reported by Carmeliet et al. (1993), Eitzman et al. (1996), Erickson et al. (1990), Kawasaki et al. (2000), and Pinsky et al. (1998).

11.6.3.15 Vitronectin

Phenotype

Normal development, fertility, and survival; serum is completely deficient in "serum spreading factor" and plasminogen activator inhibitor 1 binding activities; delayed arterial and venous thrombus formation (Eitzman et al. 2000; Zheng et al. 1995).

References and Further Reading

11.6.3.16 Urokinase, U-PA (Urinary-Type Plasminogen Activator)

Phenotype

Single u-PA deficiency: viable, fertile, normal life span; occasionally spontaneous fibrin deposits in normal and inflamed tissue; higher incidence of endotoxin-induced thrombosis. Combined t-PA and u-PA deficiency: mice survive embryonic development; retarded growth, reduced fertility, shortened life span; spontaneous fibrin deposits more extensively and in more organs (Carmeliet et al. 1998; Heckel et al. 1990).

Transgenic mice carrying the u-PA gene linked to the albumin enhancer/promoter exhibit spontaneous intestinal and intra-abdominal bleeding directly related to transgene expression in the liver and elevated

plasma u-PA levels. Fifty percent die between 3 and 84 h after birth; severe hypofibrinogenemia, loss of clotting function.

11.6.3.17 UPAR (Urinary-Type Plasminogen Activator Receptor)

Phenotype

Phenotype normal; attenuated thrombocytopenia and mortality associated with severe malaria (Bugge et al. 1995, 1996b; Dewerchin et al. 1996; Piguet et al. 2000).

References and Further Reading

Bugge TH, Suh TT, Flick MJ, Daugherty CC, Romer J, Solberg H, Ellis V, Dano K, Degen JL (1995) The receptor for urokinase-type plasminogen activator is not essential for mouse development or fertility. J Biol Chem 270:16886–16894

11.6.3.18 Gas 6 (Growth Arrest–Specific Gene 6 Product)

Phenotype

Mice are viable, fertile, appear normal; do not suffer spontaneous bleeding or thrombosis; and have normal tail bleeding time. Platelets fail to aggregate irreversibly to ADP, collagen, or U 46619. Arterial and venous thrombosis is inhibited and mice are protected from fatal thromboembolism after injection of collagen plus epinephrine (Angelillo-Scherrer et al. 2001).

References and Further Reading

11.6.3.19 GPIbalpha (Glycoprotein Ib Alpha, Part of the GP Ib-V–IX Complex)

Phenotype

Bleeding, thrombocytopenia, and giant platelets (similar to human Bernard Soulier syndrome). See Ware et al. (2000) for details.

References and Further Reading

Ware J, Russell S, Ruggeri ZM (2000) Generation and rescue of a murine model of platelet dysfunction: the Bernard-Soulier syndrome. Proc Natl Acad Sci USA 97:2803–2808

11.6.3.20 GPV (Glycoprotein V, Part of the GP Ib-V–IX Complex)

Phenotype

Increased thrombin responsiveness, GpV−/− platelets are normal in size, normal amounts in GpIb-IX, functional in vWF binding; platelets are hyperresponsive to thrombin→increased aggregation response; shorter bleeding time; →GpV = negative modulator of platelet function (Ramakrishnan et al. 1999).

References and Further Reading

11.6.3.21 Gpiib (Integrin Alpha IIb, Glycoprotein IIb, Part of the GP IIB–IIIa Complex)

Phenotype

Bleeding disorder similar to Glanzmann thrombasthenia in man; platelets failed to bind fibrinogen, to aggregate, and to retract a fibrinogen clot; α-granules do not contain fibrinogen (Tronik-Le Roux et al. 2000).

References and Further Reading

Tronik-Le Roux D, Roullot V, Poujol C, Kortulewski T, Nurden P, Marguerie G (2000) Thrombasthenic mice generated by replacement of the integrin alpha$_{IIb}$ gene: demonstration that transcriptional activation of this megakaryocytic locus precedes lineage commitment. Blood 96:1399–1408

11.6.3.22 GP IIIa (Integrin Beta3, Glycoprotein IIIa, Part of the GP IIb–IIIa Complex)

Phenotype

Viable, fertile, increased fetal mortality; features of Glanzmann thrombasthenia in man, e.g., defective platelet aggregation, clot retraction; spontaneous bleeding, prolonged bleeding times; dysfunctional osteoclasts, development of osteosclerosis with age (Hodivala-Dilke et al. 1999; McHugh et al. 2000).

References and Further Reading

Hodivala-Dilke KM, McHugh KP, Tsakiris DA, Rayburn H, Crowley D (1999) Beta3-integrin-deficient mice are a model for Glanzmann thrombasthenia showing placental defects and reduced survival. J Clin Invest 103:229–238

McHugh KP, Hodivala-Dilke K, Zheng M-H, Namba N, Lam J (2000) Mice lacking beta3 integrins are osteosclerotic because of dysfunctional osteoclasts. J Clin Invest 105:433–440

11.6.3.23 GP IIa (Glycoprotein IIa, Integrin Beta 1, Part of the GP Ia–IIa Complex)

Phenotype

Integrin beta1 null platelets from conditional knockout mice develop normally; platelet count is normal. Collagen-induced platelet aggregation is delayed but otherwise normal; tyrosine phosphorylation pattern is normal but phosphorylation is delayed. Bleeding time in bone marrow chimeric mice is normal; no major in vivo defects (Nieswandt et al. 2001).

References and Further Reading

Nieswandt B, Brakebusch C, Bergmeier W, Schulte V, Bouvard D, Mokhtari-Nejad R, Lindhout T, Heemskerk JWM, Zirngibl H, Faessler R (2001) Glycoprotein VI but not alpha2beta1 integrin is essential for platelet interaction with collagen. EMBO J 20:2120–2130

11.6.3.24 VWF (Von Willebrand Factor)

Phenotype

Factor VIII levels strongly reduced due to defective protection by vWF; highly prolonged bleeding time, hemorrhage, spontaneous bleeding; mice useful for investigating the role of vWF; delayed platelet adhesion in ferric-chloride-induced arteriolar injury (Denis et al. 1998; Ni et al. 2000).

References and Further Reading

11.6.3.25 Thromboxane A2 Receptor (TXA2r)

Phenotype

Mild bleeding disorder and altered vascular responses to TXA2 and arachidonic acid (Thomas et al. 1998).

References and Further Reading

Thomas DW, Mannon RB, Mannon PJ, Latour A, Oliver JA (1998) Coagulation defects and altered hemodynamic responses in mice lacking receptors for thromboxane A2. J Clin Invest 102:1994–2001

11.6.3.26 Prostacyclin Receptor (PGI2r)

Phenotype

Viable, fertile, normotensive; increased susceptibility to thrombosis; reduced inflammatory and pain responses (Murata et al. 1997).

11.6.3.27 References and Further Reading

Murata T, Ushikubi F, Matsuoka T, Hirata M, Yamasaki A (1997) Altered pain reception and inflammatory response in mice lacking prostacyclin receptor. Nature 388:678–682

11.6.3.28 PECAM (Platelet Endothelial Cell Adhesion Molecule)

Phenotype

Normal platelet aggregation; prolonged bleeding time as described by Duncan et al. (1999) and by Mahooti et al. (2000).

References and Further Reading

Duncan GS, Andrew DP, Takimoto H, Kaufman SA, Yoshida H (1999) Genetic evidence for functional redundancy of platelet/endothelial cell adhesion molecule-1 (PECAM-1) CD31-deficient mice reveal PECAM-1-dependent and PECAM-1-independent functions. J Immunol 162: 3022–3030

Mahooti S, Graesser D, Patil S, Newman P, Duncan G, Mak T, Madri JA (2000) PECAM-1 (CD 31) expression modulates bleeding tome in vivo. Am J Pathol 157:75–81

11.6.3.29 Pallid (Pa)

Phenotype

Among 13 hypopigment mouse mutants with storage pool deficiency, the pallid mouse is a model of the human Hermansky-Pudlak syndrome (the beige mouse is a model of the Chediak-Higashi syndrome). Pallid mice exhibit prolonged bleeding time, pigment dilution, kidney lysosomal enzyme elevation serum alpha 1 antitrypsin deficiency, and abnormal otolith formation. The gene defective in pallid mice encodes the highly charged 172-amino-acid protein pallidin that interacts with syntaxin 13, a protein-mediating vesicle docking and fusion (Huang et al. 1999).

References and Further Reading

Huang L, Kuo YM, Gitschier J (1999) The pallid gene encodes a novel, syntaxin 13-interacting protein involved in platelet storage pool deficiency. Nat Genet 23:329–332

11.6.3.30 G Alpha(q) (Guanyl Nucleotide Binding Protein G Alpha Q)

Phenotype

Defective aggregation in response ADP, TXA2, thrombin, collagen; shape change normal (Offermans et al. 1997; Ohlmann et al. 2000).

References and Further Reading

Offermans S, Toombs CF, Hu YH, Simon MI (1997) Defective platelet activation in G alpha(q)-deficient mice. Nature 389:183–186

11.6.3.31 G Z (Member of the Gi Family of G Proteins)

Phenotype

Impaired platelet aggregation to epinephrine; resistance to fatal thromboembolism; exaggerated response to cocaine, reduced effect of morphine and antidepressant drugs (Yang et al. 2000b).

References and Further Reading

Yang J, Wu J, Kowalska MA, Dalvi A, Prevost N, O'Brien PJ, Manning D, Poncz M, Lucki I, Blendy JA, Brass LF (2000) Loss of signaling through G protein, Gz, results in abnormal platelet activation and altered responses to psychoactive drugs. Proc Natl Acad Sci USA 97:9984–9989

11.6.3.32 Phospholipase C Gamma

Phenotype

Viable, fertile, decreased mature B cells; defective B cell and mast cell function; defective Fcgamma receptor signaling, therefore, loss of collagen-induced platelet aggregation (Wang et al. 2000).

References and Further Reading

Wang D, Feng J, Wen R, Marine JC, Sangster MY, Parganas E, Hoffmeyer A, Jackson CW, Cleveland JL, Murray PJ, Ihle JN (2000) Phospholipase Cgamma2 is essential in the functions of B cell and several Fc receptors. Immunity 13:25–35

11.6.3.33 CD39 (Vascular Adenosine Triphosphate Diphosphohydrolase)

Phenotype

Viable, fertile; prolonged bleeding times but minimally perturbed coagulation parameters; reduced platelet interaction with injured mesenteric vasculature in vivo. Platelets fail to aggregate to standard agonists in vitro associated with purinergic P2Y1 receptor desensitization; fibrin deposition at multiple organ sites (Enjyoji et al. 1999).

References and Further Reading

Enjyoji K, Sevigny J, Lin Y, Frenette PS, Christie PD (1999) Targeted disruption of cd39/ATP diphosphohydrolase results in disordered hemostasis and thromboregulation. Nat Med 5:1010–1017

11.6.3.34 Protein Kinase, cGMP-Dependent, Type 1

Phenotype

Viable, fertile; unresponsive to cGMP and NO; defective VASP-phosphorylation; increased adhesion and aggregation of platelets in vivo in ischemic/reperfused mesenteric microcirculation; no compensation by cAMP kinase system (Massberg et al. 1999).

References and Further Reading

Massberg S, Sausbier M, Klatt P, Bauer M, Pfeifer A, Siess W, Faessler R, Ruth P, Krombach F, Hofmann F (1999) Increased adhesion and aggregation of platelets lacking cyclic guanosine 3′,5′-monophosphate kinase I. J Exp Med 189:1255–1264

11.6.3.35 Vasodilator-Stimulated Phosphoprotein (VASP)

Phenotype

Viable, fertile; mild platelet dysfunction with megakaryocyte hyperplasia, increased collagen/thrombin activation, impaired cyclic nucleotide–mediated inhibition of platelet activation (Aszodi et al. 1999; Hauser et al. 1999).

References and Further Reading

Aszodi A, Pfeifer A, Ahmad M, Glauner M, Zhou XH, Ny L, Andersson KF, Kehrel B, Offermanns S, Faessler R (1999) The vasodilator-stimulated phosphoprotein (VASP) is involved in cGMP- and cAMP-mediated inhibition of agonist-induced platelet aggregation, but is dispensable for smooth muscle function. 11.6.3.36 Arachidonate 12-Lipoxygenase (P-12LO)

Phenotype

Platelets exhibit a selective hypersensitivity to ADP, manifested as a marked increase in slope and percent aggregation in ex vivo assays and increased mortality in an ADP-induced mouse model of thromboembolism (Chen et al. 1994; Johnson et al. 1998).

References and Further Reading

11.6.3.37 Arachidonate 5-Lipoxygenase (P-5LO)

Phenotype

Develop normally and are healthy. No difference in their reaction to endotoxin shock; however resist the lethal effects of shock induced by platelet-activating factor. Inflammation induced by arachidonic acid is markedly reduced (Chen et al. 1994; Johnson et al. 1998).

References and Further Reading

11.6.3.38 Thrombopoietin

Phenotype

TPO −/− and c-mpl −/−: both exhibit a 90% reduction in megakaryocyte and platelet levels; but even with these small platelet levels, the mice do not have excessive bleeding; all platelets which are present are morphologically normal+functionally; in vivo TPO is required for control of megakaryocyte and platelet number but not for their maturation (Lawler et al. 1998).

References and Further Reading

11.6.3.39 Thrombospondin-1

Phenotype

Normal thrombin-induced platelet aggregation; increase in circulating number of white blood cells; TSP-1 is involved in normal lung homeostasis (Lawler et al. 1998).

11.7 Critical Issues in Experimental Models

11.7.1 The Use of Positive Control

Clearly, there are many antithrombotic agents that can be used to compare and contrast the antithrombotic efficacy and safety of novel agents. The classic antithrombotic agents are heparin, warfarin, and aspirin. However, new, more selective agents such as hirudin, low-molecular-weight heparins, and clopidogrel are commercially available that will either replace or augment these older treatments. Novel antithrombotic agents should certainly be demanded to demonstrate better efficacy than currently available therapy in animal models of thrombosis. This should be demonstrated by performing dose–response experiments that include maximally effective doses of each compound in the model. At the maximally effective dose, parameters such as APTT, PT, template bleeding time, or other more sensitive measurements of systemic hypocoagulability or bleeding should be compared. A good example of this approach is a study by Schumacher et al. (1996b), who compared the antithrombotic efficacy of argatroban and dalteparin in arterial and venous models of thrombosis. Consideration of potency and safety compared to other agents should be taken into account when advancing a drug through the testing funnel.

The early in vivo evaluation of compounds that demonstrate acceptable in vitro potency and selectivity requires evaluation of each compound alone in order to demonstrate antithrombotic efficacy. The antithrombotic landscape is becoming complicated by so many agents from which to choose that it

will become increasingly difficult to design preclinical experiments that mimic the clinical setting in which polyantithrombotic therapy is required for optimal efficacy and safety. Consequently, secondary and tertiary preclinical experiments will need to be carefully designed in order to answer these specific, important questions.

11.7.2 Evaluation of Bleeding Tendency

Although the clinical relevance of animal models of thrombosis has been well established in terms of efficacy, the preclinical tests for evaluating safety, i.e., bleeding tendency, have not been as predictable. The difficulty in predicting major bleeding, such as intracranial hemorrhage, resulting from antithrombotic or thrombolytic therapy stems from the complexity and lack of understanding of the mechanisms involved in this disorder. Predictors of anticoagulant-related intracranial hemorrhages are advanced age, hypertension, intensity and duration of treatment, head trauma, and prior neurologic disease (Stieg and Kase 1998; Sloan and Gore 1992). These risk factors are clearly difficult, if not impossible, to simulate in laboratory animals. Consequently, more general tests of anticoagulation and primary hemostasis have been employed.

Coagulation assays provide an index of the systemic hypocoagulability of the blood after administration of antithrombotic agents; however, as indicated earlier, the sensitivity and specificity of these assays varies from compound-to-compound so these assays do not provide a consistent safety measure across all mechanisms of inhibition. Consequently, many laboratories have attempted to develop procedures that provide an indication of bleeding risk by evaluating primary hemostasis after generating controlled incisions in anesthetized animals. Some of the tests used in evaluating FXa inhibitors include template bleeding time, tail transection bleeding time, cuticle bleeding time, and evaluation of clinical parameters such as hemoglobin and hematocrit. Unfortunately, template bleeding tests, even when performed in humans, have not been good predictors of major bleeding events in clinical trials (Bernardi et al. 1993; Bick 1995; Rodgers and Levin 1990). However, these tests have been able to demonstrate relative advantages of certain mechanisms and agents over others. For example, hirudin, a direct thrombin inhibitor, appears to have a narrow therapeutic window when used as an adjunct to thrombolysis in clinical trials, producing unacceptable major bleeding when administered at 0.6 mg/kg i.v. bolus plus 0.2 mg/kg/h (Antman et al. 1996; GUSTO Investigators 1996). When the dose of hirudin was adjusted to avoid major bleeding (0.1 mg/kg and 0.1 mg/kg/h), no significant therapeutic advantage over heparin was observed. If the relative improvement in the ratio between efficacy and bleeding observed preclinically with Xa inhibitors compared to thrombin inhibitors such as hirudin is supported in future clinical trials, this will establish an important safety advantage for FXa inhibitors and provides valuable information for evaluating the safety of new antithrombotic agents in preclinical experiments.

11.7.3 Selection of Models Based on Species-Dependent Pharmacology/Physiology

As alluded to earlier, species selection for animal models of disease is often limited by the unique physiology of a particular disease target in different species or by the species specificity of the pharmacological agent for the target. For example, it was discovered relatively early in the development of platelet GPIIb/IIIa antagonists that these compounds were of limited use in rats (Cox et al. 1992) and that there was a dramatic species-dependent variation in the response of platelets to GPIIb/IIIa antagonists (Bostwick et al. 1996; Cook et al. 1993; Panzer-Knodle et al. 1993). This discovery leads to the widespread use of larger animals (particularly in dogs, whose platelet response to GPIIb/IIIa antagonists resembles humans) in the evaluation of GPIIb/IIIa antagonists. Of course, the larger animals required more compound for evaluation, which created a resource problem for medicinal chemists. This was especially problematic for companies that generated compounds by combinatorial parallel synthetic chemistry in which many compounds can be made, but usually in very small quantities. However, some pharmacologists devised clever experiments that partially overcame this problem. Cook et al. (1996) administered a GPIIb/IIIa antagonist orally and intravenously to rats and then mixed the platelet-rich plasma from the treated rats with platelet-rich plasma from untreated dogs. The mixture was then evaluated in an agonist-induced platelet aggregation assay, and the resulting inhibition of canine platelet aggregation (rat platelets were relatively unresponsive to this GPIIb/IIIa antagonist) was due to the drug present in the plasma obtained from the rat. Using this method, only a small amount of drug is required to determine the relative bioavailability in rats. However, the animal models chosen for efficacy in that report (guinea pigs and dogs) were selected based on their favorable platelet response to the GPIIb/IIIa antagonist.

Similarly for inhibitors of FXa, there are significant variations in the activity of certain compounds against FXa purified from plasma of different species and in plasma-based clotting assays using plasma from different species. DX-9065 is much more potent against human FXa ($Ki = 78$ nM) than against rabbit ($Ki = 102$ nM) and rat ($Ki = 1980$ nM) FXa. Likewise, in the PT assay, DX-9065a was very potent in human plasma (concentration required to double PT, PTx2, was 0.52 μM) and in squirrel monkey plasma ($PTx2 = 0.46$μM) but was much less potent in rabbit, dog, and rat plasma ($PTx2 = 1.5$, 6.5, and 22.2 μM, respectively). Other FXa inhibitors have also demonstrated these species-dependent differences in activity (Tidwell et al. 1980; Nutt et al. 1991; Taniuchi et al. 1998). Regardless, the investigator must be aware of these differences so that appropriate human doses can be extrapolated from the laboratory animal studies.

Although in many cases the exact mechanism for the species-dependent differences in response to certain therapeutic agents remains unclear, these differences must be examined to determine the appropriate species to be used for preclinical pharmacological evaluation of each agent. This evaluation can routinely be performed by in vitro coagulation or platelet aggregation tests prior to evaluation in animal models.

11.7.4 Selection of Models Based on Pharmacokinetics

Much debate surrounds the issue as to which species most resembles humans in terms of gastrointestinal absorption, clearance, and metabolism of therapeutic agents. Differences in gastrointestinal anatomy, physiology, and biochemistry between humans and commonly used laboratory animals suggest that no single animal can precisely mimic the gastrointestinal characteristics of humans (Kararli 1995). Due to resource issues (mainly compound availability) and animal care and use considerations, small rodents, such as rats, are usually considered for primary in vivo evaluation of pharmacokinetics for novel agents. However, there is great reservation about moving a compound into clinical trials based on oral bioavailability data derived from rat experiments alone. Usually, larger animals such as dogs or nonhuman primates, which have similar gastrointestinal morphology compared to humans, are the next step in the evaluation of pharmacokinetics of new agents. The pharmacokinetic characteristics of FXa inhibitor, YM-60828, have been studied extensively in a variety of laboratory animals. YM-60828 demonstrated species-dependent pharmacokinetics, with oral bioavailability estimates of approximately 4, 33, 7, and 20% in rats, guinea pigs, Beagle dogs, and squirrel monkeys, respectively. Although these results suggest that YM-60828 has somewhat limited bioavailability, evaluating the pharmacokinetic profile of novel agents in a number of species (Sanderson et al. 1998) is a well-established approach used to aid in identifying compounds for advancement to human testing. That is, acceptable bioavailability in a number of species suggests that a compound will be bioavailable in humans. Which of the laboratory species adequately represents the bioavailability of a specific compound in humans can only be determined after appropriate pharmacokinetic evaluation in humans. Nevertheless, preclinical pharmacokinetic data are important in selecting the appropriate animal model for testing the antithrombotic efficacy of compounds because the ultimate proof-of-concept experiment is to demonstrate efficacy by the intended route of administration.

11.7.5 Clinical Relevance of Data Derived from Experimental Models

Animal models of thrombosis have played a crucial role in the discovery and development of a number of compounds that are now successfully being used for the treatment and prevention of thrombotic diseases. The influential preclinical results using novel antithrombotics in a variety of laboratory animal experiments are listed in the table below, along with the early clinical trials and results for each compound. This table intentionally omits many compounds that were tested in animal models of thrombosis but failed to be successful in clinical trials or, for other reasons, did not become approved drugs. However, these negative outcomes would not have been predicted by animal models of thrombosis because the failures were generally due to other shortcomings of the drugs (e.g., toxicity, narrow therapeutic window, or undesirable pharmacokinetics or pharmacodynamics) that are not always clearly presented in the scientific literature due to proprietary restrictions in this highly competitive field.

Nonetheless, it is clear that animal models have supplied valuable information for investigators responsible for evaluating these drugs in humans, providing pharmacodynamic, pharmacokinetic, and safety data that can be used to design safe and efficient clinical trials. For detailed applications, see the following references: Bugge et al. (1995), Bugge et al. (1996a), Carmeliet et al. (1993), Carmeliet et al. (1994), Carmeliet et al., (1996), Christie et al. Animal models of thrombosis and their clinical correlates

Compound	Preclinical animal model	Preclinical results	Reference	Clinical indication	Clinical result	Reference
Recombinant tissue plasminogen activator (activase)	Rabbit pulmonary artery thrombosis	Lysis of preformed pulmonary thrombus	Matsuo et al. (1981)	Acute myocardial infarction—thrombolysis	Improved recanalization	Collen et al. (1984)
Abciximab (ReoPro)	Canine coronary cyclic flow reduction (Folts et al. 1991)	Significant inhibition of platelet-dependent thrombosis	Coller et al. (1986)	High-risk coronary angioplasty	Reduction in death, myocardial infarction, refractory ischemia, or unplanned revascularization	EPIC Investigators (1994)
Tirofiban (aggrestat)	Canine coronary cyclic flow reduction (Folts et al. 1991)	Significant inhibition of platelet-dependent thrombosis	Lynch et al. (1995)	Unstable angina	Reduction in death, myocardial infarction, refractory ischemia	Prism Investigators (1998)
Eptifibitide (Integrilin)	TPA-induced coronary thrombolysis	Significant improvement in lysis of occlusive thrombus	Nicolini et al. (1994)	Acute myocardial infarction—thrombolysis with tPA	Improvement in incidence and speed of reperfusion	Ohman et al. (1997)
Enoxaparin (Lovenox)	Canine coronary cyclic flow reduction (Folts et al. 1991)	Significant inhibition of platelet-dependent thrombosis	Leadley et al. (1998)	Unstable angina	Significant decrease in death, myocardial infarction, and need for revascularization at 30 days	Cohen et al. (1998)
Hirudin (Refludan)	Rabbit jugular vein thrombus growth	Inhibition of thrombus growth compared to standard heparin	Agnelli et al. (1990)	Deep vein thrombosis after total hip replacement	Significantly decreased rate of DVT	Eriksson et al. (1997)
Argatroban	Canine coronary artery electrolytic injury (TPA-induced thrombolysis)	Accelerated reperfusion and prevented reocclusion	Fitzgerald et al. (1989)	Unstable angina	No episodes of MI during drug infusion	Gold et al. (1993)

12.1 General Considerations

Ocular drugs, cosmetics, or all chemicals which can come in contact with the eye carry the potential of harming various ocular structures. Thus, their possible toxic effects on ocular structures must be evaluated in tests before use in humans.

At present, it has been suggested that this be done in three steps. First, a thorough review of the literature of similar compounds should be conducted to obtain theoretical knowledge about ocular toxicity. Second, tests of this substance are performed in various in vitro procedures to obtain possible serious toxic effects, which might stop further testing. Third, if no serious toxic effects have been observed, tests are conducted in the eyes of one animal followed by subsequent tests in more animals. Fourth, the substance of an ocular drug will then be subjected to clinical trials. An important feature of these preclinical tests is that they correctly predict or are in agreement with findings in humans. A recent study reviewed the principles and the available evidence that support the design and conduct of preclinical studies in a way that permits effective and safe first-dose studies of potential new medicines in humans (Greaves 2004). Another study concluded that there is indeed a relatively good agreement between certain preclinical and clinical observations (Dart 2003).

A comprehensive review of various in vitro and in vivo procedures was published by Wilhelmus in 2001.

12.2 Dendritic Cell Culture

PURPOSE AND RATIONALE

This test uses an in vitro human dendritic cell culture to obtain information of the potential for various chemicals to induce allergic contact dermatitis. This test is used as an alternative to the local lymph node assay (LLNA) to minimize or replace the use of live animal testing for predicting skin sensitization (Kimber et al. 2002, see below). The test allows for evaluation of skin sensitization by examining the presence of cell surface markers on peripheral blood mononuclear cell (PBMC)-derived dendritic cells (DC) that are known to be involved in the development of allergic contact dermatitis.

PROCEDURE

The method contains three stages including first establishing a cell line, followed by test chemical exposure, and finally evaluating for expression of cell surface markers. To establish a cell line, human leukocyte preparations are attained from a plasma distributor. The leukocyte preparations, as described by Ryan et al. (2004), are diluted with an equal part of complete medium (RPMI 1640 containing 1 × L-glutamine 1 × penicillin-streptomycin-neomycin antibiotic mixture), 30 μ2-mercaptoethanol, and 10% heat-inactivated fetal bovine serum. The diluted preparation is layered onto a Ficoll-Paque gradient to attain the PBMC. According to protocol, the PBMC concentration is adjusted with complete medium, and a proportion of the cell suspension is plated in T75 flasks and incubated for 2 h at 37°C/CO_2. Nonadherent cells are removed and discarded. A mixture containing 10 mL complete medium with 10 ng/mL granulocyte/macrophage colony-stimulating factor (GM-CSF) and interleukin-4 (IL-4) is added to the adherent cells remaining in the flask. The flasks are incubated for 48 h at 37 °C/CO_2. Following incubation, the cells are collected, centrifuged, and resuspended in fresh complete medium containing GM-CSF and IL-4 for another incubation for 72 h. Residual T cells and B cells are removed from the cultures on day 5 by two passages over CD2 (pan T cell) and CD19 (pan B cell) immunomagnetic beads. The T- and B-cell-depleted DC are resuspended in fresh cytokine containing complete medium, replated, and incubated for 48 h.

The prepared cell line is collected on the seventh day, washed, resuspended in complete medium containing GM-CSF and IL-4 and 2 mL, and plated in the wells of a six-well culture plate. One milliliter of test chemical also prepared in complete medium with GM-CSF and IL-4 is added to each well, and the plate is incubated for 24 h. Viability of the DC after test chemical exposure is then assessed by propidium iodide dye exclusion using a Coulter Epics XL flow cytometer (Ryan et al. 2004).

EVALUATION

Measurement of cell surface marker expression by flow cytometry after exposure to chemical allergens has been previously established by Ryan et al. (2004). Expression is assessed by flow cytometry using saturating concentrations of fluorochrome-conjugated monoclonal antibodies such as CD86-fluorescein isothiocyanate (FITC), CD83-FITC, CD40-phycoerythrin (PE), CD54-PE, CD80-FITC, and CD1a-FITC. The measurement of the flow cytometer represents the fluorescence intensities of the surface markers. Single parameter histograms are produced and analyzed for changes in mean fluorescence intensity (MFI) of allergen-treated DC as a percentage of the MFI of an untreated control DC (Ryan et al. 2004).

CRITICAL ASSESSMENT OF THE METHOD

Cytotoxicity may decrease cell surface expression and transcription of markers. Thus, if concentration of test chemical induces low cell viability, then measurement of cell surface expression and transcription is limited. In addition, donor variability may introduce differences in fluorochrome-conjugated monoclonal antibody expression (Aiba et al. 1997).

PBMC-derived DC serve as a surrogate marker for Langerhans cells (LC), and the chemical allergen-induced changes in cell surface markers of DC produce a similar pattern to those that occur in LC which are the antigen-presenting cell in the skin that plays a key role in the development of allergic contact dermatitis (Ryan et al. 2005).

MODIFICATION OF THE METHOD
The fluorochrome-conjugated monoclonal antibodies used may be varied. Investigation on one, a combination, or all may be performed. In addition, RNA isolation to confirm the quality of RNA and GeneChip microarray for transcript profiling may be performed after flow cytometry evaluation.

12.3 Murine Local Lymph Node Assay

PURPOSE AND RATIONALE
This test using animals seems to be the most frequently used predictive test for the identification of skin-sensitizing chemicals or for chemicals prone to cause allergic contact dermatitis. While it is most frequently used for general dermatological investigations, results can be applied to the eyelids as well (Kimber and Basketter 1992; Kimber et al. 1994).

PROCEDURE
Mice (often female mice of the CBA/CA or CBA/J strains) are exposed on the dorsum of both ears with 25 μL of two to five concentrations of the test chemical or to the same volume of the vehicle. Treatment is performed daily for 3 consecutive days. Five days following the start of the test, all mice are injected via the tail vein with 250 μL of phosphate buffered saline, which contains 20 μc Ci of tritiated methyl thymidine. Five hours later, the animals are sacrificed. The draining auricular lymph nodes are excised and pooled. A cell suspension is prepared by gentle disaggregation through a 200-mesh stainless steel gauze. The cells are washed twice with phosphate buffered saline and precipitated with 5% trichloroacetic acid at 4°C. After 12 h, the pellets are resuspended in 1 mL of trichloroacetic acid, and this volume is transferred to scintillation vials. Incorporation of tritiated methyl thymidine is determined.

EVALUATION
Activity is measured according to the increase in lymph node proliferation measured in methyl thymidine incorporation. Chemicals, which cause a threefold or greater response than the vehicle, are considered to have skin-sensitizing potential.

CRITICAL ASSESSMENT OF THE METHOD
Allergens can cause vastly different responses in individuals or the allergic response is very individualized. Nevertheless, this method will identify the majority of skin-sensitizing chemicals and has shown good agreement with human patch tests (Schneider and Akkan 2004).

MODIFICATION OF THE METHOD
The test is performed by using single lymph nodes from individual animals, which allows statistical evaluation of the results (Kimber et al. 1995).

A modification of the procedure uses 125-iododeoxy-uridine but seems to give the same results (Kimber et al. 1995).

A nonradioactive assay has been developed based on the release of IL-2 from lymph nodes of chemically exposed lymph nodes (Hariya et al. 1999). However, this assay is only valid for strong but not weak sensitizing chemicals.

A more recently developed nonradioactive test uses the incorporation of 5-bromo-2’-deoxyuridine as a measure of cell proliferation (Takeyoshi et al. 2004).

12.4 Isolated Chicken Eye

In 2008, the National Institute of Environmental Health Sciences (NIEHS) in the USA, and in 2009, WHO, both accepted and adopted recommendations of the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) for two methods that can reduce live animal use for ocular safety testing.

The two alternative test methods, the isolated chicken eye (ICE) assay and the bovine corneal opacity and permeability (BCOP) assay, do not involve the use of live animals. These are the first scientifically valid alternative methods to gain US regulatory acceptance for ocular safety testing.

However, due to space limitations, please refer to OECD guideline 438, dated September 7, 2009, for more detailed methodology and evaluation criteria. This section can only summarize purpose and procedure for the reader to consider when confronted with an anticipated ocular corrosive and severe irritant. The other alternative, BCOP, is briefly presented as an option.

PURPOSE AND RATIONALE

The isolated chicken eye (ICE) test method is an in vitro test method that can be used to classify substances as ocular corrosives and severe irritants (EU 2001; UN 2003; US EPA 1996). For the purpose of this description, severe irritants are defined as those that induce ocular lesions that persist in the rabbit for at least 21 days after administration. While it is not considered valid as a complete replacement for the in vivo rabbit eye test such as the Draize test, the ICE is recommended for use as part of a tiered testing strategy for regulatory classification and labeling within a specific applicability domain (ESAC 2007; ICCVAM 2007). If a positive response is obtained using either of the two newly approved alternative methods, the product can be labeled as causing irreversible or severe eye damage (EC 2006) and no live animal testing will be required. If the response is negative, the product is then tested in an animal to confirm that it does not cause severe or irreversible damage, as outlined in OECD Test Guideline 405 (OECD 2002).

The procedures used evaluate the potential ocular corrosivity or severe irritancy of a test substance as measured by its ability to induce toxicity in an enucleated chicken eye. Toxic effects to the cornea are measured by (1) a qualitative assessment of opacity, (2) a qualitative assessment of damage to epithelium based on application of fluorescein to the eye (fluorescein retention), (3) a quantitative measurement of increased thickness (swelling), and (4) a qualitative evaluation of macroscopic morphological damage to the surface. The corneal opacity, swelling, and damage assessments following exposure to a test substance are assessed individually and then combined to derive an eye irritancy classification.

PROCEDURE

Treated corneas are evaluated pretreatment and starting at 30, 75, 120, 180, and 240 min (±5 min) after the posttreatment rinse. The endpoints evaluated are corneal opacity, swelling, fluorescein retention, and morphological effects (e.g., pitting or loosening of the epithelium). All of the endpoints, with the exception of fluorescein retention (which is determined only at pretreatment and 30 min after test substance exposure) are determined at each of the above time points. Photographs are advisable to document corneal opacity, fluorescein retention, morphological effects, and, if conducted, histopathology.

After the final examination at 4 h, users are encouraged to preserve eyes in an appropriate fixative (e.g., neutral buffered formalin) for possible histopathological examination. Corneal swelling is determined from corneal thickness measurements made with an optical pachymeter on a slit lamp microscope. It is expressed as a percentage and is calculated from corneal thickness measurements according to the following formula:

$$\left(\frac{\textit{corneal thickness at time } t - \textit{corneal thickness at time} = 0}{\textit{corneal thickness at time} = 0}\right) \times 100$$

Table 12.1 Corneal opacity scores

Score	Observation
0	No opacity
0.5	Very faint opacity
1	Scattered or diffuse areas; details of the iris are clearly visible
2	Easily discernible translucent area; details of the iris are slightly obscured
3	Severe corneal opacity; no specific details of the iris are visible; size of the pupil is barely discernible
4	Complete corneal opacity; iris invisible

Table 12.2 Fluorescein retention scores

Score	Observation
0	No fluorescein retention
0.5	Very minor single cell staining
1	Single cell staining scattered throughout the treated area of the cornea
2	Focal or confluent dense single cell staining
3	Confluent large areas of the cornea retaining fluorescein

The mean percentage of corneal swelling for all test eyes is calculated for all observation time points. Based on the highest mean score for corneal swelling, as observed at any time point, an overall category score is then given for each test substance. Corneal opacity is calculated by using the area of the cornea that is most densely opacified for scoring. The mean corneal opacity value for all test eyes is calculated for all observation time points. Based on the highest mean score for corneal opacity, as observed at any time point, an overall category score is then given for each test substance (Table 12.1).

The mean fluorescein retention value for all test eyes is calculated for the 30-min observation time point only, which is used for the overall category score given for each test substance (Table 12.2).

Morphological effects include "pitting" of corneal epithelial cells, "loosening" of epithelium, "roughening" of the corneal surface, and "sticking" of the test substance to the cornea. These findings can vary in severity and may occur simultaneously. The classification of these findings is subjective according to the interpretation of the investigator.

EVALUATION

The ICE test method is an organotypic model that provides short-term maintenance of the chicken eye in vitro. In this test method, damage by the test substance is assessed by determination of corneal swelling, opacity, and fluorescein retention. While the latter two parameters involve a qualitative assessment, analysis of corneal swelling provides for a quantitative assessment. Each measurement is either converted into a quantitative score used to calculate an overall irritation index or assigned a qualitative categorization that is used to assign an in vitro ocular corrosivity and severe irritancy classification. Either of these outcomes can then be used to predict the in vivo ocular corrosivity and severe irritation potential of a test substance.

The overall in vitro irritancy classification for a test substance is assessed by reading the irritancy classification that corresponds to the combination of categories obtained for corneal swelling, corneal opacity, and fluorescein retention and applying the overall in vitro irritancy classification scheme. The ICE test method has an overall accuracy of 83–87%, a false positive rate of 6–8%, and a false negative rate of 41–50% for the identification of ocular corrosives and severe irritants, when compared to in vivo rabbit eye test method data.

CRITICAL ASSESSMENT OF THE METHOD

A limitation of the test method is that, although it takes into account some of the ocular effects evaluated in the rabbit ocular irritancy test method and to some degree their severity, it does not consider conjunctival and iridal injuries. Also, although the reversibility of corneal lesions cannot be evaluated per se in the ICE test method, it has been proposed, based on rabbit eye studies, that an assessment of the initial depth of corneal injury can be used to distinguish between irreversible and reversible effects (Maurer et al. 2002).

Finally, the ICE test method does not allow for an assessment of the potential for systemic toxicity associated with ocular exposure. Based on the purpose of this assay (i.e., to identify ocular corrosives/severe irritants only), false negative rates are not critical since such substances would be subsequently tested in rabbits or with other adequately validated in vitro tests, depending on regulatory requirements, using a sequential testing strategy in a weight-of-evidence approach. However, investigators could consider using this test method for testing all types of substances (including formulations), whereby a positive result could be accepted as indicative of an ocular corrosive or severe irritant response.

MODIFICATION OF THE METHOD

Even if an ocular corrosive or severe irritant classification is not obtained for a test substance, ICE data can be useful in conjunction with test data from the in vivo rabbit eye test or from an adequately validated in vitro test to further evaluate the usefulness and limitations of the ICE test method for identifying nonsevere irritants and nonirritants.

Furthermore, the aforementioned bovine corneal opacity and permeability (BCOP) assay is an approved in vitro test method that can be used under the same circumstances and same specific limitations to classify substances as ocular corrosives and severe irritants, in a similar but somewhat less reliable manner (cf. OCDE guideline 437 dated September 7, 2009). Toxic effects to the cornea are measured by (1) decreased light transmission (opacity) and (2) increased passage of sodium fluorescein dye (permeability). The opacity and permeability assessments of the cornea following exposure to a test substance are combined to derive an in vitro irritancy score (IVIS), which is used to classify the irritancy level of the test substance.

12.5 The Draize Test

PURPOSE AND RATIONALE

This test uses the eyes of a live animal, preferentially rabbits, to obtain information of the possible ocular toxicity of various chemicals. This test is most closely related to the human situation where these chemicals will later be used as ocular drugs or cosmetics or where the human eye might be exposed accidentally to these substances.

This is a classical test developed about 60 years ago (Draize et al. 1944). For further description of methods see Chaps. 8 "Peripheral Nervous System" and 15 "Skin Pharmacology".

PROCEDURE

For acute toxicity studies, 0.1 mL of a solution or ointment of the test substance is instilled into the conjunctival sacs of three to six rabbits. Readings are then taken 1, 24, and 48 h after instillation and are evaluated. If residual injuries still exist, another reading is performed after 96 h.

EVALUATION

The evaluation occurs according to a slight variation of the scoring system developed by Friedenwald et al. (1944) and presented in abbreviated form in Table 12.3.

CRITICAL ASSESSMENT OF THE METHOD

The eyes of the rabbit differ in certain aspects from the eyes of humans. They are more sensitive, have a lower tear production and blink frequency, and posses a nictitating membrane. Nevertheless, the Draize test predicts human ocular toxicity correctly in 85% cases but overestimates in 10% and underestimates in 5% (Gad and Chengelis 1991). In addition, ethical concerns have been raised in the use of animals, and benefit vs. risk of these tests for the protection of the human eye must be carefully evaluated.

MODIFICATION OF THE METHOD

Although not mentioned directly for the eye in the original paper, modifications suggested for skin testing are also applicable to the eye. These include varying the dose, using multiple applications, and washing the eyes after an application to study reversibility of observed toxicity (Draize et al. 1944).

Table 12.3 The total score is the sum of all the individual scores

Part	Tissue score
Cornea	(A) Opacities 1 or 2
	(B) Area of cornea involved 3 or 4
	Score equals A × B × 5; maximum = 80
Iris	(A) Folds, swelling, injections 1
	No reaction to light, hemorrhage 2
	Score A × 5; maximum = 10
Conjunctivae	(A) Redness, beefy red 1, 2, or 3
	(B) Chemosis, swelling, lid closing 1, 2, 3, or 4
	(C) Discharge, amounts 1, 2, or 3
	Score (A + B + C) × 2; maximum = 20

Instead of applying the test substance topically, the substance can be injected into the eye and they can then be observed for pathological changes (Veckeneer et al. 2001).

This test has been used since then many times, each with slight variations, for instance, exposure of only one eye to the test substance and no exposure of the other eye or exposure of the other eye to the vehicle. To minimize discomfort to the animal, a local anesthetic is sometimes instilled before use of the test substance. The qualitative scoring system has been extended using also measures of eye blinks or wipes. Examinations can also include magnifying glasses, slit lamp examination, fluorescein staining, and photodocumentation. After observed toxicity, animals are sacrificed; the eyes are removed and subjected to microscopic and histological examinations.

13.1 General Considerations

Morphine, as the prototype of a central analgesic drug, has characteristic adverse effects that are relevant to the treatment of patients. Important among these effects are the following:

- Respiratory depression
- Decrease of body temperature
- Tolerance
- Physical dependence
- Abuse liability

Since the ratio between therapeutic effect and adverse effects varies among opioids, great effort has been made to synthesize compounds with a better ratio of antinociceptive activity versus adverse side effects. This effort to discover better, safer compounds necessitated the development of laboratory methods that are sensitive to and, therefore, could be used to quantify the adverse effects of opioids. Moreover, the discovery of several distinct types of receptors that can interact with opioids or with endogenous peptides (e.g., μ, κ, and δ receptors) allows a more selective classification of agonists and antagonists.

13.2 Test for Respiratory Depression

PURPOSE AND RATIONALE

Respiratory depression is one of the most prominent adverse effects of μ opioid agonists (e.g., morphine). The frequency of breathing and the inspiratory volume can be affected differently by drugs and have to be measured.

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_15, © Springer-Verlag Berlin Heidelberg 2013

PROCEDURE

Male or female rabbits with a body weight between 2.5 and 3 kg are placed in restraining cages. A mask is placed over the nose of the animals which is connected with a valve opening on exhaling and closing on inhaling. The frequency of breathing is recorded from the opening and closing of the valve. The inspiratory volume is measured with a gasometer. Intravenous injection of morphine in doses between 1 and 10 mg/kg results in a dose-dependent decrease in respiratory frequency and respiratory volume. The doses are increased logarithmically after the effect of the preceding dose has subsided.

EVALUATION

Three animals are used for the test compound and the standard. Dose–response curves of the effect on respiratory frequency and volume are compared. While μ opioid agonists decrease respiratory function, κ opioid agonists either increase or have no effect on respiratory function. The magnitude of respiratory depression produced by μ opioid agonists is related to their efficacy at opioid receptors with low-efficacy agonists such as nalbuphine having much less effect on respiration as compared to morphine.

MODIFICATIONS OF THE METHOD

Nelson and Elliott (1967) compared the effects of morphine, morphinone, and thebaine on respiration and oxygen consumption in rats, and Murphy et al. (1995) provided a method for distinguishing central and peripheral mechanisms of respiratory depression in rats.

Ling et al. (1983, 1985) measured blood gas values (pO_2, pCO_2, pH) in unrestrained rats via an arterial cannula. pO_2 and pH decreased, whereas pCO_2 increased after morphine.

Studies in rhesus monkeys have compared the respiratory depressant effects of opioids to their effects on other behavior (Howell et al. 1988; Butelman et al. 1993; Gerak et al. 1994).

13.3 Decrease of Body Temperature

Opioids can have profound effects on body temperature; however, depending on the particular conditions under which the compound is evaluated, either increases or decreases in body temperature can be observed. Route of administration, dose, age of the subject, as well as ambient temperature contribute to the type of response opioids exert on body temperature. Thus, in rats, a single i.p. injection of morphine can produce hypo- or hyperthermia; restraint exaggerates the former response and attenuates the latter. Since this adverse side effect of opioid drugs is shared by several other compounds with no central antinociceptive activity, the test cannot be regarded as specific.

13.4 Methods for the Study of Tolerance

PURPOSE AND RATIONALE

Repeated tolerance treatment with opioid agonists can decrease sensitivity to drug effects, thereby limiting the effectiveness of analgesics and requiring an increase in dose for recovery of antinociceptive effects. The radiant heat or the hot plate method for testing antinociceptive activity in mice is adapted to measure drug-induced changes in the sensitivity to a noxious stimulus.

PROCEDURE

Male mice (10–12 per condition) with an initial weight of 18–20 g are used. They are placed in restraining cages. A noxious stimulus is produced by an intense light beam directed to the proximal part of the tail. The subject can respond to this stimulus by flicking its tail. The reaction time, the interval between stimulus onset and response, is automatically measured. A maximum time of exposure to the stimulus (e.g., 12 s cutoff time) prevents tissue damage. Prior to drug administration, two control measures of reaction time are obtained for each animal. After administration of the drug, the test is repeated 15, 30, and 60 min after subcutaneous injection or 30, 60, and 120 min after oral administration. In this way, time of peak activity can be determined. Mice showing a reaction time of the average control value plus two times the standard deviation in the control experiment are regarded as positive. Complete dose–response curves are determined and ED_{50} values are calculated. Subsequently, the animals are treated for 5 days once everyday with a dose which is four times higher than the ED_{50} in the first experiment. On the following day, dose–response curves are determined using at least three doses. The ED_{50} is calculated again.

EVALUATION

Reduced effectiveness of a fixed dose and/or the need for larger doses to obtain a constant response indicates the development of tolerance. ED_{50} values obtained before and after repeated daily treatment are compared to assess the magnitude of tolerance.

CRITICAL ASSESSMENT OF THE METHOD

Tolerance is observed not only with opioid agonists but also with many other drugs including barbiturates, benzodiazepines, and ethanol. The measurement of antinociception after single and repeated administration, therefore, has to be regarded as a primary test. Moreover, a decrease in the potency of a drug after daily drug treatment, while providing evidence for tolerance, does not give insight to the mechanism by which tolerance has developed (i.e., pharmacodynamic or pharmacokinetic). Demonstration that the antinociceptive effects of a new drug do not decrease after repeated daily treatment with high doses indicates that it is not necessary to escalate dose in order to maintain effectiveness and represents the first step for establishing the absence of tolerance liability.

MODIFICATIONS OF THE METHOD

Other authors (e.g., Glassman 1971) injected the dose which induced a full antinociceptive effect in mice twice daily for a period of 21 days and evaluated the stepwise decay of effectiveness. After 21 days, the effect of 10 mg/kg morphine or 30 mg/kg meperidine i.p. decreased to approximately 50% of the value of the first day.

Langerman et al. (1995) evaluated the acute tolerance to continuous morphine infusion up to 8 h in the rat with various doses using the hot plate and the tail flick assay. Tolerance was observed with the hot plate assay, but not with the tail flick assay, suggesting tolerance development at a supraspinal site.

Smith et al. (2003) used twice-daily injections of morphine and implantation of morphine-containing pellets to study mechanisms of opioid tolerance in mice.

Riba et al. (2002) showed that the role of δ opioid receptors in modifying the antinociceptive effects of μ opioid agonists changes during morphine tolerance.

13.5 Tests for Physical Dependence

PURPOSE AND RATIONALE

Withdrawal and physical dependence phenomena, either after abrupt cessation of chronic treatment or after administration of a pharmacologic antagonist (e.g., naltrexone), can be observed in a variety of nonhuman species. Importantly, the withdrawal that emerges in nonhumans topographically resembles important features of withdrawal in humans. On this basis, tests for drug dependence and withdrawal have been developed for monkeys (Seevers 1963; Seevers and Deneau 1963; Aceto 1990; Woods et al. 1993), dogs (Martin et al. 1974, 1976), rats (Buckett 1964; Cowan et al. 1988), and mice (Way et al. 1969; VonVoigtlander and Lewis 1983). Two general approaches are used to evaluate physical dependence potential: primary physical dependence and single-dose substitution. In the former, the test substance is administered repeatedly over days, and the assessment of dependence (i.e., withdrawal) occurs either after discontinuation of drug treatment or by administration of a pharmacologic antagonist. Precipitated withdrawal studies are warranted only when the mechanism or site of action of the test substance is known and when an appropriate pharmacologic antagonist is available. In a single-dose substitution study, a reference substance (e.g., morphine) is administered repeatedly over days; after discontinuation of treatment with the reference substance, and when reliable withdrawal signs have emerged, the test substance is assessed for its ability to attenuate withdrawal signs. In this type of study, the test substance can be administered just once to assess its acute withdrawal-reversing effects or can be administered repeated over days (i.e., replace the reference substance) and subsequently discontinued followed by assessment of withdrawal signs.

A well-established in vitro procedure has also been used to test for opioid dependence (i.e., antagonist-precipitated withdrawal) in opioid-treated guinea pig ileum (Rodríguez et al. 1978; Collier et al. 1979; Cruz et al. 1991).

13.5.1 Opioid Withdrawal Responses in the Guinea Pig Ileum Made Dependent In Vitro

A 40-cm long segment of the small intestine of male guinea pigs weighing 600–900 g is removed and placed in a low-magnesium Krebs solution. The terminal section of the guinea pig ileum is used after discarding the portion of 10 cm closest to the ileocecal junction. The ileum is cut in eight 3-cm long segments. The intestinal content is gently removed with the aid of a glass rod. To produce opioid dependence, segments are incubated in 500 mL Erlenmeyer flasks containing 480 nM morphine in 250 mL Krebs solution saturated with a 95% O_2/5% CO_2 gas mixture at a temperature ranging between 4°C and 6°C for 1–48 h. One hour before completion of the incubation time, the segments are removed, placed in glass chambers with 50 mL Krebs solution bubbled with 95% O_2/5% CO_2 gas mixture at 36°C, and mounted on a vertical Nichrome electrode with one edge fixed to the chamber plug and the opposite fixed to an isometrical force transducer (Grass FT 03) connected to a polygraph for recording the contractile activity of the longitudinal muscle. The ilea are set up with an initial tension of 1 g and left for a period of 30 min for stabilization. Thereafter, all segments are electrically stimulated with supramaximal rectangular pulses (10–40 V) of 0.5-ms duration at a frequency of 0.1 H.

Five min before naloxone administration, the electrical stimulation is suspended. The response to naloxone is recorded by administration of up to 100 nM. The response to the antagonist is recorded for 20 min, and thereafter, the electrical stimulation is reinitiated and maintained for 10 min.

Thirty-five minutes after naloxone administration, various doses of nicotine are administered to provide a positive control. For comparisons, a concentration–response curve for nicotine (1, 3.1, 5.6, 10, 31, and 56 μM) is obtained in untreated ilea.

Moreover, the concentration–response curve for nicotine is obtained in ilea that are (1) exposed to 10 nM naloxone for 20 min, (2) exposed to 480 nM of morphine for 1 h, or (3) pretreated for 10 min with 3 or 10 nM of naloxone and exposed to 480 nM of morphine for 1 h. The response to nicotine is attenuated after pretreatment with morphine, and this attenuation is dose-dependently antagonized by naloxone.

There is a correlation between the response to supramaximal electrical stimulation and the withdrawal response (contraction) precipitated with 100 nM naloxone as well as a correlation between withdrawal and nicotine response after long-term exposure (12–48 h) with 480 nM morphine.

13.5.2 Test for Physical Dependence in Rats

Male albino rats receive either morphine or saline i.p. twice daily. The starting dose of morphine is 20 mg/kg, followed by 40 mg/kg increments daily until by day 11 the level is 420 mg/kg. Maintenance at 400 mg/kg is continued through day 20. The test compound is similarly administered to groups of 10 rats each. The daily increments have to be adjusted to a maximum level that is not lethal for the duration of the experiment.

Primary physical dependence capacity is measured on days 11 and 17 when all animals receive an injection of 10 mg/kg of naltrexone or naloxone i.p. in the morning. Signs of withdrawal are recorded during a 30–60-min period. Rats are scored for the presence or absence of withdrawal signs (e.g., diarrhea, wet-dog-type shaking) using standardized scoring.

A single-dose substitution study substitutes either a single dose or multiple doses (from day 20 through day 23) of the test compound in morphine-dependent rats; scoring for suppression of withdrawal occurs on days 20–23 and after discontinuation of the test substance.

13.5.3 Test for Physical Dependence in Monkeys

Groups of three to four rhesus monkeys (3–6 kg body weight) receive morphine four times daily (s.c. or i.m.) beginning with a dose of 1.0 mg/kg. Progressively, the unit dose is increased to a final dose of 3.2 mg/kg/6 h. The test substance is similarly administered to groups of three to four monkeys. For the test compound, the daily increments in drug administration are adjusted to a maximally tolerated (nontoxic) dose and frequency of injection. Both groups of monkeys are then maintained at their appropriate dose levels for a minimum of 112 days. On days 35, 60, and 91, 1 mg/kg of naltrexone or naloxone is administered (s.c. or i.m.) in the morning. On days 50 and 112, all doses are omitted for 24 h. Signs of withdrawal are recorded during a 30–60-min period using standardized scoring (e.g., Katz 1986; Brandt and France 1998).

CRITICAL ASSESSMENT OF THE METHOD

The emergence of withdrawal signs after discontinuation of drug treatment is dependent of the duration of action of the treatment compound. Thus, after discontinuation of morphine treatment, withdrawal reliably emerges within 24 h. For drugs with an unusually long duration of action (e.g., buprenorphine), observations for withdrawal signs need to occur over longer periods of time (e.g., several days). Opioid antagonists will precipitate withdrawal in animals treated with opioid agonists. If a test substance has actions at nonopioid receptors, a negative result with naltrexone or naloxone in a precipitated withdrawal study will not provide useful information regarding dependence potential. Thus, both precipitated withdrawal and abstinence-induced withdrawal need to be studied for test compounds.

Rhesus monkeys have been used extensively for assessing physical dependence potential of opioid agonists. An excellent correlation between humans and rhesus monkeys has been shown regarding the physical dependence liability of opioids, although there are some compounds for which the relative potency between humans and monkeys is not what is predicted from other data. Nonhuman species can also be used to assess physical dependence potential of other classes of drugs, including sedative/hypnotics. Physical dependence potential alone cannot be assumed to predict abuse liability because some drugs that are not abused (e.g., κ opioids) can produce marked physical dependence (Gmerek et al. 1987).

MODIFICATIONS OF THE METHOD

Mouse jumping as a simple screening method to estimate the physical dependence capacity of opioid

agonists has been recommended by Saelens et al. (1971). Mice receive seven i.p. injections over 2 days. The test compound is given at doses increasing in multiples of two until a maximally tolerated dose is reached. Two hours after the last injection, the animals receive an i.p. injection of 100 mg/kg naloxone and are placed individually into glass cylinders. The number of jumps is recorded during 10 min.

Kest et al. (2002) compared naloxone-precipitated withdrawal jumping in several strains of mice after acute or multiple injections of morphine or after chronic infusion of morphine with osmotic minipump.

Yoshimura et al. (1993) studied the physical dependence on morphine induced in dogs via the use of mini-osmotic pumps. Naloxone-precipitated withdrawal signs were recorded such as hyperactivity, biting, digging, tremors, nausea, hyperthermia, and increased wakefulness and by EEG activation in the amygdala and hippocampus, followed by a dissociation of the EEG in the cortex (fast wave) from that in the limbic (slow wave) system, increased heart rate, and raised blood pressure. Withdrawal signs were more severe in animals with mini-osmotic pumps than in those receiving the same dose by syringe injections.

Pierce and Raper (1995) studied the effects of laboratory handling procedures on naloxone-precipitated withdrawal behavior in morphine-dependent rats, and Gellert and Holtzman (1978) used access to drug in drinking solutions to study morphine dependence and withdrawal in rats.

Pierce et al. (1996) used slow-release emulsion formulations of methadone to induce dependence in rats. Withdrawal was induced following i.p. challenge with either naloxone or saline, and dependence was assessed in terms of the presence or absence of characteristic withdrawal signs.

13.6 Tests for Abuse Liability

13.6.1 General Considerations

Drug abuse liability often occurs in the absence of physical dependence. Various terms have been used to describe abuse-related phenomena that are not specifically linked to physical dependence (Deneau 1964), e.g., psychological dependence, and laboratory procedures have been developed that are predictive of abuse-related effects in humans. For example, based on the early observations of Olds (Olds et al. 1956; Olds 1979) on intracranial self-stimulation, procedures have been developed for studying drug-induced changes in brain-stimulation reward (Kornetsky and Bain 1990). Moreover, self-administration procedures are used widely to study the reinforcing effects of a variety of drugs (Deneau et al. 1969; Hoffmeister 1979; Littmann et al. 1979; Woolverton and Schuster 1983; Bozarth 1987; Meisch and Carroll 1987; Weeks and Collins 1987; Yokel 1987; Woolverton and Nader 1990), and, more recently, conditioned place preference has been used in studies on abuse liability. Furthermore, drug discrimination procedures can be used to complement other assays of abuse liability; discrimination procedures have the advantage of having a high degree of pharmacologic selectivity (Holtzman 1983; Brady et al. 1987; Colpaert 1987; Overton 1987; Hoffmeister 1988; Holtzman 1990). A general discussion of abuse liability assessment, as it relates opioid analgesics as well as nonanalgesic drugs, appears elsewhere in this volume (Porsolt et al. 2002).

13.6.2 Drug Discrimination Studies

PURPOSE AND RATIONALE

Many drug discrimination laboratories have used simple two-choice discrimination methods to investigate the mechanism or site of action of new compounds by examining those compounds in animals trained to discriminate a reference substance and known drug of abuse (Shannon and Holtzman 1976; Holtzman 1983; Brady et al. 1987; Shannon and Holtzman 1986; Colpaert 1987; Overton 1987; Hoffmeister 1988; Carboni et al. 1989; Holtzman 1990).

PROCEDURE

Rats are trained to press one of two choice levers to avoid or to escape electric foot shock which is delivered intermittently beginning 5 s after the start of the trial. The occurrence of a trial is signaled by the illumination of a light in the operant chamber. A third (observing) lever is mounted in the wall of the chamber opposite the two choice levers and must be pressed before the choice response is made. This contingency prevents the rat from persevering on a single response lever; thus, the choice response in each trial is relatively independent of the consequences of choice responses in the preceding trials of the session. The rats are tested in 20-trial sessions. Animals are trained to discriminate a prototype of the drug of interest. Morphine and fentanyl have served well as training drugs for exploring the discriminative effects of classical μ opioid drugs. Training often occurs more rapidly when the dose of the training drug is the largest dose that does not disrupt behavior. For discrimination training, the animal is placed in the operant chamber and trained to perform the required response, initially under a schedule of continuous reinforcement where a single response on either lever postpones or terminates shock. As performance increases, the response requirement is increased progressively across days (e.g., to a maximum of 10 [fixed ratio 10]) and discrimination training commences, whereby responding on one lever postpones or terminates shock. In two-choice procedures, the left and the right choice lever are designated for drug and vehicle, respectively, for half of the animals in a group; the lever designation is

reversed for the other half of the animals. Acquisition of the discrimination is a function of the drug, training dose, and the number of training sessions. Training continues until the subject reaches predetermined performance criteria, which typically could be as follows: at least 80% of the total session responses on the injection (drug or vehicle) appropriate lever and less than one fixed-ratio value (e.g., 10) of responses on the injection-inappropriate lever prior to delivery of the first reinforcer (e.g., shock postponement or termination) for 6 consecutive training sessions. A morphine discrimination can be established in rats, according to these criteria, in 6–12 weeks. Once stable discrimination performance has been achieved, tests of generalization to novel drugs can be interposed among the training sessions. During test sessions, the reinforcer is available after completion of the response requirement on either lever. Complete dose–response curves for the training drug (e.g., morphine) and the test drug are obtained. In cases where the test drug does not produce responding on the training-drug-appropriate lever, the test drug should be evaluated up to doses that decrease rates of lever pressing or until other behavioral effects are observed, in order to insure that the compound is evaluated up to behaviorally active doses.

EVALUATION

Results of the stimulus-generalization test usually are evaluated with the quantitative or graded method, whereby the amount of responding on the training-drug-associated lever is expressed as a percentage of the total number of responses during a test (i.e., responding on the drug-appropriate lever plus responding on the vehicle-appropriate lever). This percentage is than compared with the percentage of drug-appropriate responses normally engendered by the training drug (reference standard). The discriminative stimulus effects of the test drug substitute for those of the training drug if the maximal percentages of drug-appropriate responding are not significantly different from each other. When stimulus control of behavior transfers from one drug to another, it can be inferred that the test drug produced discriminative effects that are similar to those of the training drug. An advantage of this procedure is that it is pharmacologically very selective and that the discriminative stimulus effects of drugs are related to and predictive of subjective effects in humans.

CRITICAL ASSESSMENT OF THE METHOD

Drug discrimination procedures display a high degree of pharmacologic selectivity. While test drugs that resemble the training drug result in dose-dependent drug-appropriate lever selection, drugs that are pharmacologically dissimilar to the training drug typically cause responding on the choice lever that is appropriate for the drug vehicle, up to behaviorally active doses. The pharmacologic selectivity of these procedures permits differentiation not only among compounds acting on different receptors or neurochemical systems (e.g., dopamine receptors vs opioid receptors) but also among compounds acting on different subtypes of receptors within the same receptor class (e.g., μ vs κ opioid receptors). Because of the importance of pharmacokinetic factors to the overall abuse liability of drugs, and because drug discrimination procedures are relatively insensitive to pharmacokinetic factors, as compared to self-administration procedures, positive results from a drug discrimination study are not in themselves sufficient to predict abuse liability. Along with other measures of drug action, results of drug discrimination studies are used to predict the likelihood of new compounds having abuse liability. Typically, self-administration data are used along with drug discrimination data, since these two assays are sensitive to different, though related aspects of drug activity.

MODIFICATIONS OF THE METHOD

Drug discrimination studies are performed in a variety of species including squirrel monkeys, rhesus monkeys, pigeons, gerbils, and mice (Hein et al. 1981; Herling and Woods 1981; Bertalmio et al. 1982; Dykstra et al. 1987, 1988; France and Woods 1993; France et al. 1994, 1995; Jarbe and Swedberg 1998; Shelton et al. 2004; Stolerman et al. 2004). Operant responding can be maintained with different reinforcers, including food, liquids, and aversive stimuli (e.g., electric shock). The pharmacologic selectivity of drug discrimination procedures is particularly evident with opioid agonists that bind selectively to different receptor subtypes. For example, monkeys trained to discriminate injections of the μ agonists codeine, etorphine, or alfentanil generalize to other μ agonists and not to nonopioid drugs, to opioid antagonists, or to opioid agonists that produce their behavioral effects through other (non-μ) opioid receptors. Conversely, monkeys trained to discriminate a κ agonist such as

ethylketocyclazocine or U-50,488 generalize to κ opioid agonists and not to μ opioid agonists, opioid antagonists, or nonopioid drugs (Woods et al. 1993; France et al. 1994).

Meert et al. (1989) used drug discrimination studies to characterize risperidone as an antagonist of LSD.

Meert and Janssen (1989) and Meert et al. (1990) showed differences between ritanserin and chlordiazepoxide in drug discrimination procedures.

Δ^9-Tetrahydrocannabinol discrimination in rats has been proposed as model for cannabis intoxication in humans (Balster and Prescott 1990).

An attempt was made to measure opiate abstinence responses in the guinea pig ileum made dependent in vitro (Cruz et al. 1991).

The drug discrimination method has also been applied to study anxiolytic drugs using pentylenetetrazol at subconvulsive doses (Sherman and Lal 1979, 1980; Sherman et al. 1979; Lal and Sherman 1980).

The conditioned taste aversion procedure has been described as a more rapid alternative to two-lever operant procedures in drug discrimination research (Garcia et al. 1955; van Heest et al. 1992).

13.6.3 Conditioned Place Preference Paradigm

PURPOSE AND RATIONALE

The conditioned place preference paradigm has been used widely to examine behavioral actions that are thought to be related to positive reinforcing effects, as measured by other procedures, such as self-administration (van der Kooy 1987; Hoffman 1989; Tzschenke 1998; Self and Stein 1992). Particular environmental stimuli are paired with the presence or absence of a presumed reinforcer (e.g., drug or

food), and later, in the absence of that reinforcer, animals are tested for their preference for either environment.

PROCEDURE

To induce place preference with food, a food-restricted animal is exposed to an experimental chamber that consists of two compartments (which differ in floor texture and wall color) and that are separated by a removable barrier. In some iterations of this procedure, the two compartments are joined by a small tunnel or a third (neutral) compartment. On alternate days, the animal is confined to one or the other compartment, with food available in only one of the compartments. Thus, food is selectively paired with one of the distinctive environments. After several (e.g., 4 in each compartment for a total of 8) conditioning sessions, the animal is placed in the same chamber without the barrier in place (for procedures that use a third [neutral] compartment, the animal is placed in that compartment and otherwise in the middle of the chamber). In the absence of the reinforcer (e.g., food), animals demonstrate a relative increase in the amount of time spent in the environment that was paired with food as compared to the compartment that was not paired with food. Place conditioning with drugs is conceptually similar and involves the differential pairing of drug effect with one compartment and the absence of drug effect (vehicle) with the other. Drugs can be administered by various different routes (Amalric et al. 1987; Bals-Kubik et al. 1988, 1990; Iwamoto 1988; Shippenberg and Herz 1987), and usually animals are placed in the chamber immediately after drug administration for a 40-min conditioning session.

Male Sprague-Dawley rats weighing 250–300 g are used for these studies. When drugs are to be administered intracerebroventricularly, rats are anesthetized with 60 mg/kg i.p. sodium hexobarbital, and 23-gauge guide cannulae aimed at the lateral ventricle ($AP = -0.9$ mm, $L = +1.5$ mm, $DV = 3.5$ mm) (Paxinos and Watson 1982) are stereotaxically implanted; conditioning commences 1 week later.

The apparatus consists of 30 × 60 × 30 cm Plexiglas boxes with a clear Plexiglas front. For conditioning sessions, each box is divided into two equal-sized compartments by means of a sliding wall. One compartment is white with a textured floor, the other black with a smooth floor. For testing, the central wall is raised 12 cm above the floor to allow passage from one compartment to the other.

Conditioning sessions are conducted once a day for 8 days and consist of administering drug or its vehicle on alternate days. The rats are immediately confined to one compartment of the box following drug injection and to the other compartment following vehicle injection. All conditioning sessions last 40 min. Test sessions are carried out 1 day after the last training session and in the absence of drug. The rats are placed in a neutral position (either in the center or in the neutral compartment) of the test box and allowed free access to both sides of the box for 15 min. A video camera with integrated stopwatch is used for data recording. Alternatively, photocells mounted along the sides of each compartment can be used to electronically monitor the location of the subject in the apparatus. The time spent in each compartment is assessed by visual analysis of the recorded videotape or by data collected through photocell beam breaks.

For intracerebroventricular injections, a 30-gauge injection needle is attached to a microsyringe via polyethylene tubing. The drug solutions are administered over a 60-s period, and the injection needles are left in place for an additional 30 s to ensure complete delivery of the solution. For antagonism tests, groups of rats receive an intracerebroventricularly injection of the antagonist (naltrexone or naloxone) or vehicle 10 min before the microinjection of the conditioning drug. At the end of the experiments, the rats are anesthetized and sacrificed by decapitation. The brains are removed and sectioned in a cryostat to verify the location of the cannulae. Alternatively, antagonists can be administered systemically.

EVALUATION

Conditioning scores represent the time spent in the drug-paired place minus the time spent in the vehicle-paired place and are expressed as means ± SE. In cases where animals show a bias toward one compartment prior to conditioning, drug conditioning can be established with the nonpreferred compartment, thereby increasing the confidence that preference for that compartment is specifically related to drug administration. Dose–response curves are analyzed with a one-way ANOVA. The Wilcoxon test, in which the time spent in the drug associated place is compared to that in the vehicle-paired place, is used to determine whether individual doses produce significant conditioning. A one-way ANOVA followed by the Student Newman–Keuls test is used to

determine the statistical significance of effects of the antagonist pretreatment.

Unlike drug discrimination, conditioned place preference is not pharmacologically selective insofar as drugs from many different classes (e.g., opioids, ethanol, stimulants) generate positive results. Generally, there is a strong positive correlation between drugs that can be used to establish conditioned place preference and those that are positive reinforcers by other measures (e.g., i.v. self-administration); however, one of the most effective reinforcers in self-administration studies, that is also widely abused by humans, does not unanimously generate strong conditioned place preference in nonhumans – cocaine. Thus, results from conditioned place preference studies should be used in concert with results from other measures of reinforcing effects (e.g., self-administration). For the purpose of opioids, in general, μ agonists are effective for establishing place preference, whereas κ agonists are not. In fact, μ antagonists or κ agonists can generate place aversion (e.g., Sante et al. 2000).

MODIFICATIONS OF THE METHOD

In order to distinguish place preference and place aversion, place-conditioning behavior can be expressed by a difference in preference pre- and postconditioning, where post- and prevalues are the difference in time spent in the preferred and the nonpreferred sides in the postconditioning and preconditioning tests, respectively. Positive values indicate preference and negative values aversion (Kitaichi et al. 1996). For nonbiased procedures, where animals do not show an inherent preference for either compartment, results are presented simply as a difference score (i.e., time spent in the drug-paired compartment minus time spent in the vehicle-paired compartment).

In addition to place preference, others (Mucha and Herz 1985; Broadbent et al. 2002) used taste preference conditioning.

Cunningham (Bormann and Cunningham 1998; Gabriel et al. 2004) used the same chamber for training and testing with the exception that floor texture varied according to treatment condition. Thus, drug and vehicle were paired with different floor textures, and during test sessions, the time spent on each section of a floor comprising the two different textures (half of the floor with each) was used as an index of preference or aversion. This procedure has the advantage that the size of the test chamber is not different from the size of the training chamber.

Perks and Clifton (1997) used sucrose solution to generate a place preference which was subsequently devalued using a LiCl taste aversion procedure.

Brockwell et al. (1996) described a computerized system for the simultaneous monitoring of place conditioning and locomotor activity in rats consisting of four independent conditioning boxes, each equipped with six pairs of photosensors connected to an experiment controller, an electronic board containing a microprocessor and a programmable timer for storing both instructions and data.

Steinpreis et al. (1996) investigated place preference in Sprague-Dawley rats treated with graded i.p. doses of methadone. Place preference for methadone peaked at 4 mg/kg, and aversion was produced at 10 mg/kg.

Using the conditioned place preference paradigm, Mamoon et al. (1995) assessed the rewarding properties of butorphanol in comparison to morphine after unilateral microinjections into the ventral tegmental area of male Lewis rats.

Gaiardi et al. (1997) assessed rewarding and aversive effects of buprenorphine by place preference and taste aversion conditioning. After subcutaneous doses of 0.025, 0.050, and 0.100 mg/kg, buprenorphine caused a significant increase in the amount of time spent on the drug-paired compartment, but no significant decrease of saccharin consumption. Rewarding and aversive effects did not occur within a similar dose range.

Contarino et al. (1997) found no tolerance to the rewarding effects of morphine.

Tsuji et al. (1996) studied the effect of microinjections of GABA agonists and antagonists into the ventral tegmental area of Sprague-Dawley rats on morphine-induced place preference.

Sufka (1994) recommended the conditioned place preference paradigm as a novel approach for assessing effects of opioids in chronic pain induced in rats by unilateral injections of Freund’s adjuvant into the hind paw.

Conditioned place avoidance was found after naloxone which was attenuated by clonidine (Kosten 1994).

In addition to morphine and other μ opioid agonists, other drugs with known or putative abuse liability

were tested in the place-conditioning paradigm, e.g., cocaine (Lepore et al. 1995; Suzuki and Misawa 1995; Calcagnetti et al. 1996; Martin-Iverson and Reimer 1996; Martin-Iverson et al. 1997), caffeine (Brockwell et al. 1991; Brockwell and Beninger 1996), cannabinoids (Lepore et al. 1995; Sañudo-Peña et al. 1997), LSD (Parker 1996), methamphetamine (Suzuki and Misawa 1995), amphetamine (Hoffman and Donovan 1995; Turenne et al. 1996), methylphenidate (Gatley et al. 1996), fenfluramine (Davies and Parker 1993), 7-OH-DPAT (Khroyan et al. 1995; Chaperon and Thiébot 1996), gamma-hydroxybutyric acid (Martellotta et al. 1997), propofol (Pain et al. 1997), and NMDA receptor antagonists (Steinpreis et al. 1995; Papp et al. 1996).

Furthermore, 5-HT_3 receptor antagonists (Acquas et al. 1990), 5-HT_3 receptor agonists (Higgins et al. 1993), dopamine release inhibitors (Schechter and Meehan 1994), D1 receptor antagonists (Acquas and Di Chiara 1994), D3 receptor–preferring agonists (Khroyan et al. 1997), and antiemetic agents (Frisch et al. 1995) were studied in the place-conditioning paradigm.

Suzuki et al. (1991, 1993) and Del Poso et al. (1996) studied opioid-induced place preference and Bechtholt et al. (2004) studied the effects of handling on conditioned place aversion and conditioned place preference by ethanol in mice.

14.1 General Considerations

14.1.1 Introduction

Studies on endocrine safety pharmacology are part of the "supplemental safety pharmacology studies" described in the ICH guideline S7A. These supplemental studies are performed in order to identify the risk of adverse effects on organ system functions which are not addressed by the general methods of the core battery (ICH 2001; Valentin et al. 2005; Porsolt 2006). Supplemental studies are often required as a consequence of endocrine-related findings in repeated-dose toxicity studies. Such findings may be organ weight changes, histopathology, abnormal findings of biochemistry, and changes in biomarkers which were monitored due to the established pharmacological profile. Frequently, there are unexpected findings related to the gonadal system (testis and ovaries in adult rats), the adrenocortical system (stress-related findings, adrenal hyperplasia, increasing blood pressure), the thyroid gland (thyroid hormone abnormalities, histopathology), the endocrine or exocrine pancreas (impaired glucose control, pancreatitis), changes of electrolytes and calcium-regulating hormones (e.g., calcitonin), and biomarkers of bone turnover. Changes may be related to hormone-producing organs and to hormone-responsive tissues. Such changes may appear at the time of performing regulatory toxicology studies or may be anticipated from conspicuous findings of receptor profiling and early toxicology.

Interpretation of the findings is a difficult matter, the key issue being risk assessment and relevance of predictions for therapeutic problems. The relevance for initiating human phase I trials needs to be assessed as well as possible implications for phase II studies (Baldrick 2008; Bass et al. 2009). The specific pharmacology of the test substance is often studied with particular reference to the proposed therapeutic indication(s). When this does not include an endocrine disorder or therapeutic condition, potential problems need to be anticipated from structural indications, results of early profiling, and repeated-dose toxicology studies. Frequently, decisions on extended endocrine safety pharmacology are taken retrospectively due to unexpected findings. In case of compounds with established endocrine activity, there is often a reliable prediction that hormone-responsive organ systems may be affected. This will inform about the inclusion of targeted investigation by repeated-dose studies, preferentially coordinated with the regulatory toxicology studies (Hayes 2001). Endocrine activities may be anticipated from in vitro findings of the early evaluation in a general pharmacology screen (Spielmann 2005; Suter 2006). The pharmacology profiling of new drugs is nowadays predominantly performed by in vitro testing (Faller et al. 2006). The application of receptor screening may be quite an effective procedure for prediction of hormonal activity; however, the final assessment can only be done by animal studies due to the complexities of signal transduction and interaction of hormonal systems (cross talk). It will be necessary to consider the level of exposure (MacDonald et al. 1994; Heinrich-Hirsch et al. 2001; Singh 2006), to establish a relation of the effects observed to the predicted therapeutic concentrations. The established primary interaction of hormones and substances with hormonal activity with an ever increasing set of membrane receptors and nuclear receptors, as well as binding proteins and enzymes, can be approached by a number of high-throughput procedures and also by specific in vitro testing (Suter 2006; Sanderson 2006). This evidence will be available at that time of designing the final strategy for toxicological evaluation of a drug candidate, including endocrine safety pharmacology. For all activities predicted from the in vitro testing, some evidence for hormone-related effects should be available from the early animal studies. At this stage, a dialogue is needed for the toxicologists and the pharmacologists. Animal studies in rodents are by preference with repeated-dose administration for several days, to allow for early feedback effects and adjustment of receptors. Identification of consistent biological response very much facilitates the safety pharmacology strategy.

Endocrine safety pharmacology studies are performed for compounds designed to enter clinical pharmacology phase I (Valentin et al. 2005, 2009). They are needed to detect undesirable pharmacodynamic effects of a substance on physiological functions in relation to exposure in the therapeutic range and above (ICH-guideline S7A, 2001). The main objective is to decide whether the test compound can be administered to humans, which effects need to be monitored in clinical pharmacology and which clinical investigations (including monitoring of biomarkers) are

required for a risk evaluation (Williams et al. 2006; Frank and Hargreaves 2003). In endocrine pharmacology, the design of specific studies will be based on the individual properties and intended clinical uses of the test substance. When planning a toxicology program, safety pharmacology endpoints (hormone determinations, biochemical parameters, biomarkers, dynamic function tests) can be incorporated in repeated-dose toxicology, in relation to toxicokinetics and whenever possible in a similar manner as known from clinical studies. Where this is not feasible, endpoints related to suspected hormone activity should be evaluated in satellite safety pharmacology and in mechanistic toxicology studies (Harvey et al. 1999a; Bass et al. 2009).

Endocrine safety pharmacology studies investigate the pharmacodynamic effects of a substance on physiological functions in relation to exposure in the biologically effective ("therapeutic") range and above (ICH S7A). They are usually initiated (a) to evaluate adverse pharmacodynamic and/or pathophysiological effects of a substance observed in toxicology and/or clinical studies and (b) to investigate the mechanism of the adverse pharmacodynamic effects observed and/or suspected. Evidence from preclinical pharmacology needs to be available to estimate biologically effective dosage (physiological range). The toxicology concept to establish the NOEL level (no observable effect) is helpful for environmental agents and chemicals, whereas for the safety pharmacology, an effective dose range is mandatory. The approach to predictive findings in toxicology with relevance for clinical pharmacology is essentially based on studies in animals (VanderGreef and McBurney 2005; Collis 2006) and includes an innovative search for mechanisms of toxicity, directly related to the effects found in regulatory toxicology studies (Liebler and Guengerich 2005; Ettlin et al. 2010a, b). The endocrine profile is increasingly important for peptides and proteins produced by biotechnology (Cavagnaro 2002), a development which was predicted at an early time by Zbinden (1990, 1991) and requires targeted animal studies.

Endocrine toxicology is extensively reviewed and discussed in many textbooks (Witorsch 1995; Harvey et al. 1999a; Thomas and Thomas 1999; Eldridge and Stevens 2010); much of the evidence is derived from studies in occupational toxicology and on chemicals with endocrine-disrupting activities (Ashby 2000; Riecke and Stahlmann 2000). There has been remarkable progress on the development of tumor models with intent to early prediction of safety issues (Arp 1999; Jacobson-Kram et al. 2004; Andersen and Krewski 2009), as well as in vitro testing targeted to prediction of toxicology (Dykens and Will 2007; Walmsley and Billinton 2011).

In this chapter, pharmacological methods are described which can be applied to the characterization of candidate compounds, their effects on endocrine functions (hormone secretion and synthesis), and their effect on target organ functions. Most frequently, these effects are directed to the reproductive system, thyroid gland, adrenal glands, pituitary hormones and gastrointestinal hormones, and hormonal factors which regulate growth and metabolism. There is a close relation to pharmacological methods designed for carbohydrate and lipid metabolism, insulin resistance, atherosclerosis, and obesity (Vogel 2008a, b, c).

Due to the complexity of endocrine investigations and the time and expense of classical assays for hormone effects, animal bioassays are no longer recommended for a standard protocol. Evidence for endocrine risks is usually obtained from in vitro studies on hormone receptors and enzymes, which should lead to the inclusion of specific study parameters in the regulatory toxicology studies. In some instances, a targeted investigation is performed for the release or inhibition of secretion of specific hormones. This may be done by single-dose tests measuring the hormone response and by acute changes in the serum concentration or associated tissue contents of hormones. Some of the classical bioassays, described in detail by Vogel (2008c), can be used for the safety pharmacological characterization. In the present section, reference is made to the selection of procedures and assays, which may be required to meet the ICH guideline S7A (2001). These studies are appropriate in the context of regulatory toxicology studies when added to the standard protocol and when monitored in satellite studies on the interference with hormone systems and hormone-responsive target organs (Harvey et al. 1999a).

14.1.2 Regulatory Toxicology Studies

The unexpected evidence in the early toxicology studies is often provided by organ weight changes (frequently testes or ovaries, thyroid gland, or adrenal glands), by significant changes in clinical chemistry

(e.g., of enzymes or of electrolytes), and very frequently by histological observations which need an explanation and interpretation. In regulatory studies, the animals should not be overburdened with supplementary examinations. Satellite groups treated with similar dosage are needed frequently to obtain serum and tissue samples and to be used for ex vivo studies. Satellite groups will also provide the necessary specimens for specific investigation, for example, of immunohistochemistry and molecular biology. With paired organs (testes, ovaries, adrenals), access to sufficient samples should represent no problem, for example, anterior pituitaries in rats may be bisected by a median sagittal cut to obtain tissue for hormone analysis, in addition to standard histology.

Some changes in hormone contents may already be detected in regulatory toxicology studies by inclusion of additional analytical parameters in the study protocol. Such hormone determinations are mostly related to the anterior pituitary, thyroid gland, adrenals, and reproductive system and less frequently to changes in growth hormone and prolactin secretion, to the assessment of endocrine pancreas function (antidiabetic agents), or to biomarkers of bone turnover (e.g., bisphosphonates, calciferols). Interference with glucose regulation may require that frequent samples are taken, animals compensate for hyperglycemia, and show no related symptoms unless dynamic function tests are applied (OGT). Major changes in electrolyte balance are readily detected with interim collection of urine specimens under controlled conditions (metabolism cages, see Sect.14.4.2); they may be found in serum samples acquired at autopsy, with adequate sampling and immediate processing. Organ weight changes and findings in histopathology may require a follow-up endocrine analysis in a mechanistic study using, for example, immunostaining and markers of cell proliferation (for instance staining for Ki 67, a nuclear protein that is associated with cellular proliferation). Frequent findings in animal studies which may not necessarily be related to similar effects in humans are thyroid enlargement, changes in ovarian or testis morphology (for instance Leydig cell hyperplasia), adrenal hyperplasia, pheochromocytoma in rats, or pancreatic tumors (e.g., beta cell hyperplasia). There is an extensive literature on the relevance of findings in toxicology studies, which may not be necessarily related to similar observations in humans and may require interpretation of their relevance for phase I studies (Thomas 1996; Capen 1998; Neubert et al. 1999; Thomas and Thomas 1999; Harvey et al. 1999a; Eldridge and Stevens 2010).

The observations are mostly from 14 to 28-day studies, less frequently from 90-day or 6-month treatments. Estrogenic effects are indicated by uterine weight, androgenic effects by epididymal weight, or more frequently by histology of the testis (Sellers et al. 2007). In satellite studies, it is useful to obtain and store a sufficient blood sample volume from treated animals and controls to be able to search for distinct hormonal changes, retrospectively, in explanation of unexpected findings. This is recommended for long-term studies where blood sampling can be performed at some time during the study without interfering with the final condition of animals at autopsy. It is advisable to perform an evaluation similar to the procedure outlined in Vogel (2008c) (Endocrine Profiling). In view of the progress in molecular biology, it may also be advisable to acquire sample suitable for, for example, genomic analysis.

14.1.3 Mechanistic Studies

A clearly defined set of questions arises from drug candidates which belong to a class that has already shown some endocrine effect or is suspected of having endocrine-mediated effects (Harvey et al. 1999b). No general recommendation can be given for the situation when specific endocrine investigations need to be performed in separate non-GLP studies. Such studies are summarized as mechanistic studies.

A detailed ex vivo biochemical analysis of drug-induced changes requires hormone determinations in brain, hypothalamic and pituitary tissue, peripheral target organs, and measurement of circulating plasma concentrations of hormones and hormone-dependent substances. Many of the analytical hormone assays are now available from commercial suppliers, mostly with adequate validation of their performance. There is a problem of species specificity which needs to be considered and confirmed before applying methods which may be suitable for clinical use (human hormones) but not for the rat or other animal species. In each case, it is advisable to validate applicability in a small study before embarking on large and expensive toxicology studies. Hypothalamic hormones in tissue samples are identified by direct measurement (for

instance, TRH, GnRH, somatostatin, GHRH, CRF). There are strict conditions for sample acquisition at autopsy: tissue samples need to be frozen immediately; enzyme inhibitors need to be added during processing in most instances. Interpretation of results of hypothalamic hormone content is always required with due consideration of related changes in serum concentration of pituitary hormones, pituitary hormone contents, organ weight changes and histological findings.

The suprahypothalamic neurotransmitter level can be assessed by a determination of catecholamines in circumscribed brain areas; the technique requires preparation of frozen tissue and isolation of specific nuclei by the micropunch technique. The catecholamines and indolamines can be measured by radioenzymatic methods and by a high-pressure liquid chromatography (HPLC) with electrochemical detection. These mechanistic investigations are difficult and time consuming; they are mostly initiated due to questions arising from the receptor interaction profile of the drug candidate. Such studies may be required to prove that receptor interactions of hypothalamic hormones at the neurotransmitter level are related to the functional state of endocrine organ functions (functional expression, e.g., for changes in prolactin secretion). Mostly, however, the peripheral effects of such neurotransmitter (for instance the effect on prolactin secretion) are sufficiently distinct and may be considered as biomarkers.

14.1.3.1 Mechanistic Studies (Single Dose)

Such studies refer in general to endocrine experiments directed at measuring the time action profile of specific hormones (Sandow 1979) in the context of establishing the dose range for investigations (physiological and supraphysiological concentrations). Reference values should be available at least for rats and dogs; dynamic function tests using an established stimulation or inhibition test are recommended. For such acute experiments, standard operating procedures are established based on the secretory kinetics of the hormones to be measured (Heinrich-Hirsch et al. 2001). When studies are performed in anesthetized animals, the anesthetic has a marked effect on hormone secretion. In some cases, animals prepared with indwelling cannulas will be required for meaningful assessment. The problem of episodic and pulsatile hormone secretion may be avoided in anesthetized animals; selection of a suitable time of the day with reference to chronobiology is recommended, and this may be different for specific hormones. Retroorbital punction in unanesthetized rats was found to be a suitable procedure for the gonadotropins and the thyroid hormones. The procedure is not suitable for growth hormone and prolactin secretion studies. The rat has limitations of sampling (retroorbital or tail vein). Dogs provide better experimental conditions for frequent sampling; they need to be trained for some time before experimentation to reduce stress-related effects. The investigator will need to know about the physiology of hormone secretion in the species to be examined; consultation with an endocrine pharmacologist is helpful, and reference may also be made to similar procedures which are established for the human (website www.endotext.org). As an example, measuring the serum concentrations of corticotropin (ACTH) is extremely difficult in dogs because they react strongly to the stress of the sampling procedure and to any changes in the laboratory environment during the experiment.

For the pituitary hormones, pancreatic hormones, and biomarkers for bone changes (including calcitropic hormones), analytical methods are in general available with species-specific reagents (mouse, rat, dog, monkey) and to a limited extent for rabbits and other species. It is recommended to perform pilot experiments for validation of commercial hormone assays. Steroid hormones can be measured readily by an array of analytical methods. Application of gene arrays and studies on gene expression are recommended for repeated-dose exposure when a steady state with meaningful changes is read (3–7 days duration).

14.1.3.2 Mechanistic Studies (Repeated Dose)

These studies are designed to investigate the context of changes, adapting experimental conditions to the questions raised by the regulatory studies (Harvey et al. 1999a). The dose range should include the anticipated therapeutic range (physiological range) and does not need to include very high doses. The purpose is to compare baseline conditions with changes observed by stimulation or inhibition of target hormone secretion after 7–28 days of treatment. Several time points need to be included, and pilot experiments are recommended unless the laboratory has some experience with the particular hormone determination. At the

end of a repeated-dose study of some duration, an important decision for the last treatment is at which time to sacrifice the animals in relation to final treatment injection. This item is important both to measure serum concentrations and to detect valid changes in the tissue content of hormones at autopsy. Changes in pituitary hormone concentration or that of other target organs are valuable indicators of the extent of the endocrine effect. Changes in tissue content do occur within hours after treatment; they may not be detected 24 h after the last treatment. This is the usual interval for autopsy in regulatory studies; the interval may not be suitable for mechanistic studies.

The biochemical parameters for evaluation of changes in hypothalamic-pituitary-target organ function are derived from hormone concentrations in tissue and should be related to those found in serum or plasma. Tissue and plasma concentration are influenced by time of the day (circadian rhythm of the hormone to be measured, chronobiology), the stress of handling, and the technique of sacrificing the animals. Plasma levels are more susceptible to modification by stress than tissue concentrations. During prolonged periods of sampling, tissue content may also change due to stress preceding autopsy. Decapitation is recommended as the established method of sacrificing animals with a minimum of endocrine interference. This refers to decapitation in a quiet operating room separate from the animal facility, preferably in small groups of animals transferred to that room immediately before the procedure. Studies on organ tissues ex vivo may be considered, for instance incubation of the testis or ovary with hormones for stimulation (functional assays).

In regulatory studies and in mechanistic studies, one may prefer to assess changes in tissue content for hormones like corticotropin (ACTH), prolactin, and growth hormone (GH), rather than serum concentrations. The tissue content of these hormones changes slowly and in a characteristic direction, whereas their plasma levels may fluctuate widely both with handling stress and due to circadian rhythm. This also indicates that for mechanistic studies, it is important to select time points of investigation for which comparative laboratory data are available and reliable publications with evidence that circadian rhythm does not interfere during the selected time period. In general, practical lab work will determine the timing, and the light schedule in the animal facility will serve as a synchronizer for adrenocortical steroids.

For the more stable secretion of thyroid-stimulating hormone (TSH, thyrotropin) and the gonadotropin (LH and FSH), plasma determinations are adequate provided that autopsy is completed within a short time and the time of autopsy is selected based on data which minimize artifacts due to circadian hormonal changes. In our laboratory, rats are sacrificed by decapitation (one experimental group at a time), and autopsies are performed during the morning period of 08:00–10:00. This is different from mechanistic studies, where it may be necessary to measure changes in hormone secretion spaced at increasing intervals after treatment or to obtain sequential tissue samples at the related time points. These recommendations are to some extent valid for basal tissue concentrations of gonadal steroids and adrenal steroids, which show considerable circadian variability.

14.2 Endocrine Profile

This is a repeated-dose test which is applied for the detection of biological effects by organ weight changes, changes in specific hormones and biomarkers, and other parameters to be added when considered helpful. The final protocol of this test is designed at the time of starting repeated-dose toxicology studies. The available information is related to in vitro pharmacology (in particular receptor screening and enzyme tests) and to single-dose or multiple-dose animal studies performed with the test substance.

The endocrine profile of a drug candidate is determined in a repeated-dose study of at least 7 days duration (Sandow 1979; Vogel 2008b). The study plan is similar to a toxicology study of 14–28 days duration in two animal species, that is, the rat and dog. The test is not suitable for mice. The S7A guidelines state “effects of the test compound on organ systems not investigated elsewhere should be assessed when there is a reason for concern.” Reasons for concern are frequently related to the reproductive system (male and female gonadal function), the adrenal system (adrenocortical function), the thyroid gland, the endocrine and exocrine pancreas, and the biomarkers of bone turnover.

Concern may be caused by previous toxicology studies with findings of histopathology, clinical chemistry, or organ weight changes. For the toxicology studies, it is helpful to determine weights of all endocrine organs (Sellers et al. 2007) including the pituitary gland.

The purpose of the endocrine profile is to inform on the design of repeated-dose toxicology studies. When a distinct endocrine profile of the drug candidate is present before starting the toxicology studies, a targeted investigation can be added to the standard toxicology protocol, satellite groups may be added, and specific mechanistic studies may be initiated in the context of the toxicology program.

In the endocrine profile, the repeated-dose administration with a design and dose selection similar to toxicology studies is preferred. Studies of up to 4 weeks' duration need to include analytical determination of serum/plasma concentrations of hormones, basal concentrations at several time points during the study, and dynamic function tests for the response of hormone secretion (e.g., LHRH, TRH, CRF/CHRH, monoiodotyrosine MIT for prolactin secretion). At autopsy, tissue samples are stored for hormone contents of endocrine organs and hormone-dependent tissues (e.g., hypothalamus, pituitary gland, reproductive organs, pancreas). In specific instances, tissue may be process by molecular biology methods. This is more in the domain of mechanistic studies when mechanisms of toxic effects observed need to be identified or excluded. In the endocrine profile, at least 7 days of treatment are mandatory to allow for adaptation and response of hormone-dependent organs to the treatment. Repeated daily dosing (once or twice per day) ensures that a steady state is reached. Selection of at least two doses is recommended for a sufficient effect size to be achieved and to detect biologically relevant/statistically significant differences between controls and treatment groups. A dose range similar to the anticipated regulatory toxicology studies is recommended.

The inclusion of untreated controls or a vehicle control group is mandatory. The additional inclusion of comparator groups (drug of known endocrine activity) may be considered. In the majority of cases, this may not be necessary, because there is an extensive database in the literature about the effect size of established drugs that affect the endocrine systems. This agrees with the guideline statement "in well-characterised in-vivo test systems, positive controls may not be necessary."

14.2.1 Endocrine System Evaluation in Rats (Endocrine Profile)

PURPOSE AND RATIONALE

This study is designed for specific endocrine evaluation, a test substance which has shown some effects on endocrine systems during the preceding toxicology evaluation (28 days treatment in rats, or in dogs), with no distinct profile related to a specific endocrine system.

This study is generally performed in rats, less frequently in dogs. In rats, extensive reference data are available for hormones and substances acting on hormone systems, including serum concentrations and tissue contents. There is considerable technical difficulty to adapt this method to mice. In the endocrine profile, several endocrine systems are examined simultaneously, preferably in the rat strain that is also used in the regulatory toxicology studies. Parameters to be investigated (see Table 14.1) are organ weight changes, histology or histopathology of hormone-producing organs and hormone-responsive tissues, specific clinical chemistry (biomarkers), and hormone concentrations. During the course of the study and (to be considered) 24 h before autopsy, hormone concentrations in blood and tissue are determined (related to function of the reproductive system, thyroid gland, adrenals, endocrine and exocrine pancreas, etc.). A particular design of this study may include specific effects on the endocrine pancreas (Vogel 2008a), for example, insulin receptor signaling, IGF-I receptor signaling, and immunohistochemistry of the pancreas. This design is applied for antidiabetic agents.

PROCEDURE

Adult male and female rats, body weight preferably 200 g, are randomly assigned to control and treatment groups, at least six animals per group and at least two doses. The dose range for treatment is selected based on pharmacodynamic information (dose-response curves from single-dose studies, in vitro findings using receptor affinity and receptor signaling, biomarkers, or enzymes). The low dose should elicit the primary pharmacodynamic effect in the test species (preferably related to the proposed therapeutic effect in humans, on target); the high dose should elicit the adverse effect(s) anticipated based on previous study results in vitro and in vivo (supraphysiological dose

Table 14.1 Endocrine profile, study parameters, and hormone systems to be investigated during repeated-dose treatment and at autopsy. Optional biomarkers to be included in the investigation during the study and at autopsy

Endocrine system	Optional biomarker
Pituitary-adrenal axis	
Pituitary weight	Corticotropin-releasing hormone in hypothalamus
Adrenal weight	Pituitary content of adrenocorticotropin and vasopressin
Thymus weight	Adrenal content of corticosterone and aldosterone
	Corticosterone and aldosterone blood level
	Electrolyte concentrations in serum (sodium, potassium chloride)
	Urinary excretion of corticosterone and aldosterone
Pituitary-gonadal axis	*Male reproduction*
Pituitary weight	LH-RH in hypothalamus
Weight of testes	Pituitary content of FSH, LH, and prolactin
Weight of seminal vesicles	Blood levels of FSH, LH, and prolactin
Weight of ventral prostate	Testosterone content in testes and serum
Weight of levator ani muscle	Growth hormone in pituitary and serum
	Female reproduction
Pituitary weight	LH-RH in hypothalamus
Weight of ovaries	Pituitary content of FSH, LH, and prolactin
Weight of uterus	Blood levels of FSH, LH, and prolactin
	Content of estradiol and progesterone in ovaries and serum
Pituitary-thyroid axis	
Pituitary weight	TRH in hypothalamus
Thyroid weight	Pituitary content of thyrotropin
	Serum content of thyrotropin, T3, and T4

range, not maximum tolerated dose). In case of two test doses, the dose increment should be at least fivefold. In accordance with guideline ICH S7A, the high test dose should produce moderate adverse effects in this study or in other studies of similar route and duration, and the adverse effects can include dose-limiting pharmacodynamic effects or other toxicity.

The duration of the treatment period should be at least 7 days, to allow for a steady state to be established. It may be extended to 28 days, based on findings of a preceding toxicology study with observations of concern, which did not include satellite groups for specific investigation of hormone-related mechanisms.

At suitable time points during the treatment period (e.g., once per week), the hormone concentrations in controls and treatment groups may be determined at baseline (always at the same time of the day, to avoid confounding effects of diurnal hormone fluctuations). Blood sampling should be done sparingly (once per week, e.g., dynamic function tests) and discontinued during the last week of the study period. A final sample 24 h before autopsy may be considered. Dynamic function tests (stimulation or inhibition) are performed at 7 days intervals, by using established diagnostic reagents that act on hormone secretion (e.g., LHRH, TRH, CRF/ACTH, somatostatin). In a similar manner as for human diagnostic procedures, reagents may be combined when their hormonal effects do not interfere (e.g., combined TRH/LHRH test). It is recommended to perform preliminary investigations to become familiar with the test and validate the analytical method selected.

Measurement of the effects by a noninvasive procedure is often possible. A preferred procedure is to use metabolism pages for collection of urine samples during the night period (activity period of rats) and urinary excretion data, when possible with correction for creatinine excretion. This approach is useful in pharmacokinetics (Sandow et al. 1990) as well as pharmacology. The noninvasive procedure is particularly helpful in the assessment of adrenocortical function in rats (Hilfenhaus 1977; Hilfenhaus and Herting 1980; Sarrieau and Mormède 1998; Eriksson et al. 2004). During the treatment period, collection of urine samples may be performed in metabolism cages during the night period, in rats which have been adapted to this procedure, at least 3 days before the first diagnostic sampling. Sampling in metabolism cages may also be included in regulatory toxicology studies. Biomarkers in urine samples are analyzed, for example, for endogenous compounds (noninvasive diagnostic procedure), electrolytes, and for the test substance excreted in the urine (pharmacokinetics). An alternative noninvasive method for the assessment of adrenal steroid excretion is collection of feces and analysis of steroid metabolites. This approach has been applied to an astounding number of animal species in veterinary medicine and zoology (Ganswindt et al. 2003); it is however time consuming and unusual.

At the end of the treatment period, groups of animals are killed under minimum stress conditions, preferably by rapid decapitation. The time point "24 hours after last dosing" is not always suitable. When changes in pituitary hormone contents need to be assessed, the time point "2 hours after last dosing" is preferable. For ex vivo studies (in vitro test on organs or cell preparations from organs) suitable interval after last treatment need to be selected. Satellite groups may be included to determine the exact time course of changes after dosing.

Endocrine organs are dissected out, and their weight is recorded. In the case of paired organs, one organ is assigned to histology (with suitable fixation), and the other organ is immediately frozen for further hormone analysis, receptor determination, or molecular biology (gene expression profiling). Organs of interest are the adrenal glands, thyroid gland, male reproductive organs (testes, seminal vesicles, ventral prostate, levator ani muscle), and female reproductive organs (uterus, ovaries).

Specific dissection is performed on the brain and pituitary gland. Hypothalamic fragments may be dissected and shock frozen immediately in liquid nitrogen, for later extraction and determination of hypothalamic peptides, and cerebral cortex fragments are analyzed for control. The pituitary gland is dissected out, and the posterior pituitary is stored separately. The anterior pituitary is halved by a median sagittal cut to obtain paired tissue samples for histology (fixation) and for subsequent analysis of hormone contents (stored frozen at $-20°C$ until hormone assay).

At the time of autopsy, other tissues of interest may be obtained (e.g., pancreas, liver, gastrointestinal tract) and processed either for histology or biochemical analysis. The decision on the supplementary selections depends on preexisting information about possible endocrine-mediated adverse effects or toxic pharmacodynamic effects known for other members of the group of compounds investigated.

The selection of the blood sampling procedure depends on the hormone to be measured. Most hormones can be reliably measured, for example, during brief carbon monoxide anesthesia or preferably during brief ether anesthesia by retroorbital venipuncture. Repeated blood sampling is not advisable in this method. Time-action profiles may be established in satellite groups with indwelling catheters, to be sampled for several hours during anesthesia with pentobarbital or ketamine. Experience with the effects of the anesthetic on the hormone to be analyzed is required.

EVALUATION

For all quantitative parameters such as organ weights, group means are calculated, and the significance of differences is assessed by the appropriate statistical methods.

Histology may be reported in descriptive terms, evaluated by semiquantitative methods or by computer-assisted histomorphometric methods (to be used for quantitative statistical analysis). For advanced methods of in situ hybridization and gene expression, a description of the observed changes is generally appropriate together with quantitative data generated by computer-assisted analysis of gene expression profiles.

MODIFICATIONS OF THE METHOD

In each case, this method needs to be adapted by establishing the dose response for new test substance (dose level and duration of action), summarizing the biological/biochemical information which gave "reasons for concern" in the planning of the study. It is helpful to have early pharmacokinetic data for assessment of exposure (MacDonald et al. 1994). The age of the test animals (or initial body weight) may be selected according to the objective of investigation. Adult animals (160–200 g initial body weight) are recommended. However, the method is also applicable to studies on pubertal development (30–40 g initial body weight). For compounds which affect, for example, body composition (antiobesic drugs) or bone density (e.g., bisphosphonates), the selection of rats 300–400 g body weight is preferable, and markedly longer treatment periods may be required (mechanistic studies beyond the endocrine profile design).

CRITICAL ASSESSMENT OF THE METHOD

The endocrine profile is a flexible approach to the investigation of several hormonal systems in one study. It is closely related to the design of subchronic toxicology studies; the specific focus on endocrine systems is very helpful in the interpretation of histological findings and organ weight changes indicative of toxicology. Toxicologist and pharmacologist should convene for the design of such studies because there are characteristic limitations of regulatory toxicology, which require satellite studies of closely related

design. Interpretation of a perceived risk for the human is primarily directed at the result of hormone assays and biomarkers, which might be included in the phase I and II clinical trials for targeted risk assessment (translational design). The spectrum of toxic changes in hormone-dependent organ systems has been reviewed and is available, with reference to the pituitary gland (Tucker 1999), thyroid and parathyroid (Capen 1999), male reproductive system (Sikka 1999), adrenocortical function (Hinson and Raven 1999), and functions of the endocrine and exocrine pancreas (Wilson and Longnecker 1999). The long-term effects of comparative endocrine carcinogenesis have been reviewed for specific instances (Gopinath 1999). These effects however remain to be addressed when results from 6- to 12-month toxicology studies become available. Their interpretation is a considerable challenge because many tumors found in rodents are not relevant for the clinical use of the same compounds, when long-term clinical observations are compared with the initial findings of concern.

14.2.1.1 New Evidence from Environmental Toxicology

A very extensive body of knowledge has been accumulated by toxicologists in programs supported by the OECD and the Environmental Protection Agency (EPA). Many of the classical endocrine bioassays have been reevaluated for the assessment of chemicals with endocrine disruptor characteristics, resulting from large-scale production of chemical products initially found to be toxic for the ecosystem, as well as for reproductive function in humans. Industrial toxicology has provided the initiative for studying many of the well-known steroid compounds as well as thyroid hormones for their effects on mammalian systems. The section on chronic treatment of rats is of particular interest for assessment of endocrine safety pharmacology, both with reference for the analytical parameters and biomarkers included and in particular for the long-term treatment effects. The characteristic difference in relation to endocrine safety pharmacology is the determination of no-observable-effect levels (NOEL) and the use of maximum tolerated doses (O'Connor et al. 2000, 2002a; Kang et al. 2004). Classical bioassays studied extensively with a number of modifications are the Hershberger assay in castrated male rats (Freyberger et al. 2007; Shin et al. 2007; Yamasaki et al. 2004) and the uterotrophic assay in immature rats (Yamasaki et al. 2003). An assay in intact male rats for antiandrogenic activity has been evaluated (O'Connor et al. 2002b; Freyberger and Ahr 2004).

14.2.2 Determination of Hypothalamic Hormones

PURPOSE AND RATIONALE

Many tests substances change the secretion of hypothalamic hormones, either by direct action or more generally by their feedback effects at the hypothalamic level. Under these conditions, the tissue concentration in hypothalamic specimens of treated rats is of interest, especially because several hypothalamic peptide assays are available and can be measured in the same specimen. The circulating concentrations for hypothalamic hormones (peptides) are difficult to measure, due to analytical problems of low concentration, rapid inactivation by enzymes, and pulsatile fluctuation. Circulating concentrations would also change immediately due to the interference of anesthesia and of the autopsy procedure. Tissue concentrations are readily measured in specimens taken rapidly and stored at frozen until assay, preferably adding enzyme inhibitors. It is therefore recommended to take samples of hypothalamic tissue and control samples of cerebral cortical tissue when the effect of a drug candidate on hypothalamic function is to be investigated.

PROCEDURE

Specific dissection is performed on the brain (cerebral cortex, the reference tissue), the hypothalamus (of rats), and pituitary gland. Hypothalamic fragments are dissected out and shock frozen immediately in liquid nitrogen, for later extraction and determination of hypothalamic peptides. The procedure is suitable for the rat and for the rabbit. Immediately after sacrifice, the skull is opened, the brain is removed, and a piece of cerebral cortex and the hypothalamic fragment at the base of the brain is clipped with scissors and stored on dry ice or in liquid nitrogen. Specimens may be shock frozen and homogenized immediately in an ice-cold buffer containing peptidase inhibitors (e.g., bacitracin or aprotinin). Specimens of cerebral cortical tissue are analyzed as controls. The pituitary gland is then dissected out and stored separately, after removing the posterior pituitary (neurohypophyseal hormones).

There are numerous publications which refer to the measurement of luteinizing hormone-releasing hormone (LHRH; Adams and Spies 1981a, b; Adams et al. 1981; Aubert et al. 1980; Berault et al. 1983; Catt et al. 1980; Chan et al. 1981; Clayton 1982a, b; Clayton and Catt 1979; Clayton et al. 1979a, b, 1980; Conn and Hazum 1981; Conn et al. 1981; Dalkin et al. 1981; Dufau et al. 1979; Hazum 1981; Heber and Odell 1978; Kuhl et al. 1980; Loughlin et al. 1981; Loumaye and Catt 1982; Naor et al. 1981; Perrin et al. 1980; Sandow 1982; Sandow et al. 1979, 1981), corticotropin-releasing hormone (CRH; Aguilera et al. 1986; Brown et al. 1988; De Souza and Battaglia 1988; De Souza 1987; Flores et al. 1990; Grino et al. 1986; Hauger et al. 1987, 1988; Millan et al. 1986; Perrin et al. 1986), and growth hormone-releasing hormone (GHRH; Abribat et al. 1990; Audhya et al. 1985; Bohlen et al. 1984; Gelato et al. 1985).

EVALUATION

The hypothalamic peptide concentration in the specimens is determined by radioimmunoassay, using a synthetic reference peptide for the standard curve. Several commercial assays are available for hypothalamic peptides (e.g., http://www.abnova.com). An alternative method is the determination of peptide content in tissue extracts by an HPLC method or by mass spectrometry.

Group means are calculated, and appropriate tests for significance are applied.

MODIFICATIONS OF THE METHOD

In the context of safety pharmacology, hypothalamic hormone concentrations are measured after repeated-dose treatment, to assess due to direct action or feedback effects elicited by the drug candidate. These measurements can be included in the conventional subacute toxicology protocols, after some practice of hypothalamic dissection.

CRITICAL ASSESSMENT OF THE METHOD

The main difficulty is experienced with rapid processing of the tissue samples and selection of an enzyme inhibitor to prevent spontaneous degradation by tissue peptidases (Elkabes et al. 1981; Griffiths and Kelly 1979; Hazum et al. 1981; Horsthemke and Bauer 1981, 1982; Horsthemke et al. 1981; McDermott et al. 1982; Posner et al. 1982). The result needs to be assessed in context with changes in pituitary hormone contents; frequently, the adaptation to treatment at the pituitary level is more informative than the level of the hypothalamic tissue contents.

In many research publications, receptors for hypothalamic peptides have been described at the endocrine target organ level, for example, LHRH receptor in the gonads (Harwood et al. 1980a, b; Pieper et al. 1980; Sharpe 1982; Sharpe and Fraser 1980) and in nonendocrine tissues, for example, the gastrointestinal tract (LHRH and GHRH receptors, Bruhn et al. 1985). These studies, however, have identified no major regulatory mechanisms which could be activated by test compounds to be developed for phase I clinical pharmacology. Application of hypothalamic hormone measurement in safety pharmacology should therefore be restricted to the level of information required for understanding interaction with the secretion of pituitary hormones.

The determination of neurotransmitter concentrations at the suprahypothalamic level is much too complex for an inclusion in safety pharmacology studies and remains an area for research.

14.2.3 Determination of Pituitary Hormone Contents

- Gonadotropins (LH and FSH)
- Thyrotropin (TSH)
- Growth hormone (GH, somatotropin) and insulin-like growth factor (IGF-1)
- Prolactin (PRL)
- Corticotropin (ACTH) and melanotropin (MSH)

PURPOSE AND RATIONALE

This section describes the measurement of pituitary hormones in the context of repeated-dose studies of 1–4 weeks' duration (endocrine profile or regulatory toxicology). In endocrine safety pharmacology studies in rats, it is advisable to determine pituitary hormone concentrations at autopsy (24 h after last treatment injection). Specific rat pituitary hormone assays are commercially available (e.g., Amersham hormone assays at http://www.gelifesciences.com) from the National Hormone and Peptide Program (http://www.humc.edu/hormones/material.html). The time point 2 h after last dosing is in general suitable, when important and characteristic changes in pituitary hormone contents need to be assessed. This will however require

the inclusion of satellite groups in regulatory toxicology studies or specific mechanistic studies.

For toxicology studies in dogs, preparation of the pituitary glands at autopsy may be performed, but this is time consuming and less advisable because of the small numbers of animals in regulatory toxicology studies. In general, homologous assays are recommended. For the rat luteinizing hormone (Daane and Parlow 1971; Niswender et al. 1968; Seki et al. 1971), rat follicle-stimulating hormone (Beastall et al. 1987; Midgley 1967) and rat thyroid-stimulating hormone (Kieffer et al. 1975; Garcia et al. 1976, 1977; DeVito et al. 1989) are glycoprotein hormones exhibiting species specificity. For pharmacological experiments in rats, the homologous assays are preferred. Reagents and advice on procedures were provided by the National Pituitary Agency, Bethesda, Md. and adapted from the standard operating procedure in safety pharmacology. For rat growth hormone (Schalch and Reichlin 1966) and rat prolactin (Niswender et al. 1969; McNeilly and Friesen 1978), specific RIA and ELISA assays are commercially available (e.g., http://www.genwaybio.com). Determination of corticotropin (ACTH) is less frequently required; commercial ELISA assays are available (e.g., http://www.calbiotech.com). For specific research investigation, there are several other methods available, such as assays for melanotropins and other specific pituitary peptides. In each case, it is recommended to perform a preliminary validation of the assay procedure and reagents to make sure that rat hormones are adequately recognized. Sample acquisition and processing may have special requirements which need to be practiced.

PROCEDURE

The skull is opened by scissors, the pituitary gland is dissected out, the posterior pituitary is stored separately (assays for vasopressin and oxytocin are rarely required), and the anterior pituitary is halved by a median sagittal cut to obtain separate tissue samples for histology (fixation) and for subsequent analysis of hormone contents (stored frozen at −20°C until hormone assay). Pituitary glands are homogenized in phosphate-buffered saline pH 7.4 and diluted to the concentration required for the radioimmunoassay. The initial homogenate may be stored deep-frozen for sequential assay of several hormones.

The recommendation for investigation of the paired pituitary halves may be particularly helpful for specific investigation of immunocytochemistry and molecular biology methods.

EVALUATION

Hormone concentrations in dilutions of pituitary homogenates are calculated from standard curves using the appropriate reference standard for rat pituitary hormones, and sample data are calculated as hormone per pituitary gland or per pituitary weight (mg). Group means are calculated, and the significance of differences is assessed by the appropriate statistical methods.

MODIFICATIONS OF THE METHOD

This approach provides a fast and flexible assessment of several pituitary hormones, and results may be compared with morphometric evaluation and immunohistochemistry for several hormones of interest.

CRITICAL ASSESSMENT OF THE METHOD

Changes in pituitary hormone contents are frequently characteristic and may be followed up by measurement of hormone secretion profiles if required. Analytical methods for the rat are often also applicable to mice. For toxicology studies in dogs, preparation of the pituitary glands at autopsy may be performed, but is time consuming and less advisable because of the small numbers of animals in such studies.

14.2.4 Dynamic Function Tests

The changes in baseline hormone secretion are useful for interpretation of drug effects; it is however often advisable to include dynamic function tests based on stimulation of pituitary hormone secretion or of gonadal and adrenal hormone secretion. Examples for pituitary testing and preclinical procedures to be applied have been mentioned above (Melmed and Kleinberg 2008). Typical pituitary function tests are the TRH test for TSH secretion, the LHRH test for secretion of FSH and LH, and the monoiodotyrosine (MIT) test for prolactin secretion. Synthetic CRF may be injected to stimulate secretion of corticotropin (ACTH); more frequently, the injection of corticotropin is used to stimulate the adrenal directly. At the target organ level, similar function tests can be performed, for example, using thyrotropin (TSH) to stimulate thyroid hormone secretion (T4 and T3), human chorionic gonadotropin (hCG) to stimulate testosterone or ovarian steroid secretion, and corticotropin (ACTH) to stimulate adrenal steroids secretion. All reagents for these tests are readily available for tests in rats and dogs; the tests can be built into a standard toxicology protocol, several days before the end of the study. Conversely, the inhibition of enhanced hormone may be tested in treated animals at the end of the study, for example, with inhibitors of prolactin secretion (bromocriptine); this is usually reserved for mechanistic studies. The application of such dynamic function tests in the endocrine diagnostics of pituitary adenoma and responsiveness to therapeutic peptides has been extensively reviewed (Arvat et al. 2001; Babic et al. 2011; Chanson and Salenave 2004; Emeric-Sauval 1986; Ho et al. 1985; Vasquez and Greenblatt 1985).

CRITICAL ASSESSMENT OF THE METHOD

There is one advantage in applying dynamic function tests; they can be included in the safety pharmacology study after 2 or 3 weeks of treatment and may then indicate dose-related changes in pituitary responsiveness caused by the drug candidate.

14.2.5 Gonadotropin Release from Anterior Pituitary Cells

PURPOSE AND RATIONALE

Anterior pituitaries may be incubated directly, kept in culture, or used for cell lines (Mittler and Meites 1964, 1966; Mittler et al. 1970; Sandow et al. 1972) in order to study the synthesis and release of gonadotropins in response to LH-RH.

PROCEDURE

Female Sprague-Dawley rats weighing 100–150 g are used as donors. Each anterior pituitary is removed and cut into four to six pieces of approximately equal size. The cultures are performed in 3.5–1-cm sterile disposable plastic Petri dishes each containing 3 ml medium consisting of nine parts DIFCO medium 199 and one part of newborn calf serum. Twenty-five U/ml penicillin and 25 μg/ml streptomycin are added. In each dish, the explants are supported at the gas interface. An atmosphere of 95% oxygen and 5% carbon dioxide and a temperature of 36°C are maintained. Opposite sides of the same pituitaries provide matched control and experimental preparations. The pituitaries are incubated for a total time of 5 days. After the first 2 days, the medium is removed and discarded. Fresh medium is then added with the LH-RH solutions. Approximately 12 h after the first change of medium and addition of LH-RH, media are removed and frozen. Fresh medium with LH-RH is again added; this procedure is repeated until six samples of medium representing the last 3 days of culture are obtained. Media are assayed for LH content by radioimmunoassay according to Niswender et al. (1968) and for FSH content according to Parlow (1964).

For preparation of pituitary cells, there are several modifications which have been successfully applied, enrichment of specific cell types has been reported, and cell lines in culture are more stable and practical than the freshly dispersed pituitary tissue.

EVALUATION

Several increasing concentrations of test preparation and LH-RH standard preparation are tested, and dose-response curves are obtained allowing calculation of potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

Pituitary halves or quarters were initially used for the assay of LH-RH as well as for the assay of TRH; cultures of enzymatically dispersed anterior pituitary cells from rats were also used (Vale et al. 1972; Martin and Sattler 1979). Loughlin et al. (1981) used perifused pituitary cultures as model for LH-RH regulation of LH secretion. O'Conner and Lapp (1984) studied the effect of pulse frequency and duration of luteinizing hormone-releasing hormone in anterior pituitary cells attached to Cytodex I beads. Functional integrity of anterior pituitary cells separated by a density gradient has been studied (Scheikl-Lenz et al. 1985). These studies have however shown that the time course of the pituitary response in vitro is quite different from the response observed in experimental animals. Receptor-binding ability to rat pituitary and human breast cancer membranes of different agonists and antagonists of luteinizing hormone-releasing hormone was studied by Fekete et al. (1989). Vigh and Schally (1984) and Czernus and Schally (1991) described in detail a cell superfusion system consisting of a Sephadex column with dispersed pituitary cells. LH response of anterior pituitary cells to 3-min exposure to various concentrations of LHRH at 30-min intervals as well as growth hormone response to human growth hormone-releasing hormone (GHRH) resulted in excellent dose-response curves. The effect of growth hormone-releasing hormone was inhibited by somatostatin. Likewise, the effect of LHRH was inhibited by pretreatment with LHRH antagonists.

The method is suitable for studies of interaction with synthetic steroid hormones and endogenous compounds which are modulating the response to releasing hormones (pituitary feedback studies).

CRITICAL ASSESSMENT OF THE METHOD

This stimulation of LH release and FSH release from pituitary cells in vitro does not reflect the time course of the pituitary hormone response found in vivo. The pituitary incubation methods are however useful early safety evaluation of compounds that have shown endocrine activity in the initial toxicology evaluation in rats, and the incubation methods are also useful for comparison of compounds and potency estimates.

14.2.6 TSH Release from Anterior Pituitary Cells

PURPOSE AND RATIONALE

The in vitro bioassay method of Saffran and Schally (1955a, b), developed for detecting CRF activity in hypothalamic extracts, was modified to measure TRH activity in vitro (Guillemin et al. 1963; Bowers et al. 1965; Schally and Redding 1967). The assay is also applicable to other hypothalamic hormones, to their analogues, and to the testing of compounds which modulate the pituitary response to hypothalamic hormones, for example, gonadal steroids and adrenal steroids as well as synthetic compounds with endocrine-modulating activity.

PROCEDURE

Male Sprague-Dawley rats weighing 150–200 g serve as donors. After removal, each pituitary is cut in half, transferred to a 15-ml beaker containing 1.5-ml Krebs-Ringer bicarbonate medium with 200 mg% glucose, and incubated for three 60-min periods. The media used in the first 2 incubations are discarded. At the beginning of the third incubation period, various amounts of test preparation or TRH standard are added to individual beakers. At the end of the third incubation period, the media from both control and experimental beakers are carefully aspirated. The remaining pituitary tissue may be stored frozen for later determination of hormone contents. The incubation media are assayed by RIA for content of TSH and other pituitary hormones of interest.

EVALUATION

Dose-response curves are established for test preparation and standard allowing calculation of potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

For the assay of TRH analogues, cultures of enzymatically dispersed anterior pituitary cells from rats can be used instead of pituitary halves (Vale et al. 1972).

Barros et al. (1986) studied the effect of TRH on cultured GH3 rat anterior pituitary cells using the whole-cell voltage clamp technique.

CRITICAL ASSESSMENT OF THE METHOD

The method of testing in vitro on dispersed pituitary cells is essentially as static method for the comparison of hormones and hormone analogues. It has also been applied to the testing and pituitary tissue ex vivo, from animals that have undergone a period of treatment with compounds that are known to modify the pituitary response, for example, synthetic corticoids.

14.2.7 GH Release from Anterior Pituitary Cells

PURPOSE AND RATIONALE

For testing of pituitary cell stimulation, isolated pituitary glands or cell cultures may be used. In the investigation of growth hormone regulation, antagonism of GH release may be tested by adding somatostatin analogues at increasing concentrations in the presence of a standard concentration of GHRH. Human GHRH and the related peptides with growth hormone-releasing activity may be tested. The effect of GHRH analogues can be tested avoiding the interference of counterregulatory somatostatin secretion which limits the duration of GH release in vivo.

PROCEDURE

The pituitaries of male Sprague-Dawley rats weighing about 100 g are quickly removed after decapitation. The posterior lobe is discarded, and the anterior lobe is divided into two halves by a midsagittal cut. Five bisected hemipituitaries are incubated in plastic vials containing 4 ml TCM 199 with 0.1% BSA, 15 μg/ml penicillin, and 25 μg/ml streptomycin. The vials are gassed with 95% O_2 and 5% CO_2. After 30 min of control incubation, the medium is changed, and various doses of standard and test substances are added for an incubation of 90 min. GH content in the medium and in the pituitary tissue after incubation is determined by a specific radioimmunoassay (Schalch and Reichlin 1966). Other of hormones may be tested in the same procedure, for example, prolactin.

EVALUATION

Dose-response curves are established for standard and test compounds measuring GH release into the medium and GH depletion from the pituitaries. Potency ratios with confidence limits may be calculated from dose-concentration curves.

MODIFICATIONS OF THE METHOD

Superfused pituitary cells may be used in measuring activity and duration of effect, as well as interaction of stimulatory and inhibitory factors. Growth hormone-releasing factor from tumors in human pancreas and from rat hypothalami as well as analogues of growth hormone-releasing hormone were evaluated in a superfused pituitary cell system (Vigh and Schally 1984; Czernus and Schally 1991; Halmos et al. 1993). Anterior pituitaries of two young adult male Sprague-Dawley rats were digested with 0.5% collagenase CLS2 (Worthington) for 50 min. After incubation, the fragments were digested into cell clusters (5–40 cells) by mechanical dispersion, transferred onto two columns, and allowed to sediment simultaneously with 0.8-ml Sephadex G-10. The dead volume of the system was set to 1 ml. Medium 199 containing BSA (2.5 g/l), $NaHCO_3$ (2.2 g/l), and gentamicin sulfate (85 μg/ml) was equilibrated with a mixture of 95% air and 5% CO_2 and used as the culture medium. The medium was pumped at a flow rate of 0.33 ml/min. During an overnight recovery period, the baseline stabilized and the cells regained their full responsiveness. The samples were then infused through a four-way valve at $5 \times 10 - 10$ M concentration for 3 min (one fraction) at 45-min intervals. Rat GH was determined by

radioimmunoassay. The same system was used by Rekasi and Schally (1993) and Kovács et al. (1996a) to evaluate the activity of growth hormone-releasing hormone antagonists. For determination of the antagonistic activity, the cells were exposed to GHRH antagonist simultaneously with GHRH or to GHRH antagonist combined with 100-mM KCl (controls for potassium stimulated GH secretion) for 3 min. After 30 min, the duration of the inhibitory effect of GHRH antagonist was also tested by repeated 3-min infusions of 10 − 9 M GHRH. Using this system with pituitaries of transgenic mice overexpressing the human GHRH gene, Kovács et al. (1997) evaluated the effects of growth hormone-releasing hormone antagonists. Horváth et al. (1995) also determined cAMP release from superfused rat pituitary cells stimulated by growth hormone-releasing hormone.

GH release was determined using cultured rat pituitary cells (Brazeau et al. 1982; Perkins et al. 1983; Scheikl-Lenz et al. 1985). Pituitary cells were prepared by enzyme dispersion with collagenase, DNAase and pancreatin. The cells were cultured for 3 days in microbiological Petri dishes in Dulbecco's modified essential medium with 20-mM HEPES, 15% fetal calf serum, 100 mU/ml penicillin-G, and 100 μg/ml streptomycin at 37°C and 10% CO_2.

Cheng et al. (1993) tested time- and dose-dependent growth hormone release by a non-peptidyl growth hormone secretagogue in rat pituitary cells. Sanchez-Hormigo et al. (1998) tested growth hormone-releasing hexapeptide on growth hormone secretion from cultured porcine somatotropes.

As a follow-up from the in vitro pituitary cells studies, Kovács et al. (1996b) measured the effects of chronic administration of a growth hormone-releasing hormone agonist on body weight, tibia length, and tail length in growth hormone-deficient (monosodium glutamate-lesioned) rats. Jacks et al. (1996) evaluated an orally active growth hormone secretagogue in dogs. Serum growth hormone levels were dose-dependently increased after oral and intravenous administration. Moreover, an increase of insulin-like growth factor and serum cortisol was found. Clearly, the pituitary incubation method can only identify compounds which are suitable for further in vivo characterization, because the responses found in test animals at the target organ level are vastly different from those found at the pituitary cell level.

CRITICAL ASSESSMENT OF THE METHOD

The advantage of pituitary cell incubation with test compounds of suspected endocrine activity is that useful initial information can be provided, especially for compounds that show neuroendocrine modulating activity, for example, neuroleptics and dopamine receptor agonists. The response at a clearly defined cellular level needs then to be compared with the response in intact animals, where multiple feedback loops are operating and may markedly change the response profile when the test result is compared in vitro and in vivo. The possibility of using pituitary cells ex vivo from treated animals should always be kept in mind.

14.2.8 Determination of Gonadal and Adrenal Steroid Hormones

PURPOSE AND RATIONALE

The gonadal steroid hormones are not species specific and can be readily determined by analytical method in mice, rats, rabbits, dogs, and other animal species used in safety evaluation. There have been many developments in technology of steroid hormone assays, in part to improve clinical diagnostics and to a large extent for research applications (Bock 2000; Henley et al. 2005; Wu 2006). Many standard assay procedures are available from commercial suppliers ("Internet Resources"). For investigation of receptor concentrations in tissue samples (Lieberman 2001) and for circulating concentrations, many methods are available (Wheeler and Morley Hutchinson 2005). In the endocrine profile protocol in rats, assays for testosterone, estradiol, and progesterone are usually required for the interpretation of effects found in the reproductive system (by organ weight changes or by histology). Reproductive organ weights (testes, seminal vesicles, uterus, and ovaries) are recorded at the end of the study. In general, effects of the test compound will be related to changes in steroid biosynthesis. In rat and dog repeated-dose studies, it is advisable to correlate the changes in organ weights with circulating concentrations of target organ hormones. In male rats, serum testosterone is determined at time of autopsy, 2 or 24 h after last treatment. In case of relevant changes, serum LH may also be determined. In female rats, serum estradiol and progesterone are determined; there is however the problem of the ovarian hormone concentrations changing with the estrous cycle. Their determination in a general procedure is relevant when major changes are found in weight of the uterus and the ovaries. Determination effects on testosterone have been helpful in toxicology studies, whereas estradiol determination in female dogs was not useful.

PROCEDURE

Blood samples are taken during the study or at autopsy. Gonadal steroid hormones are determined by specific immunoassays requiring very small sample volumes; extraction procedures are no longer needed. Steroid receptors can be determined in tissue sample storage at autopsy, for later selection of necessary investigations.

EVALUATION

Hormone concentrations are calculated from standard curves using the appropriate steroids as reference standards. Sample data are calculated as hormone concentrations in serum or per unit tissue weight (mg), when gonadal tissue is extracted. Group means are calculated, and the significance of differences is assessed by the appropriate statistical methods.

MODIFICATIONS OF THE METHOD

For the steroid hormone assays, there are many suppliers nowadays, and an Internet search for suitable reagents and methods is indicated. Due to frequent changes in suppliers, it is recommended to search for a suitable steroid assay method at the time of planning and endocrine safety pharmacology study.

CRITICAL ASSESSMENT OF THE METHOD

In the general procedure in female rats, determination of serum estradiol is useful when changes in the reproductive system are detected; concentrations may be evaluated in relation to the rat estrous cycle. In adult male rats, changes in reproductive organ weights are distinctive and generally do not require an additional measurement of testosterone for confirmation. For repeated-dose studies in dogs, testosterone measurement was found useful, whereas measurement of estradiol and progesterone concentrations did not contribute, due to the specific problems of the dog estrous cycle and due to low circulating estradiol concentrations. An alternative approach is the processing of gonadal tissue by ex vivo procedures or in vitro methods (Powlin et al. 1998), extensively applied for the characterization of endocrine-disrupting chemicals.

14.3 Hypothalamic-Pituitary-Gonadal Function

The investigations addressed here are directed at changes in gonadal function, which are either predicted or anticipated from the specific pharmacology studies with the test compound (see reviews by DeKretser (1993), Findlay (1994)). Early indications may come from receptor screening data (Sedlak et al. 2011; Sonneveld et al. 2005; Sonneveld et al. 2006; Wilkinson et al. 2008), from in vitro assays (Lamb and Chapin 1993; Scrimshaw and Lester 2004) and targeted cell-based assays (pubmed/PubChem Bioassay). There is now a wide array of sophisticated and complex research methods, including studies on mechanisms in transgenic animals (Walters et al. 2010; Zhou 2010). This includes the application of nuclear receptor technology (Chen 2008) in the search for and profiling of new chemical entities (NCEs). Application of these methods is in the research domain, whereas the safety pharmacology needs to address questions which arise from the proposed clinical indication, directed at the response of the gonadal system preferably in intact animals (mechanistic studies), with a view to understanding of hormone-dependent regulations initiated or modified by the tests compound. In particular, this includes evaluation of feedback effects which cannot be investigated by in vitro systems (Collis 2006) and findings from early exploratory toxicology studies (Kramer et al. 2007; Bass et al. 2009).

There are many methods in early toxicology of lead compounds and xenobiotics which rely on application of nuclear receptor technology (Lu et al. 2006; Houck and Kavlock 2008; Lazar 2011) and address effects on gonadal steroid biosynthesis (Sanderson 2006). There is also an extensive knowledge comprising methods for and results of assessment of endocrine-disrupting xenobiotics (Steinberger and Klinefelter 1993; Zenick et al. 1994; Hess 1998; Moffit et al. 2007; Wong and Cheng 2011; Shanle and Xu 2011). Mechanisms of male reproductive toxicology identified by classical toxicology have been reviewed extensively (Mattison 1983; Working 1989; Chapin and Williams 1989). One interesting example is the effect of ketoconazole on the male reproductive system due to inhibition of steroid biosynthesis (Sikka et al. 1985; Bhasin et al. 1986). The advancement in

technology for multiple steroid determination from mammalian blood samples (namely, experimental animals) is very impressive and for specific questions may become of practical relevance in toxicology research (Koren et al. 2012), both for gonadal function and for evaluation of adrenal steroids. For safety pharmacology, it is preferable to rely on conventional methods for gonadal steroids.

14.3.1 Repeated Dose Study in Male and Female Rat

PURPOSE AND RATIONALE

These investigations directed at gonadal function are repeated-dose studies of similar design as the regulatory toxicology studies in rats (see Sect. 14.2). The purpose is to detect changes in the secretion of gonadotropins, gonadal steroids, and associated organ weight changes. The findings need to be interpreted in the context of reproductive toxicology, which is addressed by the regulatory studies (Neubert et al. 1999; Dorato and Buckley 2006). The duration of treatment can vary from 7 to 28 days, depending on the study objective. Issues of safety pharmacology to be addressed are in the following:

Group 1: direct effects on female and male reproductive tract, due to gonadal steroid activity (direct hormone action, by interaction with nuclear hormone receptors)

Group 2: indirect effects caused by the secretion of gonadotropins and their effect on female and male reproductive tract (by interaction with gonadotropin receptors), including feedback activation or inhibition at the level of the pituitary gland

Group 3: hypothalamic or suprahypothalamic effects caused by increased secretion and synthesis of hypothalamic peptides, which stimulate secretion of gonadotropins. The hypothalamic effects may be mediated, for example, by feedback of gonadal steroids

In group 3, the gonadotropin release will induce the secretion of gonadal steroids. This is the most relevant level accessible to investigation in vitro, ex vivo, and by repeated-dose animal study. When complex hormone interactions are present, for instance, by induced changes in the secretion and synthesis of prolactin, detailed investigation of ovarian function and steroid-induced effects on the mammary gland will be required, by histology and by proliferation markers. There is considerable overlap with the findings of reproduction toxicology, and the investigation of pituitary-gonadal function should always be in the context of ovarian morphology/histology, vaginal cytology, and uterine weight/histology. Treatment periods of 4 weeks are preferred for these investigations. In male rats, weight changes of the testis and epididymis and associated histological findings need to be addressed. The related in vitro methods are directed at the Sertoli cell (FSH mediated) and Leydig cell (LH mediated, DeKretser 1993).

PROCEDURE

Male and female rats of suitable age are assigned to groups of six to eight animals, including control groups. The selection of age group depends on study objectives, generally adult animals; however, the method is also applicable to the assessment of the effect on pubertal development. For safety pharmacology, initial body weight 100–200 g is preferred, and duration of treatment should be 28 days (in some cases, a 7-day treatment period for exploratory determination of gonadotropins and gonadal steroids is acceptable, when clear indications about the anticipated effects are available from previous in vitro pharmacology investigation and from structure activity considerations). The strain of rats needs to be the same as used in the regulatory toxicology of the same institution, to avoid problems caused by strain-specific reactions, as found with, for example, Sprague-Dawley rats versus Fischer rats (Weisenberg et al. 1987; Sandusky et al. 1988; Chandra et al. 1993; Fort et al. 1995).

For specific questions, selection of rats of 30-g initial body weight or 300-g initial body weight may be advisable (concerning pubertal development or effects on the reproductive system of animals having reached full maturation, weight-plateaued female animals, and ovariectomized adult females for bone-related investigation).

The dose range is selected based on the biological dose which is known to induce an effect related to the proposed therapeutic indication (low dose or "therapeutic dose"); the high dose should at least be a tenfold increment of the biological dose. The route of application is selected by the intended route of treatment in humans; groups with additional routes of application may be included to increase exposure by achieving high initial concentrations. Pharmacokinetic monitoring of the achieved drug concentrations is essential, at

least one time point near the end of the study, with selection of adequate sampling time points based on available pharmacokinetic information. It may be necessary to treat the animals more than once daily, to achieve sufficient exposure. At the end of this study (24 h after the last drug dosing), the animals are weighed (final body weight), and the organs of the reproductive tract (see below) are dissected out, weighed, and processed for histology. In case of paired organs, the second organ specimen may be used for biochemical analysis (hormone contents) or molecular biology investigation such as in situ hybridization and gene expression pattern (genomics).

For hormone determinations, tissues are stored frozen at −20°C. For analysis of gene expression, specific conditions apply of rapid refrigeration and storage at −80°C; tissue handling should be done by specialized investigators who need to be present during the procedure of sacrificing the animals. Due to the complexity of such investigations, inclusion of further satellite groups may be advisable or mandatory.

14.3.1.1 Male Reproductive System

Reproductive organ weight and histology: dissect out and determine weight of the testes, seminal vesicles, ventral prostate, and levator ani muscle (optional for anabolic activity). Preserve for histology one testis, seminal vesicles, and ventral prostate. Optional investigation: store one testis at −20°C for determination of gonadal steroid content, perform ex vivo stimulation test with one testis by incubation for 3 h with human chorionic gonadotropin (hCG), isolate Leydig cells by collagenase, and perform stimulation tests on the Leydig cell preparation (LHCG-receptors, testosterone production).

Hypothalamus

Take hypothalamic tissue fragment at autopsy (clearly visible at base of brain, excise with curved scissors, shock freeze immediately, and store at −20°C) and record weight of fragment. For control tissue, take sample of brain cortex (about same size and weight). An alternative way of handling sample is to homogenize tissue samples immediately in cold saline-containing bacitracin or another inhibitor of peptidase activity and store homogenate at −20°C. Tissue content of luteinizing hormone-releasing hormone (LHRH gonadorelin) is determined by specific radioimmunoassay (RIA).

Anterior Pituitary

Anterior and posterior pituitary are found together at the base of the skull, once the brain has been removed. The neurohypophyseal part (posterior pituitary) is discarded, and the anterior pituitary is bisected to provide one-half for histology and the other half for hormone tissue content (median sagittal cut through the anterior pituitary). Store pituitary tissue at −20°C for measurement of hormones.
