Determination of K_m values of radiolabeled compounds is possible by using nonlinear regression (Vavricka et al. 2002). Inhibition constants (K_i) are estimated by Dixon plot analysis and linear regression using ordinary least squares.

CRITICAL ASSESSMENT OF THE METHOD

Advantages

- High expression levels.
- Low background activities of the oocytes.
- Injection of several cRNAs at the same time is possible.

Disadvantages

- Susceptible system, for example, to fluctuating temperature or transportation.
- Low reproducibility because of high variability of the oocytes.
- Fluctuating gene expression.
- Time-consuming and therefore suitable only for low throughput.
- Correlation to in vivo data is difficult.

MODIFICATION OF THE METHOD

- Alternatively, pre-injected Xenopus oocytes are commercially available by BD Biosciences, Woburn, MA.

36.2.4.1 Electrophysiological Studies

Xenopus laevis oocytes are also suitable for electrophysiological studies on electrogenic transporters. The method has been described by Wolff et al. (2007). Briefly, studies are carried out 3 days after cRNA injection at room temperature. Current recordings are made in ORI-2 without gentamicin and sodium pyruvate using the two-electrode voltage clamp technique with a commercial amplifier (OC725, Warner, Hambden, CT, USA). Borosilicate glass microelectrodes are filled with 3 M KCl and have resistances of ~1 M. The resting membrane potential of the oocytes ranged between −28 and −46 mV and holding currents to achieve a potential of −60 mV were in the range of −10 to −40 nA. Steady-state currents are obtained during 5 s voltage pulses from −60 mV to potentials between −90 and 0 mV in 10-mV steps. The current–voltage (I–V) relationships for substrate-induced currents, ΔI, are determined by subtraction of the steady-state currents in the absence of substrate from currents in the presence of substrate, respectively.

EXAMPLES

The antibiotics rifamycin SV and rifampicin reduce sulfobromophthalein (BSP) elimination in humans. Using injected oocytes, Vavricka et al. (2002) have demonstrated that rifampicin is transported by OATP1B1 (OATP-C) and OATP1B3 (OATP8) and that both rifampicin and rifamycin SV inhibit OATP1B1-, OATP1B3-, OATP2B1-, and OATP1A2-mediated BSP uptakes. These results show that rifamycin SV and rifampicin interact with OATP-mediated substrate transport to different extents. Inhibition of human liver OATPs can explain the previously observed effects of rifamycin SV and rifampicin on hepatic organic anion elimination.

36.3 Drug Efflux by ABC Transporters

36.3.1 Drug Transport Mediated by ABC Transporters Using Eukaryotic Membrane Vesicles

PURPOSE AND RATIONALE

Transporters expressed in organs such as intestine, liver, and kidney may significantly affect uptake, distribution, and elimination of drugs. Efflux transporters are often accounted for the transport of endogenous compounds and pharmaceutical drugs out of the body into bile, urine, or gut in order to protect the cell. The efflux transporters of the ATP-binding cassette (ABC) proteins use the energy of ATP hydrolysis to mediate the transport of the substrate against a concentration gradient.

In vitro studies on the function of efflux transporters are mainly performed using cell systems or vesicle preparations from various sources such as tissue, primary cells, or cell lines transfected with specific transport proteins.

In whole-cell systems, the drug efflux can be measured directly only after the cells are loaded with the study compound. Inside-out vesicles can be perfectly used to study single efflux processes because preloading of cells is not necessary and because of well-defined study conditions.

PROCEDURE

36.3.1.1 Preparation of Plasma Membrane Vesicles from Eukaryotic Cell Lines

Selection of the cell line or tissue type influences not only the technique for membrane vesicle preparation but also the resulting percentage of inside-out-oriented plasma membrane vesicles. A sufficient amount of inside-out-oriented vesicles is essential since only this fraction, with the ATP-binding domains oriented to the outer surface, mediates ATP-dependent transport of a labeled substrate into the vesicle.

The procedure described is based on references Jedlitschky et al. (1994, 1996), Leier et al. (1994a, b), and Keppler et al. (1998).

Eukaryotic cells expressing ABC transporters (e.g., HEK-MRP1) (about 3×10^9) are harvested by centrifugation ($1{,}200\times g$, 10 min, 4°C) and washed twice in ice-cold phosphate-buffered saline (PBS: 0.15 M NaCl, 50 mM KH_2PO_4, pH 7.4). Hypotonic lysis of the cell pellet (about 5 ml) is induced by 40-fold dilution with hypotonic buffer (0.5 mM sodium phosphate, pH 7.0, 0.1 mM EDTA) supplemented with proteinase inhibitors [0.1 mM phenylmethylsulfonyl fluoride (PMSF), 2.8 μM E64 [*trans*-epoxysuccinyl-L-leucylamido(4-guanidino)butane], 1 μM leupeptin, and 0.3 μM aprotinin]. After gentle stirring on ice for 1.5 h, the cell lysate is centrifuged at $100{,}000\times g$ for 40 min at 4°C. The pellet is then resuspended in 20 ml of hypotonic buffer and homogenized with a Potter-Elvehjem homogenizer (500 rpm, 2 strokes/min, 30 strokes, 4°C).

The homogenate is diluted with incubation buffer (0.25 M sucrose, 10 mM Tris–HCl, pH 7.4) and centrifuged for 10 min at $12{,}000\times g$ at 4°C. The resulting postnuclear supernatant is stored on ice. The corresponding pellet is resuspended in 20 ml of

incubation buffer supplemented with proteinase inhibitors and homogenized and centrifuged again as described earlier. Both postnuclear supernatants are combined and centrifuged at 100,000×*g* for 40 min at 4°C. The pellet is resuspended in 20 ml of incubation buffer and homogenized manually by 50 strokes with a tightly fitting Dounce B (glass/glass) homogenizer (Fisher Scientific, Pittsburgh, PA) on ice.

The homogenate is diluted by addition of 10 ml of incubation buffer to give a crude membrane fraction which is then layered on top of a 38% (w/v) sucrose solution in 5 mM HEPES-KOH, pH 7.4 and centrifuged at 280,000×*g* for 2 h at 4°C in a swing-out rotor. The turbid layer at the interface is collected and diluted in 20 ml of incubation buffer, resuspended and homogenized by 20 strokes with a Dounce B homogenizer on ice, and finally washed by centrifugation at 100,000×*g* for 40 min at 4°C. The resulting pellet is diluted in 1 ml of incubation buffer. Vesicles are formed by passing the suspension 20 times through a 27-gauge needle with a syringe. Aliquots of the membrane vesicle suspension are frozen and stored in liquid nitrogen.

36.3.1.2 Measurement of ATP-Dependent Transport of Leukotriene C_4 (LTC4) by Rapid Filtration Through Nitrocellulose Filters

Various labeled substrates for the conjugate export pumps encoded by MRP1 and MRP2 genes may serve to assess the transport rate in membrane vesicle preparations (e.g., leukotriene C4, 17β-glucuronosyl estradiol, 6α-glucuronosylhyodeoxycholate, 3α-sulfatolithocholyltaurine, glucuronosyletoposide, doxorbicin, daunorubicin, vinblastine). Because of its high affinity and specificity for MRP1 and MPR2 and commercial availability, ^{3}H-LTC4 is a preferred substrate for transport measurements. This method is based on references Bohme et al. (1993), Buchler et al. (1994), and Leier et al. (1994a).

Using LTC_4 as substrate, nitrocellulose filters (0.2 μm pore size, 25 mm diameter) are soaked in incubation buffer (0.25 mM sucrose, 10 mM Tris–HCl, pH 7.4). A rapid filtration apparatus from Millipore (Bedford, MA) is prepared. A final volume of 110 μl of transport assay mixture (4 mM ATP (potassium salt), 10 mM creatine phosphate (Tris salt), 10 mM $MgCl_2$, 10 mM Tris/HCl (pH 7.4), 5 mM glutathione (reduced), 0.25 mM sucrose, 100 μg/ml creatine phosphokinase (2 units/110 μl), 50 nM ^{3}H-LTC_4 (50 nCi/110 μl); pH 7.4) is preincubated at 37°C for 1 min. Blanks are prepared by replacing ATP by 5′-AMP.

Membrane vesicle suspension should be thawed quickly at 37°C and stored on ice for about 40 min before use. The transport assay is initiated at 37°C by addition of membrane suspension (30 μg protein) to the transport assay mixture (110 μl). Twenty microliter aliquots are removed after 30- or 60-s intervals, immediately diluted with 1 ml of ice-cold incubation buffer, and immediately filtered through nitrocellulose membrane using the vacuum of the filtration apparatus (200 mbar). Filter membranes are rinsed twice with 5 ml of cold incubation buffer, dried, and dissolved in 10 ml scintillation fluid to count for radioactivity.

The transport rate of ^{3}H-LTC_4 into the membrane vesicle is calculated by subtracting the corresponding values in the presence of 5′-AMP (blank sample) from those in the presence of ATP.

EVALUATION

The protein concentration of the membrane vesicle preparation is determined by standard protocols like the Lowry method. The measurement of the Na^+, K^+-ATPase activity may serve to assess the enrichment of plasma membranes relative to the original homogenate (Scharschmidt et al. 1979). This enrichment should be 15- to 30-fold. The sidedness of the membrane vesicle preparation may be estimated by the activity of an ectoenzyme, nucleotide pyrophosphatase (EC 3.6.1.9), in the presence or absence of Triton X-100 for solubilization of the membrane vesicle (Bohme et al. 1994). The percentage of inside-out-oriented plasma membrane vesicles from HL60 cells (Jedlitschky et al. 1994), mastocytoma cells (Leier et al. 1994b), or HeLa (Leier et al. 1994a) cells should range from 30% to 40%.

CRITICAL ASSESSMENT OF THE METHOD

Advantages

- Vesicles can be made by a various number of sources.
- Vesicles can be stored at −80°C for a month.
- Membrane vesicles are useful in assessing the mechanism of transport (driving force) and identifying substrates and inhibitors of efflux transporters.
- This assay is less time and labor-intensive compared to cellular Transwell assays.

– Drug transport by a specific transport protein can be characterized without interference from other transport processes.
– In contrast to the cellular system, the drug interacts directly with the efflux transporters in the vesicle model without preloading the cells with the drug.
– For inhibition studies, passive permeability of the potential inhibitor is not relevant, and compared to cell-based assays, the concentration of the inhibitor is known.

Disadvantages
– Preparation of membrane vesicles is a time-consuming and lab-intensive process.
– Major disadvantages in identifying substrates are that compounds with a high passive permeability can penetrate the vesicles in both directions passively much faster than by the efflux transporter.

MODIFICATION OF THE METHOD

36.3.1.3 Preparation of Plasma Membrane Vesicles

The preparation of plasma membrane vesicles from liver canalicular membrane is highly enriched with the canalicular (apical) isoform MRP2 (Buchler et al. 1996). Methods for the isolation of hepatocyte canalicular membranes from liver tissue have been described in detail (Bohme et al. 1994; Boyer and Meier 1990). The percentage of inside-out-oriented vesicles in these preparations amounts to 32%. Alternatively, transfected HEK and MDCK cells are often used to study ATP-dependent transport into inside-out vesicles (Cui et al. 1999; Leier et al. 2000).

36.3.1.4 Measurement of ATP-Dependent Transport of Leukotriene C_4 (LTC4) by Centrifugation of the Vesicles Through a Gel Matrix

For substrates more hydrophobic than LTC_4 which binds strongly to nitrocellulose filters (e.g., glucuronosyl-etoposide, glutathione S-conjugates of melphalan and chlorambucil), small Sephadex G-50 columns should be employed (Jedlitschky et al. 1996, Bohme et al. 1993, and Buchler et al. 1994). For this procedure, NICK spin columns (Pharmacia, Uppsala, Sweden) (0.2 g Sephadex G-50/3.3 ml) are prepared, rinsed with incubation buffer, and centrifuged at $400 \times g$ for 4 min at 4°C. Aliquots of the incubations are diluted in 80 µl of ice-cold incubation buffer and loaded immediately onto the columns. After rinsing with 100 µl of incubation buffer, the columns are centrifuged at $400 \times g$ for 4 min 4°C. The effluents are collected and counted for radioactivity.

EXAMPLES

Para-aminohippurate (PAH) is widely used as model substrate for organic anion transport in proximal tubule epithelia (kidney). Leier et al. (2000) investigated PAH as a substrate for the apical multidrug resistance protein MRP2 (ABCC2) which is expressed in kidney, as well as in liver and small intestine. Membrane vesicles from HEK-MRP2 cells and from control cells were incubated with various concentrations of ^{3}H-PAH, and the net ATP-dependent transport into inside-out vesicles was determined. Transport rates at 10 μM PAH were 22 pmol/mg protein/min and 1.6 pmol/mg protein/min with membrane vesicles from HEK-MRP2 and HEK-control cells, respectively. The K_m value for PAH was 880 μM. MRP2 substrate leukotriene C4 and the MRP1-inhibitor MK571 inhibited MRP2-mediated PAH (100 nM) transport with IC_{50} values of 3.3 and 4.0 μM, respectively. The nephrotoxic mycotoxin ochratoxin A inhibited MRP2-mediated PAH transport with an IC_{50} value of 58 μM. Ochratoxin A itself was a substrate of MRP2 (Leier et al. 2000).

36.3.2 Drug Transport Mediated by ABC Transporters Using Membrane Vesicles from Insect Cells

PURPOSE AND RATIONALE

Multidrug resistance proteins (MRPs) have been suggested to play an important role in the transport and detoxification of a wide range of endogenous compounds and xenobiotics. They are predominantly expressed at the apical membrane of the small intestine, proximal tubules of the kidney, and canalicular membrane of hepatocytes being involved in intestinal, renal, and hepatobiliary excretion of compounds.

To obtain a relatively high expression of transporter protein expression, baculovirus-infected Sf9 insect cells can be used.

Vesicles can be used to study substrate specificity of transporters, transport of xenobiotics and endogenous substances, transporter-mediated drug–drug interaction, hepatotoxicity, pharmacological efficacy, and transporter-metabolism interplay in drug disposition.

PROCEDURE

36.3.2.1 Preparation of Plasma Membrane Vesicles

According to Chu et al. (2004, 1997), *Spodoptera frugiperda* (Sf9) cells in suspension are grown in Sf-900 II SFM medium in the absence of serum (Invitrogen, Carlsbad, CA). About 4 × 10^{7} Sf9 cells are seeded in 175 cm^{2} tissue culture flasks. After the cells become attached, the medium is removed, and 3 ml of medium and 3 ml of virus stock containing, for example, MRP1, MRP2, or MRP3 (about 5–8 × 10^{7} recombinant baculovirus/ml) are added to infect the cells. One hour after addition of the virus to the cells, cell culture medium is added up to a final volume of 30 ml. After incubation for 72 h at 26°C, the cells are harvested and washed twice in ice-cold washing buffer (50 mM Tris/HCl, 300 mM mannitol, 0.5 mM PMSF, pH 7.0) and centrifuged at 800×*g* for 5 min at 4°C. The cell pellet is resuspended in ice-cold TMEP buffer (50 mM Tris, 50 mM mannitol, 2 mM EGTA-Tris, 2 mM DTT, aprotinin (8 μg/ml), leupeptin (10 μg/ml), PMSF (50 μg/ml), pH 7.0) and homogenized for 10 min on ice using a tight-fitting Dounce homogenizer. After centrifugation at 800 × g for 10 min at 4°C, the supernatant is collected and centrifuged at 100,000×*g* for 1 h at 4°C. The pellet is resuspended in TMEP buffer and passed 20 times through a 27-gauge needle. The vesicles are dispensed in aliquots, frozen in liquid nitrogen, and stored at −80°C until use.

36.3.2.2 Vesicular Uptake Studies by Rapid Filtration Technique

As reported by Chu et al. 1997, the transport medium contained the radiolabeled substrate (e.g., ^{3}H-ethinylestradiol-3-*O*-sulfate or –3-*O*-glucuronide, ^{3}H-estradiol-17β-D-glucuronide, ^{14}C-ethacrynic acid glutathione), 250 mM sucrose, 10 mM Tis/HCl (pH 7.4), 10 mM $MgCl_2$, 5 mM adenosine 5′ triphosphate (ATP) or 5 mM adenosine monophosphate (AMP), and an ATP-regenerating system (10 mM creatinine phosphate and 100 μg/ml creatine phosphokinase). The uptake study is performed at 37°C. After preincubation for 3 min at 37°C, the uptake study is started by the addition of vesicle suspension (10 μg protein). The final incubation volume is 20 μl. In the inhibition study, the inhibitors are dissolved in transport buffer and preincubated with radiolabeled substrates for 3 min. At designated time points, transport is terminated by

adding 1 ml of ice-cold stop solution containing 10 mM Tris/HCl (pH 7.4), 250 mM sucrose, and 100 mM NaCl. The stopped reaction mixture is filtered through 0.45 μm HA Millipore filters (Millipore Corporation, Bedford, MA) and subsequently washed twice with 5 ml ice-cold stop solution. For the uptake study with ^{3}H-estrone-3-sulfate, glass fiber (type A/E) filters (Gelman Sciences, Dorval, Quebec, Canada) are used to minimize nonspecific binding to membrane filters. The radioactivity retained on the filter and in the reaction mixture is measured in a liquid scintillation counter. ATP-dependent uptake is determined as the difference in uptake in the presence and absence of ATP.

36.3.2.3 ATPase Measurements

ATPase activity of the isolated Sf9 cell membranes is estimated by measuring inorganic phosphate liberation as described by Sarkadi et al. (1992). The differences between ATPase activities measured in the absence and presence of vanadate (100 μM) can be plotted.

EVALUATION

36.3.2.4 Membrane Preparations

The membrane protein concentrations of membrane vesicles are determined as described by Sarkadi et al. (1992).

36.3.2.5 Data Analysis

Kinetic parameters for the ATP-dependent uptake are obtained by fitting the data to the following equation:

$$V_c = V_{max} \times S/(K_m + S), \qquad (36.1)$$

where V_c is the initial uptake rate of substrate (pmol/min/mg protein), S is the substrate concentration in the medium (μM), K_m is the Michaelis constant (μM), and V_{max} is the maximum uptake rate (pmol/min/mg protein).

The inhibition constant (K_i) values for evaluating the inhibitory effect of, for example, ethinylestradiol-3-*O*-glucuronide on the uptake of ^{14}C-ethacrynic acid glutathione by MRP2 is obtained by fitting the following equation to the data as described by Chu et al. (1997):

$$V_{(+I)}/V_{(-I)} = 1/[1 + (I/K_i)], \qquad (36.2)$$

where $V_{(+I)}$ and $V_{(-I)}$ represent the transport velocity in the presence and absence of inhibitor, respectively, and I is the inhibitor concentration. This equation is derived based on the assumptions that firstly inhibition is competitive or noncompetitive and secondly that the radiolabeled substrate concentration used (e.g., ^{14}C-ethacrynic acid glutathione (2 μM)) is much lower than its K_m value (15 μM for MRP2).

CRITICAL ASSESSMENT OF THE METHOD

Advantages

- Vesicles can be stored frozen for a long period.
- High-throughput screening.
- Both uptake and efflux transporters can be studied.
- Compared to mammalian cell lines, Sf9 cells have a reduced transporter background and higher expression levels.

Disadvantages

- Lipid membrane composition and glycosylation mechanism are different in insect cells compared to eukaryotic cells.
- The reduced cholesterol content of Sf9 can influence the activity of efflux transporters.

MODIFICATION OF THE METHOD

Ready to use membrane vesicles for the ABC transporters MDR1, MRP1, MRP2, MRP3, and MXR are commercially available from Solvo Biotechnology (Hungary, Budapest; www.solvo.com) and can be used for uptake measurements. Membranes and protocols for ATPase measurements are also available.

Recombinant baculoviruses can be prepared as described by Bakos et al. (1998) by using the BaculoGold Transfection Kit according to the manufacturer's recommendations (Pharmingen, San Diego, CA) or by using the pAcUW21 plasmid (Invitrogen, San Diego, CA).

Sarkadi B, Price EM, Boucher RC, Germann UA, Scarborough GA (1992) Expression of the human multidrug resistance CDNA in insect cells generates a high activity drug-stimulated membrane ATPase. J Biol Chem 267:4854–4858

EXAMPLES

Bakos et al. (2000) studied the interactions of the human multidrug resistance proteins MRP1 and MRP2 with the organic anions probenecid, furosemide, sulfinpyrazone, penicillin G, and indomethacin. Firstly, they determined the concentrations at half-maximum uptake rates ($K_{1/2}$) for N-ethylmaleimide glutathione (NEM-GS) with $K_{1/2}$ 200 μM for MRP1 and 2.5 mM for MRP2. The effect of organic anions on the relative rate of NEM-GS uptake by MRP1 and MRP2 was then analyzed: Sulfinpyrazone and probenecid efficiently inhibited ATP-dependent active vesicular NEM-GS uptake by MRP1. In case of indomethacin, low concentrations produced a significant stimulation, and only indomethacin concentrations of more than 100 μM inhibited the NEM-GS uptake by MRP1. For MRP2, probenecid inhibited NEM-GS uptake, whereas low concentrations of sulfinpyrazone and indomethacin strongly stimulated the transport of this GS conjugate. Higher sulfinpyrazone and indomethacin concentrations were inhibitory again. The addition of methotrexate caused a slight inhibition of the NEM-GS uptake in both MRP1 and MRP2. Penicillin G caused a major stimulation of MRP2 transport, whereas benzbromarone or furosemide was inhibitory. These tracer uptake experiments clearly suggested that various organic anions acted differently on the two transporters.

36.4 Drug Uptake and Efflux

36.4.1 Drug Transport Mediated by SLC and ABC Transporters Using Double-Transfected Cells

PURPOSE AND RATIONALE

The uptake of substances into hepatocytes and the subsequent export into bile can be viewed as a vectorial transport process. This vectorial transport in human liver can be mimicked in an experimental model system using MDCK cells, which grow in polarized fashion with distinct apical and basolateral membrane domains when cultured on an appropriate filter membrane support (Kopplow et al. 2005). Prof. Keppler (DKFZ, Heidelberg, Germany) established a double-transfected Madin-Darby canine kidney (MDCK) cell line expressing the human hepatocyte basolateral uptake transporter hOATP1B3 (OATP8) and the apical conjugate export pump MRP2 (Cui et al. 2001). Also quadruple-transfected cells are generated with three basolateral transporters hOATP1B1, hOATP1B3, and hOATP1A2 and the apical transporter MRP2 (Kopplow et al. 2005).

To study the transcellular transport via basolateral and apical transporters of renal epithelial cells, Sato et al. (2008) established double-transfected MDCK cells expressing human organic cation transporter hOCT2 and hMATE1.

Double-transfected cells can give a better understanding of the synergistic role of uptake and efflux transporters and therefore facilitate the comparison to in vivo data.

PROCEDURE

36.4.1.1 Cell Culture and Cell Lines

MDCKII cells are cultured according to Cui et al. (2001). In brief, cells are cultured in minimum essential medium supplemented with 10% fetal calf serum, 2 mM L-glutamine, 100 U/ml penicillin, and 100 μg/ml streptomycin in 95% humidity, 5% CO_2 at 37°C. For selection, antibiotics are added (1 mg/ml Zeocin, 800 μg/ml G418 disulfate, 500 μg/ml hygromycin B). Cells are passaged every 3–4 days at 1:10 to 1:15 ratios.

Double-transfected MDCKII cells expressing the human uptake transporter OATP1B3 and the apical export pump MRP2 can be generated by stepwise transfection of MDCK cells. Transfectants expressing recombinant OATP1B3 are selected with hygromycin. The clone with the highest OATP1B3 expression is further transfected with the vector construct pcDNA3.1-MRP2 with the full-length human MRP2 cDNA. After selection with 950 μM hygromycin and 800 μM G418 disulfate for 3 weeks, the transfectants are screened for both MRP2 and OATP1B3 expression by immunoblot analyses (Cui et al. 2001).

36.4.1.2 Transport Measurements

According to Cui et al. (1999, 2001), for transport assays, MDCKII cells are grown on Transwell™ Clear polyester membrane inserts (pore size 0.4 μm; Corning Costar #3450, Cambridge, MA) for 8 days in culture medium without antibiotics. Medium is replaced twice. Butyrate, at a final concentration of 10 mM, is added to the medium 24 h before use of the cells. Cells are first washed with transport buffer (142 mM NaCl, 5 mM KCl, 1 mM KH_2PO_4, 1.2 mM $MgSO_4$, 1.5 mM $CaCl_2$, 5 mM glucose, and 12.5 mM HEPES, pH 7.3). Subsequently, ^{3}H-labeled substrates (^{3}H-BSP, 50–100 nM, 12.3 Ci/mmol) or nonlabeled drug candidates (50 μM) are added in transport buffer either to the apical compartments (1.5 ml) or to the basolateral compartments (2.5 ml). After 90 min, samples from the opposite compartments are taken and analyzed either by liquid scintillation spectrometry or by LC-MS/MS.

The transcellular leakage is determined by incubating cells with 50 μM ^{14}C-inulin carboxylic acid in the basolateral compartments for 30 min and measuring the radioactivity in the apical compartments. The transcellular leakage should be less than 1%.

EVALUATION

Expression and localization of OATP1B3 and MRP2 in MDCK cells was demonstrated by immunoblotting and confocal laser scanning microscopy (Cui et al. 2001). ^{3}H-labeled sulfobromophthalein (BSP) was a substrate for both transport proteins and was transferred from the basolateral to the apical compartment at a rate at least six times faster by double-transfected MDCK-OATP1B3/MRP2 cells than by single-transfected MDCK-OATP1B3 or MDCK-MRP2 cells.

CRITICAL ASSESSMENT OF THE METHOD

Advantages

– Opportunity to study transcellular/vectorial transport of a compound
– Study of efflux transporters without preloading of cells or preparation of membrane vesicles
– Facilitates the comparison to in vivo data

Disadvantages

– No complete human tissue model, just providing information on partial function.
– For drugs, which are highly membrane permeable, the permeation rate across the cell monolayer on the Transwell membrane insert might overcompensate the active transport of the drug. In these cases, the transport rate does not differ between double-transfected, single-transfected, and wild-type cells.
– Only MDCK cells are suitable, HEK293 or CHO cells are not growing tight enough and therefore show too much transcellular leakage.
– The evaluation and quantification of the results is more difficult by using multiple-transfected cells.

MODIFICATION OF THE METHOD

For inhibition studies, the inhibitors are preincubated in both apical and basolateral compartments for one hour and then added simultaneously with ^{3}H-BSP into the basolateral compartment and without ^{3}H-BSP into the apical compartment. After 90 min, the radioactivity is measured in the apical compartment. Using different inhibitor concentrations, the K_i (IC_{50}) value can be calculated. This technique can also be used for drug–drug interaction studies on the level of transporters.

Yamazaki M, Akiyama S, Ni'inuma K, Nishigaki R, Sugiyama Y (1997) Biliary excretion of pravastatin in rats: contribution of the excretion pathway mediated by canalicular multispecific organic anion transporter. Drug Metab Dispos 25:1123–1129

EXAMPLES

Sasaki et al. (2002) established the double-transfected MDCK cell line, which expresses both OATP1B1 (OATP2) and MRP2 on basal and apical membranes. They measured the basolateral-to-apical transport of the lipid-lowering drug pravastatin. The K_m value of pravastatin was 24.3 +/− 10.4 μM, which was in the same magnitude to the K_m of estradiol-17β-glucuronide and comparable with the K_m reported for OATP1B1 only (33.7 μM, Hsiang et al. 1999). Because pravastatin is a low-affinity substrate of MRP2 (220 μM, Yamazaki et al. 1997), the rate-determining step in the transcellular transport of this compound is the uptake mediated by OATP1B1. This hypothesis is consistent with the previous observations that uptake is the rate-determining step for the biliary excretion of pravastatin in rats (Yamazaki et al. 1997).

Double-transfected MDCK cell are established within the members of SLC transporter family only, as shown for OCT1 or OCT2 in combination with MATE1 (Konig et al. 2011). The double-transfected MDCK-OCT1-MATE1 cells and MDCK-OCT2-MATE1 cells demonstrated a significantly higher transcellular transport of metformin (by 50 μM) compared to control cells or single (OCT1, OCT2, or MATE1)-transfected cell. The total metformin transcellular transport and the net-transcellular transport (from the basal into apical compartment) were 6- to 12-fold. The vectorial transport was not saturated up to 2.5 mM concentration of metformin. These in vitro experiments underline the coordinated hepatic elimination of drugs by OCT1 and MATE1 as well as the renal elimination of metformin in proximal tubule cells by OCT2 and MATE1.

36.4.2 Liver-Specific Drug Transport in Sandwich-Cultured Hepatocytes

PURPOSE AND RATIONALE

The knowledge regarding hepatic drug uptake and efflux of compounds in humans is an essential part of the drug development process.

Several human SLC uptake transporters (OATP1B1, OATP1B3, OATP2B1, OAT2, OCT1, NTCP) are expressed on the basolateral (sinusoidal) membrane of human hepatocytes and mediate the hepatic uptake of hydrophilic charged compounds. The apical (canicular) efflux from hepatocytes to bile is driven by ATP-dependent ABC transporters comprising MDR1, BSEP, BCRP, and MRP2. Basolateral excretion of bile acids from hepatocytes into blood is mediated by MRP3 and MRP4.

Primary hepatocyte culture is a reliable in vitro model to study transporter-mediated substrate uptake and efflux in the liver and to evaluate the cooperation of these different drug transporters. Compared to monolayer hepatocytes, freshly or cryopreserved hepatocytes cultured between two layers of gelled collagen (SCH = sandwich-cultured hepatocytes) retain more in vivo–like properties, including formation of intact canalicular network and polarized excretory function. Therefore, SCH are utilized for long-term studies.

In addition, this SCH in vitro model system can also be used to study species differences in drug transport, transport regulation, drug–drug interactions, drug–transporter–enzyme interaction, and hepatotoxicity.

PROCEDURE

36.4.2.1 Hepatocyte Isolation and Culture

Male Wistar rats (250–280 g) can be obtained from Charles River. They are allowed to free access to food (laboratory rodent diet 5001, PMI Feeds, St. Louis, MO) and water and are housed in a constant alternating 12-h light (6:00 a.m. to 6:00 p.m.) and dark cycle.

According to Liu et al. (1999b), hepatocytes are isolated with a two-step perfusion method, and according to LeCluyse et al. (1996), Anneart et al. (2001) and Chandra et al. (2001), after the rat is anesthetized (60 mg/kg ketamine + 12 mg/kg xylazine intraperitoneal), the portal vein is cannulated, and the liver is perfused with a Ca^{2+}-free buffer (118.1 mM NaCl, 25 mM $NaHCO_3$, 5.5 mM glucose, 1 mM EGTA, 4.7 mM KCl, 1.2 mM KH_2PO_4, pH 7.4) equilibrated with 95% O_2/5% CO_2 at a rate of 30 ml/min. The inferior vena cava is cannulated to establish a recirculating system (100 ml Ca^{2+}-free buffer). After 10 min of perfusion, 0.05–0.075 g of collagenase and 4 mg of soybean trypsin inhibitor are added to the

perfusate reservoir to obtain a final collagenase concentration of ~200 U/ml; 1 min later, 1 ml of $CaCl_2$ is added. The liver is perfused for ~10 min with the collagenase buffer, removed from the rat, and immersed in ice-cold medium (DMEM containing 5% FBS, 50 U/ml penicillin, 50 μg/ml streptomycin, 4 mg/l insulin, and 1 μM dexamethasone). The capsule surrounding the liver is torn gently in order to release the hepatocytes. The cells are filtered through a 70-μm mesh filter and then centrifuged (50×*g*) for 2 min at 4°C. The pellet is resuspended in equal parts of medium and isotonic Percoll and centrifuged (70×*g*) for 5 min at 4°C to separate out the nonviable cells. The pellet is resuspended in medium and centrifuged (50×*g*) for 2 min at 4°C. Hepatocytes are counted in a hemocytometer, and viability is determined using the trypan blue exclusion method. Viability is always >90% with a yield of 2–3 × 10^8 cells. Cells are resuspended in medium and diluted to a final concentration of 1 × 10^6 cells/ml.

36.4.2.2 Preparation of Sandwich-Cultured Hepatocytes (SCH)

According to Abe et al. 2008, hepatocytes are seeded at a density of 1.75 million cells per well on 6-well BioCoat™ plated (BD Biosciences Discovery Labware) in 1.5 ml Dulbecco's modified Eagle's medium (DMEM) containing 5% FBS, 10 mM insulin, 1 μM dexamethasone, 2 mM L-glutamine, 1% MEM nonessential amino acids, 100 units penicillin G sodium, and 100 μg streptomycin sulfate. Cells are incubated at 37°C in a humidified incubator with 95% O_2/5% CO_2 and allowed to attach for 2 h, at which time the media is aspired to remove unattached cells and fresh media is added. Twenty-four hours later, cells are overlaid with BD Matrigel™ basement membrane matrix (BD Biosciences Discovery Labware) at a concentration of 0.25 mg/ml in 2 ml ice-cold DMEM containing ITS™ (insulin/transferring/selenium culture supplements from BD), 0,1 μM dexamethasone, 2 mM L-glutamine, 1% MEM nonessential amino acids, 100 units penicillin G sodium, and 100 μg streptomycin sulfate. Hepatocytes are cultured for 4 days; media is changed daily.

36.4.2.3 Accumulation in Sandwich-Cultured Hepatocytes

According to Abe et al. 2008, on day 4, hepatocytes are rinsed twice and then preincubated for 10 min at 37°C with 2 ml of warmed Hank's balanced salt solution (HBSS) containing Ca^{2+} (standard; cells + bile) or Ca^{2+} -free HBSS (cells), in order to maintain or disrupt the tight junctions sealing bile canalicular network, respectively. Subsequently, hepatocytes are incubated with test compound (0.5–30 μM for ARB or statin; 1 μM for [^{3}H]taurocholate or [^{3}H] E2-17ßG) in standard HBSS for 5–20 min (ARB or statin) or 10 min ([^{3}H]taurocholate or [^{3}H]E2-17ßG) at 37°C. For uptake inhibition studies, BSP (a known inhibitor of organic anion transporters and Na^+ taurocholate-cotransporting polypeptide) is added simultaneously with test compound to the hepatocytes. After incubation, the dosing solution is aspirated from the cells, and uptake is stopped by washing the cells three times with ice-cold standard HBSS. For radiolabeled compounds, cells are lysed with 1 ml of 0.5% Triton X-100 in phosphate-buffered saline. For ARBs and statins, cells are lysed with 1 ml of 70% (v/v) methanol and sonicated for 20 s with a sonic dismembrator (model 100; Thermo Fisher Scientific, Waltham, MA) and stored at <−70°C until analysis. The samples are analyzed for drug concentrations by liquid scintillation counting or by liquid chromatography with tandem mass spectrometry.

36.4.2.4 Efflux Studies in Sandwich-Cultured Hepatocytes

Compared to the accumulation protocol, basolateral and canalicular efflux studies in SCH are defined by the reversal of substrate incubation and tight junction disruption steps. According to Liu et al. (1999a, b), hepatocytes cultured in a collagen-sandwich configuration are incubated in 3 ml of standard buffer (Hanks' balanced salt solution: 1.3 mM $CaCl_2$, 0.8 mM $MgSO_4$, 5.4 mM KCl, 0.4 mM KH_2PO_4, 0.3 mM Na_2HPO_4, 4.2 mM $NaHCO_3$, 136.9 mM NaCl, and 5.6 mM D-glucose) at 37°C for 10 min. Each dish received 3 ml of standard buffer containing 1 μM ^{3}H-taurocholate or 3.6 μM ^{14}C-salicylate followed by incubation at 37°C for 10 min. Subsequently, the incubation buffer is removed, and cultures are washed four times with 3 ml ice-cold standard buffer to quench the transport processes and remove extracellular substrate. Efflux is initiated by addition of 3 ml of standard buffer or Ca^{2+}-free buffer to each dish. Aliquots of efflux buffer (0.1 ml) are removed at designated times and analyzed by liquid scintillation spectrometry.

EVALUATION

– Taurocholate, a model bile acid, has been used to evaluate the potential for drugs to inhibit bile acid transport in the SCH.
– Time and concentration should be within the linear range of uptake, preferably within the first 10–15 min.
– Substrate accumulations are corrected for nonspecific binding by using Matrixgel-precoated dishes without cells.
– Determination of protein levels of transporter in freshly isolated hepatocytes day 0 and SCRH and on day 4 of culture by immunoblot analysis.
– Efflux or uptake data is normalized to the total solubilized protein content. Bio-Rad DC protein assay kit (Bio-Rad Laboratories) can be used to determine the protein concentration in the culture extracts using BSA as standard. Triton X-100 (1%) does not interfere with this assay.

36.4.2.5 Data Calculation

Hepatic uptake clearance of substrates may be quantified based on the total accumulation of substrate in standard HBSS in the linear range of uptake according the following equation:

$$\text{In vitro Cl}_{\text{uptake}} = \frac{\text{Accumulation (cells + bile)}}{\text{AUC}_{0-\text{T}}}.$$

The accumulation (pmol/mg protein), biliary excretion index (BEI;%), and in vitro intrinsic $\text{Cl}_{\text{biliary}}$ (ml/min/kg) are calculated using B-Clear® technology (Qualyst, Inc, Raleigh, NC) based on following equations (Liu et al. 1999a):

$$\text{BEI (\%)} = \frac{\text{Accumulation (cells + bile)} - \text{Accumulation (cells)}}{\text{Accumulation (cells + bile)}} \times 100.$$

The in vitro biliary clearance may be quantified based on the total accumulation of substrate in the bile canalicular network divided by the area under the concentration curve of the dosing medium using the following equation:

$$\text{In vitro Cl}_{\text{biliary}} = \frac{\text{Accumulation (cells + bile)} - \text{Accumulation (cells)}}{\text{AUC}_{0-\text{T}}}.$$

CRITICAL ASSESSMENT OF THE METHOD

Advantages

– Investigate hepatic uptake and efflux kinetics of substrates in in vivo–like properties.
– Most hepatic transporters and drug-enzymes are expressed.
– Compared to freshly isolated hepatocytes, SCH can be used for long-term studies.
– Good in vitro and in vivo correlation.
– Cryopreserved hepatocytes are a good alternative compared to freshly isolated hepatocytes.

Disadvantages

– Isolation of hepatocytes is an intensive method that has to be optimized for each species.
– SCH is a static model with no bile and blood flow.
– Using primary cultures of hepatocytes, the retention of transporter expression and activity needs to be evaluated after each preparation.
– The extent of bile canalicular network formation and optimal levels of metabolizing enzymes and transport proteins are important factors to consider when determining the appropriate time in culture to conduct functional studies.

MODIFICATION OF THE METHOD

An exclusive sandwich-cultured hepatocyte system for hepatobiliary disposition is also commercially available by Qualyst, Inc. (www.qualyst.com), named B-CLEAR™.

36.4.2.6 Cryopreserved Hepatocytes as SCH

Hepatocytes cryopreserved is an enabling technology with the advantages over freshly isolated cells including long-term storage, ease of experimental scheduling, choice of precharacterized lots for experiments, and repeat experiments with hepatocytes from the same donors. Application of this model has been extended to include hepatocytes from other species (Rose et al. 2006 and Swift and Brouwer 2010).

Cryopreserved human hepatocytes are also commercial available from Invitrogen life technologies (http://www.invitrogen.com), BD Biosciences (http://www.bdbiosciences.com/eu/index.jsp), and Celsis (http://www.celsis.com/), and the use has been successfully established by Li et al. (2010) and Maeda et al. (2010).

De Bruyn et al. (2011) determined transporter-mediated substrate uptake activities in individual and pooled batches of cryopreserved human hepatocytes and showed accumulation values that were comparable with the mean of the individual batches.

Houle et al. (2003) compared the transporter activities in cryopreserved and freshly isolated hepatocytes and found no significant difference in the transport rates of ^{14}C-taurocholate, ^{3}H-estrone sulfate, and ^{3}H-estradiol-17β-D-glucuronide.

36.4.2.7 Accumulation Studies with Fluorescence Substrates

Another unique tool that has been utilized with the SCH model system is incubation with fluorescence probes to study transport function. For MDR1-mediated in vitro biliary excretion, rhodamine 123 and ^{3}H-digoxin can be used in accumulation studies according to Annaert et al. (2001). Cells are rinsed twice with 2 ml of warm standard HBSS and incubated in 3 ml of the same buffer for 10 min at 37°C for experiments in which the effect of a Pgp modulator (e.g., GF120918; GlaxoSmithKline) is investigated, cells are preincubated for 60 min with the appropriate concentration of the Pgp modulator. Subsequently, cells are incubated in 3 ml of 1 μM substrate dissolved either in standard or Ca^{2+}-free HBSS for 1–30 min and subsequently rinsed for times with 3 ml of ice-cold HBSS. For rinsing of ^{3}H-digoxin-treated hepatocytes, 10 μM unlabeled digoxin is added to the rinsing buffer to reduce nonspecific binding. Hepatocytes are lysed with 3 ml of 0.5% Triton X-100 solution by placing plates on a rotator for 20 min at room temperature. Cell lysates are analyzed by fluorescence spectroscopy for Rh123 analysis and by liquid scintillation spectroscopy for ^{3}H-digoxin.

EXAMPLES

In vitro $Cl_{biliary}$ values have been shown to correlate well with in vivo intrinsic $Cl_{biliary}$ values in rats and humans for a number of compounds.

Abe et al. (2008) studied in vitro the biliary clearance in sandwich-cultured human hepatocytes of angiotensin II receptor blockers and HMG-CoA reductase inhibitors that undergo limited metabolism and compared the predicted in vitro values with estimated in vivo hepatic clearance data in rats.

The average biliary excretion index and in vitro intrinsic $Cl_{biliary}$ values of olmesartan, valsartan, pravastatin, rosuvastatin, and pitavastatin were 35%, 23%, 31%, 25%, and 16%, respectively, and 0.943, 1.20, 0.484, 3.39, and 5.48 ml/min/kg, respectively. $Cl_{biliary}$ values predicted from sandwich-cultured human hepatocytes correlated with estimated in vivo hepatic clearance values based on published data (no in vivo data in humans was available for pitavastatin), and the rank order was also consistent. BSP, an OATP inhibitor, inhibited the uptake of all drugs. BEI and $Cl_{biliary}$ values of olmesartan, valsartan, pravastatin, and rosuvastatin, known Mrp2 substrates, were reduced in SCH from Mrp2-deficient (TR^{-}) compared to wild-type (WT) rats.

Thus, in vitro $Cl_{biliary}$ determined in rat SCH can be used to estimate and compare in vivo $Cl_{biliary}$ of compounds in rat and to characterize transport proteins responsible for their hepatic uptake and excretion.

37.1 Distribution In Vivo QWBA

PURPOSE AND RATIONALE

Distribution studies with radiolabeled test substances in animals are an important part of the drug development process. Traditional routine methods used for these studies are quantitative tissue distribution studies (QTD) and alternatively whole-body autoradiography (WBA) with detection of the radioactivity in whole-body sections on X-ray film (Baker 1989). WBA is a qualitative detection method with a very high local resolution which includes all organs and many small substructures.

Radioluminography (RLG) is an alternative method of radiation detection based on the phosphorus imaging technique. RLG is much more sensitive than the WBA technique, its exposure time is much shorter, and it has a much wider linear measure range. Because of the latter property, RLG enables a quantification of drug concentrations in whole-body sections.

Quantitative whole-body autoradiography (QWBA) is based on the RLG technique and the use of standards obtained from dilution series containing known concentrations of radioactivity. Isotopes used in QWBA are mainly ^{14}C and ^{3}H. These standards were cut together with the whole-body sections to ensure an identical thickness and used for the internal calibration. The information of the calibration curve allows the determination of the concentrations in the organs and tissues of interest which can be derived from the measured area and the section thickness.

The results of distribution studies form the principal basis for the assessment of exposure and the elimination of residues in human organs and tissues. Direct

DOI 10.1007/978-3-642-25240-2_42, © Springer-Verlag Berlin Heidelberg 2013

determinations of exposure in man are generally limited to measurements in blood and plasma, which is easily accessible. Distribution patterns are determined in animals, usually rats, instead. Apart from the standard study design described below, all kinds of animals can be used, up to the size of rabbits. The results obtained with QWBA provide pharmacokinetic data on the test substance and/or its metabolites and evidence for interpretations regarding potential toxicological and pharmacological target organs.

Additionally, before the first study with radiolabeled test substance in man can be started, a risk assessment of a human radiokinetic study is mandatory. The estimation of the radiation exposure in humans given a radiolabeled dose is based on exposure data obtained typically from QWBA studies in animals.

PROCEDURE

Male pigmented and nonpigmented rats, weighing approx. 200 g, are used. At pre-selected time points (e.g., 0.25, 1, 2, 4, 8, 24, 72, 168 h) after administration of the radiolabeled test compound, the animals are sacrificed by CO_2 overdose, fixed on a piece of cardboard, embedded in sodium carboxymethyl cellulose, and immediately deep-frozen using liquid nitrogen (−197°C). In these frozen blocks, a certain number of holes are drilled and filled with radioactive standards (with definite concentrations of radioactivity obtained from dilution series). These blocks are put into a Cryotome (cooled microtome at a temperature of approx. −18°C, e.g., Leica CM3600), and sagittal whole-body sections are cut at different section levels (eye, brain, adrenal, kidney, thyroid; other sections as well). Before sectioning, adhesive tape is placed on top of the frozen surface to enable easy handling of the sections. The thickness of the section amounts to 25 µm. The sections are dehydrated for at least 12–16 h in the chamber of the Cryotome (freeze-drying). Then the sections are cut out of the tape, fixed on a cardboard, and covered with a special plastic foil (e.g., Leica, 2-µm thickness) to prevent the sections from sticking on the detection medium. Subsequently, the cardboard with the section is placed on the photosensitive surface of an imaging plate (IP), and both are put into a black plastic bag for exposure. The bag is sealed using the vacuum-technique (Kloss 1973) to enable an intimate contact with the photosensitive medium. Exposure time is at least 48 h in a shielding box at room temperature. Subsequently, the IPs are scanned with an image reader (e.g., BAS5000, raytest), and digitized autoradiograms are obtained (Fig. 37.1).

In parallel to these investigations, the biostability of the labeling position in the radiolabeled test compound is examined. For this purpose, the volatile radioactivity in the cage air after administration is monitored over 24 h.

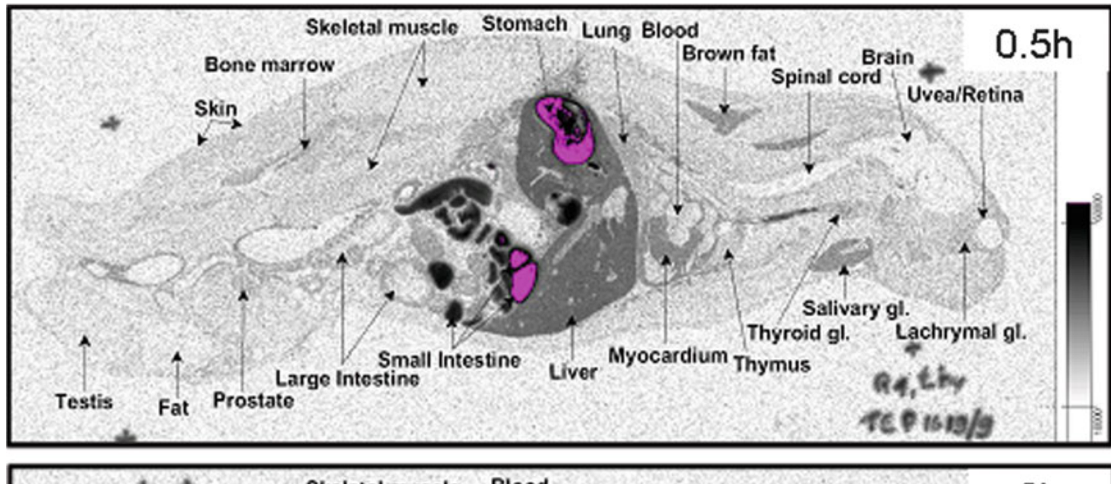
In addition to this standard procedure, the following special issues should be mentioned when autoradiography is also used: drug penetration of blood-brain barrier, placental transfer, drug excretion via milk in dams, more detailed distribution in organs and tissues (e.g., distribution pattern in the brain: sequential coronal sectioning in anteroposterior direction; drugs being developed for treatment of, e.g., osteoarthritis: extent of penetration of drug in cartilage of, e.g., the knee joint), drug (e.g., herbicides) localization in plants, drug distribution at cellular and subcellular level, and receptor microscopic autoradiography (Stumpf 2003).

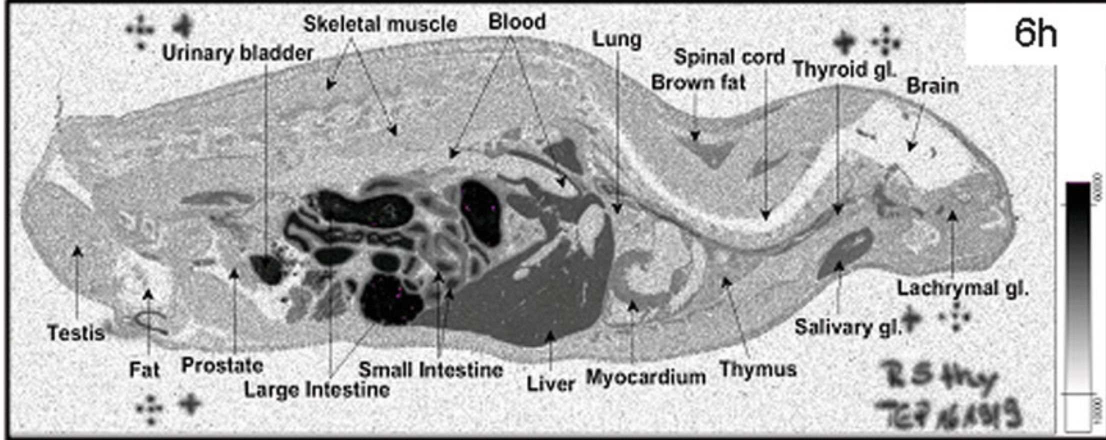
EVALUATION

The digitized autoradiograms are analyzed with appropriate software (e.g., AIDA, raytest); regions around the organs/tissues of interest can be drawn electronically (Fig. 37.2). The radioactive standards, cut together with the whole-body sections, are used as internal calibration. The information of the calibration curve provides the link between counts/area and radioactivity/area and allows the determination of the concentrations in the organs and tissues of interest which can be derived from the measured area and the section thickness. Considering the background counts of the IP, the specific radioactivity of the labeled test compound, and the area size of the region of interest, the corrected counts can be transferred into (amount of drug equivalent/g tissue) (due to the fact that only radioactivity can be measured, the value is defined as "equivalent"). The concentrations in the organs/tissues at different time points after administration are listed in tables and can be depicted as concentration-time profiles, bar charts, etc. (Fig. 37.3).

CRITICAL ASSESSMENT OF THE METHOD

Pros:
Distribution of compound and/or metabolites detected.
In situ situation in the body reflected.
Different subunits of organs can be regarded separately.
Rapid, impressive, accepted method (Fig. 37.4).





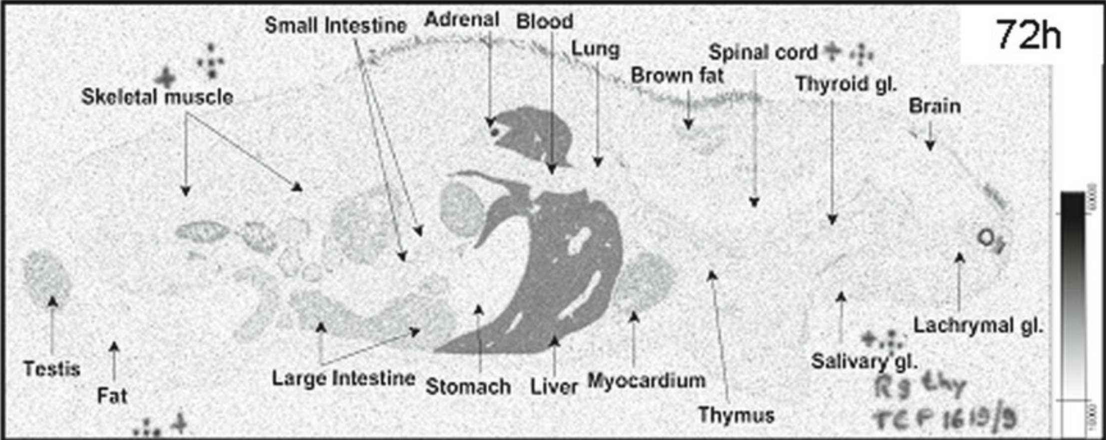


Fig. 37.1 Three autoradiograms at different time points (0.5, 6, 72 h) after oral administration of the radiolabeled test compound. The different radioactivity concentrations are depicted as shades of *gray*, from dark (high concentrations) to *white* (low concentrations)

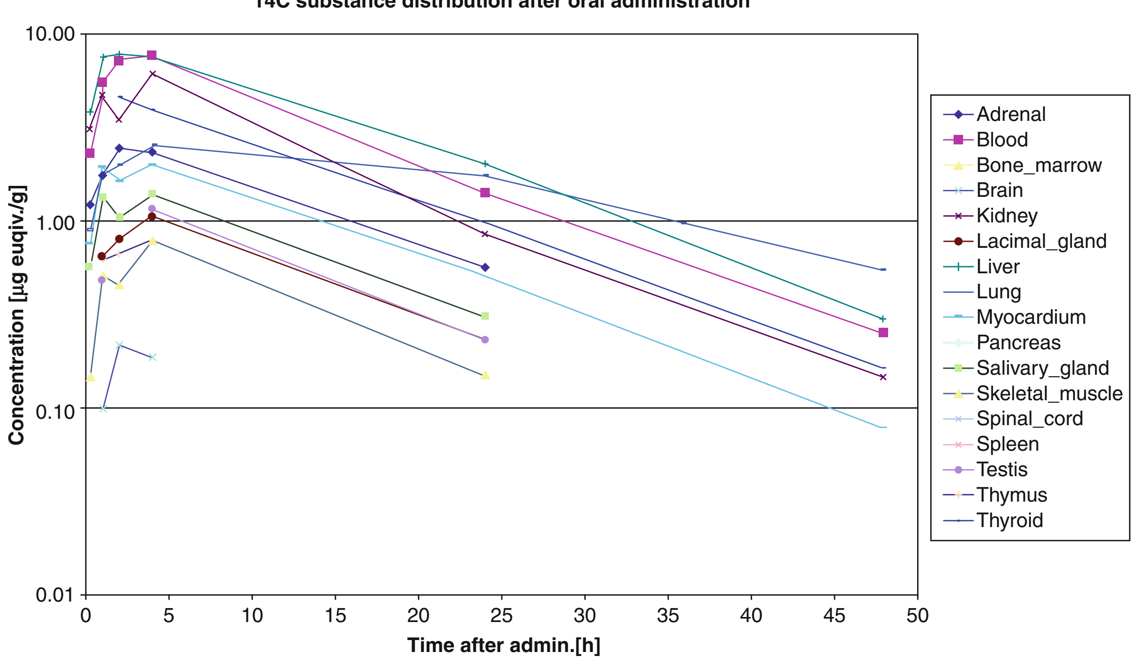
Fig. 37.2 Analysis of a digitized autoradiogram. Regions of interest are marked with thin *lines*. Oval areas around the autoradiogram were used for subtraction of the background, and the *circles* below with different shades of *gray* correspond to the radioactive standards used for calibration



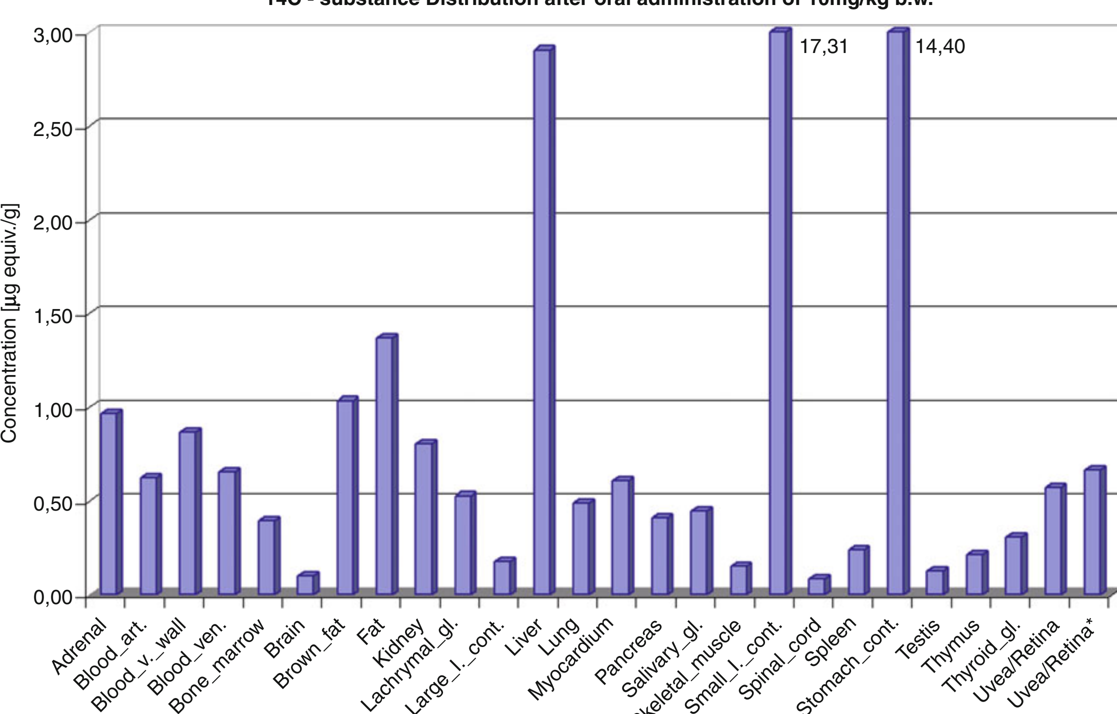


Fig. 37.3 Quantitative analysis of organs and tissues. The concentrations (expressed as drug equivalents/g) were calculated by dividing the measured radioactivity concentrations by the specific radioactivity of the administered compound. *Upper plot* shows the concentration-time profile; *lower plot* shows the concentrations at the time of Cmax

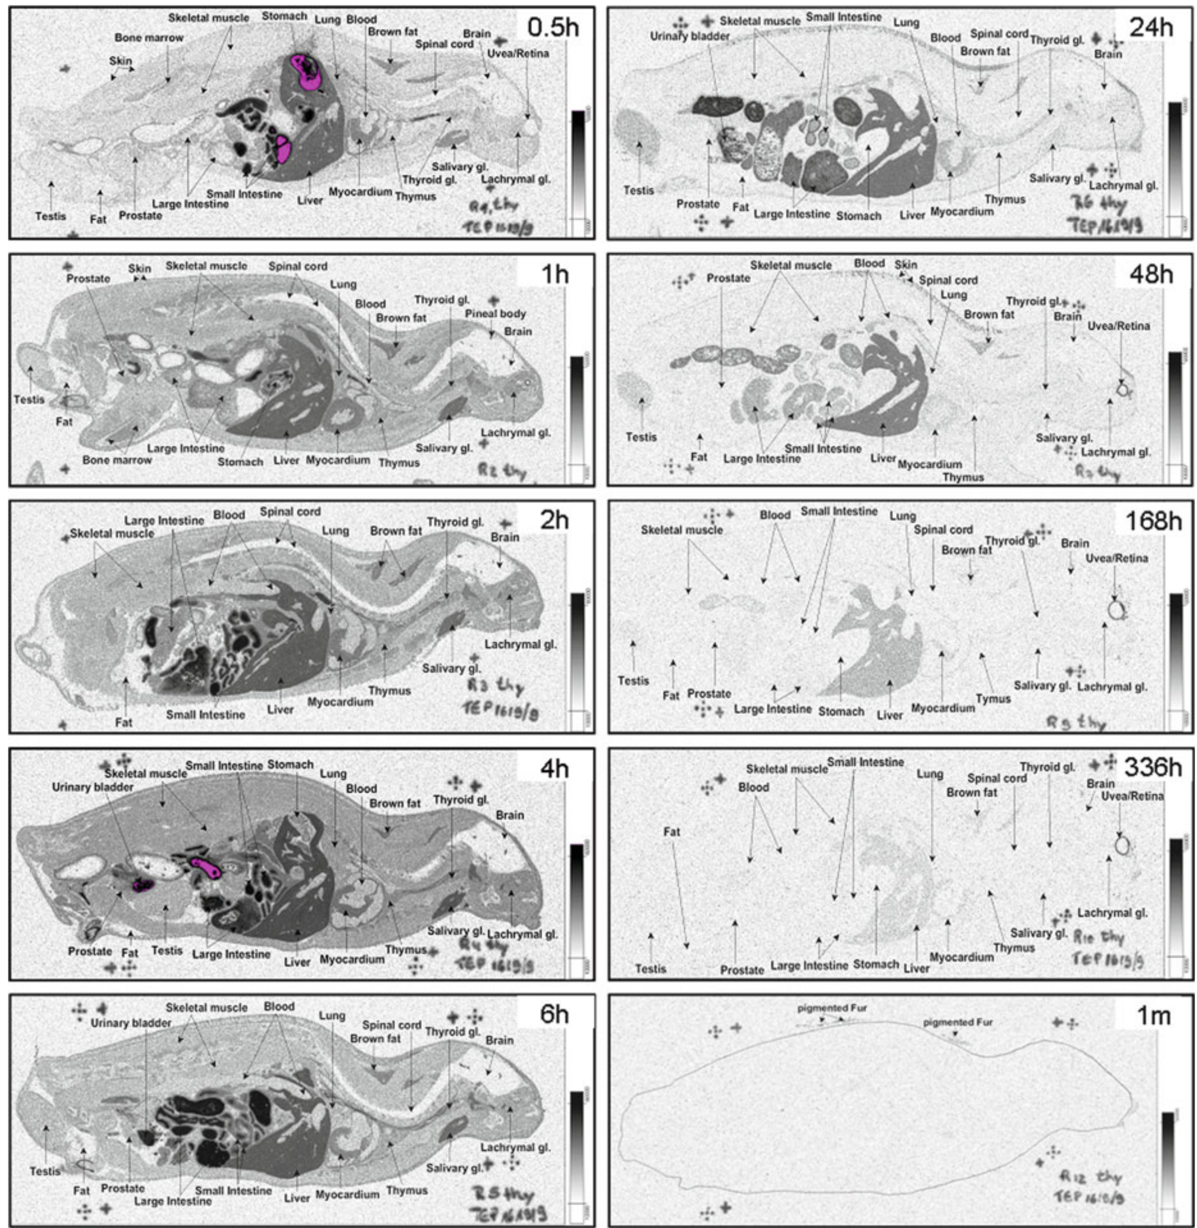

Fig. 37.4 Digitized autoradiograms at different time points (0.5 h–1 month) after oral administration of the radiolabeled test compound. The different radioactivity concentrations are depicted as shades of *gray*, from *dark* (high concentrations) to *white* (low concentrations)

Accepted as basis for human mass balance studies (dosimetry calculations).

Cons:

Radiolabeled compound required.

Total radioactivity detected, not parent compound or any metabolites.

Blood content of the organs and tissues not exactly known.

It is not possible to differentiate parent compound from conjugated metabolites or other radiolabeled fragments of the original molecule.

MODIFICATION OF THE METHOD

Although WBA is a relatively old method having its origin in the beginning of the twentieth century, this technique was undergoing some considerable modifications during the last 20 years and is now used widely in the chemical and pharmaceutical industries. The first whole-body autoradiogram (WBA) of a frog which had been exposed to radium and was placed on a photographic plate was published by E.H. London (1904). The original WBA technique was invented by Swen Ullberg (1954). He did research in the field of antibiotics and wanted to investigate whether the concentrations in the different infected organs or tissues in the body were high enough for therapeutic effects. There was no sufficient method available, so he developed a technique to get the appropriate information in situ. Mice were injected with radiolabeled penicillin and snap frozen in liquid air. Whole-body sections were cut on a hand-driven sledge microtome in a freezer room at −15°C. Frozen and dehydrated sections were exposed to X-ray film. Using different section levels, a qualitative estimation of the distribution in organs and tissues could be obtained.

The evolution from qualitative to quantitative WBA occurred during the last 20 years: from X-ray films and introduction of tritium film (increased sensitivity and removal of the antiscratch layer) to the semiquantitative analysis in the 1980s using densitometry to the quantification in the 1990s when digitized autoradiograms and radioluminography (RLG) were developed as new methods of radiation detection (Mori and Hamaoka 1994; Steinke et al. 2000).

37.2 Distribution In Vivo QTD

PURPOSE AND RATIONALE

Distribution studies with radiolabeled test substances in animals are an important part of the drug development process. Routine methods used for these studies are quantitative whole-body autoradiography (QWBA) and alternatively quantitative tissue distribution studies (QTD) with dissection of the animals and measurement of radioactivity in preselected organs and tissues using a liquid scintillation counter.

The results of these studies form the principal basis for the assessment of exposure and the elimination of residues in human organs and tissues, in which direct determination is of course impossible. Direct determinations of exposure in man are generally limited to measurements in blood or plasma, which is easily accessible. Distribution patterns and pharmacokinetic parameters (e.g., elimination half-lives, time of maximum concentrations in organs and tissues) are determined in animals, usually rats, instead. Radiolabeled test substance is administered to ensure, as far as possible, determination of the whole of the parent compound and its metabolites. The results provide pharmacokinetic data on the distribution of the total radioactivity, information on any accumulation or specific affinities of the test substance or its metabolites, and evidence for interpretations regarding potential toxicological and pharmacological target organs (Steinke et al. 2000).

Additionally, before the first study with radiolabeled test substance in man can be started, a risk assessment of a human radiokinetic study is mandatory. The estimation of the radiation exposure in humans given a radiolabeled dose is based on exposure data obtained typically from QTD—or QWBA—studies in animals.

PROCEDURE

Male rats, weighing approx. 200 g, are used. At preselected time points (e.g., 0.25, 1, 2, 8, 24, 96 h; 3 animals per group) after administration of the radiolabeled test compound, the animals are sacrificed

(CO_2 overdose, exsanguination) and immediately dissected. Organs and tissues are removed in the following dissection order (from expected low to high concentrations to avoid cross contaminations): blood, plasma, eyes, brain, skin (without hair and subcutaneous fat), subcutaneous fat, skeletal muscle, bone (femur), bone marrow, thyroid, lungs, thymus, heart, testis, prostate, retroperitoneal fat, spleen, kidney, adrenal, urinary bladder, liver, pancreas, mesenteric lymph nodes, stomach contents, small intestine contents, large intestine contents, stomach wall, small intestine wall, and large intestine wall.

Blood and plasma samples are taken on Combusto-Cones (e.g., Canberra-Packard), weighed, dried at room temperature, and combusted in a sample oxidizer (e.g., Canberra-Packard GmbH, Model Oximate 80/307, Frankfurt am Main, FRG), and the $^{14}CO_2$ formed is absorbed with Carbo-Sorb® (e.g., Canberra-Packard). The subsequent radioactivity measurements are carried out after addition of scintillator to the samples.

After removal, larger organs and tissues are homogenized with ULTRA-TURRAX® appliances (e.g., IKA, Staufen, Germany) after addition of deionized water, the amount of which depended on the consistency of the tissue. Smaller tissues are finely cut. The specimens are dissolved in volumetric flasks at 60–70°C in a mixture of Digestin® (e.g., Merck, Darmstadt, Germany) and water, ethanol is added if required to prevent foam formation, addition of approx. 0.3 ml Perhydrol® (e.g., Riedel de Haën, Seelze, FRG) is sufficient to remove discolorations, and measurements are then performed after addition of the scintillator.

Radioactivity measurements are carried out by the liquid scintillation counting procedure in β-spectrometers (e.g., Canberra-Packard 4530), using an external standard device which permitted the counting efficiency to be determined by the channel ratio method (Dyer 1980).

The scintillators Permafluor E+, recommended by Canberra-Packard for their automatic combusters, and Rotiszint eco plus (e.g., Roth, Karlsruhe, Germany) for dissolved samples are used, and blank values are concurrently measured in the studies and deducted from those measured. These blank values originate from material of untreated animals.

EVALUATION

Considering the count conditions of the analytic device, the specific radioactivity of the labeled test compound, and the weights of the analyzed specimen, the corrected counts can be transferred into (amount of drug equivalent/g tissue) (due to the fact that only radioactivity can be measured, the value is defined as "equivalent").

The concentrations are expressed in μg equivalents drug/g tissue and in % of administered radioactivity, i.e., they represent the sum of the original compound and/or radioactively labeled metabolites. To obtain a unit independent of metabolization, the test preparation concentrations in μg equivalents/g can be converted to nmol using the molecular weight:

1 μg of the free compound is equivalent to (1,000/MW) nmol.

The pharmokinetic parameters in the blood, plasma, and excreta and the kinetics in organs and tissues are calculated using an appropriate pharmacokinetics software (e.g., WinNonlin).

The detection limit is determined using the individual blank values for the corresponding biological material by the following formula:

$$\text{Detection limit} = \text{background (Bq)}/(\text{initial weight (g)}^{*}\ \text{specific radioactivity}(\text{Bq}/\mu\text{g})).$$

At least the double blank value (Bq) is required for evidence of a significant concentration value (μg equivalents per g or ml).

The concentrations in the organs/tissues at different time points after administration are listed in tables and can be depicted as concentration-time profiles, bar charts, etc.

CRITICAL ASSESSMENT OF THE METHOD

QTD was the "golden standard" when the method of WBA (Ullberg 1954) was not yet able to quantify the distribution.

The results of the two methods complemented one another. Whole-body autoradiography is a qualitative detection method with a very high local resolution which includes all organs and many small substructures, whereas measurement after dissection yields quantitative concentration data for a limited, preselected number of organs.

A vast change occurred when a new technology allowed the quantification of WBA in the 1990s. Digitized autoradiograms and radioluminography (RLG) were developed as new methods of radiation detection (Mori and Hamaoka 1994).

Since the organs and tissues are not destroyed during a QWBA study (in contrast to the

Fig. 37.5 QWBA. Concentrations in organs and tissues after oral (0.5 h–6 m) or after intravenous (0.083 h) administration of the radiolabeled drug. The concentrations (expressed as drug equivalents/g) were calculated by dividing the measured radioactivity concentrations by the specific radioactivity of the administered drug. The limit of quantification (LOQ) in this study amounted to 0.014 µgEq/g; concentrations below were marked as BLQ

homogenization of the organs and tissues for LSC measurements), substructures can be distinguished clearly (e.g., adrenal medulla and adrenal cortex often show very different concentrations of radioactivity) (Fig. 37.5).

To save animals and time, the quantitative tissue distribution study is more and more replaced by the quantitative whole-body autoradiography.

MODIFICATION OF THE METHOD

As the procedure of the animal study part of this method is well established, modifications occur mainly in the technological part by improvement of the performance of liquid scintillation counters and the appropriate software. As this method belongs no longer to the "cutting edge" skills in the drug development process, modification activities are moderate.

38.1 Positron Emission Tomography

PURPOSE AND RATIONALE

Distribution in vivo could be studied by positron emission tomography (PET). Positron emission tomography is a sensitive and specific functional noninvasive three-dimensional imaging method that permits rapidly and directly measurement of the total radioactivity from a drug labeled with a positron-emitting radionuclide (Gupta et al. 2002).

PROCEDURE

The drug should be labeled with positron-emitting isotopes such as carbon-11, oxygen-15, nitrogen-13, and fluorine-18. The radionuclides are predominantly produced by charged particle nuclear reactions using a cyclotron. Radiotracers are produced after replacement of a normal constituent in a biologically active compound of interest with a radionuclide without modifying their pharmaceutical, biological, or biochemical properties.

The optimal isotopes should be selected depending of the pharmacokinetic of the drug and their half-life values (20.4, 2.03, 10, and 109.8 min for ^{11}C, ^{15}O, ^{13}N, and ^{18}F, respectively).

The labeled compounds are generally administered by intravenous infusion to avoid local radiation damage. The amounts of radioactivity injected varied between 200 and 800 MBq (Bergström et al. 2003). Just after administration, the camera is activated to start the acquisition. When a positron-emitting radionuclide is decaying, it emits a positron that will interact with an electron in an annihilation event whereby these particles jointly are converted to two oppositely directed gamma rays of 511 keV energy. The gamma

rays readily penetrate the tissue and a fraction of them emerge out of the body to be recorded by the PET camera with rings of external nuclear detectors, which has high resolution and sensitivity. Computer processing of data generates sets of tomographic images with a spatial resolution of 0.5–5 mm depending of the scanner type (0.5–1 mm on animal scanners and 2–5 mm on clinical scanners) after correction for attenuation and detector efficiency. An image is acquired for a predefined time length and at a predefined time after administration. Timing of PET imaging should be well selected depending of the radionuclide and the drug. The data depict the spatial and temporal distribution of total radioactivity. Images are displayed on a computer monitor for inspection. Quantitative values on the drugs/tracers radioactivity concentrations in different organs are determined. For this, regions of interest are manually outlined in the images to represent targeted regions for analysis. Within these regions, the radioactivity concentration is determined for each image in the sequence, resulting in a time-radioactivity data set. The radioactivity is rapidly decaying according to the half-life of the radionuclide, and therefore, a correction is applied to compensate for this. Integral methods or compartmental analysis are used to analyze PET data. The most widely used integral method is the standardized uptake value SUV: SUV = local radioactivity concentration (administered radioactivity/body weight). Arterial blood and tissue combined data are needed in compartmental modeling in order to define exchange parameters and assess steady-state distribution volumes of the drug in organs.

EVALUATION

Quantitative values on the drugs/tracers radioactivity concentration-time profile in different organs or subregions of organs are determined.

CRITICAL ASSESSMENT OF THE METHOD

PET has a number of advantages. The entire time course of the distribution can be determined quantitatively in a living animal or human with a temporal resolution of seconds to minutes. Each subject can be used as its own control. PET is highly sensitive with the capacity to detect subnanomolar concentrations of radiotracers.

PET has a number of disadvantages: tracers with short half-lives limit the time during which they can be studied. For example, drugs labeled with ^{11}C may be too rapidly metabolized relative to the 20.4 min half-life and thus meaningful information may be limited. The logistics is challenging with the need of a cyclotron. PET can only measure radioactivity and not discern the chemical form of it; it is not possible in a PET study to be certain that the radioactivity signal is related to the original compound or including metabolites thereof. In order to make it likely that the proper conclusion is drawn, it is recommended that metabolism studies be performed in which the fraction of radioactivity constituted by intact tracer is determined in plasma and in the target organ. Additionally, the plasma profile of radioactive metabolites should be assessed in the PET study. Timing of PET imaging is not so easy to determine.

MODIFICATIONS OF THE METHOD

New materials with higher sensitivity or resolution have been designed: A three-dimensional PET scanner using gadolinium oxyorthosilicate (GSO) crystals (Surti and Karp 2004).

38.1.1 Example

PET has already been applied to a wide number of drugs to demonstrate activity in vivo from standard chemotherapy such as 5-fluorouracil (5-FU). The pharmacokinetics of 5-FU has been successfully

investigated using radiotracers and is the most common anticancer drug imaged with PET (Kissel et al. 1997). This is due to the ease of chemical synthesis of ^{18}F-fluorouracil (5–[^{18}F] FU). A pharmacokinetic quantitative model to quantify the intracellular 5–[^{18}F] FU concentration in liver metastases of patients with colon cancer revealed extrahepatic and intrahepatic clearances of 0.66 ± 0.33 and 0.52 ± 0.25 L/min, respectively. A pharmacodynamic relationship between tumor uptake of 5–FU and response, first seen in mice, has also been demonstrated in humans by PET methodology (Moehler et al. 1998). Studies showed that colorectal liver metastases with a higher uptake of 5–FU at 2 h, as measured by a standard uptake value (SUV), had a negative growth rate, whereas those with a low SUV had disease progression. Therefore, PET helps to differentiate between responding and nonresponding metastatic sites.

38.2 Microdialysis

PURPOSE AND RATIONALE

Distribution in vivo could be studied by microdialysis. Microdialysis is an in vivo technique that permits measurement of unbound drug or metabolite concentrations in extracellular fluid of specific tissue location. The unbound drug concentrations have been shown to be responsible for the pharmacological effects. The basic principle is to mimic the function of a capillary blood vessel by perfusing a thin dialysis tube implanted into the tissue with a physiological liquid (Ungerstedt 1991).

PROCEDURE

A microdialysis probe is inserted in a selected tissue or fluids (like brain, muscle, skin, liver, tumor, blood, and bile (Elmquist and Sawchuk 1997)) of an animal (mouse, rat, rabbit, dog, and monkey) or a human. The probe consists of a small semipermeable hollow fiber membrane, connected to an inlet and outlet tubing with a small diameter. The probe is continuously perfused with a physiological solution such as a Krebs-Ringer solution (Na^+ 148 mM, K^+ 4.0 mM, Ca^{2+} 2.3 mM, and Cl^- 156 mM) (Benveniste and Huttemeier 1990). The perfusate should have an ionic composition comparable to the extracellular fluid surrounding the probe and should be at ambient temperature. After a 24-h recovery, the drug is administered by a relevant route (orally, intravenously) to an animal or a human and the perfusate is infused at a flow rate of 0.1–5 μl/min. The drug able to pass the semipermeable membrane will diffuse over the membrane down their concentration gradient into or out of perfusate. The solution that exits the probe, the dialysate, can be collected during interval periods. The concentrations of the drug in the dialysate reflect the concentrations in the extracellular fluid around the semipermeable part of the probe. However, as the dialysis procedure is not performed under equilibrium conditions, the concentration in the dialysate will be less than that in the extracellular fluid. The in vivo recovery, used to describe this relationship, is determined by the use of an internal standard by retrodialysis (Larsson 1991). The concentrations of the drug are determined by a relevant and sensitive analytical method and then are corrected for in vivo recovery.

EVALUATION

Quantitative values on the unbound drug or metabolite concentration-time profile in different tissues or subregions of tissues are determined.

CRITICAL ASSESSMENT OF THE METHOD

Microdialysis has a number of advantages: concentration profiles of drug could be obtained without fluid loss from freely moving individual subjects in specific subregions of tissues.

Microdialysis has also a number of disadvantages: the probe could elicit tissue trauma after implantation, the determination of in vivo recovery is time consuming, and sensitive analytical methods are needed due to the diluting effect (De Lange et al. 2000).

MODIFICATIONS OF THE METHOD

New probes (Evrard et al. 1996) and methods for analysis and for recovery are developed. The optimal conditions for composition of the perfusion solution, the flow rate, and the postsurgery interval are searched.

Microdialysis probes are now commercially available in various sizes, designs, and materials. Microdialysis probes can be flexible for soft peripheral tissues and fluids or rigid for brain. Four probe geometries are available: linear, loop, side-by-side, and concentric. The semipermeable membrane is generally chosen as long as possible, typically between 1 and 10 mm. The probe radius is generally chosen as small

as possible, typically between 200 and 400 μm O.D. to cause minimal disturbances within the tissue. Dialysis probes are made of various materials (e.g., celluloses and copolymers like polyacetonitrile/sodium methallyl sulfonate and polycarbonate/ether). The molecular mass cutoff (5–50 kDa), inertness, and permeability to solutes of the probes could be different.

Perfusion solution used in microdialysis experiments vary widely in composition and pH. Ideally, the composition, ion strength, osmotic value, and pH of the perfusion solution should be as close as possible to those of the extracellular fluid of the dialyzed tissue. Perfusion fluids should be at body temperature.

Perfusion flow rates range between 0.1 and 5 μl/min. The tendency is to use lower flow rates as this may increase recovery, provided that an analytical technique is available to deal with the smaller-sized samples.

Experiments should be executed between 24 and 48 h after implantation, after recovery from early tissue reactions and before the start of long-term reactions.

Sensitive analytical methods should be used such as liquid chromatography combined with mass spectroscopy, microbore liquid chromatography, and capillary electrophoreses.

Different methods to determine in vivo recovery could be used: extrapolation to zero-flow rate (Jacobson et al. 1985), no-net-flux (Lonnroth et al. 1987), dynamic-no-net flux (Olson and Justice 1993), and retrodialysis using an internal standard (Larsson 1991). The zero-flow rate method is based on the principle that recovery is a function of flow rate. The dialysate concentrations are plotted as a function of flow rate and by extrapolating to zero-flow rate where the dialysate is in equilibrium with the extracellular fluid; the dialysate concentration found at zero-flow rate should equal the actual in vivo concentration. The no-net-flux method is based on the principle that drug transport across the membrane is a function of perfusate concentration while maintaining the extracellular concentration of the analyte at steady state. Different concentrations are perfused through the membrane. The dynamic-no-net-flux method, an extended version of the no-net-flux method, allowed the estimation of the recovery as a function of time. Several animals are continuously perfused with one perfusion concentration. The retrodialysis method is based on the principle that an internal standard with membrane diffusion characteristics close to the analyte of interest is added to the perfusate and its relative loss by retrodialysis is calculated. The assumption is that in vivo retrodialysis of the internal standard is the same as in vivo dialysis of the analyte. An advantage of this method is that fluctuations in recovery of the probe during the experiment are taken into account by the continuous retrodialysis of the marker during the entire experiment.

Recovery of lipophilic compounds binding to components of the dialysis equipment could be increased by including albumin or a lipid emulsion to the dialysate (Carneheim and Ståhle 1991).

38.2.1 Example

Microdialysis was used to assess morphine 6-beta-D-glucuronide (M6G) and morphine brain distribution in extracellular fluid after systemic administration in rats (Stain-Texier et al. 1999). M6G penetrated into the brain was distributed and trapped preferentially than

morphine in the extracellular fluid and therefore was available to bind at opioid receptors, explaining how M6G induces more potent central analgesia than morphine.

PURPOSE AND RATIONALE

Enzyme induction can be considered a natural defense mechanism against xenobiotics such as environmental agents (e.g., dioxins), tobacco smoke, ethanol, nutritional constituents in grilled meat or cruciferous vegetables, herbal medicines such as St. John's wort, and therapeutic drugs. Following ingestion, the first barriers for xenobiotics are metabolizing enzymes in the intestinal epithelium and efflux transporter proteins, most notably P-glycoprotein, that transport substances from the epithelial cells back into the intestinal lumen. The remaining xenobiotics pass via the portal circulation into the liver – the organ specialized in xenobiotic metabolism and the major site of enzyme induction. Thus, as a defense mechanism, the metabolizing enzymes and P-glycoprotein can be induced, enhancing xenobiotics elimination in rate and capacity.

For therapeutic drugs, induction of drug-metabolizing enzymes and drug transporters is defined as an increase in activity levels in response to multiple exposures to the drug. The major consequences of enzyme induction are pharmacokinetic drug–drug interactions leading to a faster metabolic elimination of coadministered drugs by the induced enzyme. As a consequence, plasma concentrations may remain subtherapeutic resulting in loss of efficacy. Alternatively, the induced metabolic pathway could lead to increased formation of an active metabolite from an inactive prodrug or to increased formation of toxic metabolites, resulting in adverse effects.

Some well-known human enzyme inducers are listed in Table 39.1. Carbamazepine and phenobarbital induce metabolizing pathways that metabolize these inducers themselves, a process called autoinduction.

DOI 10.1007/978-3-642-25240-2_43, © Springer-Verlag Berlin Heidelberg 2013

Table 39.1 Examples of in vivo human enzyme inducers and the induced drug-metabolizing enzymes

Inducer	Major enzymes induced
Carbamazepine	CYP3A4, UGT
Omeprazole	CYP1A2
Phenobarbital	CYP2B6, CYP3A4, UGT
Phenytoin	CYP2B6, CYP3A4, UGT
Rifampicin	CYP2B6, CYP3A4, UGT
St. John's wort	CYP3A4
Troglitazone	CYP2B6, CYP3A4

Table 39.2 Nuclear receptors (NR) for inducers of drug-metabolizing enzymes and transporter proteins. The receptors listed are the aryl hydrocarbon receptor (AhR), constitutive androstane receptor (CAR), pregnane X receptor (PXR), and glucocorticoid receptor (GR). Major enzyme isoforms regulated by the corresponding receptors are shown in bold

NR	Enzymes induced	Examples of inducers
AhR	**CYP1A1**, **CYP1A2**, CYP1B1, UGT1A1, SULT1A1, GST-A2, ALDH, MDR1	Aryl hydrocarbons Dioxins
CAR	**CYP2B6**, UGT1A1, CYP2C8, CYP2C9, CYP3A4, CYP2A6, SULT1A1, OATPs, MRP3, MRP2	Phenobarbital
PXR	**CYP3A4**, CYP2B6, CYP2C8, CYP2C9, UGT1A1, GST-A2, MDR1, MRP2, OATP2, OCT1	Rifampicin
GR	**CYP3A4**, other PXR-induced enzymes	Dexamethasone

Enzyme induction, with some exceptions, is initiated via the binding of the inducers to nuclear receptors leading to increased gene expression and protein synthesis (Waxman 1999; Honkakoski and Negishi 2000; Jones et al. 2000; Sueyoshi and Negishi 2001; Kewley et al. 2004). Differences in induction potential result from different affinities of inducers to the nuclear receptors, which also explains the observed species differences in induction. The key nuclear receptors for enzyme inducers are listed in Table 39.2.

- *Aryl hydrocarbon receptor (AhR)*: AhR is a basic helix-loop-helix protein belonging to the PER-ARNT-SIM family of transcription factors (Kewley et al. 2004). AhR is the key receptor for CYP1A gene activation by aryl hydrocarbons (e.g., 3-methylcholanthrene) and dioxins. AhR resides in the cytoplasm and, upon ligand binding, translocates to the nucleus. In the nucleus, AhR forms a heterodimer with the AhR nuclear translocator (ARNT) which then binds to the dioxin-response elements of the cytochrome P450 1A (CYP1A) and other responsive genes. This process is limited by a negative feedback mechanism: AhR activates its own repressor (AhR repressor). Evidence for AhR induction of CYP1A includes that AhR knockout mice are resistant to dioxin-elicited CYP1A1 induction.
- *Constitutive androstane receptor (CAR)*: CAR is also known as constitutively active receptor; it is called "constitutive" because it transactivates retinoid acid response element without binding to any ligand. CAR induces CYP2B6 and, to a lesser extent, CYP3A4. Responding to phenobarbital exposure in liver, CAR translocates to the nucleus, forms a dimer with the retinoid X receptor (RXR), and activates the phenobarbital-responsive enhancer module by binding to DR-4 motifs (Sueyoshi and Negishi 2001). The mechanism of phenobarbital activation of CYP2B6 is unknown. Phenobarbital is not a ligand to CAR but may affect CAR via a kinase pathway. CAR translocation and activation are inhibited by protein phosphatase and kinase inhibitors.

  Pregnane X receptor (PXR): PXR, also called SXR, is responsible for CYP3A4 induction (Lehmann et al. 1998) as well as CYP2C8 and CYP2C9 induction. Activators of PXR include pharmaceuticals such as rifampicin, phenobarbital, nifedipine, clotrimazole, mifepristone and metyrapone. Many PXR ligands also activate CAR. The mechanism of the PXR response to inducers consists in ligand binding, formation of a heterodimer with the retinoid X receptor-α, RXR-α, and transactivation of the ER6 (everted repeat with a six base pair spacer) elements upstream of the cytochrome P450 genes. PXR and RXR-α are induced by activation of the glucocorticoid receptor (GR); glucocorticoids, e.g., dexamethasone, activate GR and lead to the induction of PXR and RXR, resulting in CYP3A4 induction. Downregulation of PXR and CAR is mediated by cytokines such as interleukin-6 and results in repression of several cytochrome P450 isoforms (Lee et al. 2006). Species differences in the affinity of PXR for the inducers (Jones et al. 2000) account for the dramatic rodent–human difference in response to rifampicin (LeClyse 2001). Rifampicin is a potent inducer of CYP3A4 in humans but a poor CYP3A2 inducer in rodents (Lu and Li 2001).

Stronger induction in rodents than in humans is known for dexamethasone inducing CYP3A2 in rats.

- *Glucocorticoid receptor (GR)*: Glucocorticoids, e.g., dexamethasone, bind to GR and induce PXR and RXR expression. As a result, the induction effects of PXR ligands are enhanced in general and, in particular, CYP3A4 induction in human hepatocytes. The mechanism is protein–protein interplay (cross-talk) between GR and other receptors rather than direct binding of GR to cytochrome P450 genes.
- *Nonreceptor-related mechanisms*: Enzyme induction may occur via nonreceptor-related mechanisms. CYP2A6 induction by phenobarbital and rifampicin, although known to be mediated via receptor-dependent mechanisms, may involve mRNA stabilization. Likewise, the CYP2E1 induction mechanism includes stabilization of mRNA and protein.

Enzyme induction in laboratory animals may be observed in preclinical toxicity studies in which drugs are administered repeatedly in high doses. The induction response is rapid; increases in microsomal enzymes may be detected as early as 1 day after treatment. Peak induction responses may require 4–7 days or more, depending on the inducer, the dose, and the enzyme. The dose–response curve for enzyme induction is generally steep and shows saturation; the induction response is reversible upon discontinuation of treatment. If metabolizing pathways are induced that metabolize the inducer itself (autoinduction), this may lead to a decreased exposure in the animals and a reduced safety margin.

In rats, induction of drug-metabolizing enzymes may affect the microsomal cytochrome P450 enzymes, epoxide hydrolase, and glucuronyl transferases, among other enzymes. The profile of induced enzymes differs between the genders. Microsomal enzyme induction in rats is generally associated with proliferation of smooth endoplasmic reticulum and liver hypertrophy which is evident from increases in liver weight and histological changes (Amacher et al. 1998). Occasionally, mild increases in serum alanine transaminase may be observed. In conclusion, rat microsomal enzyme induction, as well as hepatomegaly, is generally not accompanied by adverse histological effects on the liver or substantial clinical chemistry changes in serum. Enzyme induction is viewed as a benign, adaptive change in response to xenobiotics that stimulate the hepatic drug-metabolizing enzyme system.

However, particular sensitivity to enzyme induction in rats is seen in thyroid hormone homeostasis. Mechanisms involved are increased glucuronidation and increased hepatic uptake of thyroid hormones (Cunha and van Ravenzwaay 2005). The alterations in thyroid hormone clearance are accompanied by an increase in serum levels of thyroid-stimulating hormone and, after long-term treatment, follicular cell proliferation of the thyroid gland that promotes thyroid tumor formation.

In dog toxicity studies, microsomal enzyme activities may be significantly elevated without any indication of hepatocellular or hepatobiliary damage like increased liver weight, histological changes, or serum chemistry changes (Amacher et al. 2001). In conclusion, the hepatic enzyme induction in dogs is seen as a benign adaptive response. The cytochrome P450 enzyme induction profile in dogs resembles the profile observed in humans more than the profile in rats (Graham et al. 2002).

In humans, the possible pharmacokinetic consequences of enzyme induction include decreased or absent bioavailability for orally administered drugs, increased hepatic clearance, or accelerated formation of active or toxic metabolites. Most of the effects of inducers are not detected against the background of interindividual variability of exposure in humans. However, the addition of a potent inducer to, or its withdrawal from, an existing drug regimen may cause pronounced changes in the plasma levels of coadministered drugs and may cause severe drug–drug interactions. Alternatively, if metabolizing pathways are induced that metabolize the inducer itself (e.g., carbamazepine, phenobarbital), this may result in subtherapeutic plasma concentrations and consequently loss of efficacy.

Toxicological consequences of enzyme induction in humans are rare and appear to be limited to hepatotoxicity in ethanol-type induction of CYP2E1. Chronic ethanol intake induces CYP2E1 which increases the transformation of paracetamol to the hepatotoxic metabolite N-acetyl-p-benzoquinone imine (Raucy et al. 1989). Increased risk of paracetamol-induced hepatotoxicity in human following regular ethanol consumption has been conjectured (Chandok and Watt 2010). The likely mechanism of increased

toxicity is that the first step of paracetamol activation mediated by CYP2E1 is accelerated by long-term ethanol exposure, whereas inactivating enzymes are unchanged or even expressed in decreased amounts if alcoholic liver disease is already present.

Clinically relevant drug–drug interactions may emerge when a potent inducer, in particular an inducer of CYP3A4, is coadministered with a drug that is a substrate of CYP3A4. For example, anticonvulsants and antibiotics are known to cause failure of contraception and breakthrough bleeding. Such drugs include phenytoin, carbamazepine, phenobarbital, rifampicin, and griseofulvin which induce cytochrome P450 enzymes, including CYP3A4 (Li et al. 1999; Wang et al. 2004). At a dose of 300 mg daily, rifampicin was found to reduce the plasma levels of ethinylestradiol and norethindrone by about 60% (LeBel et al. 1998).

An even more pronounced interaction of rifampicin was observed with verapamil. Long-term treatment with rifampicin reduced the oral bioavailability of verapamil by 96% (Fromm et al. 1996). In contrast, after intravenous administration of verapamil, the plasma AUC was reduced by only 20%. The difference in plasma exposure after oral and intravenous dosing demonstrates the strong effect of enzyme induction on first-pass metabolism.

Cytochrome P450 enzyme induction can affect the pharmacokinetics of a drug molecule upon multiple dosing and can result in pharmacokinetic drug–drug interactions with coadministered drugs causing potential therapeutic failure. Therefore, it is important that investigational drugs are explored for possible enzyme induction. Optimally, a sequence of enzyme induction studies is planned, moving from in vitro studies to in vivo human studies.

Initial in vitro evaluation of an investigational drug can focus on CYP1A2, CYP2B6, and CYP3A4 induction, reflecting the three important mechanisms of cytochrome P450 induction mediated by the AhR, CAR, and PXR pathways. The mechanistic basis of drug–drug interactions enables more general approaches. If it is confirmed that the investigational drug does not induce CYP3A4, it can be concluded that it is also not an inducer of CYP2C8 or CYP2C9. When an in vitro evaluation cannot rule out the possibility that an investigational drug is an inducer of CYP3A4, an in vivo evaluation can be conducted using the most sensitive CYP3A4 substrate, e.g., oral midazolam. Negative results in a clinical interaction study with midazolam rule out that the investigational drug induces CYP3A4, rendering further clinical investigations of CYP3A4 induction unnecessary. In case of positive results, less sensitive but clinically relevant CYP3A4 substrates, e.g., oral contraceptives, may need to be tested for clinically relevant interaction.

The “gold standard” accepted for in vitro enzyme induction assays are freshly isolated human hepatocytes. However, for routine application in the drug discovery setting, the availability of such cells poses severe limitations, and new in vitro approaches to evaluate enzyme induction have been developed (McGinnity et al. 2009).

- *Reporter cell lines*: Reporter cell lines are suitable for early screening of enzyme inducers that act through AhR and PXR that control the expression of drug-metabolizing enzymes and drug transporters. Cell lines with AhR or PXR and their respective responsive gene elements linked to a reporter gene, e.g., luciferase (Raucy and Lasker 2010), can be engineered by transient or stable transfection. The results with reporter cell lines are in general similar to those of freshly isolated human hepatocytes. However, reporter cell lines may lack some drug-metabolizing enzymes and drug transporters that are present in hepatocytes, and this may explain some incidences of significantly different results. In addition, with CAR, no unequivocal results were obtained from such transactivation assays.
- *Ligand binding assays*: These assays assess the binding of ligands to nuclear receptors (Raucy and Lasker 2010). Results have shown good correlation with cell-based transactivation assays. Examples are the scintillation proximity assay, fluorescent polarization, or fluorescence resonance energy transfer assays. Compounds are tested for their ability to compete with a labeled ligand for the ligand-binding domain of the nuclear receptors. However, both agonists and antagonists are detected in this type of competitive binding assay and, in addition, some other disadvantages are inherent to this type of assay. A further type of binding assay is based on the yeast two-hybrid system; these assays also constitute a powerful screening tool.

- *Immortalized hepatocytes*: Immortalized hepatocytes allow the expansion of hepatocytes in culture and thus overcome the major drawback of freshly isolated human hepatocytes. Cell lines may be derived from human hepatomas, e.g., HEPG2 or HepaRG, or obtained by transfection of human hepatocytes such as the immortalized Fa2N-4 cell line (McGinnity et al. 2009). Not all cell lines reflect freshly isolated human hepatocytes in all respects, however. HepG2 cells carry the embryonic cytochrome P450 isoforms CYP1A1 and CYP3A7 rather than CYP1A2 and CYP3A4 found in the adult human liver. Fa2N-4 cells do not carry functional CAR; they are suitable for AhR-mediated CYP1A2 and PXR-mediated CYP3A4 induction, but not CAR-mediated CYP2B6 induction. HepaRG cells are very promising for the assessment of induction potential of test compounds. They show differentiated hepatocyte morphology and can express phase I and phase II drug-metabolizing enzymes as well as drug transporters normally found in the liver. In addition, HepaRG express AhR, CAR, and PXR at levels comparable to cultured human hepatocytes. If it is confirmed that CAR-mediated induction is present in this cell line, HepaRG cells will offer clear advantages for use in drug discovery.
- *Cryopreserved human hepatocytes*: Attachable cryopreserved human hepatocytes allow planning of experiments and therefore are more convenient than freshly isolated human hepatocytes for enzyme induction studies. Cryopreserved human hepatocytes are a reliable test system for the evaluation of enzyme induction. Catalytic activities and mRNA levels of CYP1A2, 2B6, 2C9, 2E1, and 3A4 remain inducible by the standard cytochrome P450 enzyme inducers after cryopreservation (Roymans et al. 2005). It has been shown that human hepatocytes cultured after cryopreservation are responsive to CYP1A2, CYP2B6, and CYP3A4 inducers, but they have significantly lower basal (uninduced) levels of these enzymes than freshly isolated human hepatocytes.

The above-mentioned experimental systems are more convenient than freshly isolated human hepatocytes. However, freshly isolated human hepatocytes are universally accepted as the "gold standard," as the known mechanisms of enzyme induction, including induction of gene expression, mRNA stabilization, and protein stabilization, can be adequately studied. The following procedure describes a study design and methods for the evaluation of the in vitro induction potential of an investigational drug (test compound) in cultures of freshly isolated human hepatocytes (Koose and Bünning 2010). The induction potential is assessed by determining CYP1A2, CYP2B6, and CYP3A4 enzyme activities and mRNA levels. This protocol is based on various publications (Madan et al. 2003; LeClyse et al. 2005; Hewitt et al. 2007b, 2007c).

39.1 Procedure for In Vitro Induction Studies in Freshly Isolated Human Hepatocytes

39.1.1 Human Hepatocytes

The induction potential of a test compound is evaluated in cultures of freshly isolated human hepatocytes from at least three donors. Hepatocyte cultures are obtained from commercial vendors. The donor demographic information includes age, gender, ethnicity, and pathology. Inclusion criteria are that donors are aged 18 or older and tested negative for HIV, hepatitis B, and hepatitis C infection. The hepatocytes are plated in 6-well collagen-coated plates at a cell density of 2.1×10^5 cells/cm^2 (2×10^6 cells/well). To be acceptable for an enzyme induction study, the viability of the hepatocytes has to be >80% after isolation, and the cultures have to be confluent after overnight incubation. Cultures are shipped at 37°C; a short transportation time is advantageous. Hepatocyte cultures are received approximately 20 h after isolation and are placed in a humidified 5% CO_2 incubator at 37°C for about 20 h. Hepatocyte treatment starts about 40 h after isolation of the hepatocytes.

39.1.2 Study Design

Hepatocyte treatment is started by replacing the culture medium with 2,400 μL/well of hepatocyte incubation medium. The hepatocyte incubation medium consists of Williams Medium E containing GlutaMax I (equivalent to 4 mM L-glutamine),

penicillin G (100 units/mL), streptomycin sulfate (100 μg/mL), insulin (40 μg/mL), and dexamethasone (100 nM). For each treatment, six wells are designated for enzyme activity evaluation and three wells for mRNA determination. The following treatments are performed:

- 0.1% DMSO (vehicle control)

  Attention should be paid to the effects of organic solvents and their concentrations (Easterbrook et al. 2001; Iwase et al. 2006).
- 10, 25, and 60 μM omeprazole in 0.1% DMSO.
- 500, 750, and 1,000 μM phenobarbital in 0.1% DMSO.
- 5, 10, and 30 μM rifampicin in 0.1% DMSO.

  This protocol includes three concentrations of the reference inducers to determine the maximum induction effect of the reference inducers which varies from batch to batch of human hepatocytes.
- At least four concentrations of test compound in 0.1% DMSO.

  For selection of test compound concentrations, the solubility of the test compound is determined by incubation in hepatocyte incubation medium with 0.1% DMSO, at 37°C for 24 h. Test compound concentrations span two to three orders of magnitude, or if plasma levels from clinical studies are known, test compound concentrations will span plasma levels up to a concentration 10-fold to 100-fold above the highest plasma level.

The incubation medium is replaced with fresh incubation medium containing the relevant compound every 24 h up to a total treatment period of 72 h. The medium removed after 24-, 48-, and 72-h treatment periods is tested for lactate dehydrogenase (LDH) activity in a cytotoxicity assay.

39.1.3 Morphology

The cell morphology of the hepatocyte cultures is evaluated by phase-contrast microscopy upon receipt of the cells and at the start and the end of the 72-h treatment period.

39.1.4 Cytotoxicity

Cytotoxicity is assessed on the base of LDH release from human hepatocytes after 24, 48, and 72 h of treatment. Vehicle-treated (0.1% DMSO) and triton X100-treated (0.5% triton X100) hepatocyte cultures are included as references, and tamoxifen-treated (10, 20, 30, 40, 60, and 100 μM tamoxifen) hepatocyte cultures are included as positive control. Colorimetric determinations of LDH activity of four replicates per well with 100 μL culture medium are carried out in 96-well plates using a cytotoxicity detection kit (LDH). The absorbance of the samples is measured at 492 nm in a microplate reader. Cellular viability is calculated by:

$$\text{Cellular Viability }(\%) = \frac{\text{Absorbance (Treatment Sample)} - \text{Mean Absorbance (Triton} \times 100)}{\text{Mean Absorbance (Vehicle)} - \text{Mean Absorbance (Triton} \times 100)} \times 100$$

Noncytotoxic concentrations of the test article should be used. Cytotoxicity may lead to an erroneous conclusion of no induction, as cytochrome P450 enzyme activities may be decreased due to the lower number of viable cells or compromised cell metabolism.

39.1.5 Evaluation of CYP1A2, CYP2B6, and CYP3A4 Activities

Preparation of hepatocyte homogenates: After 72-h treatment with vehicle, reference inducers, and test compound, the hepatocyte cultures are harvested. From the six identically treated wells, designated for enzyme activity evaluation, the hepatocytes from two wells are combined to give triplicate samples for each treatment. Each well is treated by the following procedure. The hepatocyte incubation medium is removed from the well and replaced with 1 mL ice-cold phosphate-buffered saline (PBS); the cells are scraped and transferred to a 50-mL centrifugation tube. The well is washed three times with 3 mL ice-cold PBS buffer which is added to the centrifugation tube. The hepatocytes from two wells are combined in the centrifugation tube and are centrifuged at 863×*g* for 10 min at 4°C.

Table 39.3 Sample dilution and LC-MS/MS injection volume

CYP enzyme	Marker metabolite (analyte)	Sample dilution	LC-MS/MS injection volume
CYP1A2	4-Acetamidophenol	20 μL + 80 μL gradient solution A	10 μL
CYP2B6	Hydroxybupropion	10 μL + 90 μL gradient solution A	10 μL
CYP3A4	6β-Hydroxytestosterone	32 μL + 77 μL gradient solution A	20 μL

The supernatant is removed, and the hepatocyte pellet is suspended in 250 μL ice-cold PBS buffer. The hepatocyte suspensions are kept at 4°C while they are homogenized by ultrasonic disruption in a beaker resonator with 3 rounds of 12 strokes, each stroke with 70% of the maximal energy for 1 s. The homogenate is immediately shock frozen and stored at −80°C until used for preparation of S9 fraction and for determination of enzyme activity and protein concentration.

Incubations of S9 fractions with probe substrates: As selective probe substrates, 100 μM phenacetin for CYP1A2, 500 μM bupropion for CYP2B6, and 200 μM testosterone for CYP3A4 assays are used. Phenacetin and testosterone are dissolved in acetonitrile and bupropion in acetonitrile/water 1:1 (v/v) at their 1,000-fold final concentrations. The stock solutions are diluted 1:500 (v/v) in 100 mM potassium phosphate buffer, pH 7.4, and are finally diluted 1:1 (v/v) into the reaction mixtures. Hepatocyte homogenates are thawed and centrifuged at 9,000×*g* for 30 min at 4°C. The supernatant S9 fractions (20 μL) are added to reaction mixtures, containing 70 μL water, 30 μL of 40 mM magnesium chloride, and 150 μL probe substrate in 100 mM potassium phosphate buffer, pH 7.4. The reaction mixtures are brought to 37°C for 10 min before the enzyme reactions are initiated by addition of 30 μL of 10 mM NADPH. After a 15-min incubation period, 100 μL reaction mixture is removed and added to 300 μL acetonitrile containing internal LC-MS/MS standard. Incubations are performed on triplicate samples for each treatment. Samples are kept frozen at −20°C until LC-MS/MS analysis.

Analytical LC-MS/MS methods: The amounts of marker metabolites formed in the reaction mixtures are quantified by LC-MS/MS analysis (CTC HTS PAL autosampler, Agilent 1100 HPLC system coupled to an Applied Biosystems API4000 with turbo ion spray). $[D_4]$-4-Acetamidophenol is used as internal standard for CYP1A2, $[^{13}C_6]$-hydroxybupropion for CYP2B6, and $[D_4]$-6β-hydroxytestosterone for CYP3A4 assays. Calibration ranges are 1–1,000 ng/mL for 4-acetamidophenol, 0.3–300 ng/mL for hydroxybupropion, and 4–4000 ng/mL for 6β-hydroxytestosterone. Frozen incubation samples, calibration standards, and quality control samples are thawed, centrifuged for 5 min at 14,800×*g* and diluted, and an aliquot is applied to LC-MS/MS analysis (Tables 39.3–39.6).

Table 39.4 HPLC systems

Column	Luna C18(2), 3 μ, 100 × 2 mm, Phenomenex
Guard column	C18 (ODS), 4 × 2 mm, Phenomenex
Temperature	40°C +/− 1°C (4-acetamidophenol and 6β-hydroxytestosterone)
	22°C +/− 2°C (hydroxybupropion)
Gradient (mobile phase)	A: 0.1% (v/v) formic acid/water
	B: 0.1% (v/v) formic acid/acetonitrile

Analytical data treatment: The software Analyst version 1.4.2 (Applied Biosystems) is used for data acquisition, integration, and generation of standard curves and calculation of product concentrations. The peak area ratios (analyte/internal standard) for calibration standards are plotted against nominal concentrations to construct calibration curves using weighted ($1/x^2$) linear regression parameters. The acceptance criteria of the quality control and calibration standard results, expressed as the absolute percent difference, are set at 20% for the low calibration standard and low level quality control and at 15% for other calibration standards and quality controls. Analytical runs are accepted if at least 2/3 of all the quality control samples and at least 1/2 of the quality control samples at each quality control level meet the acceptance criteria. The calibration range is adjusted in case a rejected standard falls at either end. Data below limit of quantification (LOQ) of the assay are not used for calculation.

Determination of protein concentration: Protein concentrations of hepatocyte S9 fractions are determined with a bicinchoninic acid protein assay kit.

Table 39.5 HPLC gradients for LC-MS/MS analysis

CYP enzyme	Marker metabolite (analyte)	Time (min)	%A	%B	Flow rate (μL/min)
CYP1A2	4-Acetamidophenol	0–1.0	98	2	350
		1.0–3.0	98 → 10	2 → 90	
		3.0–6.5	10	90	
		6.5–7.0	10 → 98	90 → 2	
		7.0–12.0	98	2	
CYP2B6	Hydroxybupropion	0–1.0	85	15	350
		1.0–3.0	85 → 55	15 → 45	
		3.0–3.5	55 → 10	45 → 90	
		3.5–6.5	10	90	
		6.5–7.0	10 → 85	90 → 15	
		7.0–11.0	85	15	
CYP3A4	6β-Hydroxytestosterone	0–3.0	80	20	350
		3.0–7.2	80 → 58	20 → 42	
		7.2–8.2	58 → 10	42 → 90	
		8.2–12.5	10	90	
		12.5–13.0	10 → 80	90 → 20	
		13.0–16.0	80	20	

Table 39.6 Mass spectrometer quantitation method parameters

CYP enzyme	Marker metabolite (analyte)/internal standard	Polarity	Transition (m/z)	Collision energy (eV)
CYP1A2	4-Acetamidophenol	Positive	152.02→110.14	23
	[D_4]-4-Acetamidophenol	Positive	156.12→114.14	23
CYP2B6	Hydroxybupropion	Positive	256.19→139.02	37
	[$^{13}C_6$]-Hydroxybupropion	Positive	262.18→145.11	37
CYP3A4	6β-Hydroxytestosterone	Positive	305.19→269.13	21
	[D_4]-6β-Hydroxytestosterone	Positive	309.19→273.18	21

Colorimetric measurements in two dilutions are carried out using the microplate procedure with a sample/working reagent ratio of 1:20 and bovine serum albumin as standard. The absorbance is measured at 570 nm using a microplate reader. Protein concentrations are used to normalize enzyme activities.

Calculation of enzyme activities: Enzyme activities, E, are expressed in pmol $\times$ min^{-1} $\times$ mg^{-1} as the formation of marker metabolite relative to protein. From incubations of the triplicate samples for each treatment, the arithmetic mean and arithmetic standard deviation of the enzyme activities are calculated. If the triplicates of the enzyme activities differ by more than 30% (coefficient of variation), one value is excluded from calculations of the arithmetic mean and arithmetic standard deviation.

39.1.6 Determination of CYP1A2, CYP2B6, and CYP3A4 mRNA Levels

Total RNA preparation: After 72 h of treatment, the hepatocyte incubation medium is removed from the cultures, and 600 μL of lysis buffer from the MagNA Pure Compact RNA Isolation Kit is added to each of the wells designated for mRNA analysis. The plates are stored frozen at −80°C until RNA preparation. Extraction of total RNA from cell lysates is performed using the MagNA Pure Compact RNA Isolation Kit on the MagNA Pure Compact instrument; isolated RNA is stored at < -60°C.

cDNA synthesis and quantitative real-time PCR: mRNA is reverse transcribed into single-stranded cDNA using oligo-p(dT)$_{15}$ primers and AMV reverse transcriptase of a first-strand cDNA synthesis kit for

Table 39.7 LightCycler parameters

Denaturation	95°C for 10 min	
Amplification	35 Cycles	
	Segment 1	95°C for 10 s
	Segment 2	68°C (decreasing 0.5°C/cycle until reaching 58°C) for 10 s
	Segment 3	72°C for 16s

RT-PCR (AMV). Reverse transcription is performed in a final volume of 30 μL which contains 12 μL of the isolated RNA. After the reverse transcription reaction has been stopped, the reaction mixtures are diluted 1:10 with RNase-free water and stored in aliquots at < -60°C. Real-time PCR reactions are performed in capillaries using a LightCycler 1.5 instrument. For analysis, 10 μL of cDNA is amplified using the LightCycler fast start DNA Master^{PLUS} SYBR Green I Kit and the LightCycler primer sets obtained from Search-LC (Search-LC 2010). "Touchdown PCR" is performed in a final volume of 20 μL. Quantification is performed using calibration standards supplied with the LightCycler primer sets. LightCycler data are analyzed using LightCycler software version 3.5. The fluorescence signal readings are analyzed using the fit points method. The copy numbers for both the genes of interest – human CYP1A2, CYP2B6, and CYP3A4 – and the housekeeping genes – human β-actin, cyclophilin B, and glyceraldehyde-3-phosphate dehydrogenase – are determined out of the same cDNA sample in triplicates. LightCycler primer sets are designed such that all PCR reactions use the same temperature profile (Table 39.7).

Analytical data treatment: Transcript copy numbers are obtained from PCR reactions of triplicate samples for each treatment. The transcript copy number of each gene of interest (GOI) – CYP1A2, CYP2B6, and CYP3A4 – is normalized to the transcript copy number of each of the three housekeeping genes (HKG) – β-actin, cyclophilin B, and glyceraldehyde-3-phosphate dehydrogenase . Multiple normalization of target gene expression by using multiple housekeeping genes (e.g., β-actin, cyclophilin B, and glyceraldehyde-3-phosphate dehydrogenase expression) has been shown to be superior to normalization by a single housekeeping gene (Marker 2007). For normalization, the transcript copy number (transcripts/10 μL 1:10 diluted cDNA) of the gene of interest (C_{GOI}) is divided by the transcript copy numbers of each of the three housekeeping genes (C_{HKG}) of the same sample. The arithmetic mean of C_{GOI}/C_{HKG} is formed for each of the three HKG (HKG, $_{1-3}$) from the transcript copy numbers obtained from the PCR reactions of the triplicate samples. The arithmetic mean, E, and the arithmetic standard deviations of the normalizations to the three housekeeping genes are formed.

$$\bar{x}_1 = \frac{1}{n}\sum_{n=1}^{3}\frac{C_{GOI}}{C_{HKG,1}} \quad \bar{x}_2 = \frac{1}{n}\sum_{n=1}^{3}\frac{C_{GOI}}{C_{HKG,2}} \quad \bar{x}_3 = \frac{1}{n}\sum_{n=1}^{3}\frac{C_{GOI}}{C_{HKG,3}}$$

$$E = \frac{1}{3}\sum \bar{x}_1 + \bar{x}_2 + \bar{x}_3$$

39.2 Evaluation of Enzyme Induction

Enzyme activity represents the most relevant endpoint for drug–drug interaction evaluations. However, there are inducers which are also enzyme inhibitors; quantification of enzyme activity, as well as either mRNA (e.g., quantitative RT-PCR) or total protein (e.g., using Western blotting), will allow the evaluation of such compounds. An example is ritonavir; it is an inducer and also a potent inhibitor of CYP3A4 (Foisy et al. 2008). The induction effect of ritonavir does not show up in enzyme activity but becomes apparent in gene expression (quantification of CYP3A4 mRNA).

Solvent control: The study includes a solvent sample as negative control to determine the level of induction (see below).

Positive control: The study includes positive controls with known inducers (e.g., omeprazole, phenobarbital, and rifampicin for CYP1A2, CYP2B6, and CYP3A4, respectively). The positive controls are necessary to demonstrate that the experimental conditions are adequate for the evaluation of induction. A study is considered valid only if the positive controls are found to significantly induce the corresponding cytochrome P450 isoforms. In the current protocol, the maximum induction effect of the reference inducers is assessed by including three concentrations of the reference inducers to accommodate batch-to-batch variations of human hepatocytes. The maximal induction of the reference inducers is compared to the induction caused by the test compound.

Criteria for in vitro induction: Enzyme activity represents the most relevant endpoint for drug–drug interaction evaluations. For subsequent prediction of clinical enzyme induction, the following aspects are to be considered (Hewitt et al. 2007a; Chu et al. 2009; FDA 2012).

- A drug that produces a change that is equal to or greater than 40% of the positive control can be considered as an enzyme inducer in vitro, and in vivo evaluation is warranted.
- An alternative endpoint is the use of an EC_{50} value which represents a potency that can be used to compare the potency of different compounds.
- If induction studies with a test compound confirm that it is not an inducer of CYP3A4, then it can be concluded that the test compound is also not an inducer of CYP2C8 or CYP2C9.

Calculation of % positive control: The induction, expressed as percent of positive control, resulting from treatment with test compound is calculated for enzyme activity and mRNA expression by:

$$\%\ \text{positve control} = \frac{E_{\text{test compound}} - E_{\text{vehicle control}}}{E_{\text{positive control}} - E_{\text{vehicle control}}} \times 100$$

E_{compound}: enzyme activity or normalized mRNA expression with test compound treatment

$E_{\text{positive control}}$: enzyme activity or normalized mRNA expression with reference inducer treatment (of the three concentrations of reference inducer, the concentration is chosen as the positive control which shows the largest induction)

$E_{\text{vehicle control}}$: enzyme activity or normalized mRNA expression with vehicle treatment

Calculation of fold induction: The induction, expressed as fold induction over vehicle control, resulting from treatment with test compound is calculated for enzyme activity and mRNA expression by:

Fold induction over vehicle control $= E_{\text{compound}}/E_{\text{vehicle control}}$

E_{compound}: enzyme activity or normalized mRNA expression with test compound treatment

$E_{\text{vehicle control}}$: enzyme activity or normalized mRNA expression with vehicle treatment

In vitro–in vivo correlation of CYP3A4 induction: Recently, predictive models have been developed to facilitate extrapolation of CYP3A4 induction from in vitro systems such as freshly isolated human hepatocytes and cryopreserved human hepatocytes to clinical CYP3A4 induction (Shou et al. 2008; Kaneko et al. 2010). Shou et al. include the following parameters into the prediction of the drug–drug interaction from freshly isolated human hepatocytes: EC_{50} and E_{max} of CYP3A4 induction in vitro, fractions unbound of the inducer in human plasma ($_{fu,\ p}$), and hepatocytes ($f_{u,\ hep}$), relevant clinical in vivo plasma concentrations of the inducer ($[Ind]_{max,\ ss}$), and fractions of the affected drugs cleared by CYP3A4 ($_{fm,\ CYP3A4}$). The model has the potential to be used for classifying an inducer in vitro as none, weak, moderate, and strong, corresponding to in vivo induction based on the AUC in the induced state compared to the control and ranked as none (≥75%), weak (50–75%), moderate (20–50%), or strong (≤20%). Kaneko et al. predict clinical CYP3A4 induction from in vitro data using cryopreserved human hepatocytes. The parameters of the model include the free human plasma concentration at steady state ($C_{ss,\ u}$) and the relative factor (RF) determined from the in vitro ratio of the concentration of an inducer to the reference standard. Inducers are classified by the $C_{ss,u}$/RF values into categories of no, low, medium, and high potency inducers correlating to the predicted degree of CYP3A4 induction in vivo in humans.

EXAMPLE

The induction profile of the reference inducers of human cytochrome P450 enzymes omeprazole, phenobarbital, and rifampicin – each at three different concentrations – was studied in freshly isolated human hepatocytes from three donors. Both the induction of CYP1A2, CYP2B6, and CYP3A4 enzyme activities (Table 39.8) and mRNA levels (Table 39.9) were investigated. The induction responses are reported relative to the maximal observed induction – set as 100%, and the fold induction relative to the solvent control is given in parenthesis.

Regarding the enzyme activity, the largest induction responses for CYP1A2 were observed at a concentration of 25 μM omeprazole for all three donors with an 8.9- to 11-fold induction. For CYP2B6, 1,000 μM phenobarbital showed the maximum response with a 12- to 23-fold induction. For CYP3A4, the maximum response was observed at 10 μM rifampicin for one donor and at 30 μM rifampicin for two donors with a 9.1- to 19-fold induction.

Regarding the mRNA level, CYP1A2 maximum expression levels were observed at 60 μM omeprazole for all donors with a 19- to 46-fold induction. Highest

[a]Reference positive control

Expression of the results: % positive control = $\frac{E_{compound} - E_{vehicle\ control}}{E_{positive\ control} - E_{vehicle\ control}} \times 100\%$ fold induction = $E_{compound}/E_{vehicle\ control}$

$E_{compound}$: normalized mRNA expression with test compound treatment

$E_{positive\ control}$: normalized mRNA expression with reference inducer treatment

$E_{vehicle\ control}$: normalized mRNA expression with vehicle treatment

CYP2B6 mRNA expression levels were observed at 1,000 μM phenobarbital for all three donors with an 8.5- to 16-fold induction. For CYP3A4, 10 μM rifampicin showed the maximum response for one donor and 30 μM rifampicin for two donors with a 5.8- to 100-fold induction.

These results demonstrate the degree of variability in the induction response by human hepatocyte cultures from various donors.

Acknowledgments The author would like to thank Dr. Martin Burschka for critical reading of this chapter.

40.1 Introduction

Inhibitory drug interactions have received considerable attention in the 1990s because some prominent drugs (e.g., terfenadine) caused life-threatening adverse effects when prescribed with other commonly used comedications (e.g., antibiotics). At about the same time, in vitro technologies were developed to study drug interactions with individual human P450 enzymes by using either enzyme-specific substrates or recombinant P450 isoenzymes. Along with guidance documents issued by the US FDA and European Agency for the Evaluation of Medicinal Products, the evaluation of in vitro drug interactions and the subsequent prediction of in vivo drug–drug interactions from in vitro data have become an integral part of the drug development process (revised draft guidance FDA 2006; EMEA 2010).

The following discussions and assay descriptions are related to cytochrome P450 inhibition. Although most drug interaction studies are related to P450 isoenzymes, other enzyme systems may also contribute to significant drug interactions such as phase II enzymes (e.g., Dietmann and Stork 1976; Kumar et al. 1996; Zucker et al. 2001; Rayer et al. 2001), cytosolic enzymes (Obach et al. 2004), or transporters (e.g., Floren et al. 1997; Abel et al. 2001). Additional assays related to phase II, cytosolic enzyme, or P-glycoprotein interactions are published in literature (e.g., Obach et al. 2004; bdbiosciences.com; Polli et al. 2001; Schwab et al. 2003; Schinkel and Jonker 2003).

Inhibitory drug interactions generally fall into two categories – "direct" and time-dependent inhibition. "Direct" inhibition occurs when a drug inhibits P450

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_44, © Springer-Verlag Berlin Heidelberg 2013

isoenzyme without requiring biotransformation. Traditionally, direct inhibition has been divided in three categories: competitive, noncompetitive, and uncompetitive inhibition (Madan et al. 2002). Competitive inhibition occurs when substrate and inhibitor compete for binding at the same active site at the enzyme. Based on the Michaelis-Menten kinetics, V_{max} is unchanged whereas K_m increases. In case of noncompetitive inhibition, the inhibitor and the substrate bind to different sites at the enzyme. V_{max} decreases whereas the K_m value is unaffected. Binding of the inhibitor only to the enzyme-substrate complex is described as uncompetitive inhibition. Both V_{max} and K_m decrease. Finally, mixed (competitive-noncompetitive) inhibition occurs, either the inhibitor binds to the active or to another site on the enzyme, or the inhibitor binds to the active site but does not block the binding of the substrate. Enzyme kinetics and the mode of inhibition are well described by transformation of the Michaelis-Menten equation. The binding affinity of the inhibitor to the enzyme is defined as the inhibition constant Ki, whereas the affinity, with which the substrate binds, is referred to the Michaelis-Menten coefficient Km. Michaelis-Menten kinetics base on three assumptions:

1. The dissociation of the enzyme-inhibitor or the enzyme-substrate complex is the rate-limiting step.
2. The enzyme concentration is negligible compared to the concentration of the substrate or inhibitor.
3. The free concentration of inhibitor and substrate is known or approximated by the total concentration of substrate and inhibitor.

Identifying a drug as an inhibitor of a given P450 isoenzyme does not necessarily imply that the drug will cause clinically relevant drug interactions. The clinical inhibition potential must be considered in the following context:

1. The pharmacokinetics of the inhibitory drug, particularly maximum exposure and half-life.
2. The potential of coadministering the inhibitory drug together with other drugs that are substrates of the same isoenzyme (inhibition of the comedication by the new chemical entity ("NCE") must be considered separately from inhibition of the NCE metabolism by the comedication).
3. The extent to which clearance of the comedication is dependent on the related isoenzyme.
4. The potential of saturating the capacity of the related isoenzyme.
5. The clinical consequences of alteration of the pharmacokinetics of the affected drug (depending on the drug's therapeutic index).

The K_i determination is inevitable to understand the mechanism of inhibition and for risk assessment.

The second type of drug inhibition results from "irreversible" (or "quasi-irreversible") inhibition of cytochrome P450 and often involves metabolism-dependent inhibition or suicide inactivation of cytochrome P450 (Ortiz de Montellano 1995). Irreversible or mechanism-based inactivation occurs when a compound is metabolized by a CYP to a reactive intermediate which modifies and inactivates the enzyme. At least three different mechanisms are discussed which lead to enzyme inactivation (Polasek and Miners 2007):

1. Reaction with amino acids in the active site of the CYP enzyme.
2. Reaction with the heme nitrogen.
3. Coordination to the heme iron to form a metabolite-intermediate complex (MIC).

The first two mechanisms are classified as true irreversible inhibition, because covalent modification causes inactivation whereas coordination to the heme iron is considered as quasi-irreversible since MIC formation does not actually destroy the enzyme. However, catalytically active CYP can be regenerated in vitro, e.g., by ultrafiltration, dialysis, or oxidation with ferrycanide, but not in vivo. Mechanism-based inhibition is characterized by time- and dose-dependency with a 1:1 stoichiometry, involvement of a catalytic step (NADPH-dependent), saturation of inactivation kinetics, and blockage by other substrates or competitive inhibitors. Chemical substituents frequently associated with cytochrome P450 time-dependent inhibition are aliphatic, alicyclic, or cyclopropylamine; methylenedioxyphenyl; furan; thiophene; alkene; alkyne; 2-alkylimidazole; 3-alkylindole; dihaloalkane; hydrazine; aminophenol; and phenol (Grimm et al. 2009). Due to the chemical modification of the active site, the enzyme activity is permanently lost and can only be re-established by de novo synthesis of the enzyme. Hence, the duration of clinical interactions lasts longer than the actual half-life of the MBI. Mechanism-based inactivation ("MBI") accounts for some of the most potent clinically observed drug–drug interactions (e.g., with mibefradil and tienilic acid, Zhou et al. 2007).

Quantitative prediction of drug-drug interactions bridges the gap between in vitro studies and clinics and provides valuable information to avoid toxic interactions in clinical practice.

In the presence of competitive inhibition, the AUC ratio, reflecting the fold reduction in clearance after oral coadministration of substrate ("victim") and inhibitor ("perpetrator"), is determined by the concentration of the inhibitor also called perpetrator at the enzyme site (I) and its associated equilibrium dissociation constant (K_i) as illustrated in Fig. 40.1, with the following equation: $AUC_i/AUC = 1 + I/K_i$. I/K_i reflects the strength of inhibition of a compound for a given in vivo concentration, qualifying the inhibition risk: the higher the ratio, the higher the risk. A value above 0.1 is considered positive according to the FDA guidance, reflecting a potential inhibition risk.

Regarding MBI, the relationship between AUC ratio, reflecting the fold reduction in clearance is described by the following equation: $AUC_I/AUC = 1/(k_{deg}/(k_{deg} + (I{*}k_{inact}))/(I + K_I))$ (Mayhew et al. 2000), with K_I, the inhibitor concentration at which half maximal inactivation rate is achieved; k_{inact}, the first-order inactivation rate constant; k_{deg}, the natural degradation rate constant for the enzyme in the liver; and I, the inhibitor concentration at the enzymatic site. However, this equation is sometimes used with caution because of the level of uncertainty linked to the natural enzyme turnover k_{deg} and the inhibitor concentrations (Grimm et al. 2009).

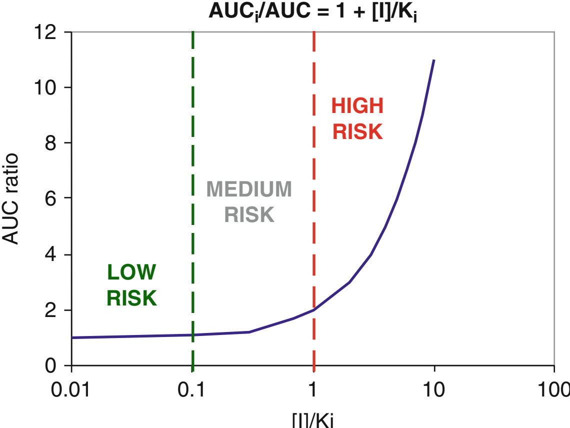

Fig. 40.1 Plot of the relative increase in exposure AUCi/AUC versus I/K_i related to potential risk for drug interaction of direct inhibitors

For CYP3A4, as an example, for which the highest number of mechanism-based inhibitors has been described, this parameter is still debated in the literature. However, once k_{deg} is selected, risk assessment can be proposed positioning the compound of interest (as an inhibitor) on an abacus, taking into account the in vitro parameters k_{inact} and K_I and the inhibitor concentration [I] (Fig. 40.2).

For more information on prediction of clinical drug-drug interactions, please refer to the literature (e.g., Mayhew et al. 2000; Ito et al. 2004; Obach et al. 2006, 2007; Venkatakrishnan and Obach 2007; Fowler and Zhang 2008).

40.1.1 Assays Available

Besides liver slices, isolated/cultured hepatocytes; purified, reconstituted P450 isoenzymes; human liver microsomes; and microsomes from cell lines transfected with cDNA encoding a given human P450 isoenzyme (recombinant P450 isoenzymes) are used for drug interaction studies, most commonly human liver microsomes and recombinant P450 isoenzymes. During the early drug discovery phase, IC_{50} determinations are typically performed in an HTS format using fluorescence marker substrates and recombinant P450 isoenzymes. The method is a fast and cost-effective way to perform thousands of IC_{50}s per year.

Since human liver microsomes contain a complex mixture of CYPs that more closely approximates an intact liver, CYP inhibition data from human liver microsomes are considered as more reliable. For large amounts of compounds, either 1 or 2 concentrations of a potential inhibitor are tested using the classical marker substrates (Table 40.2). With the development of more sensitive LC-MS/MS instruments and the ability to analyze more analytes in parallel, pooled samples for analysis or cassette substrates in incubation to assess full IC_{50}s have further enhanced the throughput of LC-MS/MS-based CYP inhibition assays in human liver microsomes (Dierks et al. 2001; Peng et al. 2003). In the area of ultrafast LC-MS/MS techniques, e.g., LDTD instruments (Phytronix) or RapidFire™ (Perloff et al. 2009; Miller et al. 2009; Luippold et al. 2011), full IC_{50} determination and screening for mechanism-based inhibition in human liver microsomes have become common already in the early

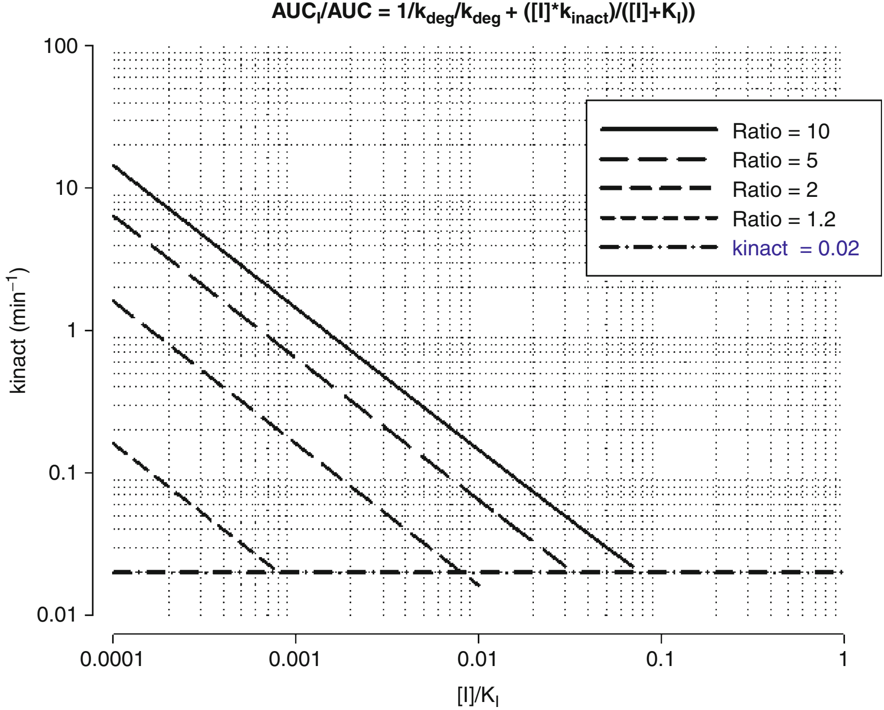

Fig. 40.2 Abacus for MBI risk assessment, assuming $k_{deg} = 0.00016\ min^{-1}$. Ratio represents the AUC ratio with and without coadministration of inhibitor. The threshold $k_{inact} = 0.02\ min^{-1}$ corresponds to the accepted lowest detectable limit using the classical in vitro test

[b]Strongly recommended to use at least two structurally unrelated substrates

discovery process. In the drug development phase, detailed CYP interaction studies to evaluate the mode of inhibition, K_i and K_I/k_{inact} determination are usually required for intermediate and potential direct and mechanism-based CYP inhibitors.

Interaction studies in suspended/cultured hepatocytes (Oleson et al. 2004; Gómez-Lechón et al. 2004) and liver slices are less common since a couple of competing reactions occur, e.g., uptake pathways or phase II metabolism of the NCE and/or marker substrate, which make it difficult to interpret the data mechanistically. However, interaction studies in human hepatocytes are recommended when drug candidates are extensively metabolized by non-CYP enzymes to prevent over- or underprediction of the interaction potential from human liver microsome studies (Parkinson et al. 2010).

40.2 "Direct" Cytochrome P450 Inhibition

40.2.1 CYP Inhibition Studies Using Recombinant P450 Isoenzymes

Combinatorial chemistry and high-throughput screening for pharmacological activity have identified a relatively large number of compounds, which have potential drug properties. Since inhibitory drug interaction has been associated with life-threatening adverse effects, an early identification for potential drug interaction of NCE is desirable. The availability of high-throughput assays for cytochrome P450 inhibition facilitates the identification of those drug candidates, which have lower potential for drug-drug interactions.

Table 40.1 summarizes typical assay conditions for CYP inhibition studies of the most relevant P450 enzymes using recombinant P450 isoenzymes (Supersomes®) which are applicable to 96 and 384 well formats. Assay conditions for additional P450 isoenzymes can be found under www.bdbiosciences.com.

40.2.1.1 IC_{50} Determination

Usually, the NCE is pipetted together with the enzyme-substrate complex, and the reaction is started with the addition of the cofactor solution. Incubation times vary between 15 and 45 min at 37°C. Afterward, the reaction is stopped by the addition of a TRIS/acetonitile solution and applied to fluorescence read-out. IC_{50} determinations are calculated using standard software tools, e.g., ExcelFit® or SigmaPlot®.

EVALUATION

The assays are usually performed in parallel to solvent control and a well-known inhibitor of the P450 isoenzyme investigated (positive control).

CRITICAL ASSESSMENT OF THE METHOD

For overexpressing P450 isoenzymes, several heterologous expression systems have been established, that includes bacteria (*Escherichia coli*), yeast (Saccharomyces cerevisiae, Schizosaccharomyces pombe), insect cells (baculovirus), and mammalian cells (V79, CHO, HepG2, NIH 3 T3, human lymphoblast cells) (Crespi and Miller 1999). High active P450 isoenzymes, overexpressed in human lymphoblast cells (BD Supersomes®, BD Biosciences, Franklin Lakes, NJ) and in insect cells (Baculosomes®, Panvera, Madison WI), have been asserted in the market and are commercially available. However, the Supersomes® and Baculosomes® have not been thoroughly characterized with respect to their kinetic properties and substrates/inhibitors specificities. Usually, the expression of the cytochrome b5 and/or NADPH-cytochrome P450 reductase varies from batch to batch, which can affect the turnover number (V_{max}) for a given enzyme, although the affinity (K_m value) of P450 enzymes toward marker substrates is generally comparable between recombinant enzymes and human liver microsomes (McGinnity et al. 1999). Moreover, the catalytically inactive apoprotein contributes significantly to the total protein concentration. On the other hand, the simplicity of the test system (separate study of the P450 isoenzyme, fluorescence labeled marker substrates, which allows a rapid, compound-independent read-out without any extraction procedures) allows a quick estimation of the interaction potential of NCEs in an HTS format with an excellent sensitivity, reproducibility, and throughput (thousands of compounds/year and person). In addition, polymorphic P450 isoenzymes with different genotypes are available, which allow detailed interaction studies. Sometimes, fluorescent excitation and emission overlaps between NCEs/metabolites, NADPH, and marker substrate, which results in

assay failure but might be overcome by alternative read-out methods (e.g., LC-MS/MS technologies).

A major disadvantage is that inhibitory metabolites generated from other CYPs are overseen in the assays (false negatives). False positives are due to enzymes involved in the metabolic turnover other than the particular one studied.

MODIFICATION OF THE METHOD

Additional fluorescence labeled marker substrates with different extension/emission wavelengths are on the market, e.g., from Invitrogen™ (www.invitrogen.com), which allow some variation if the NCE/metabolite interferes with the fluorescence read-out.

"P450-Glo™ Assays" from Promega Biosciences Inc. (www.promega.com) – a luminescent cytochrome P450 assay – was introduced as alternative CYP inhibition assay. The marker substrates are luciferin derivatives (luciferin 6′-chloroethyl-ether, luciferin 6′-methylether, 6′-deoxyluciferin and luciferin 6′-benzylether, ethylene glycol ester of deoxyluciferin, ethylene glycol ester of luciferin 6′-methylether, Cali et al. 2006), which are converted from recombinant P450 isoenzymes (Supersomes®, Baculosomes®, or yeast expression systems) to luciferin, which in turn reacts with luciferase to an amount of light that is directly proportional to P450 activity. The assay promises an exquisite sensitivity with low background signals and a broad dynamic range. Since no information of NCEs toward their luciferase inhibition potential is known, an inhibition study has to be performed in parallel. The same is true for quench effect of the NCE that might alter the read-out. The marker substrates are not specific for any single P450 isoenzyme, except for 6′-deoxyluciferin (human CYP2C9). Hence, application to HLM or cell-based assays is critical today. Marker substrates for CYP2A6, CYP2B6, and CYP2E1 are currently missing. The assay is applicable to 96-, 384-, and 1536-well format. Furthermore, the luciferase readout reaction needs additional 20 min incubation time.

40.2.2 CYP Inhibition Studies Using Human Liver Microsomes

Human liver microsomes contain all P450 isoenzymes expressed in human livers, although their content and genotype, especially for polymorphic P450 isoenzymes such as CYP2D6, CYP2C9, CYP2C19, and 2B6, can vary from sample to sample. To overcome the problem of variability, several individual human liver samples are pooled to get an “average” of all P450 enzymes expressed in human livers. Individual and pooled human liver microsomes are commercially available. Since all P450 isoenzymes are present in microsomes, enzyme-selective substrates must be used. Table 40.2 summarized recommended substrates.

40.2.2.1 IC_{50} Determination

Each drug, one or two concentrations (e.g., 1 and 10 μM) in the early discovery stage, or more concentrations (up to ten concentrations which cover two orders of magnitude) for detailed IC_{50} determination, is incubated with human liver microsomes in the presence of the marker substrate (FDA 2006). Reactions are initiated with addition of $NADP^+$/regeneration system or NADPH at 37°C. According to the Michaelis-Menten assumptions, the marker substrates should be

used at concentrations below or around the corresponding K_m values, which have to be determined once for each specific substrate prior to the incubation. The microsomal protein concentration should be as low as possible to circumvent unspecific binding. Cofactors, such as $NADP^+$, G6P, G6P-DH, and $MgCl_2$, are usually used at concentrations of 0.5 mM, 5 mM, 0.5 U/mL, and 6 mM, respectively, in 50 mM phosphate buffer pH 7.4. Organic solvent should be minimized as much as possible to avoid inhibitory effects of the solvents (Busby et al. 1999; Yuan et al. 2002). Addition of ice-cold acetonitrile solution containing an appropriate amount of internal standard followed by a sharp centrifugation step stops the reactions. The supernatants are either pooled or applied directly to LC-MS/MS analytics for quantification of the marker metabolite generated from the respective marker substrate. IC_{50} determinations are calculated using standard software tools, e.g., Excelfit® or SigmaPlot®.

Table 40.3 summarizes typical incubation conditions and kinetic constants of marker substrate reactions of human P450 enzymes in a pool of human liver microsomes.

40.2.2.2 K_i Determination

Based on the result from the IC_{50} determination, determination of additional kinetic parameters such as K_i for the assessment of clinical drug-drug interactions and the inhibition mode are useful. K_i experiments are typically performed with variable substrate and inhibitor concentrations, spanning at least 0.5–5 x of the expected K_i (according to $K_i = IC_{50}/2$) and K_m concentrations using the same incubation conditions as outlined above. Transformation of the Michaelis-Menten equation is used both for the calculation the K_i value as well as for graphical depiction of the type of inhibition (e.g., direct plot ([rate]/[substrate]), Dixon plot [1/rate]/[inhibitor], Linewaver-Burk plot [1/rate]/[1/substrate], or Eadie-Hofstee plot [rate]/[rate/substrate]). K_i is easily taken from Dixon plots and the inhibition mode from the Eadie-Hofstee plot (Segel 1993).

EVALUATION

The assays are usually performed in parallel to solvent control and a well-known inhibitor of the P450 isoenzyme investigated.

CRITICAL ASSESSMENT OF THE METHOD

The Michaelis-Menten assumption can be violated in the case of P450 enzymes, depending on the CYP isoenzyme on the in vitro system used. CYP3A4 and CYP2C9 are known to show atypical enzyme kinetics such as enzyme activation or partial inhibition which illustrates possible pitfalls especially when testing only two concentrations during the discovery phase. The "free" concentration of substrate or inhibitor may differ significantly from the total concentration, since microsomes usually contain a large amount of lipids and proteins that can decrease the free concentration of the drug and the marker substrate in the medium. The potency of some inhibitors is such that the free concentration of the inhibitor is in the same range as the

Table 40.3 Typical incubation conditions and kinetic constants of marker substrate reactions of human P450 enzymes in a pool of human liver microsomes (Madan et al. 2002; Bourrier et al. 1996; Transon et al. 1996; and Hesse et al. 2000)

CYP	Marker reaction	Protein(mg/ml)	Incubation time (min)	K_m (μ)	V_{max} (pmol/min/mg)
1A2	Phenacetin O-deethylation	0.1	10	30.1 ± 9.3	7,700 ± 4,500

3A1	Testosterone 6β-hydroxylation	0.1	10	110 ± 10	9,800 ± 490
	Midazolam 1′hydroxylation	0.1	10	3.3 ± 1.3	577 ± 375
4A9/11	Lauric acid 12-hydroxylation	0.1	5	7.6 ± 1.2	2,200 ± 100

enzyme concentration. This problem can be overcome by lowering the enzyme concentration (often limited by analytical sensitivity of the assay) or by estimating an "apparent" K_i, by correcting for the fraction of the inhibitor that is bound to the enzyme, which is calculated as the product of the fractional inhibition in the presence of a given inhibitor concentration and enzyme content (Gibbs et al. 1999). Note that IC_{50} values are extrinsic constants whereas K_i values are intrinsic constants. Consequently, IC_{50} values (but not K_i values) are dependent on the type of substrate and incubation conditions and are difficult to reproduce between different laboratories. On the other hand, IC_{50} determination is less time consuming, and an external quality control can be achieved by using standard inhibitors in parallel. Nevertheless, the FDA has accepted the method of predicting the potential for drug interaction by a drug based on K_i values (together with the free plasma concentration of the drug).

MODIFICATION OF THE METHOD

The most critical step in the interaction studies is a sensitive and reproducible method for quantification of the marker substrates and the corresponding metabolite. Analytical methods are usually applied to time- and resources-consuming HPLC (UV/fluorescence/radioactivity detection) or LC-MS/MS detection.

An alternative detection method was introduced by Yang (Yang et al. 1991), Bloomer (Bloomer et al. 1992, 1995), Rodrigues (Rodrigues et al. 1994, 1997; Rodrigues 1996), and Riley (Riley and Howbrook 1997). They used ^{14}C-nitrosodimethylamine, [O-methyl-^{14}C]dextromethorphan, [O-ethyl-^{14}C]phenacetin, and [N-methyl-^{14}C]erythromycin as marker substrates for CYP2E1, CYP2D6, CYP1A2, and CYP3A4, respectively, with a [^{14}C]formaldehyde or [^{14}C]acetaldehyde read-out after a simple and rapid extraction method.

40.3 Time-Dependent CYP Inhibition

40.3.1 IC_{50} Shift Assay

A simple method to evaluate potential time-dependent inhibitors is to preincubate an NCE at various concentrations for 30 min in presence and absence of NADPH in *rh*CYP (Burt et al. 2010) or in human liver microsomes (Grimm et al. 2009, incubation conditions; see Chap. 2 "Safety Pharmacology: Introduction" or Obach et al. 2007), with or without a dilution step in between following addition of the marker substrate to determine the residual P450 enzyme activity usually by LC-MS/MS analysis. A significant IC_{50} shift indicates mechanism-based inactivation of the related P450 isoenzyme, for which K_I and k_{inact} determination are usually done as follow-up investigations. For screening purposes to identify potential MBIs, preincubation is usually done with one or two concentrations (often 1 and 10 μM) with subsequent LC-MS/MS analysis to increase throughput.

40.3.2 Time-Dependent Inhibition Screening Using Recombinant Human P450 Isoenzymes

A high-throughput assay for the evaluation on MBI potential using recombinant P450 isoenzyme was introduced by Abecassis (2003), deploying a change of the apparent IC_{50} value with time. According to Maurer (2000), who derived a mathematical relationship between the inhibitory potency at any time $IC_{50}^{(t)}$ as outlined in Fig. 40.3, a decrease of the IC_{50} value with time indicates a mechanism-based inhibition whereas competitive inhibition is time independent and shows no changes of the IC_{50}. The slope value has a direct proportionality to K_I/k_{inact}, and slope divided by IC_{50} is directly proportional to k_{inact}.

Serial dilution of an NCE (5–10 concentrations) is pipetted together with the enzyme-substrate complex and cofactor solution (saturated conditions, e.g., 12 nM for rhCYP3A4, 7-benzoquinoleine 10 μM (~K_m), 4 mM $MgCl_2$, 3.3 mM glucose-6-phosphate, 1 U/mL glucose-6-phosphate dehydrogenase, 0.1 mg/mL BSA in 0.3 M potassium phosphate buffer pH 7.4 in a total volume of 100 μL on a 96-deep-well plate. A well-known mechanism-based inhibitor, e.g., mifepristone, and – if feasible – a competitive inhibitor are investigated as positive and negative controls in parallel. Reaction starts with addition of 1 mM NADPH. Fluorescence (excitation/emission wavelength: 410 and 538 nm) is measured in a real-time course every 30 s for 15 min on a Fluoroscan Ascent Labsystem (ThermoFisher Instruments). IC_{50} values at each time point are automatically fitted by standard software tools, and the $\ln(IC_{50})$ is plotted versus the incubation time.

40.3.3 Determination of the Apparent Partition Ratio

Alternatively, the MBI potential can be determined based on the apparent partition ratio according to Lim et al. (2005). The enzyme activity is measured after 1-h incubation time with an NCE in presence and absence of NADPH in comparison to a known positive control. A decrease of the enzyme activity after preincubation of the NCE in presence of NADPH indicates MBI. The primary incubation usually contains 2 mg/mL HLM, various concentrations of the test compound, 10 mM $MgCl_2$, 2 mM EDTA, 100 mM potassium phosphate

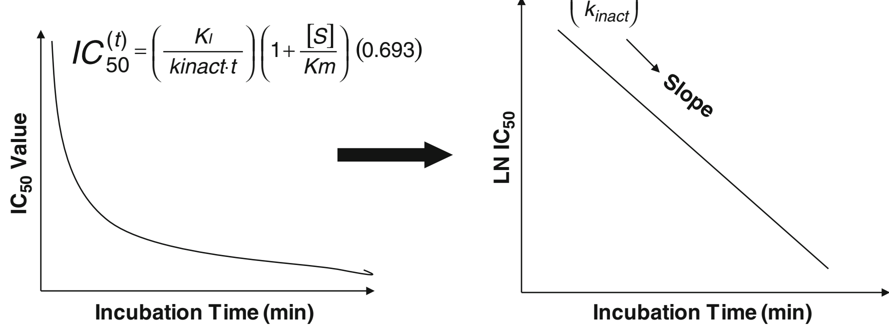

Fig. 40.3 Mathematical relationship between the inhibitory potency with time and kinetic parameter. IC_{50} values decrease with incubation time due to strong/irreversible interaction with reactive intermediate and the P450 enzyme

buffer pH 7.4, 1 mM $NADPH^+$, 10 mM glucose-6-phosphate, and 2 U/mL glucose-6-phosphate dehydrogenase in a total volume of 200 µL. The reactions are initiated by adding NADPH-regenerating system and incubated for 1 h at 37°C to ensure complete inactivation. To analyze the residual catalytic activity, an aliquot of the incubation solution (usually 10–20 µL) is transferred to a mixture containing the identical concentration of cofactors as described above and the marker substrate at saturated concentration (5 × Km) instead of the test compound (1:20 dilution). The secondary incubation is incubated for additional 20 min and stopped afterward with acetonitrile containing internal standard. Microsomal proteins are pelled by centrifugation, and an aliquot of the supernatant is analyzed by LC-MS/MS analytics. The APRs are calculated plotting percent activity remaining as a function of the molar ratio of the test compound to P450 isoenzyme (Fig. 40.4). Values from the respective control incubation were set to 100%. Investigation on the reversibility of the inactivation can be achieved either by oxidation with ferricyanide or by dialysis to distinguish between true MBIs and quasi-irreversible inhibitors (Lim et al. 2005).

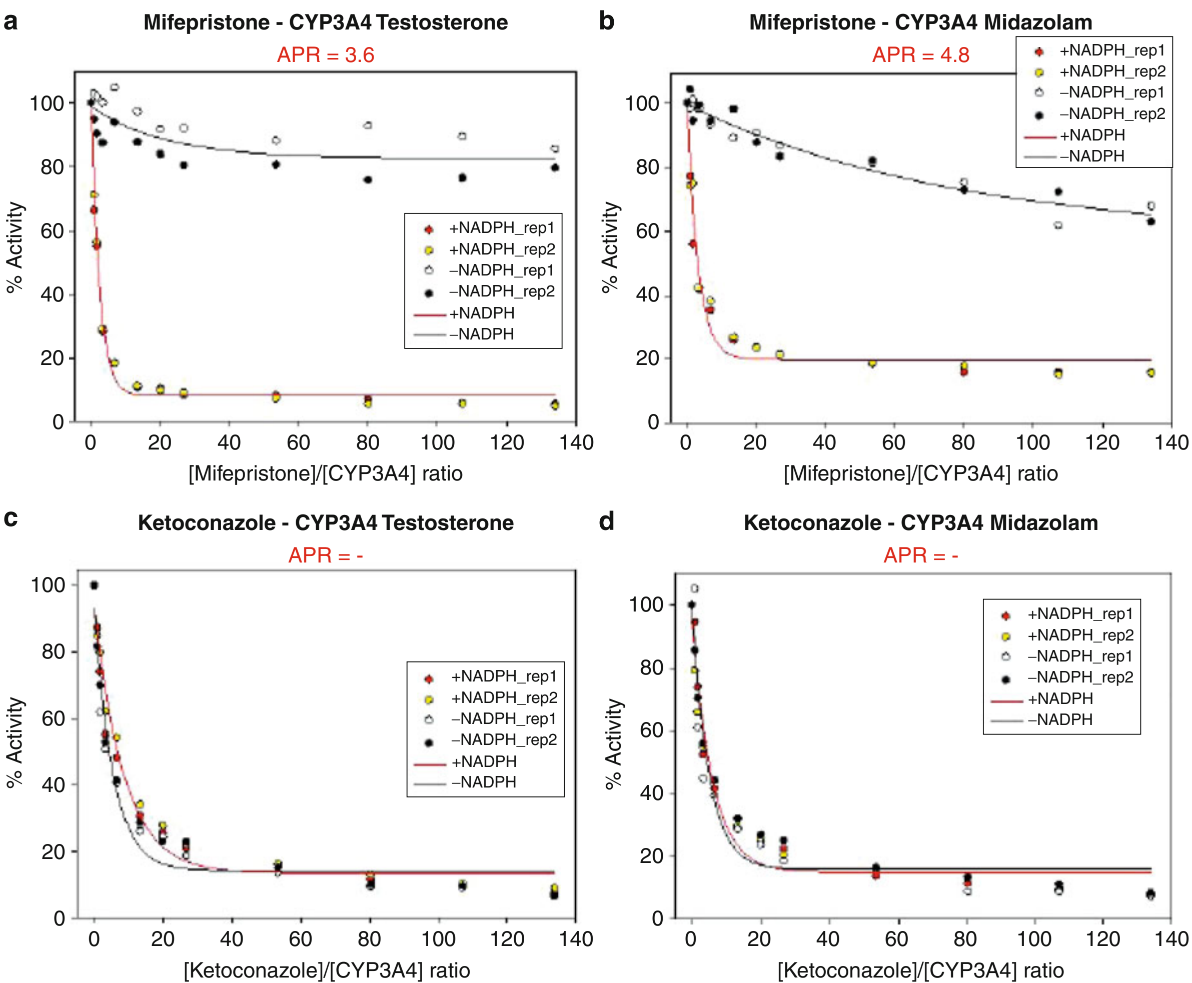

Fig. 40.4 Curves corresponding to the percentage of the remaining enzyme activity in presence and absence of NADPH-regenerating system were plotted as function of the molar ratio of test compound to P450 isoenzyme (data related to CYP3A4, using testosterone and midazolam as CYP3A4 marker substrate). Mifepristone serves as positive control (graph A and B) and ketoconazole as negative control (graph C and D)

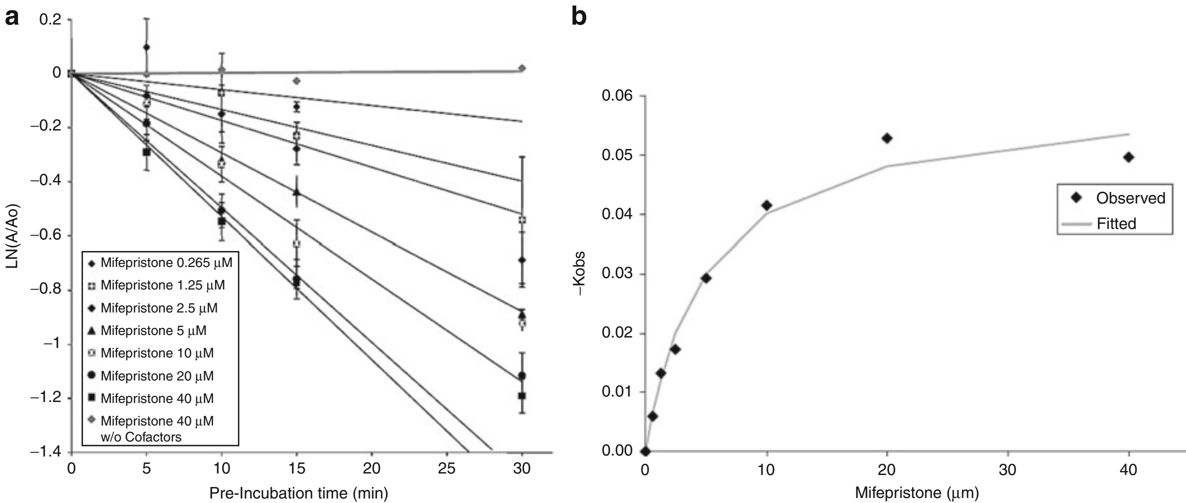

Fig. 40.5 (**a**) Time-dependent inhibition of midazolam hydroxylase activity by Mifepristone in HLM. (**b**) Observed inactivation rates at different mifepristone concentrations

40.3.4 K_I/K_{inact} Determination

K_I and k_{inact} determination are principally done according to Lim et al. using additional preincubation times (e.g., 5, 10, 15, 30 min depending on the inhibitor). Kinetic parameters (k_{inact}, K_I) are obtained by plotting the natural logarithm of the residual enzyme activity (Ln A/A0) against the preincubation time (Fig. 40.5a and b). The inactivation rate K_{obs} is determined as the negative slopes of the lines reflecting the inactivation process. Apparent K_I and k_{inact} values are determined using Kitz-Wilson plot and by nonlinear regression analysis of

$$-K_{obs} = k_{inact} * [I]/K_I + \{[I]$$

where K_{obs} (min^{-1}) is the inactivation rats for a given test compound concentration,

I in µM is the concentration of the test compound,

k_{inact} (min^{-1}) is the maximal rate of enzyme inactivation, and

K_I (µM) is the concentration required to achieve the half-maximal rate of the enzyme inactivation.

EVALUATION

The assays are usually performed in parallel to solvent control, a well-known mechanism-based inhibitor as positive and a competitive inhibitor as negative control of the respective P450 isoenzyme. To increase throughput, samples are either pooled or analyzed separately with ultrafast LC-MS/MS techniques. Assay variability and the analytical accuracy must be small enough to identify IC_{50} shifts produced by low-potency TDI substances.

CRITICAL ASSESSMENT OF THE METHODS

In terms of MBI, discrepancies between human recombinant CYPs and HLM have been observed internally and are reported by various authors (e.g., Palamanda et al. 2005; Polasek and Miners 2007). A different CYP: oxidoreductase molar ratio of approximately 1:1 in *E. coli* expression system versus 1:10 or 1:20 in HLM might be one reason for these differences as reactive intermediates are likely to be generated more efficiently in recombinant CYPs because of higher rates of electron transfer by the advantageous CYP: oxidoreductase molar ratio (Polasek and Miners 2007). Additionally, competition between multiple CYPs for the oxidoreductase in human liver microsomes could lead to comparably less catalytic turnover to reactive intermediates. This may clarify why the differences in MBI occurs prevalently with drugs that form alkylamine MICs (Benoussan et al. 1995; Polasek and Miners 2007). N-terminal modifications are frequently incorporated into wild-type cDNAs to increase expression levels of human CYP in *E. coli* (Boye et al. 2004). Alteration in this region may affect membrane anchoring but can also influence the aggregation

characteristics of CYP with the oxidoreductase and other CYP enzymes (Backes 2003; Polasek and Miners 2007).

Dilution factors in the IC_{50} shift assay needs to be selected carefully: IC_{50} values for direct-acting inhibitors vary with the dilution factor unless they are based on the final (postdilution) inhibitor concentration, whereas the IC_{50} values for mechanism-based inactivators vary with the dilution factor unless they are based on the initial (prediluted) concentration (Parkinson et al. 2011). Preincubation times and the numbers of preincubation times in case if K_I/k_{inact} determination have to be chosen properly – potent TDI usually requires short incubation times, whereas for less effective TDIs, longer preincubation times are necessary to get sufficient data on enzyme inactivation. Metabolites, which are more potent inhibitors than the parent substances, appear like TDIs in the IC_{50} shift assay. For the prediction of clinical drug interaction studies, kinetic data are usually corrected for nonspecific binding.

41.1 Introduction

The pressure on research efficiency and cost in the pharmaceutical industry has resulted in a paradigm shift to bring active molecules earlier to the market (Wess 2002; Lawrence 2002). Increasing expenses by attrition in late stage development are partially attributed to an inadequate understanding of pharmacokinetic and toxicological behavior of drugs (Prentis et al. 1988;? Kennedy 1997; Drews 2000). The conversion of biologically active molecules into effective and safe pharmaceuticals adds substantial value to the drug discovery process. Consequently, the improvement of a compound profile toward a clinical candidate is one of the essential skills in integrated drug discovery teams. Those candidate requirements include multiple parameters including potency and efficacy, selectivity against related proteins or "antitargets," favorable physicochemical and pharmacokinetic properties leading to the required bioavailability after oral administration, and an acceptable half-life of elimination of the final candidate. A simultaneous optimization of multiple parameters in carefully planned iterations is therefore required to arrive at molecules with suitable properties and profiles.

The requirement for shortening pharmaceutical discovery caused the integration of pharmacokinetic and developmental efforts into earlier research to focus on molecules with increased optimization potential. It is mandatory to initiate time-consuming optimization programs only for those series which show a potential to be convertible into drug molecules.

Within the discovery process, in silico approaches to identify or improve chemical structures are utilized in the lead generation and optimization phase. First, lead

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_45, © Springer-Verlag Berlin Heidelberg 2013

series are identified with activity and selectivity in relevant assays (Wess et al. 2001; Bleicher et al. 2003). In this phase, mainly global in silico models are applied. The following lead optimization phase is the most challenging part of drug research (Wess et al. 2001; Wess 2002). Its ultimate object is to turn an efficacious molecule into an effective and safe drug. This is accomplished by structural variations to improve the molecule such that its profile fulfills defined criteria for its therapeutic application. During this phase, the ADME (absorption, distribution, metabolism, excretion), as well as the toxicity properties of the drug candidate, is being optimized. These activities are mainly supported by local in silico models. Although the clinical development is also supported by in silico tools to describe the pharmacokinetic behavior of the drug candidate, a description of these tools is beyond the scope of this chapter.

The introduction of several new technologies like protein crystallography, ADME assays, medicinal chemistry automation, and others has added not only new opportunities but also more complexity to the lead optimization phase. Consequently, it is vital for success to conceive lead optimization as simultaneous multidimensional optimization of compound properties rather than addressing one parameter at a time. Traditionally, binding affinity is first optimized, while ADME parameters are addressed later in this process (Oprea 2002; Zamora et al. 2003a). This approach, however, showed only limited success as optimizing for affinity only can result in chemical classes, where further improvement becomes impossible. The efficiency of the drug discovery process is expected to improve if both aspects are considered simultaneously. Besides high biological activity in vitro, it is of great importance to simultaneously ensure sufficiently high drug concentrations at the target site in vivo by seeking for favorable ADME properties. To this end, various in vitro assays have been introduced to monitor compounds as early as possible for their ADME characteristics. However, all these techniques require the synthesis of the compound to be tested. To save time and chemical resources, it is desirable to introduce in silico tools into the drug development process, allowing the reliable assessment of compound properties prior to synthesis and subsequently the drawing up of a priority list of the most promising compounds to be synthesized. Thus, facing the requirements of modern drug development, rational approaches to alter molecules being originally directed by quantitative structure-activity relationship (QSAR) and structure-based design become more and more a tight interplay between multiple disciplines: medicinal chemistry, structural biology, pharmacology, and pharmacokinetics.

This chapter discusses selected computational methods and strategies toward the generation and application of in silico models in drug discovery. In silico models can be classified in general and local, chemotype-specific models. This grouping broadly reflects the range and diversity of chemotypes incorporated in the training set for establishing the model. The underlying assumption is that general models might find wider applicability to novel structures for prediction, while local models are focused toward a particular class. Thus, general models might be of interest in earlier phases of a discovery project (library design, hit exploration) without much experimental ADME data for a particular chemotype. Local models on the other hand are based on previous knowledge for one series and are more useful in the lead optimization phase. Frequently, experimental data for one particular ADME property is then available to build a model. Then, this information can be turned into a more focused model with, of course, less wide applicability, but the resulting model certainly will help more to direct further synthesis efforts.

It is beyond the scope of this chapter to provide an exhaustive list of software tools, descriptors, models, and approaches to address multiple ADME issues. We rather discuss a selected list of approaches which have shown to be valuable in several drug discovery projects. The entire field, the methods, and descriptors are changing rapidly, and the interested reader thus is referred to recent review articles for this purpose (Clark and Pickett 2000; Clark 2001; Matter et al. 2001; van de Waterbeemd and Gifford 2003; Dearden 2007; Hou and Wang 2008; Vaz et al. 2010; Tarcsay and Keserü 2011; Gleeson et al. 2011a, b).

Any approach to correlate chemical structures to experimental data requires first an appropriate description of structures by molecular descriptors and second a robust statistical technique unveiling those structural features correlated with the ADME property. These quantitative structure-activity relationships (QSARs) result in models quantifying the influence of various descriptors on estimating the activity. However, it is of utmost importance to realize that statistical approaches can only highlight correlations between descriptors

and activity, but cannot prove any causality. Hence, in silico models require careful validation to avoid overfitting and erroneous conclusions.

The presented computational approaches can be grouped based on their description of molecular structures: (a) simple physicochemical or topological descriptors like PSA (polar surface area); (b) alignment-free descriptors capturing global information from 3D molecular representations like VolSurf and QikProp descriptors; (c) combinations of physicochemical, structural, and topological descriptors from 2D molecular representation like MOE or DRAGON descriptors; and (d) 3D descriptors, which depend on the alignment of molecules to obtain spatially resolved information on regions affecting the interesting property, like CoMFA and GRID descriptors. This range of different descriptors is analyzed using a variety of statistical methods to establish predictive models, for example, using linear regression models like PLS, nonlinear regression models, decision trees, and regression trees. In contrast to these QSAR-based approaches, a method named MetaSite (Cruciani et al. 2005; Vaz et al. 2010) is described for in silico prediction of the site of metabolism (SOM) in a ligand by distinct cytochrome P450 enzymes. This approach does not depend on a training set of molecules. In contrast, this method derives its prediction from a combination of the lability of ligand hydrogen atoms plus orientation effects of this ligand in the CYP450-binding site, which is estimated by available 3D structures of a CYP450 enzyme from X-ray crystallography or homology modeling.

In the following sections, this overview provides examples for both global and local ADME models to highlight different approaches. Datasets for intestinal human absorption, human serum albumin binding, plasma protein binding, and CYP2C9 inhibition will be discussed in detail, while predictive models for other important ADME properties have also been developed. The prediction of the site of metabolism will be discussed with some examples. In addition, the development and application of a local QSAR model addressing intestinal absorption from an in vivo perspective for a congeneric series will also be outlined.

It has to be pointed out that prediction failures of general ADME models are often related to two major sources, namely, the quality of experimental data used to derive the model and the interpretation of the final model. These problems are discussed in depth by Stouch et al. (2003). Some models fail as they were built from data collected from different sources and laboratories. Although this might work for some robust assays, it could produce incomparable data for others. Such problems have been reported, for example, for Caco-2 assays run in different laboratories. Even if experimental data are collected in a single laboratory or under strictly harmonized conditions, as nowadays routinely performed within the pharmaceutical industry, another potential source of errors can occur if such a model is transferred to another place where a slightly different assay protocol is utilized to monitor the predictivity of the model. Furthermore, it is ambitious to derive a truly general model for a wide range of chemotypes. Often the limited coverage of training set chemical space plus the presence of novel compound classes to be predicted in research projects which are very dissimilar to any training molecule might also significantly limit the scope of a particular model. Finally, a classification model should not be used to rank order compounds but only to filter undesirable compounds. Any other application would lead to an overinterpretation of the model's precision. Furthermore, it has to be emphasized here that adding more compounds with additional experimental data to an existing general model does not guarantee that its predictivity will increase. This is because the addition of new compounds might introduce new modes of interaction and/or new reaction mechanisms.

Although the ADME space is of lower dimensionality that means there are less descriptors building the structure-property model, ADME properties in practice are more difficult to predict than biological receptor affinities, as corresponding experimental screens are often multimechanism rather than single-mechanism systems (Lipinski 2000). In contrast, biological assays for the majority of pharmacological targets are typical single-mechanism systems for which computational models to correlate structural descriptors are easier to develop and resulting predictions tend to be more robust. Computational models based on experimental data combining multiple underlying biological mechanisms tend to get worse if more data for more diverse molecules are integrated into the training set. This is mainly due to the fact that the increase of assay data relates to an increase of underlying mechanisms, on which those data have been obtained and the noise level rises for each individual mechanistic component (Lipinski 2000). For smaller,

structurally, and thus probably mechanistically homogeneous datasets, acceptable correlations are obtained, while the ability of descriptors to capture a more diverse experimental dataset is limited. Although the same descriptors might still have statistical significance and thus explain trends for inhomogeneous data, their predictivity is often too low to be useful for lead optimization purposes. This only allows implementing validated filters based on property distributions. Hence, it is mandatory to use high-quality single-mechanism ADME experimental data for building single-mechanism predictive models (Lipinski 2000). Alternatively, the assumption might be valid that congeneric series behave similar in multiple mechanism assays so that a local model for this series is primarily capturing the main trend of this series.

To further illustrate this point, one should be aware that poor intestinal absorption of a lead structure, for example, can be attributed to either insufficient physicochemical properties or poor membrane permeation but also to the net result of efflux mediated by transporter proteins including the multidrug resistance protein MDR1 (or P-glycoprotein, P-gp) or multidrug resistance-related proteins (MRPs) in the intestinal membrane. Cell lines with only one single efflux transporter are currently engineered for in vitro permeability assays to get suitable data for reliable QSAR models. In addition, successful efforts to gain deeper insight into P-gp and other ATP-binding cassette (ABC) transporters on a structural basis have been reported (Litman et al. 2001; Rosenberg et al. 2003; Demel et al. 2008; Broccatelli et al. 2011). These examples further illustrate the complexity when dealing with different assays and molecules.

41.2 Computational Approaches

41.2.1 Polar Surface Area (PSA)

PURPOSE AND RATIONALE

As for most drugs, the preferred route of administration is *per os*; many efforts have been made to identify physicochemical properties that favor intestinal absorption as single component to oral bioavailability. While for many ADME properties only qualitative in silico assessment can be realistically expected, more quantitative rankings are possible with regard to passive drug permeability across the intestinal epithelium and the endothelium of the blood-brain barrier (Pickett et al. 2000; Artursson and Bergström 2003). Among the strategies to predict intestinal absorption in silico, the use of molecular surface areas was among the first ones and is still employed due to speed and simplicity. Molecular surface areas have been used 40 years in the modeling of solvation and partitioning processes (Hermann 1972; Pearlman 1980). More recently, ADME properties were predicted using a term derived from the molecular surface known as the polar surface area (PSA). Some reviews highlight the importance of this simple descriptor with physicochemical relevance (Artursson and Bergström 2003) to understand passive transport problems across membranes.

PROCEDURE

The PSA of a molecule is defined as van der Waals surface from all oxygen and nitrogen atoms including attached hydrogen atoms; it relates to the capacity to form hydrogen bonds as essential determinant for passive intestinal absorption.

There are different methods to calculate PSA values. The dynamic polar surface area PSA_d is obtained from a Boltzmann-weighted average from low-energy conformers (Palm et al. 1996; 1997; van de Waterbeemd et al. 1996; Krarup et al. 1998). To this end, all low-energy conformations from a conformational analysis with a certain energy cutoff are taken into account. The probability of a molecule to adopt a certain conformation is calculated from a normalized Boltzmann distribution (Palm et al. 1996; Lipkowitz et al. 1989). The energy cutoff value of 2.5 kcal/mol ensures that all conformations that contribute more than 1% to the conformational space are considered.

The polar surface area of a single conformer PSA_s is calculated from the global minimum conformation of a molecule (van de Waterbeemd et al. 1996; Clark 1999a). Alternatively, the 3D structure of the molecule could be generated by 2D/3D converters like CONCORD (Pearlman 1987; Balducci et al. 1699), or CORINA (Sadowski et al. 1992, 1994a), followed by energy minimization. Finally, the PSA of the minimized conformation is calculated, for example, by MOLVOL (Dodd and Theodorou 1991) or other approaches.

While these descriptors above rely on the 3D molecular structure, the topological polar surface area (TPSA) is calculated by simply summing up tabulated surface contributions of polar fragments rapidly obtained from SMILES representations (Daylight Chemical Information Systems Inc) of 2D chemical structures (Ertl et al. 2000). For that purpose, a set of fragments comprising 43 polar atom types was defined. The contributions of these atom types were determined by least-squares fitting to the single conformer 3D PSA (PSA_s) of a large subset of drug-like structures from the World Drug Index (World Drug Index Database). From this database, all molecules with apparent valence errors, molecular weights outside the interval of 100–800, and molecules not having at least one oxygen, nitrogen, sulfur, or phosphorus atom were removed. The remaining set used for the least-squares fitting consisted of 34,810 reasonably drug-like molecules. A comparison of PSA_s and PSA_d of β-adrenoreceptor blocking drugs revealed that correlations between surface properties of the global minimum conformations and permeability were only slightly poorer than correlations obtained using the dynamic properties (Palm et al. 1996). Furthermore, the efficient 2D-TPSA showed a very good correlation with PSA_s ($r = 0.99$) and PSA_d ($r = 0.98$). Finally, the TPSA method has proven its applicability to predict not only intestinal absorption but also blood-brain barrier penetration and Caco-2 cell permeability (Ertl et al. 2000), providing results of the same quality as with PSA_s and PSA_d data.

EVALUATION

Two of the major physicochemical determinants of passive absorption are lipophilicity and hydrogen bonding potential. PSA is a good predictor for hydrogen bonding potential (Palm et al. 1997) while it is not directly related to lipophilicity, as shown by Clark (1999a) considering a series of aliphatic alcohols. In this series, PSA is constant, while the lipophilicity increases with increasing carbon chain length. Thus, one could expect that a combination of lipophilicity data and PSA data should result in an even better predictor to guide drug design toward orally available compounds. In fact, modern approaches to derive in silico ADME models often include informative combinations of multiple descriptors, while individual descriptors capturing hydrogen bonding and lipophilicity are often among the very informative ones to derive an individual structure-activity relationship.

CRITICAL ASSESSMENT OF THE METHOD

Using small datasets, it was initially shown that the dynamic PSA is strongly correlated with the membrane permeability of a series of β-adrenoreceptor blocking agents (Palm et al. 1996). Subsequently, it was found that PSA_d is able to predict the absorption after oral administration to humans of 20 structurally diverse drug molecules (Palm et al. 1997). The resulting sigmoidal correlation between fractional dose absorption and PSA_s for 20 drug molecules is given in Fig. 41.1. From these results, it was concluded that drugs with complete oral absorption should have a PSA_d value of <60 Å^2, while >140 Å^2 is seen as threshold for compounds with low absorption. For molecules with a higher PSA value, a poor absorption is very likely if no active transport mechanisms are involved. However, low PSA values are necessary, but not a sufficient criterion for good absorption. For example, highly hydrophobic compounds may have

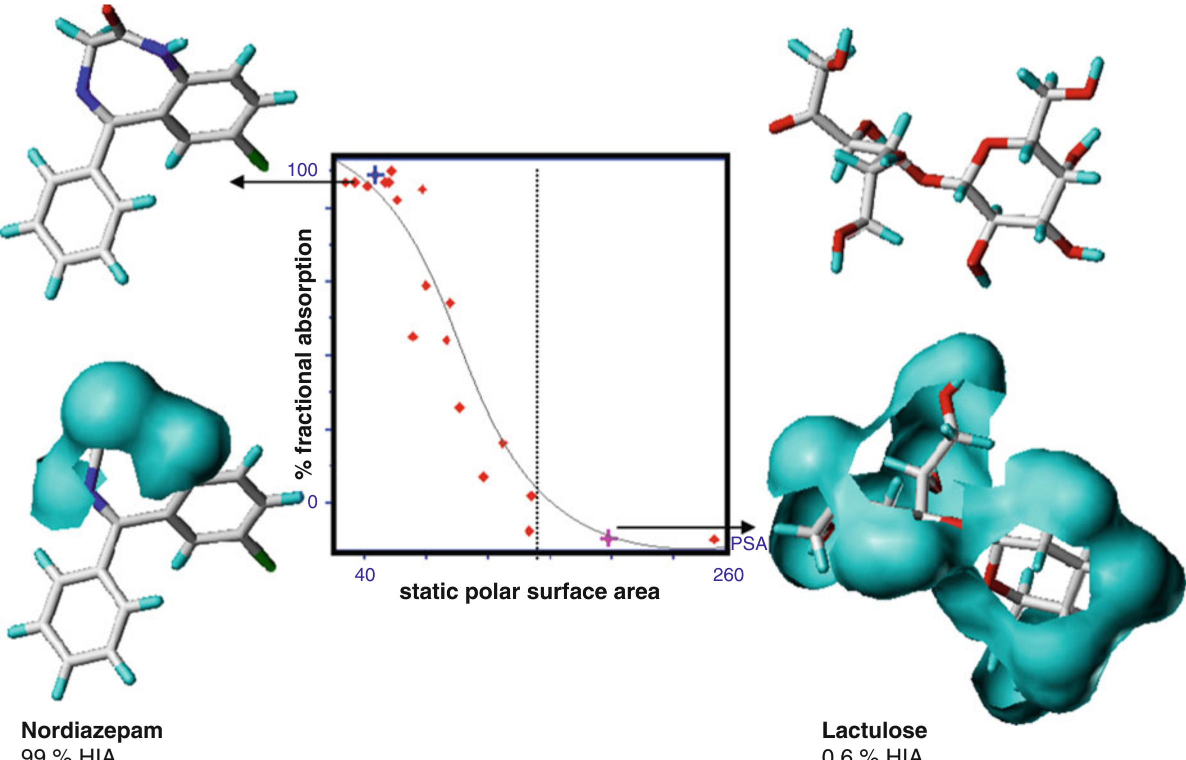

Fig. 41.1 Sigmoidal correlation between human fractional dose absorption and PSA_d for 20 drugs (Data from Palm et al. 1997). The influence of the polar surface area on fractional absorption is illustrated by comparing PSA regions for the orally available nordiazepam (*left*) to the nonavailable lactulose (*right*)

a low PSA value, but due to their low solubility, their intestinal absorption is low. Therefore, it is important not to use PSA naively as a guide to absorption but to couple it to other information and existing knowledge.

These findings were confirmed by Kelder et al. (1999) calculating the PSA values for approximately 2,000 orally available drug-like molecules that have reached at least clinical phase II. They concluded that orally active drugs that are transported passively by the transcellular route should not display a PSA > 120 Å^2. In addition, oral drugs tailored to brain penetration were shown to have PSA values of <70 Å^2. A very similar finding was reported by Clark (1999b), who derived a simple quantitative structure-activity relationship (QSAR) for brain penetration from a combination of logP and PSA. The resulting interpretation that smaller PSA values are more favorable for brain penetration is reasonable as it is known that the endothelial cell monolayer of the BBB forms a much tighter barrier than the intestinal epithelial cell barrier (Artursson and Karlsson 1991; Pardridge 1996).

MODIFICATIONS OF THE METHOD

It has been estimated that the scatter in the correlation between PSA and transcellular membrane permeability is likely to increase with more chemotypes from different therapeutic classes to be incorporated. Hence, to improve predictivity, PSA was combined with other predictive molecular descriptors such as logP (Clark 1999b; Egan et al. 2000a) and number of rotatable bonds (Veber et al. 2002). However, the effect in particular of rotatable bonds was discussed controversially in the medicinal chemistry literature (Lu et al. 2004).

In addition to the PSA, a nonpolar surface area (NPSA) can be computed by taking the total surface area minus the PSA into account. A linear combination of PSA and NPSA was reported to give satisfactory models for analogue series like dipeptides and endothelin receptor antagonists, where PSA alone was not a satisfactory predictor of passive membrane permeability (Stenberg et al. 1999a, b). Collectively, these results suggested that a more general model of passive membrane permeability should incorporate different molecular descriptors capturing information about polarity and lipophilicity.

This led to the concept of fragmentation of the total molecular surface area in combination with multivariate analysis (Stenberg et al. 2001) toward predictive models of drug permeability for more complex datasets. Permeability models were established based on so-called "partitioned total surface area (PTSA)" descriptors. Each of the PTSA descriptors corresponds to the surface of a certain atom type, differentiated by hybridization, which results in individual descriptors, for example, sp^3, sp^2, and sp carbon atoms. The resulting permeability model based on 19 descriptors finally consisted of oxygen, nitrogen, and polar hydrogen surfaces, while the main contribution for prediction of Caco-2 permeability was attributed to PSA. In addition, some more lipophilic contributions were seen as relevant to obtain a significant PLS model.

This work was expanded toward a classification of drug molecules into the established biopharmaceutical classification system (BCS) on the basis of PTSA descriptors alone, which included separate models for solubility and permeability (Bergström et al. 2003). The PLS models reported for solubility and permeability resulted in a correct biopharmaceutical classification for as many as 85% of the studied compounds, while an external FDA standard drug test set was correctly classified with 77% accuracy.

While models to understand a single chemotype were reported to include only a few informative descriptors from this surface area family for larger and more diverse datasets, multivariate analysis of multiple descriptors might be more useful.

41.2.2 Alignment-Free 3D Descriptors (VolSurf)

PURPOSE AND RATIONALE

As described above, molecular surface areas were successful to predict important ADME properties like passive membrane permeability and intestinal absorption. This concept was taken further toward the development of a set of descriptors capturing a wide range of physicochemical relevant properties extracted from molecular interaction fields of three-dimensional (3D) structures. To this end, Cruciani et al. developed a tool called VolSurf (Cruciani et al. 2000a, b, 2003), integrating enhanced molecular descriptors with multivariate statistical tools for the analysis of physicochemical and pharmacokinetic data. VolSurf transforms the information present in 3D molecular interaction fields into a limited set of descriptors. Those have been shown to carry relevant information related to ADME properties, like polarity, hydrogen bonding, lipophilicity, size, polarizability, and others. As these descriptors are easy to calculate, to understand, and to interpret from a chemistry point of view, they provide further design guidelines for chemical optimization after a linear model has been established.

PROCEDURE

The interaction of drug molecules with biological membranes is a three-dimensional recognition that is

mediated by surface properties. Information about surface properties of drug molecules and other solutes can be extracted from 3D molecular interaction fields. In VolSurf, the information from calculated molecular interaction fields is extracted and compressed in a few informative descriptors, as outlined in Fig. 41.2. Those descriptors capture various aspects of physicochemical molecular properties and thus can be successfully correlated to pharmacokinetic properties. To this end, the 3D grid maps of interaction energies between drug molecules with particular probe atoms are calculated using the GRID force field (Goodford 1985). This advanced force field is able to calculate energetically favorable interaction sites for a variety of chemically relevant probe atoms and functional groups around a molecule in a given 3D conformation. As the information contained in 3D molecular fields is related to the interacting molecular partners, the amount of information captured in those interaction fields is generally superior to global descriptors or those computed from only the 2D chemical structure.

In most cases, the GRID water, the hydrophobic (DRY), and the carbonyl oxygen (O) probes have been utilized for computing molecular interaction fields which are then analyzed using VolSurf to extract meaningful descriptors. GRID uses a potential based on the total energy of interactions (Lennard-Jones, H-binding, and electrostatic terms) between a target molecule and a probe and can be used to characterize putative polar and hydrophobic interaction sites around target molecules. The water probe simulates solvation/desolvation processes, while the DRY and the O probes encounter drug-membrane interactions. This treatment of hydrophobic interactions is done at each grid point by a combination of the following terms: $E_{Entropy} + E_{Lennard\text{-}Jones} - E_{H\text{-}bonding}$. $E_{Entropy}$ is

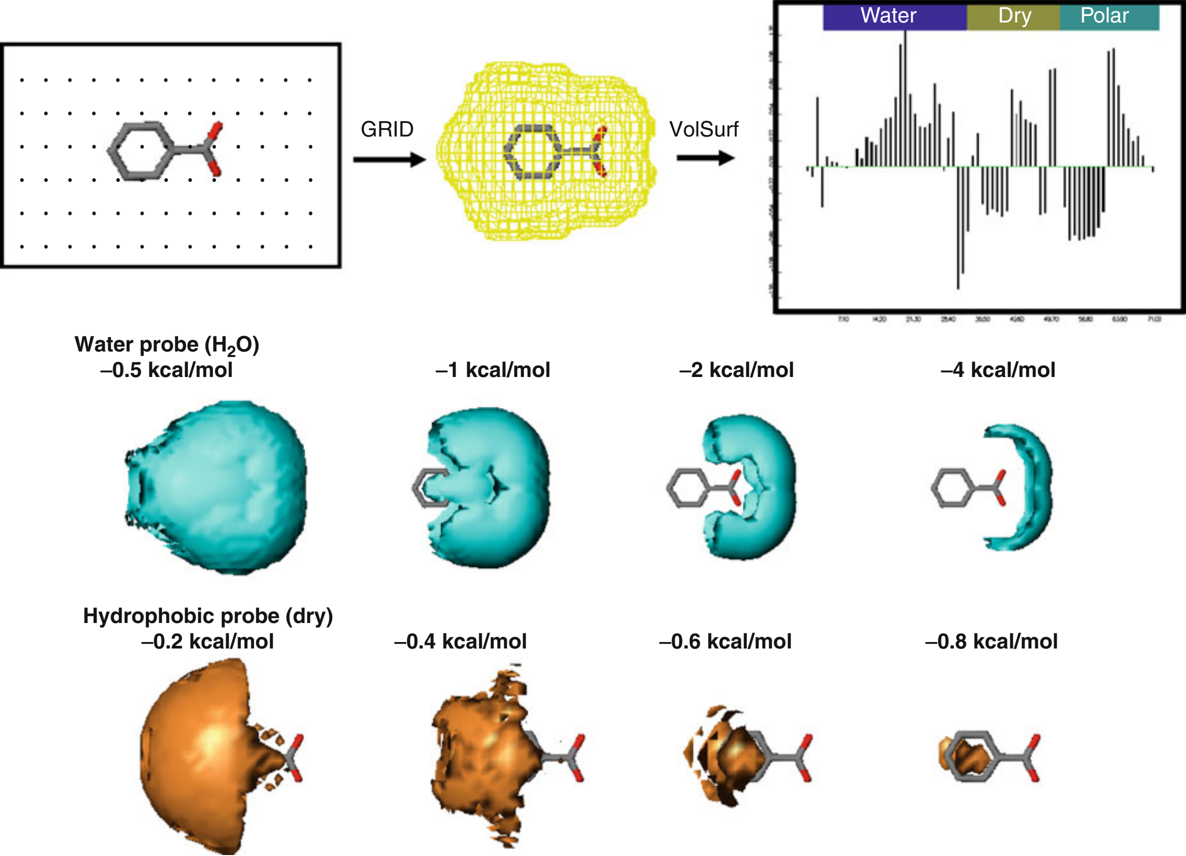

Fig. 41.2 Computation of VolSurf descriptors (Cruciani et al. 2000a) derived from GRID molecular interaction fields. For any molecule, interactions with GRID water and dry probes at different energy levels are used for contouring. Those levels serve to compute vectors of 72 volume, size, and surface-related descriptors

the ideal entropic component of the hydrophobic effect in aqueous environment, $E_{Lennard\text{-}Jones}$ accounts for induction and dispersion interaction occurring between any pair of molecules, and $E_{H\text{-}bonding}$ subtracts the effect of hydrogen-bonding contributions between water and polar parts of the solute surface.

Each drug molecule is characterized by its potential hydrogen bonding, polar and hydrophobic interactions, starting from its three-dimensional structure, but without the necessity to bring different molecules into an alignment by atom-based or field-based superposition methods.

Subsequently, VolSurf extracts information present in these 3D molecular fields and transforms it into a limited number of descriptors, as shown in Fig. 41.2. These descriptors capture relevant molecular properties which are related to ADME and pharmacokinetic properties, like polarity, hydrogen bonding, lipophilicity, size, shape, polarizability, and others. In particular, the size and shape of hydrophilic and hydrophobic molecular regions at different interaction energy levels and the balance between these regions are extracted by VolSurf. Other descriptors for quantitative ADME models are the amphiphilic moments and critical packing parameters. A detailed account of these descriptors and the approach to extract shape and surface information are given by Cruciani et al. (2000a).

The originality of VolSurf resides in the fact that surfaces, volumes, and other descriptors can be obtained from 3D molecular fields without complex algorithms of trigonometric projections, recursive generations, and tessellations. In total, the analysis of molecular recognition is achieved by image analysis approaches, while the image compression step involves chemical knowledge by selecting an appropriate parameterization according to the 3D map of interest. The resulting set of descriptors thus has a clear chemical meaning.

EVALUATION

The descriptors generated by VolSurf have been successfully correlated using multivariate statistical techniques like partial least-squares projection to latent structures (PLS) in literature and in internal studies with bioavailability, blood-brain partitioning, membrane transport, and other relevant ADME and pharmacokinetic properties (Alifrangis et al. 2000; Crivori et al. 2000; Cruciani et al. 2000c, 2003; Guba and Cruciani 2000). One earlier example is the study by Guba and Cruciani to unravel essential molecular features correlated to human intestinal absorption of 20 drug molecules (Guba and Cruciani 2000). The correlation of VolSurf descriptors for 20 diverse drugs to this pharmacokinetic parameter is shown in Fig. 41.3. The interpretation of PLS models for factors influencing permeability and absorption is in agreement with earlier, qualitative findings based on global molecular properties represented by descriptors like logP and others. However, due to the nature of the descriptors, this approach allows to better understand physicochemical requirements for a pharmacokinetic effect and to use it for design, for example, the balance between lipophilic and hydrophilic parts in combination with size, volume, and other effects. A special emphasis in the analysis of VolSurf models can be placed on the interpretation after multivariate statistics because any rational design to improve molecular properties depends on the understanding of how molecular features influence physicochemical and ADME properties.

The successful use of VolSurf was also reported for predicting absorption properties (Cruciani et al. 2000c) from drug permeability data of 55 molecule compounds (Irvine et al. 1999) in Caco-2 cells (human intestinal epithelial cell line derived from a colorectal carcinoma) and MDCK (Madin-Darby canine kidney) cell monolayers. In this interesting case, it was shown that models including counterions for charged molecules clearly show significantly better statistical quality and overall performance. The final model was also able to correctly predict to a great extent the relative ranking of molecules from another Caco-2 permeability study by Yazdanian et al. (1998).

This model recently has been extended (Cruciani et al. 2003) to a dataset of 450 carefully selected Caco-2 data from the literature, excluding compounds showing high efflux rates which might indicate active transport by P-glycoprotein (P-gp) through the intestinal membrane. This attempt was done to compile a dataset of molecules having a similar mechanism of transport. However, as a quantitative comparison of Caco-2 data from different laboratories is nearly impossible due to experimental uncertainties and variations of conditions, the molecules were classified in low and high permeable compounds. The use of partial least-squares discriminant analysis (DA-PLS) resulted in a statistically significant model after crossvalidation which allows discriminating in the 2D PLS score plot between compounds with low and high permeability

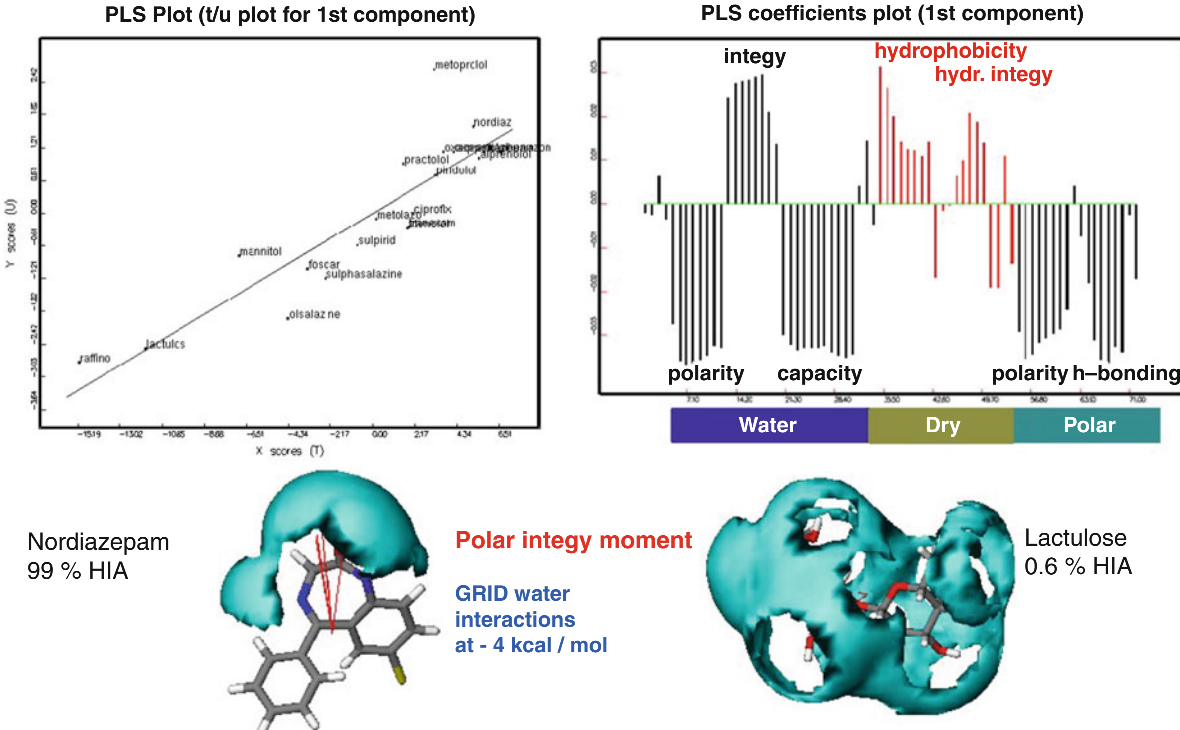

Fig. 41.3 Correlation of VolSurf descriptors with human intestinal absorption using multivariate statistics (PLS) based on 20 drug molecules as reported by Guba and Cruciani (2000). The PLS plot (u1 versus t1) and the corresponding PLS coefficient plot are shown. Different interaction patterns with the GRID water probe are displayed for the orally available nordiazepam (*left*) versus the large area for the nonavailable lactulose (*right*)

while compounds at the interface of both classes could not be predicted with high certainty. Classification models like this are valuable for earlier phases of the lead optimization process, as external compounds can be projected in the chemical space represented by such a model in order to classify Caco-2 permeability potential for novel, untested molecules. Of course, the prediction accuracy of classification models is lower, and results are only meant to be used in a qualitative sense for design and decision making.

The suitability of VolSurf to describe the interaction of compounds with membranes was reported by Alifrangis et al. (2000). They established a structure-property model for membrane partitioning for 20 peptides, with experimental data tested in two chromatographic systems with phospholipids as stationary phase, immobilized artificial membranes (IAMs), and immobilized membrane chromatography (ILC). The relationship between these measures and the sets of calculated descriptors derived from molecular surface area, MolSurf, and VolSurf were analyzed using PLS, showing that the VolSurf-derived model was significantly better than both other models. Especially the VolSurf critical packing descriptor, developed to describe the interaction of amphiphilic molecules with membranes, was found to be important to explain the peptide membrane partitioning ability.

In addition to the above mentioned properties of VolSurf, no alignment of the compounds is necessary prior to the calculation of the molecular interaction fields and the following generation of the VolSurf descriptors. Furthermore, this approach is often hardly influenced by conformational sampling and averaging (Mannhold et al. 1999; Crivori et al. 2000; Cruciani et al. 2000a; Guba and Cruciani 2000). This is probably due to the peculiarity of the GRID force field which allows for the conformational flexibility of external groups, hydrogen atoms, and electron lone pairs. In general, the automated protocol consisting in a simple 2D-to-3D structure conversion followed by energy minimization produces good results, without the need of molecular dynamic sampling or Boltzmann

averaging. This makes VolSurf descriptors computationally efficient and well suited for fast quantitative structure-property relationship studies, especially when dealing with a large number of compounds.

VolSurf descriptors were also successfully used to build a classification model for predicting blood-brain barrier (BBB) permeability for drug-like molecules (Cruciani et al. 2000c; Crivori et al. 2000). Based on 72 descriptors, a discriminant PLS analysis was performed to build a model for qualitative experimental BBB permeation data for 110 molecules. Another 120 molecules served for model validation by external prediction. For racemic compounds, all stereoisomers were used to generate descriptors based on the reasonable assumption of negligible stereoselectivity in passive membrane permeation. Based on both datasets and combined discriminant PLS, a new model with 229 molecules was derived. It correctly predicts 90% of the BBB data, and the interpretation of the PLS coefficients provides insights to drug design, pharmacological profiling, and screening. Descriptors encoding polarity such as the hydrophilic water-accessible surface regions, capacity factors (volume/total surface at distinct energy levels, that is, number of polar interactions per surface unit), and hydrogen bonding are inversely correlated with BBB permeability. Hence, BBB permeability decreases with increasing polar surface in agreement with the PSA model discussed above. Some more quantitative information can be extracted, such as the influence of charge distribution and electron lone pairs. The influence of capacity factors means that although diffuse polar regions are tolerable, dense and localized polar regions are detrimental for BBB permeation. All descriptors encoding hydrophobic interactions show less influence but are directly correlated with BBB permeation. While size and shape of the molecules have no influence, the critical packing and hydrophilic-lipophilic balance are important showing that a balance of nearly all descriptors is relevant for BB permeation. Utilizing all molecules from another dataset (Luco 1999) for external prediction, the VolSurf model was able to correctly predict the BBB permeability range for more than 75% of the compounds (Cruciani et al. 2000c), which is encouraging, as BBB permeation is dependent not only on passive diffusion but also on active transport and metabolism.

Other important applications include the generation of a model to predict thermodynamic water solubility (Cruciani et al. 2003). This model is based on consistent solubility data from literature plus additional measurements for 970 compounds. Its quality allows to differentiate between very poorly, poorly, medium, highly, and very highly soluble molecules while exact rankings within individual classes are not possible. However, given the different factors influencing experimental thermodynamic solubility data, it is not likely that significantly improved models for this key property in pharmaceutical sciences can be derived.

VolSurf was also used in a study to obtain information about metabolic stability in human liver preparations (Cruciani et al. 2003). A training set of 500 compounds with data from metabolic stability testing of the compounds in human CYP3A4 cDNA-expressed microsomal preparations was used to build a model using principal component analysis (PCA). Although this statistical approach did not incorporate any experimental information about compound stability, a grouping of metabolically instable molecules in one focused region in the final model was observed upon inspection of the PCA score plots. This model has also been improved (Crivori et al. 2004) by adding other GRID-derived descriptors in addition to VolSurf. These descriptors named GRid-INdependent Descriptors (GRINDs, Pastor et al. 2000) are implemented in the program Almond (see below). On an extended training set of 1,800 compounds tested in one laboratory at a pharmaceutical company, a classification model using discriminant PLS was established and validated using different test sets. This extended model correctly predicted 75% internal compounds and 85% public drugs and revealed an overall precision of 86% correct selection of metabolically stable compounds.

CRITICAL ASSESSMENT OF THE METHOD

Many published and internal VolSurf applications underscore the assumption that these 3D molecular descriptors capture relevant information about physicochemical and pharmacokinetic properties of drug molecules. Other studies have shown that the method is not significantly depending on the chosen conformation, as long as they are consistently generated. Often molecular 2D/3D converters like CONCORD (Pearlman 1987) and CORINA (Sadowski et al. 1992, 1994b) followed by energy minimization can be applied. Hence, these descriptors are extending concepts like PSA and logP by capturing similar

information to those in a series of carefully chosen descriptors. In combination with multivariate statistics, the resulting models then allow a more quantitative understanding of factors influencing the physicochemical or ADME property of interest, which in combination with its intrinsic chemical interpretability provide important guidelines for compound optimization.

The suitability of these descriptors for database mining was investigated in a comparative analysis (Cruciani et al. 2002). While 2D descriptors like Unity fingerprints and MACCS keys were shown to outperform VolSurf descriptors and logP in studies related to pharmacodynamics (clustering behavior on chemically homogeneous series with different pharmacological effect), VolSurf shows the most realistic clustering for pharmacokinetic aspects exemplified by solubility and blood-brain partitioning behavior.

MODIFICATIONS OF THE METHOD

While VolSurf has first been developed to model pharmacokinetic properties, it has recently been shown to capture relevant information for protein-ligand interactions (Zamora et al. 2003b). Steric, hydrophobic, and hydrogen-bonding interactions from these descriptors were also useful for describing ligand binding affinities to various proteins. Significant PLS models for diverse set of protein-ligand complexes and a congeneric series of ligands to a single binding site were reported, which would allow for a simultaneous optimization of ligand binding affinity and pharmacokinetic properties using a framework of consistent descriptors.

Additional shape descriptors in an extended VolSurf approach have been applied to model biological activity of a series of quinolones using a quantitative structure-activity relationship (QSAR) approach (Cianchetta et al. 2004). The molecular shape function used to augment the VolSurf approach is constructed from probe-drug interaction energies from the GRID force field. It can be seen as a combination of steric vector descriptors with one extreme in the center of mass of a molecule and with the other located in the molecular surface. These extended VolSurf descriptors now might allow for a simultaneous optimization of affinity and pharmacokinetic properties using multivariate statistical analysis using two or more dependent variables (i.e., biological properties) to model. Any resulting model then might allow identifying favorable descriptor combinations for both properties under investigation and thus enabling a more focused lead optimization by concentration on those regions in chemistry space, which result in acceptable properties simultaneously.

Another modification of the VolSurf approach to analyze molecular interaction fields was described by Pastor et al. (2000). The same information previously been used to compute VolSurf descriptors now served to compute GRIND descriptors. In contrast to VolSurf, these descriptors capture information about pharmacophore distances within individual molecules. These descriptors represent favorable interaction energy regions where groups of a potential protein would interact favorably with the ligand. Hence, this set of descriptors is ideally suited to model ADME properties related to molecular recognition events between a protein and a series of ligands like, for example, inhibition of or substrate binding to cytochrome P450 isoforms (Afzelius et al. 2002a, 2004a), as well as binding to transporters like P-gp (Cianchetta et al. 2005; Crivori et al. 2006), PEPT1 (Larsen et al. 2008), and among others.

41.2.3 3D-QSAR (Comparative Molecular Field Analysis, CoMFA)

PURPOSE AND RATIONALE

The relationship between chemical properties like solvent partitioning and biological activity was first discovered over a century ago (Meyer 1899), while the field of quantitative structure activity relationship (QSAR) was opened by Hansch and Fujita (1964) with statistical correlations of descriptors like logP, molar refractivity, and shape to activity of congeneric series. Numerous applications of QSAR over the following four decades highlighted the fundamental relation between chemical structure and biological activity, which allows estimating the activity of untested molecules based on a validated "QSAR equation." However, the identification of important global descriptors often does not lead to a design of new compounds, as these descriptors do not capture specific, spatially resolved information about molecular recognition events. The approaches discussed in previous sections are describing properties like passive permeability which are related to fundamental physicochemical behavior. But the understanding of structural requirements for protein-ligand recognition in ADME like binding and inhibition of drug molecules to the family of cytochrome P450 enzymes or specific transporters like P-gp or Pep-T1 requires a more specific description of molecules and their putative modes of interaction with their macromolecular partners. The idea that three-dimensional molecular interaction fields (Goodford 1985) can be combined with multivariate statistics like PLS (Wold et al. 1984; Dunn et al. 1984) led to a popular approach for 3D-QSAR named comparative molecular field analysis (CoMFA) (Cramer et al. 1988a; Clark et al. 1990). Statistical relationships are derived between molecular property fields of aligned compounds and biological activities. Electrostatic and steric interaction energies are computed between each ligand and a probe atom located on

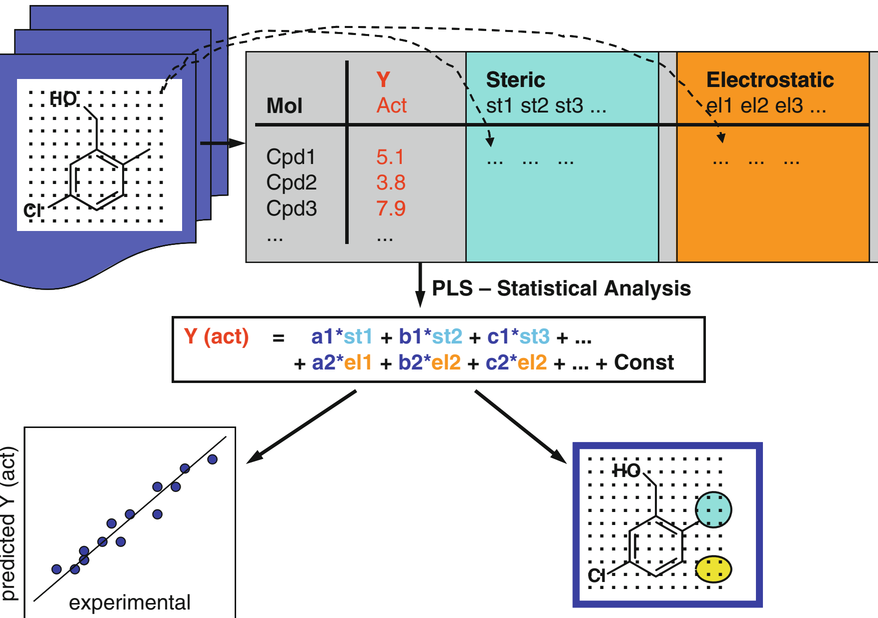

Fig. 41.4 The CoMFA process consists of individual steps (Cramer et al. 1988b). First, interaction energies are computed between all molecules in alignment and a probe atom on a regular grid. This information is stored in a particular format in order to allow for multivariate statistical analysis. The PLS method then produces a statistical model which can be interpreted and used for prediction

predefined grid points for CoMFA, as summarized in Fig. 41.4. These fields have been successfully replaced or augmented by alternative approaches to compute molecular interaction fields, for example, various probes from the GRID force field (Goodford 1985; Baroni et al. 1993), lipophilic fields (Kellogg et al. 1991), or the comparative molecular similarity index analysis (CoMSIA, Klebe et al. 1994a).

PROCEDURE

The first step of a 3D-QSAR study is to superimpose all molecules, which is critical for the success of this investigation. There are multiple approaches toward a reasonable alignment including the use of X-ray crystallography for template molecules (Waller et al. 1993), docking into experimentally determined binding sites or homology models, an automated pharmacophore-based alignment (Martin et al. 1993; Greene et al. 1994; Sprague 1995; Jones et al. 1995), field fit similarity methods (Clark et al. 1990; Klebe and Abraham 1993), flexible molecular alignments (Klebe et al. 1994b; Lemmen et al. 1998), and manual alignment strategies based on conformational searching and chemical intuition. While sometimes a simple alignment onto a common core produces a chemically meaningful model, this only allows interpreting the influence of different substitution properties to biological activity. The real value of 3D-QSAR, however, is that not only models for congeneric series can be established but also that different series could be merged into a single model, given that a reliable alignment of core structures could be obtained. This step is mainly driven by the identification of pharmacophore points, namely, those molecular features that are likely to interact with the protein binding site. The 3D-QSAR statistical models might then allow discriminating between different alignment hypotheses simply on the basis of the comparison of the predictivity of both alternative models. Although the dependency of grid-based 3D-QSAR methods of the alignment is often seen as disadvantage, a careful and stepwise alignment procedure might produce deeper insights than might be extracted from quantitative information about pharmacophore hypotheses (Kellogg and Semus 2003).

After superposition, steric and electrostatic interaction energies between a probe atom and every molecule are calculated at surrounding points of a predefined grid box. The nature of the probe is depending on the property to be mapped. Typically, this is based on a volume-dependent lattice with 1 or 2 Å grid spacing, a positively charged carbon atom, and a distance-dependent dielectric constant. The magnitude of the regions is typically defined to extend the superimposed conformers by 4.0 Å along the principal axes. The maximum field values have to be truncated for mathematical reasons at cutoff values, often 30 kcal/mol for steric and +/− 30 kcal/mol for electrostatic energies. For points “inside” a molecule

(steric energy above the cutoff), no electrostatic energy is computed; those values were set to the mean of the related column. Consequently, these maps can be perceived as 3D profiles, which might correspond to binding site recognition requirements in terms of steric, electrostatic, and hydrophobic complementarity.

In CoMSIA, molecular interaction fields are replaced by fields based on similarity indices between probe atoms and each molecule. The same alignment can be used to compute steric, electrostatic, and hydrophobic similarity index fields for CoMSIA. Hydrophobicity in this context is based on Crippen's partial atomic hydrophobicities (Ghose and Crippen 1986). The advantage of CoMSIA fields is that no singularities occur at atomic positions due to a Gaussian-type distance dependence of the physicochemical properties; thus, no arbitrary cutoffs are required. Similarity indices (Kearsley and Smith 1990) are typically computed using a probe with charge +1, a radius of +1, a hydrophobicity of +1, and an attenuation factor α of 0.3 for the Gaussian-type distance dependence.

Equal weights for different CoMFA or CoMSIA fields were assigned using the CoMFA_STD scaling or block scaling option, while columns, that is, grid points with no or little variations, are often rejected prior to statistical analysis. Then PLS is used as multivariate statistical approach to derive a linear relationship for highly underdetermined matrices, while crossvalidation (Wold 1978) is used to check for consistency and predictivity. A faster approach to crossvalidation has been implemented in SAMPLS (Sheridan et al. 1994).

The resulting std*coeff (standard deviation * PLS coefficient) contour maps from 3D-QSAR models enhance the understanding of electrostatic, hydrophobic, and steric requirements for ligand binding, guiding the design of novel molecules to those regions where variations altering steric or electrostatic fields reveal a significant correlation to biological properties.

EVALUATION

A survey on 3D-QSAR literature (Oprea 2004) reported more than 1,100 entries in the Chemical Abstracts database on CoMFA, 3D-QSAR, and related keywords. As the number of potential targets in drug discovery is steadily increasing, it is likely that 3D-QSAR models will continue to be developed in the future. Successful applications were not only reported to understand target-related affinity, but also for some ADME relevant targets like transporters and cytochrome P450 isoforms. For example, a 3D-QSAR model for peptide substrates of the mammalian H^+/peptide cotransporter PEPT1 (Gebauer et al. 2003) showed a high degree of internal consistency and was able to correctly predict a test set of 19 peptide derivatives. In another example, structural features for the P-glycoprotein (P-gp)-mediated transport of a series of glucocorticoids were recently identified by means of CoMFA and CoMSIA models (Yates et al. 2003). Further applications in the area of ADME modeling include the generation of 3D-QSAR models for cytochrome P450 2C9 inhibitors (Rao et al. 2000; Yasuo et al. 2009), 2D6 inhibitors (Vaz et al. 2005), and 2D6 substrates (Haji-Momenian et al. 2003) to predict potential drug-drug interactions.

CRITICAL ASSESSMENT OF THE METHOD

As for all statistical approaches, there is a need for robust validation to ensure that the resulting models are not misleading due to chance correlation and that these models are predictive for novel molecules. Hence, their successful application depends on the chosen validation strategy plus its rigorous application to independent external test sets. Furthermore, the choice of descriptors leading to directly interpretable 3D-QSAR models is crucial for interpretation and discussions with medicinal chemists.

The use of 3D-QSAR is based on a series of particular approximations (Oprea 2004), as given in the following. The ligand and not a metabolite nor a covalently linked inhibitor must be responsible for the biological effect. Ligands should also be modeled in their presumable "bioactive" conformation. No significant conformational changes should occur upon binding to the target, and the binding site should be the same for all ligands. Kinetic effects are neglected which requires the system to be in equilibrium. The entropic contributions to the free energy of binding should be comparable across the entire ligand series, while solvent effects, temperature, diffusion, transport, pH, and salt concentrations known to contribute to the binding energy are neglected.

The alignment rule significantly impacts results and predictivity of the final 3D-QSAR models. Hence, the use of consistent alignment rules for novel molecules that are less similar to the training site molecules is one of the main prerequisites of this approach. It has clearly been recognized that the definition of a justified

alignment rule matching a user-defined pharmacophore is important to avoid wrong conclusions and errors in CoMFA studies (Kubinyi 1998). Whenever possible, experimentally determined alignment should be given preference in 3D-QSAR. Despite those limitations, the arsenal of 3D-QSAR methods is an important tool in the daily practice of drug discovery programs, especially in the absence of experimental 3D structure of macromolecular receptors or ADME antitarget in complex with representative ligands.

MODIFICATIONS OF THE METHOD

Other approaches are also employed to compute molecular interaction fields and derived descriptors on a regular grid, like the GRID force field (Goodford 1985; Baroni et al. 1993), lipophilic fields (Kellogg et al. 1991), or comparative molecular similarity index analysis (CoMSIA, Klebe et al. 1994a). Further additions to the family of 3D-QSAR methods include 4D-QSAR (Dunn and Hopfinger 1998), CoMPASS (Jain et al. 1994), receptor surface models (Hahn and Rogers 1998), the pseudoreceptor approach (Gurrath et al. 1998), and comparative molecular surface analysis (CoMSA, Polanski et al. 2002). As there is still no general solution of the alignment problem, further research led to the development of alignment-free 3D descriptors like, for example, GRIND descriptors (see above; Pastor et al. 2000) or Topomer CoMFA (Cramer 2003). The latter approach, for example, combines the CoMFA methodology with a highly standardized method to generate fragment conformers, so-called topomers. A series of input structures is disconnected into two or more fragments at a central acyclic single bond while removing any core fragment structurally common to the entire series. Individual steric and electrostatic field descriptors are then generated for each fragment and combined in a standard PLS analysis. Successful applications of this automated 3D-QSAR method and its application to virtual screening for alternative substituents have been reported (Cramer 2003; Cramer et al. 2008). One interesting recent application is the combination of Topomer CoMFA with a quantitative series enrichment analysis (Wendt and Cramer 2008) to automatically build models from large chemogenomic spaces extracted from public databases like ChEMBL, PubChem, and ChemBank (Wendt et al. 2011a). This approach was, for example, applied to successfully build and utilize a Topomer CoMFA model for a series of toluidinesulfonamides, as HIF-1 inhibitors with CYP2C9 inhibition as undesirable side effect using CYP2C9 structure-activity data from the PubChem database (Wendt et al. 2011b).

Furthermore, the use of predictive and validated CATALYST pharmacophore models (Greene et al. 1994; Sprague 1995) has also been found wide application to understand structure-activity relationships. This approach has also been successfully applied to ADME relevant targets like human cytochrome P450 datasets (Ekins et al. 2001) to understand structural requirements of their active sites on the basis of inhibitor and substrate series in the absence of crystal structures for these human enzymes.

41.2.4 Predicting the Site of Drug Metabolism by Cytochromes (MetaSite)

PURPOSE AND RATIONALE

The oxidative metabolism of drug molecules is significantly mediated by cytochrome P450 (CYP) enzymes, which constitute a large superfamily of heme-containing monooxygenases occurring in most living organisms. CYP-mediated biotransformations are involved in various physiological and pathophysiological processes (Brown et al. 2008). While this includes the process of detoxification of potentially harmful xenobiotic compounds, it could also result in the generation of toxic reactive intermediates (Tarcsay and Keserü 2011). Seven of the known 57 human CYP isoforms are responsible for the metabolism of ~90% of the current pharmaceutical substances (de Groot 2006). Several aspects of these enzymes such as rate and site of metabolism have to be taken into account to support lead optimization efforts. Hence, it would be valuable to have computational approaches addressing these individual aspects. In particular, the fast and reliable computational estimation of the site of metabolism (SOM) could support optimization by blocking a labile substructure or altering essential features of the CYP substrate molecular recognition. Furthermore, any predicted metabolite might serve as starting point to assess its potential toxicological side effects.

The underlying mechanisms responsible for drug metabolism have been extensively reviewed (Guengerich 1991; Tarcsay and Keserü 2011), including our knowledge on the CYP catalytic cycle, as supported by X-ray structures of crucial intermediates (Schlichting et al. 2000; Denisov et al. 2005). Kinetic isotope effect studies and computational results have shown that the insertion of the heme-iron-bound oxygen into the bound substrate is the rate-limiting step of this cycle (Guengerich et al. 2004; Bach 2010). This catalytic process for CYP-mediated biotransformations is both influenced by steric effects (e.g., recognition of the substrate in its CYP binding site) and electronic effects (e.g., abstraction of hydrogen radicals).

Various sites of metabolism prediction tools capture different states of the catalytic cycle and can be classified as (Tarcsay and Keserü 2011) (1) orientation effect-based methods which predict the first substrate recognition step using information either from the protein structure or the spatial alignment of known ligands, (2) mechanism-based methods, which focus on the electronic effects of the rate-limiting step by calculating hydrogen-bond abstraction energy in model systems, (3) combined models which take orientation effect as well as mechanism-based electronic effects into account, and (4) empirical models which consider the outcome of the catalytic cycle as represented in the database of known biotransformations. The availability of multiple X-ray structures of important human cytochromes today including CYP3A4 (Yano et al. 2004; Williams et al. 2004; Ekroos and Sjogren 2006; Sevrioukova and Poulos 2010) led to an increasing number of approaches focusing on the CYP substrate recognition step based on atomic coordinates of relevant CYP binding sites.

As comprehensive overviews of in silico approaches representing all four classes have recently been given (Vaz et al. 2010; Tarcsay and Keserü 2011), we focus in this section on one promising approach combining X-ray structures with substrate reactivity, which was successfully applied in internal projects, namely, the program MetaSite (Zamora et al. 2003a; Cruciani et al. 2005). MetaSite utilizes a molecular interaction field similarity metric as well as reactivity combined with specific correction terms for the type of biotransformation reaction plus the CYP isoforms. This approach relies first on the spatial alignment of the interaction pattern of the CYP active site and its substrate to explore the ligands' substructure exposed to the CYP heme group. Chemically reactive moieties in the neighborhood of the heme iron then will be assigned as SOM. There are different algorithms with different requirements on the accuracy of the protein active site geometric structure, allowing for evaluating the binding pose of a substrate within the CYP binding site. MetaSite relies on a description of the CYP binding site by molecular interaction fields (MIFs) using the program GRID (Goodford 1985), which requires high-resolution structural information of the protein. Favorable regions for interaction are those obtained from analysis of these interaction fields. This approach represents not only a simplification but also an important modification compared to docking, as multiple CYP X-ray structures reveal significant degrees of binding site flexibility, which is partially considered using this simpler and fuzzier representation. Hence, MetaSite provides an interesting alternative to regular QSAR methods, as it does not depend on an a priori

training dataset, but it is based on a combination of first-principle arguments to predict potential sites of metabolism.

PROCEDURE

In detail, MetaSite evaluates the complementarity of molecular interaction fields of cytochrome P450 substrate binding site and its ligand while exploring different binding poses of the ligand with respect to the orientation of the heme iron (Zamora et al. 2003b; Cruciani et al. 2005). GRID-derived molecular interaction fields are computed using a hydrophobic (DRY), an amide donor nitrogen (N1), and a carbonyl acceptor oxygen (O) probe atom (Goodford 1985). This computational step allows for limited protein site chain flexibility by using the GRID-directive MOVE, which mimics the limited mobility of amino acid residues to slightly accommodate for ligand binding. The GRID interaction points are then filtered by interaction energy. In a next step, the distance between those points to the oxygen atom attached to the heme iron in *compound I* of the catalytic cycle (Schlichting et al. 2000; Tarcsay and Keserü 2011) is used to generate a new set of descriptors that represent the interaction energy in a distance-binning fingerprint. The maximum of the GRID interaction energy for each distance bin is used as descriptor after conversion into a fingerprint. Multiple crystal structures of homology models for those cytochromes without an X-ray structure can be easily incorporated, and they definitively influence the outcome of the MetaSite predictions.

The descriptor generation for the ligand molecule is performed in a similar manner, replacing the distance to the heme-bound oxygen species with distances to each individual ligand hydrogen atom, as they will be replaced by the active oxygen in the CYP hydroxylation process. Hence, for each hydrogen atom as reference, a different distance-binning scheme is generated for the same ligand and converted into a separate fingerprint.

The binning-derived fingerprint descriptors for the protein and the ligand with different hydrogen references are then evaluated by computing their fingerprint similarity. The intramolecular environment of a ligand candidate atom in a molecule to its CYP binding environment around the heme-bound oxygen is thus matched. The fundamental idea of this approach then is that the reference hydrogen atom, for which the fingerprint shows the closest match to the protein binding site descriptor, is the predicted SOM. Atoms that closely match the heme environment are presumably more likely to be oxidized.

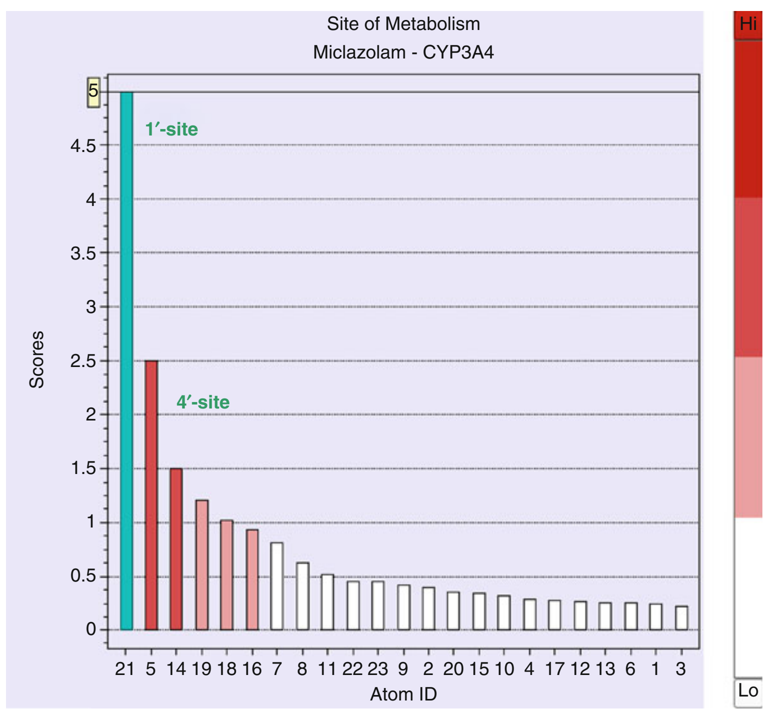
Ranking of different substrate atoms assigned as SOM is then performed on the basis of their in silico reactivity, as computed from a mixture of molecular orbital calculations and fragment recognition. The reactivity R_i of a particular atom represents the activation energy required to produce the reactive intermediate (e.g., for hydrogen radical abstraction). This reactivity depends on the ligand 3D structure and on the mechanism of the reaction.

In addition to the accessibility and reactivity components to the MetaSite assessment of individual atoms, versions 3.0 and higher have incorporated a new term accounting for the ease of hydrogen abstraction. Furthermore, every metabolic reaction can have a component factor for each individual CYP, indicating the propensity of a particular isoforms toward a particular reaction, like the increased likelihood for CYP3A4 to participate in N-demethylation reactions compared to CYP2C9 (Vaz et al. 2010).

EVALUATION

For metabolically labile compounds with an experimentally confirmed or an in silico hypothesis about the SOM, chemically blocking the site of metabolism is a very common approach during lead optimization to modulate substrate turnover and thus improving metabolic stability. The interpretation of MetaSite results may allow formulating a hypothesis on the site of metabolism and on the molecular features, which are involved in substrate interactions to its binding site.

When possible metabolites are experimentally found by mass spectrometric methods, the MetaSite contribution plot is an important tool providing guidance for further optimization. The MetaSite prediction of metabolites for midazolam is shown as an example in Fig. 41.5. The score plot (upper panel) provides information on the likelihood of individual atoms in midazolam to be metabolized by CYP3A4 from the MetaSite analysis using the internal CYP3A4 structure in MetaSite version 3.0. The 1’-product, which is most likely, is highlighted by a blue circle in the chemical structure on the left. The second likely product is the 4’-product; both are indeed experimentally observed (Gorski et al. 1994; Khan et al. 2002). Some other labile atoms are also detected by MetaSite, as indicated by light red labels, while they are less likely to result in



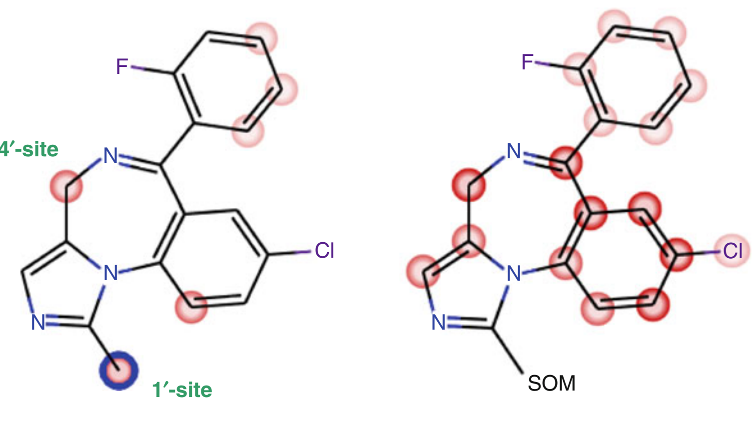


Fig. 41.5 MetaSite prediction of CYP3A4 metabolites for midazolam. The score plot (*upper*) indicates the likelihood of atoms to be metabolized by CYP3A4. The 1’-product is highlighted by a *blue circle* in the site-of-metabolism plot (*left*); different colors indicate likelihoods of atoms for metabolization. The contribution plot (*right*) indicates which groups contribute significantly to the recognition to the CYP binding site for a particular SOM

a corresponding biotransformation product. The typical use of MetaSite also includes applying different CYP3A4 X-ray structures for reference compounds with experimentally known metabolism from the same series to evaluate, which X-ray structure matches best the experimental metabolite pattern when using it for MetaSite. This structure then is routinely used for further predictions in a particular series.

In addition to this site-of-metabolism plot, the contribution plot for midazolam is shown in Fig. 41.5 on the right. This plot displays the contributions of interactions of ligand groups with the CYP enzyme in the particular pose, which results in the 1’-product. This might be useful, exploring those interaction patterns of different SOMs. Interestingly, comparing the 4’- and 1’-product, the contribution of the CYP3A4 interaction with the fluorobenzene ring is weaker for the formation of the 1’-product (Vaz et al. 2010).

In addition, MetaSite CYP3A4 predictions are shown in Fig. 41.6 for the indomethacin derivative

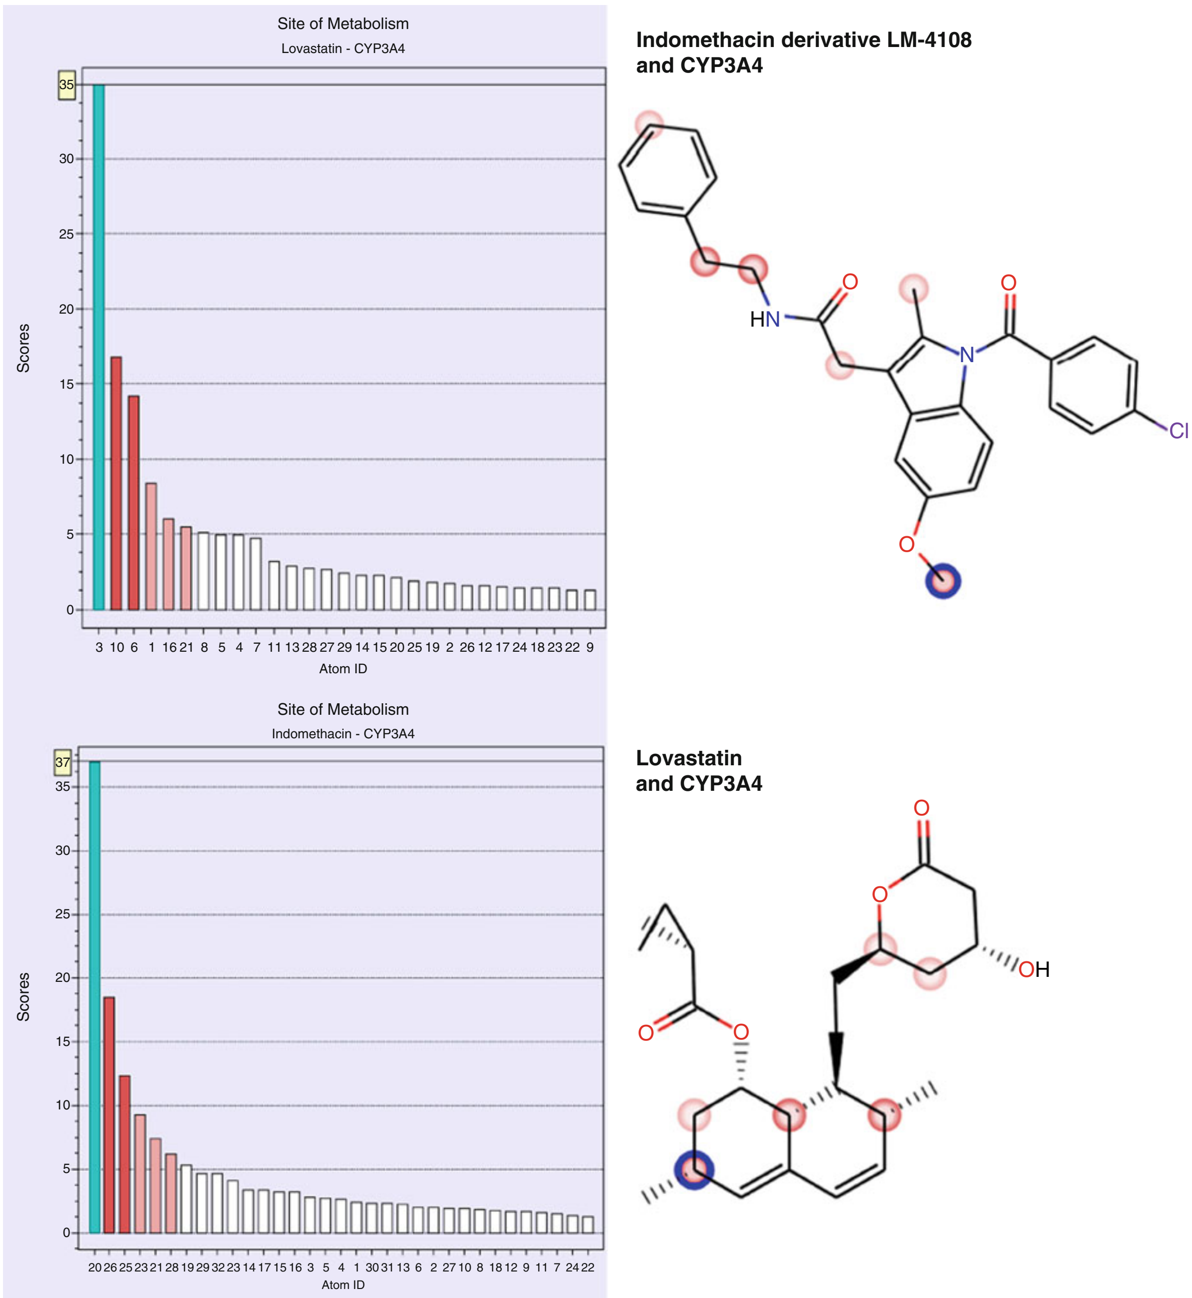

Fig. 41.6 MetaSite prediction of CYP3A4 metabolites for the indomethacin derivative LM-4108 (*upper panel*) and lovastatin (*lower panel*)

LM-4108 (upper panel, Remmel et al. 2004; Boyer et al. 2009) and the cholesterin-lowering drug lovastatin (lower panel, Caron et al. 2007). For LM-4108, the addition of the reaction mechanism-based probability in MetaSite suggests the benzylic hydrogen position as labile and as probable SOM. In addition, the methoxy group at the indole was detected as most probable SOM (blue circle in Fig. 41.6, upper panel). The third most important position is the CH_2 group, next to the amide nitrogen. Indeed, all three positions correspond to experimentally detected metabolites for this molecule (Remmel et al. 2004). Based on this

knowledge of potentially labile positions, several metabolically more stable analogues were synthesized, primarily by more polar modifications at the benzylic and amide CH_2 positions (Boyer et al. 2009).

For lovastatin, three main metabolites are experimentally reported; two of them (hydrogen elimination and hydroxylation) are in agreement with the most likely SOM from the MetaSite analysis, as indicated by a blue circle in Fig. 41.6 (lower panel). The other potential SOMs are much less likely. However, the third experimental metabolite, a hydroxylation in the aliphatic ester side chain, is given only a low priority.

CRITICAL ASSESSMENT OF THE METHOD

Tremendous progress has been made in the area of in silico prediction toward the identification of the site of metabolism in oxidative CYP-mediated metabolism in the past few years. The demonstrated agreement for these few MetaSite results in Figs. 41.5 and 41.6 is representative, as not always all experimentally detected SOMs are predicted. A broad comparison of prediction quality for MetaSite, although an older version, to other approaches is provided in a comprehensive overview by Tarcsay and Keserü (2011), further underscoring the value of using MetaSite for various CYP isoforms.

A recent comprehensive investigation on 227 known CYP3A4 substrates with a total of 325 metabolic pathways was carried out using MetaSite in comparison to docking studies (Zhou et al. 2006). Using either the CYP3A4 crystal structure or a homology model, both with the reactivity factor included, resulted in a prediction success of 78% correct prediction. The validation of the SOM prediction was based on counting the number of experimentally reported metabolic pathways that were found among the first, second, and third SOM sites as ranked by this approach. The employed docking method had relatively lower prediction accuracy (57%), although the value of such a docking-based approach is that it might provide useful insights into protein-substrate interactions, which could be additionally explored in future compound design (Zhou et al. 2006).

Site-of-metabolism prediction might significantly contribute to the drug discovery process, especially during earlier phases of research projects. At such an early project phase, when many potential hit series are evaluated as promising starting point for lead optimization, SOM predictions might contribute to this evaluation, as there are too many compounds to be characterized by experimental metabolite identification (ID) studies employing mass spectrometric methods despite their rapid turnaround times today. This in silico profiling might also be used for evaluating and ranking compound libraries. During the following optimization phase, SOM predictions are useful, complementing these rapid metabolite ID studies, in particular in those cases where experimentally an SOM can only be attributed to a large substructure at this early phase of discovery. A combination of metabolite ID and SOM prediction then clearly helps to formulate a hypothesis and thus stimulates chemical synthesis for specifically addressing this site.

MODIFICATIONS OF THE METHOD

In particular, the application of MetaSite for in silico enumeration of metabolites to aid metabolite identification appears to be very promising and further extends the use of this approach. A robust soft spot identification procedure combining MetaSite prediction rankings and rapid mass spectrometric confirmation has been described (Trunzer et al. 2009). While MetaSite's first rank predictions were experimentally confirmed in only 55 of the cases, for additional 29% of the investigated compounds, the second or third ranked SOM was detected. The proposed automatic and high-throughput reprioritization of a likely SOM thus significantly increases the likelihood to focus the next compound design to the correct SOM to more than 80%. This information allows to rapidly establish structure-metabolism relationships and to explore them by further chemical synthesis.

In another study, a recent modification of MetaSite was combined with mass spectroscopic data to mimic the rationalization of fragment ions routinely performed by a metabolism scientist during structure elucidation (Bonn et al. 2010). For 96% of the metabolites, the chemical structures were correctly assigned. Furthermore, for $\sim$80% of the cases, this correctly assigned structure was selected at first rank in comparison to manual inspection of the data supported by additional mass spectroscopic data. Hence, this MetaSite modification might be a very promising addition, allowing to automatically assign the chemical structure to a majority of experimentally detected metabolites (Bonn et al. 2010).

41.3 Examples for Global and Local In Silico ADME Models

This section will provide an overview on global and local ADME models from our group to illustrate our approach for building predictive models on structurally diverse training sets. We will discuss datasets for human intestinal absorption, human serum albumin binding, and CYP2C9 inhibition more in detail as examples for the construction of general models. Significant models for other relevant ADME properties have also been obtained. The main application of these models is seen in earlier phases of the drug discovery process related to library design and lead identification when no or little information on analogues is available. In addition, we will also show the generation of local, chemotype-specific models using permeability prediction for thrombin inhibitors and prediction of systemic exposure following oral administration of MMP-8 inhibitors. These models exemplify the typical situation in lead optimization where a collection of analogues was experimentally profiled. Those models are typically used in combination with

appropriate QSAR models tailored for affinity and selectivity for individual projects in the frame of multidimensional lead optimization.

41.3.1 Prediction of Human Intestinal Absorption

PURPOSE AND RATIONALE

The knowledge of the extent of human intestinal absorption is an important factor in the design of novel drug candidates. Several in silico models to predict human oral absorption have been reported in the literature (Agatonovich-Kustrin et al. 2001; Deretey et al. 2002; Egan et al. 2000b; Fu et al. 2001; Klopman et al. 2002; Norinder and Österberg 2001; Oprea and Gottfries 1999; Raevsky et al. 2000; Sugawara et al. 1998; Zhao et al. 2001). Simple models are based on only few physicochemical descriptors like logP, logD, or polar surface area (PSA). Consistently, all these models are only applicable if the compounds are passively absorbed. In case of absorption via active transporters or if efflux is involved, prediction of absorption is still not successful. This is a typical example where the attempt to predict data related to multiple underlying mechanisms do not produce significant models.

Prediction of systemic exposure or bioavailability from molecular structure is much more difficult since these parameters depend on solubility, absorption, and first-pass clearance. To this end, Yoshida and Topliss (2000) generated a QSAR model by applying "fuzzy adaptive least squares," using logD at pH 7.4 and 6.5 as physicochemical properties and the presence of key functional groups as structural descriptor. They achieved a classification of drugs into one of four bioavailability categories with an overall accuracy of 60% (Yoshida and Topliss 2000). Another recent approach uses neural networks and a collection of chemical descriptors to arrive at a model with good predictability (Turner et al. 2004).

While the majority of published models are based on a limited number of drug molecules, especially the study of Zhao et al. (2001) provides the most extensive compilation from available literature data and a statistical model derived from those using Abraham descriptors. We used this carefully selected dataset to build a quantitative model for human intestinal absorption employing VolSurf descriptors (see Sect. 41.2.2 and Cruciani et al. 2000a).

PROCEDURE

A dataset of 169 drugs and drug-like molecules was extracted from the compilation of literature data from Zhao et al. (2001). These molecules are considered to have reliable data about human intestinal absorption. Biological data were used as percent human intestinal absorption (%HIA) for statistical analysis. All molecules were treated as neutral and converted into their 3D structures using CORINA (Sadowski et al. 1992). The molecules were not aligned to each other. After 3D conversion, no further energy minimization was employed. Molecular interaction fields were computed using the GRID force field in VolSurf employing the water, dry, and carbonyl oxygen probes. Subsequently, a series of 72 VolSurf descriptors was computed from analysis of these three molecular interaction fields. These descriptors encode the following information (Cruciani et al. 2000b):

- Total volume (at an energy level of 0.25 kcal/mol)
- Total surface (at an energy level of 0.25 kcal/mol)
- Rugosity as ratio between total volume/total surface
- Globularity
- Volumes of interactions with GRID water probe at eight energy levels (−0.2 to −6.0 kcal/mol)
- Integy moments as distance from the center of mass to the center of interaction with the water probe eight energy levels
- Capacity factors as ratio of water volumes of interactions to total surface at eight energy levels
- Local interaction energy minima and distances
- Volumes of interactions with GRID dry probe at eight energy levels (−0.2 to −1.6 kcal/mol)
- Integy moments as distance from the center of mass to the center of interactions with the dry probe at eight energy levels
- Hydrophilic versus lipophilic balance (from −3, −4 kcal/mol water probe to −0.6, −0.8 kcal/mol dry probe)
- Amphiphilic moment as vector from hydrophobic to hydrophilic domain center
- Critical packing parameter defined as the volume of the hydrophobic part divided by the product of the surface of the hydrophilic part times the length of the hydrophobic part
- Volumes of interactions with GRID carbonyl oxygen probe at eight energy levels (−0.2 to −6.0 kcal/mol) to model hydrogen bonding capacity

All descriptors were normalized using autoscaling and subjected to multivariate statistical analysis

using PLS. From initial models encompassing all 72 descriptors, a set of 40 informative descriptors was selected using fractional factorial design (FFD) implemented in VolSurf (Baroni et al. 1993; Cruciani et al. 2000c).

EVALUATION

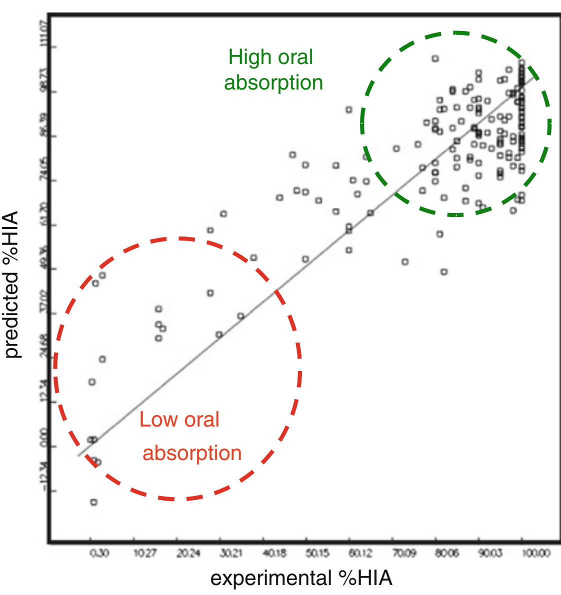
This procedure led to a predictive PLS model for 40 VolSurf descriptors and four relevant PLS components with a crossvalidated r^2(cv) value after leave-one-out crossvalidation of 0.662 and a conventional r^2 value of 0.709[1]. Further statistical validations using leave-two-out and leave-multiple-groups-out crossvalidation procedures further underscore the significance of the final model. The overall statistical quality of this model is similar to the model reported by Zhao et al. (2001; model 5; r^2: 0.74; r^2(cv): 0.72). This model also favorably compares to a previously reported VolSurf model for human intestinal absorption based on 20 drug molecules only. This earlier model with one PLS component showed an r^2(cv) of 0.726 and a conventional r^2 value of 0.782 for 72 descriptors without variable selection (Guba and Cruciani 2000; cf. Fig. 41.3), while the structural range of molecules in the extended dataset from Zhao et al. (2001) certainly encompasses more chemotypes and relevant functional groups.

The correlation of VolSurf descriptors to the human intestinal absorption for 169 drugs is shown in Fig. 41.7 from the final four component PLS model. On the left panel, the plot of experimental versus predicted %HIA is displayed. Although the data points do not fall onto a straight line, the model clearly is able to discriminate between compounds with high, medium, or low intestinal absorption. The analysis of PLS coefficients from this model allows for a chemical interpretation of the importance of individual descriptors contributing to the model, as shown in Fig. 41.7 on the right panel. Factors like rugosity (ROH2), integy moment derived from water interactions (Iw*OH2), hydrophobic contributions at lower energy levels (D2DRY), and hydrogen bonding (HB*O) are positively correlated to human intestinal absorption. Thus, if a chemical modification of the underlying structure increases any of these descriptors, it is likely that the intestinal absorption will be positively affected. In contrast, the increase of polarity from both water and carbonyl O probes (W*OH2, W*O), the associated capacity factor (Cw*OH2), and the hydrophobic integy moment are detrimental for intestinal absorption. These conclusions for factors influencing permeability and thus intestinal absorption are in agreement with earlier findings pointing to the positive impact of hydrophobicity, integy moment, shape, and hydrogen bonding, while polarity derived using the GRID water and carbonyl O probes as well as the capacity factors from polar interactions on the entire surface is detrimental. Previous work also suggests H-bond donors, acceptors, and polar surface contributions as important to model human intestinal absorption (Clark 1999a; Wessel et al. 1998; Palm et al. 1997). However, due to the nature of the VolSurf descriptors in combination with multivariate statistical analysis, this approach led to an enhanced understanding and quantitative modeling of physicochemical requirements influencing this pharmacokinetic observable. In particular, the balance between lipophilic and hydrophilic parts in combination with size, volume, and other effects guides the design of new compounds.

CRITICAL ASSESSMENT OF THE METHOD

VolSurf descriptors are able to predict absorption for a diverse set of drugs. The presented model is derived using a consistent frame of relevant chemically interpretable descriptors, which find applications in different local and general models. However, absorption is not only controlled by passive membrane permeability. There are other factors influencing in vivo human absorption, namely, the in vivo dissolution rate in small intestinal fluid and the dose used for the human study. Furthermore, active transport or efflux mechanisms are difficult to rule out and can only be identified by additional in vitro experiments. These important pieces of information should be known before any QSAR analysis is attempted on human absorption. This lack of consistent information throughout the literature is difficult to overcome, in particular for human studies. Hence, this study for the dataset from Zhao et al. (2001) provides a reasonable attempt to address these problems to carefully selecting members of the final dataset.

[1] r^2(cv), which is also known as q^2, indicates the crossvalidated r^2. Each compound is removed once from the final model, then a submodel is generated, and the removed compound is predicted using this submodel. The subsequent analysis of all prediction errors produces r^2(cv) (Wold 1978; Cramer et al. 1988b).



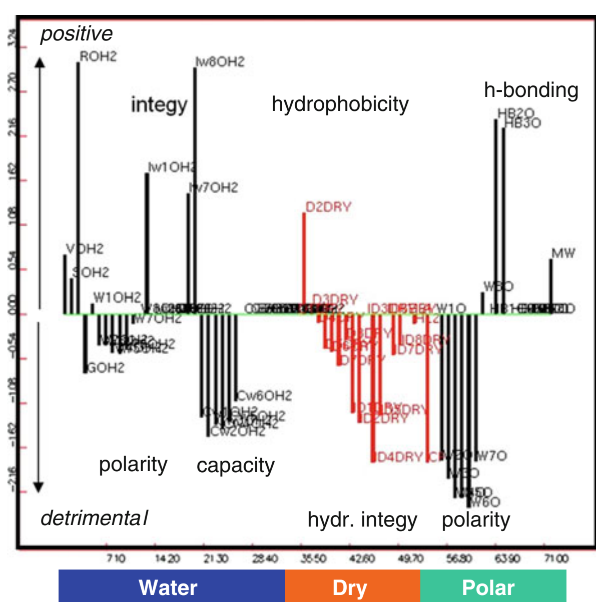


Fig. 41.7 Correlation of VolSurf descriptors with human intestinal absorption for 169 drug molecules. *Left*: predicted versus experimental %HIA (human intestinal absorption) from final 4-component PLS model. *Right*: PLS loadings showing the importance of VolSurf descriptors to the prediction of human intestinal absorption

Another problem for this and related datasets is the skewed distribution of the biological observable. There are too many compounds with high absorption, as this information gets primarily published after a successful drug discovery program. Compounds with no or low absorption by design or as failures are much harder to find in the public domain. Furthermore, this model is built within a limited chemical space which certainly does not reflect the chemical diversity in typical corporate libraries within the pharmaceutical industry. Although individual members of the training set are quite diverse to each other, the global coverage of chemical space is limited.

This collection of limiting factors clearly influences the quality of the model and its predictive power. In view of these sources of inconsistencies and errors in determining the intestinal absorption in humans, it is impressive that the quality of the model is as good as it is. In particular, this model was shown to be of particular use as general model in earlier phase for classification of molecules. Any significant improvement is likely not to come from statistical or computational methods but from more consistent data on a broader collection of drug-like molecules, preferably by an in vitro system eliminating some sources of experimental errors.

MODIFICATIONS OF THE METHOD

From a recent compilation of relevant human intestinal absorption data by Hou et al. (2007), a significantly larger dataset from public sources became available to us for model building. From a total of 648 chemical compounds from this work, 579 were believed by the authors to be transported by passive diffusion (Hou et al. 2007). From those molecules, we selected a training set of 453 molecules and a test set of 98 molecules by statistical design after elimination of some structures. However, this new dataset does still not overcome the skewed distribution of intestinal absorption data, as observed for the smaller dataset described above (Zhao et al 2001). After compound standardization and 3D conversion, a total of 184 descriptors were computed using the software package MOE (CCG). We then employed the program Cubist (RuleQuest) to derive regression tree models (Quinlan 1992; Butina and Gola 2003) based on the training dataset and all 184 descriptors. Cubist first builds a collection of rules to partition the training dataset into nodes in analogy to a decision tree structure. Each rule, however, has an associated multiple linear regression (MLR) model describing the SAR for all molecules as members of this rule. Thus, Cubist effectively classifies a set of

compounds according to structural parameters and evaluates a separate SAR model for each of these subsets rather than attempting to build a single model for the entire dataset (Quinlan 1992; Butina and Gola 2003). After the first predictive regression tree model from this approach, we then used a genetic algorithm to select useful descriptors in order to improve the statistical quality of the training set in terms of regression coefficients and to show the best performance on the test set. The finally selected regression tree model is based on four rules and 20 descriptors selected by our GA procedure after 1,000 iterations. While for the training set a r^2 value of 0.810 and a crossvalidated r^2(cv) value of 0.689 (tenfold crossvalidation) were obtained, the predictive r^2 of 0.846 for the test set of 98 molecules suggests a significant and useful model, which we then have implemented for design.

41.3.2 Predicting Human Serum Albumin and Plasma Protein Binding

PURPOSE AND RATIONALE

Problems related to poor systemic exposure of drug molecules can also be related to their volume of distribution, which is indirectly related to plasma protein binding. Human plasma contains more than 60 different proteins of which the major components are serum albumin (HSA, 60%) and glycosylated proteins like α-acid glycoprotein (AGP). Human serum albumin (66 kDa) is the most abundant protein in blood plasma with concentrations of 0.53–0.75 mM. Eighteen different variants arising from single amino acid mutations have been identified, accounting for different protein binding. Allelic variation makes data consistency difficult and hence modeling of the resultant data less reliable (Kariv et al. 2002). Considering the high concentration of albumin and the wide range of effective concentrations of therapeutic drugs from nanomolar to millimolar, the free concentration for a therapeutic effect can be significantly reduced for drugs with high binding to plasma proteins, independent of the fact that the affinity of drugs to their target protein is often higher than for plasma proteins. A total of eight hydrophobic binding sites for fatty acids have been identified, while for drug-like compounds, two high affinity binding sites were postulated in subdomains IIA and IIIA. The analysis of HSA X-ray structures (Bhattacharya et al. 2000; Petitpas et al. 2001) also showed that increased ligand concentrations led to binding to all known binding sites with different affinities and different pharmacological relevance.

There have been only a limited number of attempts to understand the molecular factors influencing drug binding to HSA (Colmenarejo et al. 2001; Colmenarejo 2003; Kratochwil et al. 2002; Saiakhov et al. 2000; Hajduk et al. 2003). Although it has been assumed that plasma protein binding is only related to ligand lipophilicity, a study by Kratochwil et al. (2002) demonstrated that lipophilicity is rather poorly correlated to HSA binding for a diverse set of molecules, in contrast to congeneric series, where lipophilicity is often found to be the dominant factor. This suggests that specific molecular recognition elements plus other physicochemical properties are involved in binding. This led these authors to derive a model based on pharmacophore similarity for 138 molecules and a comprehensive list of pharmacologically relevant first HSA association constants from the literature.

Colmenarejo et al. (2001, 2003) reported another significant and predictive computational model to predict binding to HSA based on a series of 95 drug-like molecules, again aiming to cover a large region of the chemical space. A set of consistent experimental data from a single laboratory were generated using high-performance affinity chromatography with HSA-immobilized stationary phases. We decided to use this homogeneous experimental data for HSA binding to build a quantitative model. Since our rational is to build many different models of ADME relevance with a consistent frame of informative descriptors, we employed the VolSurf descriptors (Cruciani et al. 2000a) already used for correlation of 3D structures to human intestinal absorption.

PROCEDURE

The set of 95 drugs and drug-like molecules from the study of Colmenarejo et al. (2001) was used. From experimental HPLC retention times, the $\log K_{(HSA)}$ values were used for statistical analysis. All molecules were treated in their neutral form and converted into their 3D structures using CORINA (Sadowski et al. 1992). From GRID molecular interaction fields for water, dry, and carbonyl oxygen probes, a set of 72 VolSurf descriptors (Cruciani et al. 2000b) was computed and analyzed as described above. All descriptors were normalized using autoscaling and subjected to PLS analysis. In the process of model building, two structurally unique outliers were rejected (Ebselen, Captopril). From initial models with only 93 compounds, a set of 47 informative descriptors was selected using fractional factorial design (FFD) implemented in VolSurf (Baroni et al. 1993; Cruciani et al. 2000c).

EVALUATION

This procedure led to a predictive 6-component PLS model for 47 VolSurf descriptors with a crossvalidated r^2(cv) value after leave-one-out crossvalidation of 0.671 and a conventional r^2 value of 0.755. Statistical validation using leave-two-out and leave-multiple-groups-out crossvalidation procedures underscores the significance of the final model. The graph of experimental versus calculated $-\log K_{(HSA)}$ values is shown

in Fig. 41.8 on the left. This model quality corresponds to the model reported by Colmenarejo et al. (2001).

The predictivity of this model to external compounds was further evaluated by splitting the dataset into a training set of 83 compounds and a test set of 10 molecules. One approach was to use the test set from Colmenarejo et al. (2001; model B), while another test set was generated using statistical design after a principal component analysis (PCA) on VolSurf descriptors (model A). The design was done by selecting the most descriptive compounds from the PCA scores (Hudson et al. 1996a). Scaling and variable selections were done independently for these smaller training sets, resulting in significant PLS models. For model A, a 6-component PLS model with a crossvalidated $r^2(cv)$ value of 0.668 and a conventional r^2 value of 0.763 indicates a statistically significant model. The standard error of prediction of 0.233 for 10 external compounds counts for a model with high predictivity (41.9 left). For model B, a crossvalidated $r^2(cv)$ value of 0.646 and a conventional r^2 value of 0.745 with an SDEP of 0.274 were observed (Fig. 41.9 right), leading to the same conclusion. For both models, the graph of experimental versus calculated $-\log K_{(HSA)}$ values is shown in Fig. 41.9. Both test sets are indicated by filled squares. In both cases, the agreement between experiment and prediction was very good.

The analysis of PLS coefficients from the final model allows to assess the importance of individual descriptors contributing to the model. The corresponding PLS coefficient plot for the final model is shown in Fig. 41.8 on the right. Factors like volume (VOH2), shape and rugosity (ROH2), integy moment from water interactions (Iw*OH2), hydrophobic contributions at lower energy levels (D3DRY), hydrophobicity (D3DRY), and molecular weight (MW) are positively correlated with HSA binding of drug molecules. In contrast, polarity (W*OH2), integy moment from the dry probe (Iw*DRY), and hydrogen bonding terms (HB5O) are negatively correlated to albumin binding. Any increase in those molecular properties is likely to decrease binding of drug-like molecules to HSA.

The interpretation for human serum albumin is in accord with literature findings and X-ray information on warfarin binding to the first drug-binding site in HSA (Petitpas et al. 2001). The influence of hydrophobicity in combination with geometry factors like shape, volume, and size is often discussed (Colmenarejo et al. 2001; Colmenarejo 2003). It also is in accord with the findings of Kratochwil et al. (2002) demonstrating that lipophilicity influences albumin binding, but certainly not to a very significant extent. Obviously, factors like pharmacophore similarity which might translate into different shape-related VolSurf descriptors are more

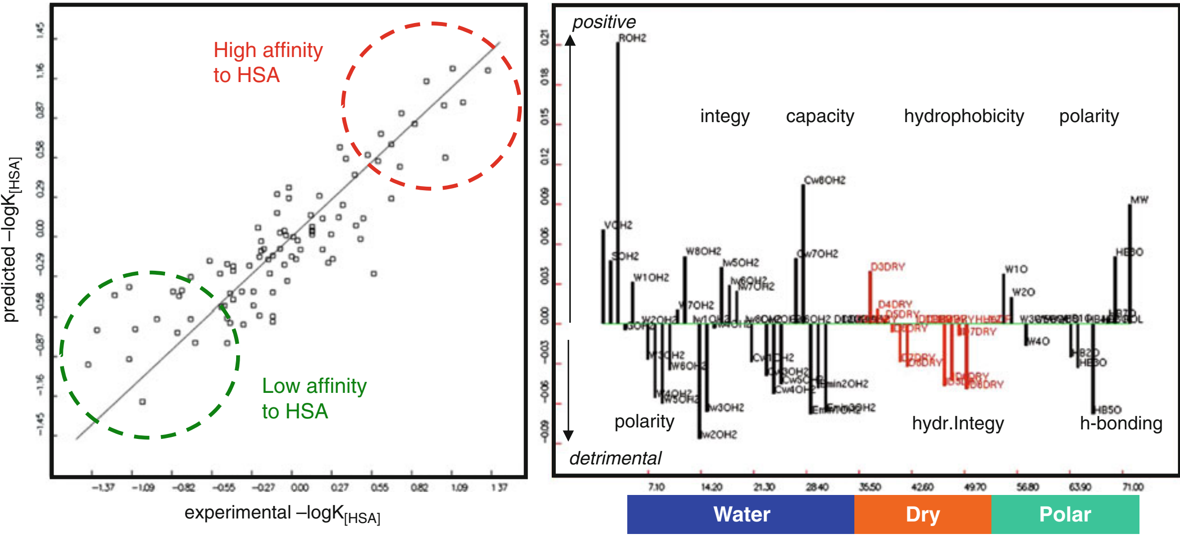

Fig. 41.8 Correlation of VolSurf descriptors with human serum albumin binding affinity for 93 drug-like molecules. *Left*: predicted versus experimental $-\log K_{(HSA)}$ from the final 6-component PLS model. *Right*: PLS loadings showing the importance of VolSurf descriptors to the prediction of human serum albumin binding

important. Any increase in polarity reduces HSA binding which can be understood by the mentioned physicochemical requirements of the albumin drug-binding sites. The striking effect of shape descriptors on the other hand corresponds to the topological requirements of the binding sites.

CRITICAL ASSESSMENT OF THE METHOD

The presented general in silico model for HSA binding is built on a dataset from a solid in vitro assay conducted in a single laboratory. Hence, the quality of data certainly is not a limitation for this model. However, this assay is intrinsically not able to differentiate between drugs binding to different albumin binding sites. This uncertainty might affect the overall quality of the model and adds another mechanistic dimension to the data. Hajduk et al. (2003) reported a detailed statistical analysis of 889 diverse molecules binding to the binding site in albumin subdomain IIIA only. This analysis was based on data from heteronuclear NMR correlation and fluorescence spectroscopy which enabled the measurement of dissociation constants to only one binding site. However, approaches like these are not routinely used in experimental profiling for this property.

Before such a model can be applied to another binding site or a different pharmaceutical company, careful validation and harmonization studies have to be conducted in order to ensure that the experimental data used for building the model correspond to a certain extent to those data used to evaluate it. Typical assays in this area even do not differentiate between drugs binding to albumin or other serum proteins like α-acid glycoprotein. Furthermore, there is a dynamic equilibrium between albumin-bound and free drug molecules. While binding is focused on one aspect in the transport of drug molecules, the kinetic aspect of k_{on} and k_{off} rates is equally important to understand the complex equilibrium between bound drug, free drug, and drug bound often in a tighter fashion to its target protein. Those aspects have not been incorporated into such a model.

The present model is significant, as it allows guiding library design and hit exploration on the basis of solid in vitro data without knowledge of close analogues. As drugs with high affinity for albumin exhibit markedly reduced efficacy in vivo, this model offers a method to reduce albumin binding of potential candidates while maintaining high affinity at the therapeutic target. However, the real significant of such a model can only be assessed in the context of the experimental setup for drug discovery within a particular organization.

MODIFICATIONS OF THE METHOD

Other models to predict HSA binding have been reported, including a predictive group contribution

model involving 74 chemically intuitive fragments linked to serum albumin binding from the detailed analysis of 889 compounds at Abbott (Hajduk et al 2003). However, human plasma protein binding (PPB), as combined experimental parameter, is experimentally determined more often for novel structures instead of HSA binding alone, causing multiple computational models to be developed for this complex property as well. In a large and comprehensive QSAR model building investigation, Votano et al. (2006) compiled training and test sets of 808 and 200 compounds with PPB data from various public sources. Four modeling approaches (multiple linear regression, artificial neural networks, k-nearest neighbors, and support vector machines) involving topological descriptors were successfully applied for model building in this case on this larger dataset. Gleeson (2007) established PLS models for human and rat PPB in-house data from GlaxoSmithKline, employing training sets of 686 and 1081 compounds, respectively. A collection of 30 different descriptors including TPSA, molecular weight, and various pKa- and logD-derived properties were employed for model building. The final models displayed promising predictive ability on large test and validation sets. This analysis, however, also revealed significant species differences with respect to PPB.

Recently, a large compilation of publicly available human clinical pharmacokinetic data was reported by Obach et al. (2008), where the authors collected and compiled i.v. data for 670 drugs. These data encompass clearance, volume of distribution at steady state, mean residence time, terminal phase half-life, and plasma protein binding data given as fraction unbound (fu) to PPB. PPB data are available for 551 individual compounds in this database.

From this collection, we then selected a training set of 496 molecules and a test set of 55 molecules by statistical design. The PPB fraction unbound (fu) data were normalized according to Gleeson (2007) to result in a pseudoequilibrium constant logK = log ((1−fu)/fu). After a compound regularization and standardization process and 3D conversion, a total of 184 descriptors were computed using the software package MOE (CCG). We then applied the program Cubist (RuleQuest) for regression tree models (Quinlan 1992; Butina and Gola 2003) based on the training dataset. Cubist builds a collection of rules to partition the training dataset. Each rule has an associated multiple linear regression (MLR) model (see above). Based on a first model, we applied a genetic algorithm to select informative descriptors to improve the statistical quality of the model. The selection is driven by the training set correlation coefficient plus the performance on the test set. The final regression tree model for the PPB dataset is based on six rules and 47 descriptors. The correlation of MOE descriptors with plasma protein binding is shown in Fig. 41.10 on the left for the training set and on the right for the test set. While for the training set an r^2 value of 0.757 and a crossvalidated $r^2(cv)$ value of 0.578 (tenfold crossvalidation) are obtained, the predictive r^2 of 0.792 for the test set indicates a significant and useful model, which we have implemented for design. This model was applied to a novel set of 40 internal molecules with high-quality PPB data, which results in a predictive r^2 value of 0.547, thus underscoring the value of such a model for further design. Interestingly,

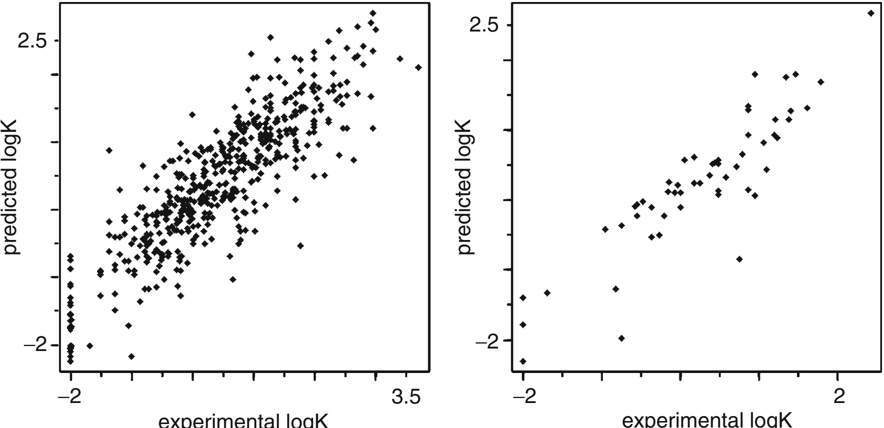

Fig. 41.10 Correlation of MOE descriptors with human plasma protein binding data (logK derived from fraction unbound). *Left*: predicted versus experimental logK values for the training set of 496 molecules. *Right*: predicted versus experimental logK values for the test set of 55 molecules

the application of simple descriptors like logD or logP does not provide the same prediction quality for this dataset.

41.3.3 Prediction of Cytochrome P450 2C9 (CYP2C9) Inhibition

PURPOSE AND RATIONALE

Mammalian cytochrome P450s (CYPs) represent a class of membrane-associated heme-containing proteins that metabolize a range of xenobiotics (see above). The major human isoforms contribute to the oxidative metabolism of approximately 90% of pharmaceuticals, while CYP2C9 is responsible for about 18% of all catalyzed reactions (Smith et al. 1997; Rettie and Jones 2005; de Groot 2006). While typical CYP2C9 substrates belong to the class of nonsteroidal anti-inflammatory drugs (e.g., diclofenac, ibuprofen, naproxen, flurbiprofen, piroxicam), polar acidic drugs, progesterone, hypoglycemics, and coumarin-based anticoagulants are also metabolized. Any interference of potential drug candidates with these metabolism pathways might cause undesirable drug-drug interactions upon comedication (Rettie and Jones 2005), which can be a major hurdle to the clinical development of new drug molecules. Therefore, a reliable prediction of CYP2C9 inhibition potential for novel chemical structures would be useful in early discovery phases.

Earlier investigations studied smaller chemical series to establish the structure-activity relationship for CYP2C9 substrates and inhibitors (Jones et al. 1993, 1996a; Mancy et al. 1995). 3D-QSAR approaches were also employed for model building on smaller datasets (Jones et al. 1996b; Rao et al. 2000; Ekins et al. 2000; Afzelius et al. 2002b, 2004b). Subsequently, the 3D structure of CYP2C9 has been first deduced from X-ray studies of the homolog rabbit CYP2C5 (Williams et al. 2000). Some years later, Williams and coworkers

(2003) indeed determined the structure of human CYP2C9 with S-warfarin, while Wester et al. (2004) crystallized a different human CYP2C9 construct with flurbiprofen at a resolution of 2.0 Å. Here, a particular conformation of the helix B to helix C region allows Arg108 to form hydrogen bonds with Asp293 and Asn289 and to interact with the flurbiprofen carboxylate, thus positioning the substrate for regioselective oxidation in the site (Wester et al. 2004). Site-directed mutagenesis also supports the importance of Asn289 plus Ser286 in the CYP2C9 binding site for interacting with diclofenac and ibuprofen (Klose et al. 1998), which also explains its preference for smaller, acidic, and lipophilic ligands.

In order to detect inhibitors for major human CYP450 enzymes early in discovery, we set out to develop fast QSAR models for this (Byvatov et al. 2007) and other CYPs as "antitarget," namely, CYP3A4 and CYP2D6. To be of practical use for internal discovery, any model should be based on experimental data obtained under *identical* conditions for a wide range of diverse compounds. The purpose of our model differs from classical QSAR such that many diverse structures and chemical series provide the basis for its development, and it will be applied to predict diverse candidate molecules. For larger datasets, the use of descriptors requiring information about a putative alignment of 3D structures is often not possible due to structural diversity of the ligands and the lack of a consistent alignment hypothesis. Consequently, we have used two sets of descriptors known to capture information relevant for protein-ligand interactions in our own model building approach (Byvatov et al. 2007).

First, we computed three-point pharmacophore (3PP) fingerprints from 2D structures using MOE (CCG), where each bit encodes the presence of a pharmacophore triangle with specific distances. For this descriptor, the support vector machine statistical approach (SVM) (Cortes and Vapnik 1995) was found to be useful for model building, as it can handle large numbers of descriptors (Byvatov and Schneider 2003), while the application of PLS (Wold et al. 1984; Dunn et al. 1984) did not result in useful models. In order to build PLS models, we additionally employed a collection of descriptors (CMQA) consisting of 163 substructure keys following the MACCS key definitions, 150 CATS topological pharmacophore descriptors (Schneider et al. 1999), pKa values for basic and acidic groups from ACD/Labs, and surface-based descriptors computed using QikProp (Duffy and Jorgensen 2000, Schrödinger). This collection was useful in other projects for deriving significant models.

PROCEDURE

A dataset of 1,338 compounds representing multiple chemical series from various discovery programs was extracted from our internal database, for which IC_{50} values for CYP2C9 inhibition were previously determined using a harmonized protocol employing human recombinant CYP2C9 and 7-MFC (7-methoxy-4-trifluorocoumarin) as substrate (Byvatov et al. 2007). IC_{50} data were converted into pIC50 values. The quality of some data points was limited by low solubility, as estimated by prediction or experimental solubility testing. Any interpretation in those cases was done with care. All molecules were treated as neutral; counterions and salts were removed. Canonical 3D structures were generated using CORINA (Sadowski et al. 1992). The dataset was divided into a training set of 1,100 and a test set of 238 molecules using statistical design. Classification for actives and inactives was done using an IC_{50} threshold of 10 μM.

EVALUATION

Linear SVM regression with 3PP fingerprints produced a model with a crossvalidated $r^2(cv)$ of 0.34 (leave-25%-out crossvalidation) and an r^2 value of 0.81, which correctly predicts the test set of 238 compounds (predictive r^2 value of 0.63). For CMQA descriptors, a PLS model with six components results in a crossvalidated $r^2(cv)$ of 0.34 (leave-one-out method), a conventional r^2 of 0.48 and a predictive r^2 value of 0.55 for 238 test molecules. The training and test set predictions are shown in Fig. 41.11 for the SVM model (upper) and the PLS model (lower) with test set predictions shown on the right.

Most outliers are localized in three regions: very active compounds ($IC_{50} > 0.4$ μM, upper right circle), medium active compounds (central circle), and inactive compounds (lower left circle). Inactive outliers are often due to insufficient solubility at assay concentration. A similar observation was made for some medium active compounds with IC_{50} values greater than 2 μM. Again low solubility is the limiting factor to obtain a more accurate value. In contrast, some compounds with high affinity were predicted to be only moderately active; on the other hand, some of

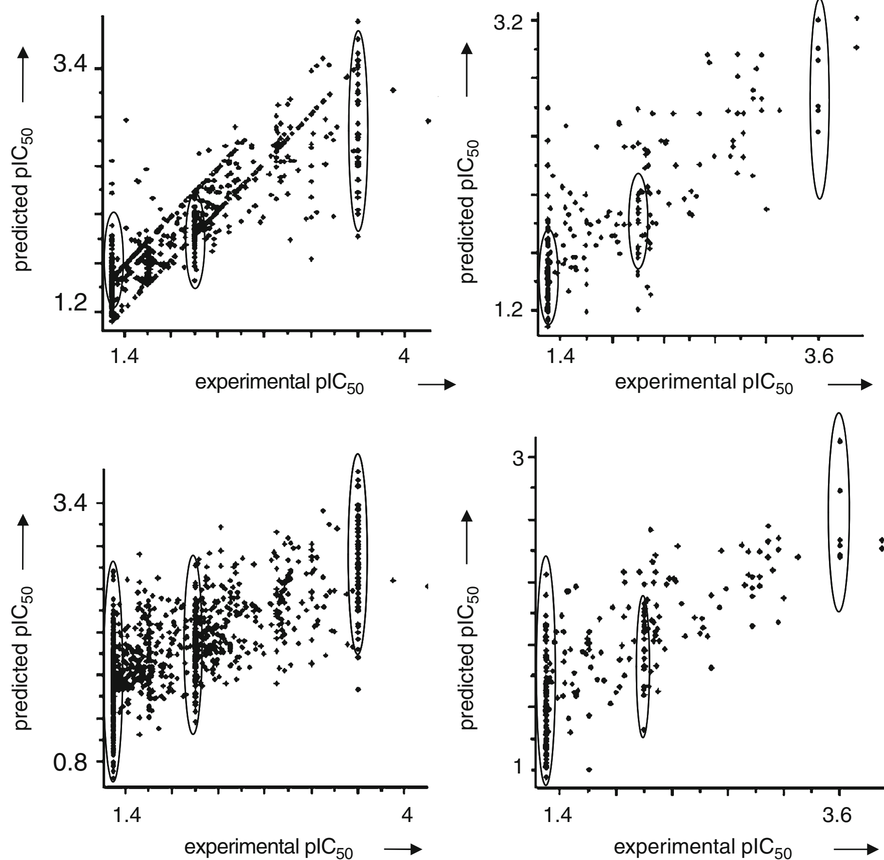

Fig. 41.11 Predicted versus experimental pIC_{50} values for selected QSAR models to identify potential CYP2C9 inhibitors. *Upper panel*: SVM-3PP based model with training set (1,100 molecules, *left*) and test set performance (238 molecules, *right*). *Lower*: PLS-CMQA-based model with training (*left*) and test set performance (*right*)

the inactive compounds were predicted to have binding activity for CYP2C9—both a consequence of the complexity of interactions with CYP2C9.

For further model validation, we employed a second in-house dataset with 344 compounds from a focused library for G protein-coupled receptor (GPCR) targets and data from the same CYP2C9 inhibition assay (Byvatov et al. 2007). In addition, a third dataset by Afzelius et al. (2002, 2004) with 34 active and 49 inactive molecules and CYP2C9 inhibition Ki values from AstraZeneca was used. In both cases, the performance was monitored using receiver operating characteristic (ROC) curves as index of the ability of a classifier to discriminate between actives and inactives. While for the 238 compounds test set 6% false positives using SVM-3PP and 3% using PLS-CMQA were observed, the number of false negatives is significantly higher with 16% and 22%, respectively (Byvatov et al. 2007). This picture is related for the GPCR dataset with 5% false positives for SVM-3PP and PLS-CMQA, but 24 and 26% for the GPCR library, respectively. Furthermore, a total of 75% from the Afzelius dataset was correctly classified, providing additional evidence for the reliability of this model.

CRITICAL ASSESSMENT OF THE METHOD

Both computational models from a consistent dataset with values from a single laboratory are able to identify true CYP2C9 inhibitors with a relatively small rate of false positives and thus provide relevant filters to detect potential CYP2C9 inhibitors early in discovery (Byvatov et al. 2007). This fits to the primary application scenario in an industrial setting, where active compounds should be flagged with high reliability and inactive CYP2C9 inhibitors will be subsequently tested. Thus, additional experimental validation is required for those molecules passing the initial filter to identify false negatives. These types of filters are usually the ones, which will be implemented in multidimensional compound design and optimization.

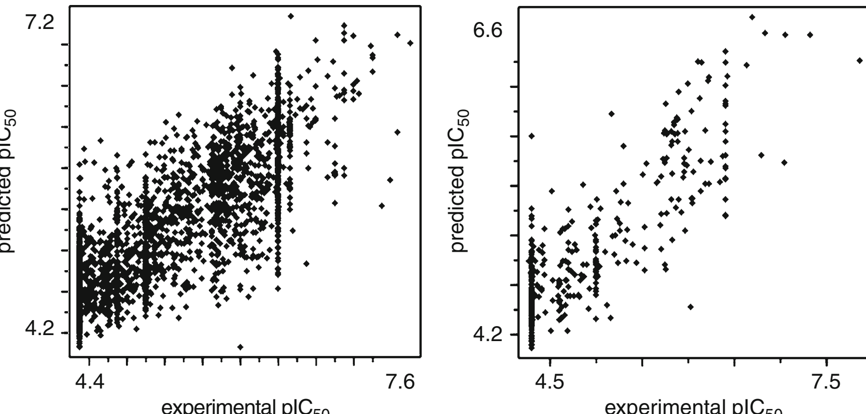

Fig. 41.12 Correlation of MOE descriptors with human CYP2C9 inhibition (pIC_{50}). *Left*: predicted versus experimental pIC_{50} values for the training set of 2484 molecules. *Right*: predicted versus experimental pIC_{50} values for the test set of 454 molecules

MODIFICATION OF THE METHOD

Following our positive experience upon prospective application of this CYP2C9 inhibition model after a certain period of time, we extracted a significantly larger dataset from our internal collection of CYP2C9 data accumulated after a period of experimental testing for numerous discovery projects. From this pool, we selected a representative training set of 2,484 molecules and a test set of 454 molecules employing statistical design. As our experience using the combination of MOE descriptors plus Cubist-based regression trees was also very positive, we decided to apply this combination of methods for this updated dataset.

After compound standardization and 3D conversion, a total of 184 descriptors were computed using the software package MOE (CCG). We then used Cubist (RuleQuest) to derive regression tree models (Quinlan 1992; Butina and Gola 2003) based on the training dataset and all descriptors. As previously mentioned above, Cubist builds a collection of rules with associated multiple linear regression (MLR) models to partition the training dataset and capture the SAR for all members of a particular rule. We used a genetic algorithm to select useful descriptors from an initial model toward an improvement in terms of regression coefficients and to obtain a model with reasonable test set performance.

The final regression tree model after this procedure is based on 18 rules and 56 descriptors. While for the training set an r^2 value of 0.674 and a crossvalidated $r^2(cv)$ value of 0.504 (tenfold crossvalidation) were obtained, the predictive r^2 value of 0.723 for the test set of 454 molecules indicates a useful model, which we have implemented for design. The plot of experimental versus predicted pIC_{50} values for the model is shown in Fig. 41.12. We now use this model in a semiquantitative way for classification of potentially active CYP2C9 inhibitors.

The further availability of consistent inhibition data from globally harmonized CYP450 inhibition assays for CYP3A4 and CYP2D6 together with a broad coverage of chemical space also prompted us to establish predictive models using the same setup for these "antitargets." Model building was done accordingly to CYP2C9, which resulted for CYP2D6 in a model with 23 rules and 60 descriptors from 1,862 training set and 484 test set molecules. The r^2 value for the training set is 0.706, the crossvalidated $r^2(cv)$ value is 0.504, while the predictive r^2 value is 0.792. A related result was obtained for CYP3A4 with a training set of 2,435 and a test set of 426 compounds. Here, the final model consists of 20 rules and 69 descriptors with a training set r^2 value of 0.640, a crossvalidated $r^2(cv)$ value of 0.436, and a predictive r^2 value of 0.672. Both models are characterized by high predictive r^2 values and thus were investigated further in prospective applications. In total, we have now implemented significant and predictive QSAR models to identify potential inhibitors for the three major CYP450 isoforms: CYP2C9, CYP2D6, and CYP3A4.

41.3.4 Predicting Paracellular Intestinal Permeability for Thrombin Inhibitors

PURPOSE AND RATIONALE

During lead optimization, the use of chemotype-specific models offers advantages over general models, including the coverage of the relevant chemistry space for a discovery project and the availability of experimental data for a series of analogues usually from a single laboratory. Even if these data are not strict single-mechanism data, there is often evidence that molecules on a particular chemotype share a particular mechanism of action.

Many pharmaceutical companies are actively working on the development of orally active inhibitors of the serine protease thrombin as one important enzyme in the blood coagulation cascade. In many cases, however, the systemic exposure to thrombin inhibitors

following oral administration is limited due to low intestinal permeability rather than low solubility or metabolic instability. Most synthetic inhibitors require a highly basic functional group like benzamidine or guanidine for favorable interactions to the S1 pocket of thrombin, thus gaining a significant portion of its binding affinity. However, these moieties often cause low intestinal permeability.

To obtain more insight into the problem of permeability for benzamidine derivatives, Sugano et al. (2000) studied the membrane permeation of 51 benzamidine-based thrombin inhibitors in a rat-everted sac permeability model. They reported significant membrane permeability in this in vitro model, which they attributed to passive paracellular transport, an absorption mechanism being different to transcellular permeability. Using Caco-2 cell experiments, they confirmed that opening the tight junctions increases permeability of some compounds which underscores that this paracellular pathway is dominating for this chemotype. Using physicochemical descriptors, the authors obtained significant models to understand structural determinants for paracellular intestinal permeability. This homogeneous experimental dataset for permeability of a congeneric series was used by us to build a quantitative local model employing VolSurf descriptors (Cruciani et al. 2000a). Such a chemotype-specific model in combination with similar models for related properties like solubility and others could be valuable during multidimensional compound optimization in the lead optimization phase. We use this model as an example to illustrate the generation and use of related local models in optimization.

PROCEDURE

The set of 51 benzamidine-based thrombin inhibitors was taken from the study of Sugano et al. (2000). Experimental rat-everted sac permeability was expressed as log(ESA) value[2]. The experimental permeability in this assay is expressed as ratio of outer (mucosal side) concentration of the drug and inner (serosal side) concentration after 1-h incubation of the everted sac of rat small intestine. All molecules were treated in their neutral form and converted into their 3D structures using CORINA (Sadowski et al. 1992). From GRID molecular interaction fields for water, dry, and carbonyl oxygen probes, a set of 72 VolSurf descriptors (Cruciani et al. 2000b) was computed and analyzed as described above. All descriptors were normalized using autoscaling and subjected to PLS analysis. No further variable selection was performed (Cruciani et al. 2000c).

EVALUATION

This procedure led to a predictive 4-component PLS model for 72 VolSurf descriptors and 51 thrombin inhibitors. A crossvalidated r^2(cv) value of 0.599 after leave-one-out crossvalidation and a conventional r^2 value of 0.812 were obtained. Statistical validation using leave-two-out and leave-multiple-groups-out crossvalidation procedures underscores the significance of the final model. The graph of experimental versus calculated log(ESA) permeability values is shown in Fig. 41.13 on the left. The overall model quality corresponds to the model reported by Sugano et al. (2000).

Based on the study of Sugano et al. (2000) and our predictive VolSurf model for this series, it can be concluded that factors like size and shape previously reported to affect paracellular permeability are indeed important to explain the local structure-permeability relationship of this chemotype. Usually, permeability via paracellular aqueous pore diffusion depends on the size of the solute and its diffusion coefficient in water. Another important factor is lipophilicity. Between intestinal absorption and both volume and lipophilicity, a negative correlation was reported for this series of thrombin inhibitors. In addition, hydrogen bonding properties and polarity are factors that determine the permeability of these benzamidine analogues. These findings are in good agreement to the interpretation of the VolSurf model from inspection of the PLS coefficient plot for the four-component model (Fig. 41.13 right). This plot is the result from the multivariate statistical analysis showing that factors like hydrophilicity from water interactions (W*), capacity factors (Cw*), and hydrogen bonding properties (HB*) are positively correlated with log(ESA). Increasing these descriptors will positively affect the passive paracellular permeability in this series. In contrast, factors like volume (V), surface area (S), shape (R), lipophilicity (D*), polarizability (POL), and molecular weight (MW) are negatively correlated with permeability.

[2]According to the authors, everted sac permeability was abbreviated by ESA.

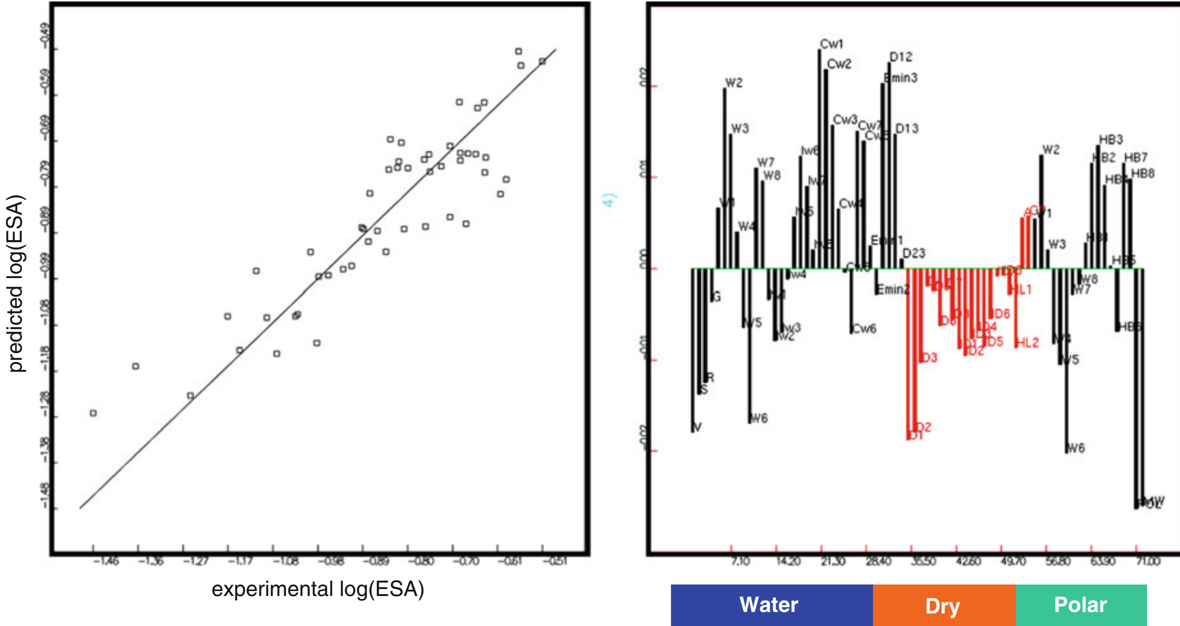

Fig. 41.13 Correlation of VolSurf descriptors with intestinal paracellular passive absorption for 51 benzamidine-based thrombin inhibitors. *Left*: predicted versus experimental permeability log(ESA) from the 4-component PLS model. *Right*: PLS loadings showing the importance of VolSurf descriptors to the prediction of paracellular permeability

CRITICAL ASSESSMENT OF THE METHOD

This example shows that a quantitative structure-permeability relationship could be established in a local series of thrombin inhibitors predominantly following a particular route of intestinal permeability via the paracellular pathway. The presented VolSurf model does not only agree to dominant factors discussed in the literature but also builds a statistical basis to quantify individual influences by informative descriptors of physicochemical relevance. Although permeability in general is related to different underlying mechanisms, there is evidence that in this local series the permeability follows only a single route. The detailed structure-permeability relationship on the other hand will guide drug discovery project teams to introduce structural variations into the presented thrombin inhibitor scaffold and quantitatively assess the potential for paracellular permeability before synthesis. However, it is an intrinsic limitation of such a chemotype-specific model that predictions for structurally less related structures are not possible. Furthermore, it cannot be ruled out that a particular derivate does not follow any longer this primary route of permeability which is assumed to form the basis for the present investigation. Besides the molecular modeling aspects of this model, the clinical relevance of paracellular transport, as shown by this example, remains to be elucidated.

Hence, local statistical models provide a qualitative ranking of candidates and, thus, are valuable for optimization of pharmaceutically relevant compounds, especially if combined with additional models to understand affinity, selectivity, or any particular pharmacokinetic behavior.

41.3.5 Predicting Rabbit Systemic Exposure for MMP-8 Inhibitors

PURPOSE AND RATIONALE

In search for potent and systemically available inhibitors of the matrix metalloproteinase MMP-8 (Matter et al. 1999, 2002) following oral administration, a local ADME model was derived to support lead optimization. For an internal series of inhibitors on the tetrahydroisoquinoline scaffold, hydroxamic acids for zinc ion binding in three position are essential for MMP affinity in first-generation inhibitors. However, those compounds are characterized by insufficient pharmacokinetic properties and low systemic exposure following oral administration. Driven by X-ray and 3D-QSAR studies (CoMFA), alternative Zn^{2+} binding groups like carboxylates were investigated. The expected loss in affinity for some members of this series was compensated by filling the MMP-8 S1' pocket close to the catalytic zinc ion. The design and structure-activity relationship (SAR) for this series are in agreement with protein binding site requirements and monitored multiple properties including selectivity against the undesirable MMP-1.

We decided to build a chemotype-specific VolSurf model (Chap. 2.2 "Safety Pharmacology: Introduction" and Cruciani et al. 2000a) for 49 MMP-8 inhibitors to better understand molecular and physicochemical factors controlling the systemic exposure following oral administration in a rabbit animal model. This study provides an example where in vivo data have been employed fulfilling certain requirements to build a model for some pharmacokinetic aspects. However, one has to be aware that the obtained experimental data after oral dosing to rabbits do certainly not fulfill the requirement of representing only a single mechanism. Hence, in the initial phase of model building, compounds with metabolic instability from in vitro S9 assays and very low solubility were rejected from the dataset in order to primarily focus on the absorption aspect of the systemic exposure in rabbits following oral administration. This model illustrates the use of local models from in vivo data after filtering by in vitro properties in lead optimization.

PROCEDURE

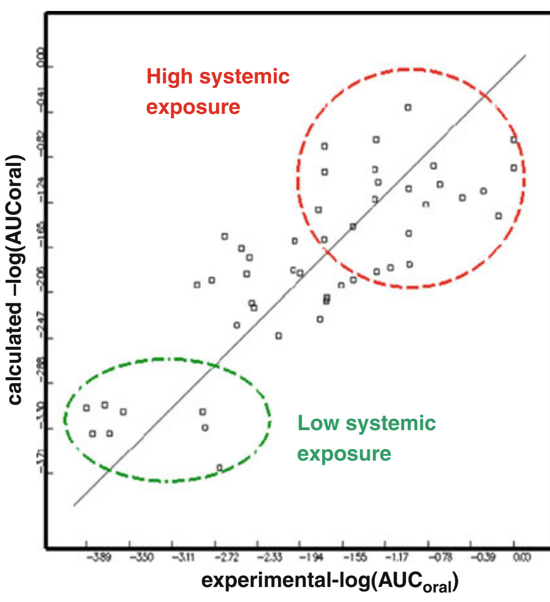
The systemic exposure of a series of 49 MMP-8 inhibitors was determined following oral administration to rabbits under consistent conditions for inhibitor dosing and formulation. These inhibitors represent different scaffolds and zinc ion-binding functionalities. From the pharmacokinetic profiles of these animal studies, the total area under the curve $AUC_{(oral)}$ was converted into $-\log(AUC_{(oral)})$ values and used to build the statistical model. All molecules were treated in their neutral form and converted into their 3D structures using CORINA (Sadowski et al. 1992). From GRID molecular interaction fields for water, dry, and carbonyl oxygen probes, a set of 72 VolSurf descriptors (Cruciani et al. 2000b) was computed and analyzed as described above. All descriptors were normalized using autoscaling and subjected to PLS analysis. From initial models, a set of 46 informative descriptors was selected using fractional factorial design (FFD) implemented in VolSurf (Baroni et al. 1993; Cruciani et al. 2000c).

EVALUATION

For these 49 MMP-8 inhibitors, the systemic exposure in rabbits following oral administration was successfully correlated to VolSurf descriptors. A semiquantitative four-component PLS model using 46 descriptors was obtained with a crossvalidated $r^2(cv)$ value of 0.424 after leave-one-out crossvalidation and a conventional r^2 value of 0.646. Statistical validation using leave-two-out and leave-multiple-groups-out crossvalidation underscores the significance of the model. The validation suggests applying the final model in a semiquantitative way by classification of novel compounds into those with low, medium, or high systemic exposure. The graph of experimental versus calculated $-\log(AUC_{(oral)})$ permeability values is shown in Fig. 41.14 on the left.

Further validation of this model was done by splitting the dataset into a training set of 39 and a test set of 10 compounds using statistical design after a principal component analysis (PCA) on VolSurf descriptors following the most descriptive compound (MDC) algorithm (Hudson et al. 1996b). A 3-component PLS model with a crossvalidated $r^2(cv)$ value of 0.457 and a conventional r^2 value of 0.673 indicates a statistically significant model. The standard error of prediction for 10 external compounds indicates medium predictivity but reasonable classification into low, medium, and high systemic exposure.

The analysis of PLS coefficients from the final model allows to assess the importance of individual descriptors contributing to the systemic exposure in rabbits following oral administration in this series. The corresponding PLS coefficient plot is shown in



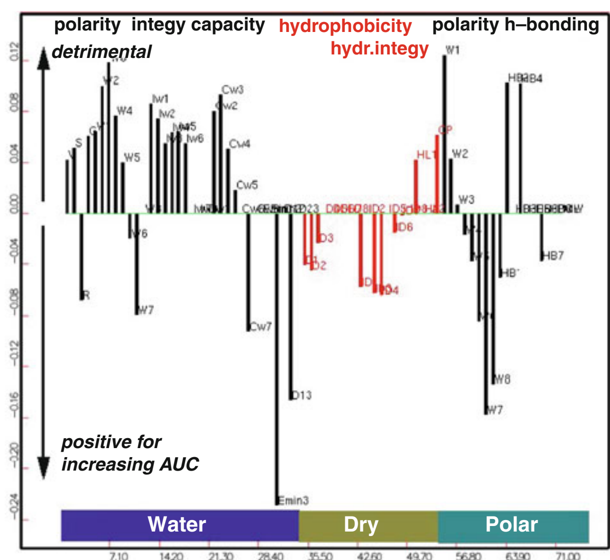


Fig. 41.14 Correlation of VolSurf descriptors with systemic exposure after oral administration in rabbits for 49 structurally diverse MMP-8 inhibitors. *Left*: predicted versus experimental systemic exposure $-\log(\text{AUC}_{(\text{oral})})$ from the 4-component PLS model. *Right*: PLS loadings showing the importance of VolSurf descriptors to the prediction of the systemic exposure in rabbits

Fig. 41.14 on the right. Please note that due to the chosen logarithmic scale for AUC values, favorable descriptors are now located in the lower area of this plot. Factors like shape (R), strength of interaction energy with water (Emin3), hydrophobicity (D*), integy moment from hydrophobic interactions (ID*), and interactions to the carbonyl O probe (W*) are favorable for the systemic exposure. Increasing these descriptors might lead to increased AUC after oral dosing. In contrast, polarity from the water probe interactions (W*), integy moment from the water probe (Iw*), capacity factor (Cw*), and hydrogen-bonding terms (HB*) are negatively correlated to the systemic exposure.

This interpretation, although derived for a local series of MMP inhibitors, is in qualitative agreement to models for permeability and intestinal absorption. The effects of polarity versus hydrophobicity and the importance of hydrogen-bonding interactions are consistently highlighted in comparison to general absorption model but with different importance of individual descriptors which have been tailored by PLS to the problem under study.

CRITICAL ASSESSMENT OF THE METHOD

While the chemical interpretation of this model qualitatively agrees to general models for permeability and absorption, those conclusions were derived only for a small, limited series of analogues on representative scaffolds. Furthermore, all published models in this field either describe human intestinal absorption or in vitro permeability assay data, while there are significant differences between rabbits, rats, and humans in terms of permeability and metabolism. Consequently, it cannot be ruled out that this model is very focused to the rabbit situation, because important animal studies to profile MMP-8 are conducted using rabbits. Although this model is not based on single-mechanism data, the focus on a particular series of related scaffolds might help to partially solve this problem. The quality of the model also suggests that more than one mechanism actually is responsible for the observed pharmacokinetic profile for which the AUC is only one appropriate way to summarize this behavior. Thus, a combination of such a final model from in vivo studies combined with some appropriate filters from informative in vitro assays might help to resolve this problem.

The resulting semiquantitative model was used in conjunction with structure-based docking and scoring, 3D-QSAR-based affinity and selectivity predictions, and in silico ADME models to estimate membrane permeability, solubility, and other key properties for the optimization process in this series. Hence, in

this as well as in other series, multiple models can be collectively applied for ranking and prioritizing synthesis candidates and focused virtual libraries during advanced stages of multidimensional compound optimization.

41.4 Conclusion and Outlook

In recent years, the pharmaceutical industry has come under increasing pressure to reduce the time as well as the expenditure for the discovery and development of novel drugs. As a consequence, sophisticated in vitro assays have been introduced aiming at the simulation and prediction of the in vivo situation. However, besides the generation of huge sets of data all these assays still need the synthesis of the compounds. To overcome the issue of handling the generated information as well as to support medicinal chemists in selecting the most promising compounds for synthesis, in silico approaches revealed to be indispensable tools. in silico tools can be used to extract relevant information from large datasets, thereby assisting in the improvement of the understanding of factors controlling affinity, selectivity, as well as ADME and physicochemical compound properties. Furthermore, in silico approaches are extremely valuable tools for the design of new compounds with improved properties during a multidimensional optimization phase. Hence, these tools represent a key technology in the transformation from time-consuming trial-and-error strategies to faster prediction approaches.

Facing the growing number of in silico approaches, the list of tools discussed in this chapter can only represent a selection to illustrate application areas. The tools described in more detail have proven their suitability to support the success of drug discovery project teams. The ADME models discussed in this chapter are dominated by physicochemical molecular properties. Models for other ADME properties like transporter binding have not been discussed because they are dominated by complementarity in protein-ligand interactions. Although also important, the discussion of these models was beyond the scope of this chapter.

In different phases of a drug discovery project, different in silico models are applied, namely, general models in earlier phases and chemotype specific models later when more experimental information about analogues is available for a research team. Hence, the effective generation and storage of meaningful data in databases to address specific ADME and pharmacokinetic properties are essential for timely success of a project. That does not only imply the use of advanced in vitro assay technology toward single-mechanism ADME data but also a data infrastructure for re-using valuable data and knowledge in subsequent design phases to effectively support lead optimization.

The problems of today's in silico models for ADME properties are mainly associated with data availability, consistency, and quality to solve particular problems. Accurate and consistent date is an indispensable prerequisite for predictive models. In particular the use of multi-mechanism data often results in failures in model building and application. Using complex data might only be possible, if congeneric series are monitored as related compounds might act by similar mechanisms.

Finally, it is important to note that neither a single approach is likely to solve all problems for a chemotype nor is an approach equally well suited for every problem. The challenge lies in the selection of the most suited model for a given problem and in the effective integration of experimental and computational tools. Once the suited in silico tools are established, they can make a major contribution to the successful lead optimization process resulting in a novel drug.

42.1 Introduction

In the era of combinatorial chemistry and high-throughput screening, a huge number of hits and structural analogs potentially interesting as new chemical entities (NCEs) can be produced in a short period of time. Drug metabolism is a decisive determinant of the pharmacokinetic behavior of these compounds. Approximately three quarters of the top 200 prescribed drugs in the United States in 2002 are cleared by metabolism, one-third are cleared via the kidney, while biliary clearance of unchanged drug plays only a minor role (Williams et al. 2004). Thus, understanding and description of the metabolism of a new chemical entity is an essential part of the submission dossier (Weaver and Jochemsen 2009) as well as an important optimization parameter in drug discovery programs to reduce attrition in drug development (Kola and Landis 2004).

In vitro biotransformation tests are one piece of the puzzle to understand the pharmacokinetic characteristics of a given compound, to optimize PK parameters, and to select the most drug-like compounds that will progress into development (Eddershaw et al. 2000; Li 2004; Masimirembwa et al. 2003; Wang 2009; Baranczewski et al. 2006). Relatively recent prospect of obtaining equivalent data from in vitro and in vivo studies has provided the pharmaceutical industry with an incentive to validate in vitro models with respect to increase throughput and/or to replace animal studies where appropriate. Moreover, in vitro test systems are the only humanized models in early development (Coleman et al. 2001). An early assessment using animal in vitro and in vivo data together with

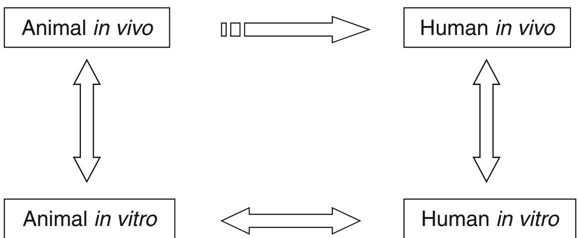

Fig. 42.1 Qualitative prediction of compound properties in humans from animal models using in vitro and in vivo data

human in vitro data allows a qualitative prediction whether humans will act in similar (path-) ways as did the animal models (Fig. 42.1).

In vivo biotransformation studies play a role later in development in both animals and humans (Gupta and Atul 2000; Inskeep and Day 1999; Pool 1999). Use of transgenic animals facilitates understanding the role of drug-metabolizing enzymes in the organism (Gonzalez and Kimura 2003). However, animal studies cannot entirely replace clinical studies in predicting all responses in human, particularly because of pronounced species differences between humans and the important laboratory animals (Martignoni et al. 2006), but, for ethical reasons, the risk to human volunteers participating in early clinical studies should be minimized (Cross and Bayliss 2000). This is supported by a variety of in vitro metabolism studies.

Metabolic stability tests can be performed in higher throughput (White 2001), especially due to the development of more sensitive LC-MS/MS instruments and the ability to analyze more analytes in parallel. They allow ranking of compounds and ensure that the molecules resulting from the optimization process retain favorable metabolic properties. In addition, they give rise to set up computational models predictive for the in vitro test which helps to speed up the selection and optimization processes although applications on the biotransformation of drugs are still limited (Lipscomp et al. 2008; Chohan et al. 2006; Li 2002; Gombar et al. 2003; Yu and Adedoyin 2003; Bugrim et al. 2004; see also Chap. 51, "In Silico Methods").

Metabolite structure elucidation studies enable the identification of toxicologically relevant biotransformation ("hot spots," Kalgutkar et al. 2005; Prakash et al. 2008) and positions of metabolic attack ("soft spots"). During discovery programs, this is mainly based on in vitro studies to support medicinal chemists in improving metabolic characteristics (Nassar and Talaat 2004a) because of high efforts due to intense sample clean-up procedures and the effort to generate the samples.

Investigation of metabolic profiles in vivo ultimatively proves the validity of pharmacological and toxicological data obtained in animal models for humans. The toxicological aspect is highlighted in a series of publications on "metabolites in safety testing" (Baillie et al. 2002, 2003; Hastings et al. 2003; Davis-Bruno and Atrakchi 2006; Guengerich 2006; Smith and Obach 2006; Humphreys and Unger 2006) followed by regulatory guidances published by FDA (US-FDA 2008) and ICH (ICH 2009). The impact on the strategies applied in industry to meet these regulations has been expressed in technical considerations (Luffer-Atlas 2008; Zhang et al. 2009; Gao et al. 2010) as well as strategy proposals to organize the sequence of metabolism studies differently along the drug development phases (Obach et al. 2012). This has impact on the conduct and timing of the radioactive human ADME study by classical means (Krone et al. 2011 and literature cited therein) or the use of accelerator mass spectrometry (AMS) in microtracer studies (Smith 2011; Lappin et al. 2008 and literature cited therein, Garner 2000; Garner et al. 2000).

In vitro metabolism studies are indispensible for predicting drug–drug interactions (US-FDA 2012; EMA 2012; Tucker et al. 2001; Bjornsson et al. 2003; Zhang et al. 2007) and variability in exposure due to pharmacogenetic differences in the population. Besides studies on enzyme inhibition (see Chap. 40, "Drug -Drug Interaction – Enzyme Inhibition") and induction (see Chap. 39, "Drug -Drug Interaction – Enzyme Induction"), information has to be generated on the enzymes involved in the biotransformation of a drug particularly for drugs which are subject to high metabolic clearance in the liver. This reaction phenotyping is essential part of submission dossiers. A stepwise approach is recommended comprising of correlation analyses in individual livers, incubations in recombinant enzymes, and incubation in human liver microsomes using inhibitors or antibodies specific for the particular isozyme (Wienkers et al. 2003; Lu et al. 2003).

Metabolism of many xenobiotics, including drugs and toxic compounds, occurs mainly in the liver (De Kanter et al. 1999). Until now, in vitro studies on the metabolism of xenobiotics were usually performed using liver preparations as a first step such as isolated perfused livers,

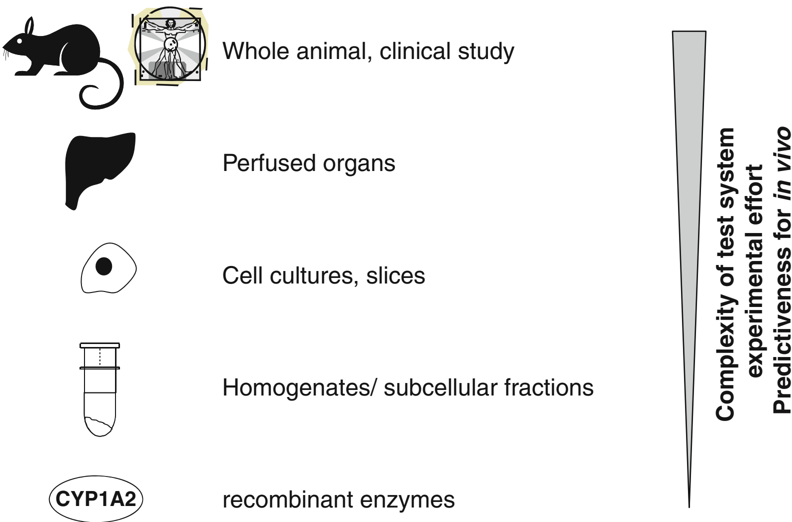

Fig. 42.2 Test systems for studying drug metabolism

Table 42.1 Comparison of in vitro test systems to study biotransformation (in part from Plant 2004)

In vitro system	Pros	Cons
Perfused organs	All metabolic active enzymes for phases I and II present including cofactors, whole metabolic profile observed, best correlation to in vivo	Expensive, ex vivo animal trial, complex methodology, high technical effort, batch variability, more complicated than enzyme-only system, quality control, limited use for multiple compounds
Slices	All metabolic active enzymes for phases I and II present including cofactors, whole metabolic profile observed, good correlation to in vivo	Expensive, ex vivo animal trial, diffusion controlled, complex methodology, high technical effort, batch variability, more complicated than enzyme-only system, quality control, limited use for multiple compounds
Cells in primary culture (e.g., hepatocytes)	All metabolic active enzymes for phases I and II present including cofactors, whole metabolic profile, population pools for cryopreserved hepatocytes possible, good correlation to in vivo	Expensive, batch variability, quality control, complex methodology, high technical effort, limited use for multiple compounds
S9 fraction	Easy to use, cheap, phases I and II present, whole metabolic profile observed	Addition of cofactors, lower enzyme activity than microsomes/supersomes
Microsomes	Easy to use, cheap, "population" pools	Addition of cofactors, only membrane-bound metabolizing enzymes such as CYPs, FMOs, and UGTs partial metabolic profile
Cytosol	Easy to use, cheap	Addition of cofactors, only soluble metabolizing enzymes such as alcohol dehydrogenases, sulfotransferases, glutathione *S*-transferase, *N*-acetyl transferases partial metabolic profile
Supersomes	Easy to use, moderately cheap, single enzyme only	Currently only CYPs, FMOs, UGTs, GSTs, and SULTs, single enzyme only, different CYP: oxidoreductase molar ratio, accuracy of kinetics questionable

liver slices, liver homogenates, isolated hepatocytes, subcellular liver fractions (S9, cytosol, microsomes), or overexpressed recombinant metabolizing enzymes, particularly cytochrome P450 isozymes. The decreasing order of tissue organization goes in parallel with the technical effort of using these models (Fig. 42.2).

Each of these in vitro systems has their specific values and limitations regarding availability of tissues,

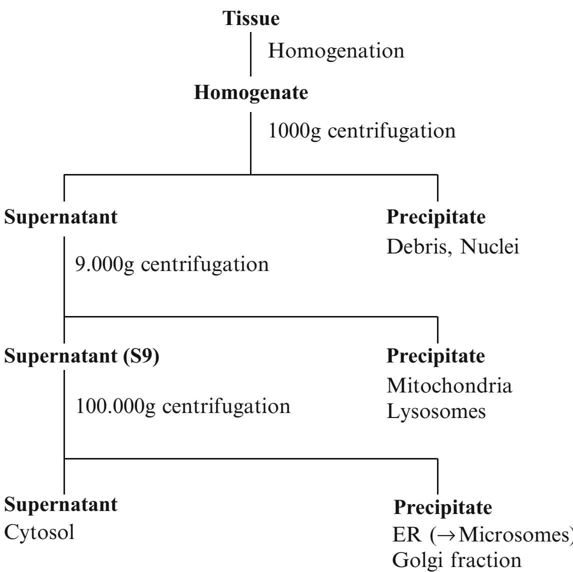

Fig. 42.3 Preparation of subcellular organ fractions by differential centrifugation (according to Ekins et al. 1999)

costs, completeness of enzymatic capability, ease of handling, and sensitivity to population differences (Plant 2004). Pros and cons have to be considered under the specific application intended, e.g., if higher throughput even in an automated environment is needed at the early stage of drug discovery support or if regulatory aspects are concerned. A comparison between the various systems to study the metabolism of a drug in vitro is given in Table 42.1 based on a review elsewhere (Plant 2004, see also Brandon et al. 2003).

Whereas sophisticated technologies are required for slices or organ perfusion studies (see also Chap. 35, "Distribution - In Vivo - Perfused Organs"), others can be easily performed with cells (Li 1999) or fractions commercially available. A typical preparation scheme for preparation of subcellular fractions by differential centrifugation is given in Fig. 42.3.

The biological function of metabolic transformation is to increase the water solubility of a drug. Typically, metabolism is divided into two steps

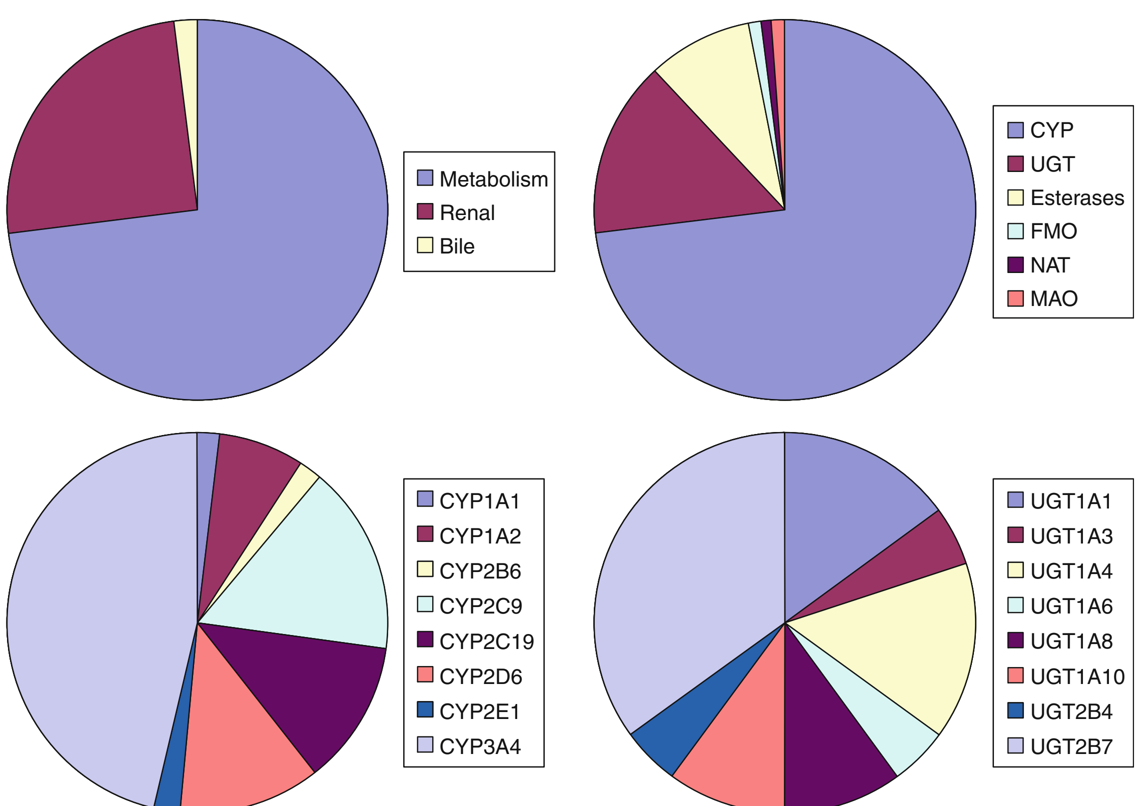

Fig. 42.4 Importance of clearance mechanism and the relative role of drug-metabolizing enzymes (Williams et al. 2004)

Table 42.2 Characteristics of cytochrome P450 isozymes (Donato and Castell 2003; Brandon et al. 2003)

Isoform	Occurrence	Major polymorphic variant alleles	Model substrates	Inhibitor	Inducer	Abundance in human liver
CYP1A1	Mainly extrahepatic	*CYP1A1*2*	7-ethoxyresorufin *O*-deethylation	alpha-Naphthoflavone (acceptable[a], inhibits also CYP3A4)	Polycyclic hydrocarbons	<1%
		*CYP1A1*3*				
CYP1A2	Liver		Phenacetin *O*-deethylation (preferred[a])	Furafylline (preferred[a])	Smoking	8–15%
					3-Methylcholanthrene	
			Caffeine N3-demethylation (acceptable[a])		Char-grilled meat	
					Rifampicin	
CYP2A6	Liver	*CYP2A6*2*	Coumarin 7-hydroxylation (preferred[a])	Coumarin (acceptable[a])	Pyrazole	5–12%
		*CYP2A6*3*			Barbiturates	
		*CYP2A6*4*				
		*CYP2A6*5*				
CYP2B1/2			Pentoxyresorufin *O*-dealkylation			
CYP2B6	Liver		(*S*)-mephenytoin *N*-demethylation (preferred[a])	Sertraline (acceptable[a], also inhibits CYP2D6)		1–5%
			Bupropion hydroxylation (acceptable[a])			
CYP2C8	Liver, Intestine		Paclitaxel 6-α-hydroxylation (preferred[a])	Glitazones (preferred[a])	Rifampicin, Barbiturates	10%
CYP2C9	Liver, Intestine	*CYP2C9*2*	(*S*)-warfarin C6-, C7 hydroxylation (preferred[a])	Sulfaphenazole (preferred[a])	Rifampicin	15–20%
		*CYP2C9*3*	Diclofenac 4′-hydroxylation (acceptable[a])		Phenobarbital	
			Tolbutamide para CH3-hydroxylation (acceptable[a])			
CYP2C18/2C19	Liver	*CYP2C19*2*	(S)-mephenytoin 4′-hydroxylation (preferred[a])	Ticlopidine (acceptable[a], also inhibits CYP2D6)	Rifampicin	<5%
		*CYP2C19*3*		Ketoconazole	Carbamazepine	
CYP2D6	Liver, Intestine, Kidney	*CYP2D6*2* × *n*	Bufuralol 1′-hydroxylation (preferred[a])	Quinidine (preferred[a])		2%
		*CYP2D6*4*	Dextromethorphan *O*-demethylation (preferred[a])	Haloperidol		
		*CYP2D6*5*	Codeine *O*-demethylation (acceptable[a])			
		*CYP2D6*10*				
		*CYP2D6*17*				
CYP2E1	Liver, Intestine, Leukocytes	*CYP2E1*2*	Chlorzoxazone 6-hydroxylation (preferred[a])	Diethyl-dithiocarbamate	Ethanol	7–11%
		*CYP2E1*3*	Lauric acid ω-1-hydroxylation (acceptable[a])	4-methyl pyrazole (acceptable[a])		
		*CYP2E1*4*				
CYP3A4	Liver, GI tract	*CYP3A4*2*	Midazolam 1′-hydroxylation (preferred[a])	Ketoconazole (preferred[a])	Rifampicin	30–40%
				Troleandomycin (preferred[a])	Barbiturates	
		*CYP3A4*3*	Testosterone 6β-hydroxylation (preferred)	Cyclosporine (acceptable[a])		
				Grapefruit juice		
CYP4A11	Liver, Kidney		Lauric acid ω-hydroxylation	17-Octadecynoic acid		

[a]Recommendation according to Tucker et al. 2001
More recent recommendations of substrates and inhibitors can be found in the EMA guidance on drug-drug interactions (EMA 2012)

Table 42.3 Characteristics of individual isozymes in the human UGT family (Coughtrie and Fisher 2003; Ritter 2000; Ohno and Nakajin 2009)

Isozyme	Probe substrates	Tissues	Reported inducers
UGTIA1	Bilirubin β-estradiol (3-gluc) 17α-ethinylestradiol (3-gluc)	Liver, small intestine, colon, stomach	3-methylcholanthrene, phenobarbital, oltipraz; phenytoin
UGTIA3	Hyodeoxycholic acid (COO-gluc)	Liver, small intestine, colon	
UGTIA4	Imipramine Trifluoperazine	Liver, small intestine, colon	
UGTIA6	Serotonin	Liver, brain, small intestine, colon, stomach	TCDD, TBHQ
UGTIA7	Benzo[a]pyrene metabolites	Stomach, colon, esophagus	
UGTIA8	Not known	Small intestine, colon, esophagus	
UGTIA9	Propofol	Liver, kidney, intestine, colon esophagus	TCDD, TBHQ
UGTIA10	Not known	Stomach, small intestine, solon, esophagus	
UGT2B4	Hyodeoxycholic acid (6-gluc)	Liver, intestine	
UGT2B7	AZT, morphine	Liver, kidney, small intestine, colon, esophagus	TBHQ
UGT2B10	Not known	Liver, kidney, intestine	
UGT2B11	Not known	Liver, prostate, mammary	
UGT2B15	(S)-oxazepam	Liver, prostate, small intestine, colon, stomach, esophagus	
UGT2B17	Dihydrotestosterone	Prostate, liver, small intestine, colon, stomach	

TCDD 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, *TBHQ* *ter*-butylhydroquinone

(Lee et al. 2003): firstly, named phase I, functionalization of the molecule takes place leading to introduction or liberation of polar groups like alcohols, phenols, and amines by hydroxylation, dealkylation, heteroatom oxidation, and oxidative dehalogenation. Also, esters and amides are hydrolyzed.

Phase I metabolites, together with unchanged parent compound, are excreted via bile and urine, if sufficient solubility and/or transporter specificity is given. In a second step, conjugation reactions often increase polarity even more by glucuronidation, sulfation, or glutathione conjugation (phase II).

Enzymes responsible for these biotransformation reactions are present in many organs and tissues, the most important one in general being the liver. Under the enzymes involved in the biotransformation of drugs, the cytochrome P450 superfamily plays the most important role, especially CYP3A, followed by involvement of glucuronidases and esterases (Wrighton and Stevens 1992; Donato and Castell 2003; Kumar and Surapaneni 2001; Williams et al. 2004; Arinc 2010). The relative contribution of metabolic clearance pathways and the role of P450 isozymes to the biotransformation of drugs are shown in Fig. 42.4 (Williams et al. 2004).

Cytochrome P450s are present in the endoplasmic reticulum and therefore present in microsomal preparations. An overview on isoforms, polymorphisms, substrates, inhibitors, inducers, and occurrence of cytochrome P450s is given in Table 42.2 (Donato and Castell 2003; Brandon et al. 2003). It is noteworthy to mention that CYP3A being the isoform of highest abundance and predominantly involved in the metabolism of drugs is also highly present in the intestine (Galetin et al. 2008) and thus plays an important role in the intestinal first-pass metabolism of drugs.

As total inhibitors of the P450 enzyme family, 1-aminobenzotriazole (Lee and Slattery 1997) and proadifen (SKF525A) (Lee et al. 1998) are suitable to distinguish from non-cytochrome P450-mediated pathways. Other oxidative pathways are dependent on, e.g., flavin-containing monooxygenases (FMOs), molybdenum hydrolases (aldehyde oxidase and xanthine oxidase), amine oxidases, alcohol dehydrogenases or aldehyde dehydrogenases (Benedetti et al. 2006).

Table 42.4 Some properties of the human sulfotransferase enzyme family (Coughtrie and Fisher 2003)

SULT isoform	Probe substrates	Known drug substrates	Major sites of expression
SULT1A1	4-Nitrophenol	Acetaminophen, troglitazone, minoxidil, 4-OH tamoxifen, apomorphine	Adult liver, adult GI tract, adult platelets, placenta
SULT1A2	No selective substrate known	–	?
SULT1A3	Dopamine	Salbutamol, dobutamine	Adult GI tract, adult platelets, adult brain, placenta, fetal liver
SULT1B1	No selective substrate known	–	Adult liver, adult GI tract, fetal GI tract
SULT1C2	No selective substrate known	–	Fetal kidney, fetal lung, fetal GI tract
SULT1C4	No selective substrate known	–	Fetal kidney, fetal lung
SULT1E1	17β-Estradiol	17α-Ethinylestradiol	Fetal liver, fetal lung, fetal kidney, adult liver, endometrium
SULT2A1	Dehydroepiandrosterone	Budesonide, Dehydroepiandrosterone, Pregnenolone	Fetal adrenal, fetal liver, adult liver, adult adrenal
SULT2B1	Cholesterol (2B1b), Pregnenolone (2B1b)	–	Adult skin, prostate, placenta
SULT4A1	No selective substrate known	–	Brain

Also present in microsomes are flavin-containing monooxygenases (FMOs) involved in oxygenation of heteroatoms like nitrogen and sulfur (Lang and Kalgutkar 2003). Five different isoforms of FMOs are currently characterized. In adult human liver, FMO1 and FMO3 play an important role. Selective marker substrates for FMO1 are imipramine and orphenadrine. Methimazole inhibits FMO-dependent pathways (Wynalda et al. 2003) but also CYP2B6, CYP2C9, and CYP3A4.

Monoamine oxidases (MAOs) are present in the mitochondria and are involved in oxidation of endogenous and exogenous amines (Lang and Kalgutkar 2003).

Carbonyl reductases and alcohol and aldehyde dehydrogenases are cytosolic enzymes being involved in the oxidation of alcohols and aldehydes and in the reduction of aldehydes and ketones (Lang and Kalgutkar 2003; Garattini et al. 2008).

Uridine diphosphoglucuronosyl transferases (UGTs) are the most prominent enzymes within the phase II enzymes present in microsomes (Coughtrie and Fisher 2003). An overview on isoforms, substrates, and tissue expression is given in Table 42.3. UGT2B7, UGT1A1, and UGT1A6 are responsible for glucuronidation of two-thirds of the top 200 prescribed drugs in the United States in 2002 (Williams et al. 2004). Special attention is given to UGT1A1 with respect to phenotyping and drug interaction, since UGT1A1 is responsible for the conjugation of bilirubin (deficiencies in patients suffering of hyperbilirubinemia as Crigler-Najjar and Gilbert's diseases). UGTs are involved in the formation of *O*-, *N*-, and *S*-glucuronides. Formation of acyl glucuronides is considered to be of potential risk as they can form reactive intermediates (Shipkova et al. 2003). As for CYP3A, intestinal UGTs are discussed as potential modifiers of pharmacokinetics of drugs (Ritter 2006).

Cytosolic sulfotransferases are involved in the sulfation of endogenous compounds and drugs (Coughtrie and Fisher 2003). An overview on isoforms and their characteristics is given in Table 42.4.

Other important drug-metabolizing enzymes are microsomal and soluble epoxide hydrolases (Hassett et al. 1997; Srivastava et al. 2004; Omiecinski et al. 2000), glutathione *S*-transferases (Igarashi and Satoh 1989; Strange et al. 2001), *N*-acetyltransferases (Price-Evans 1989), and methyltransferases (Weinshilboum et al. 1999). Genetic polymorphisms of these enzymes play a role in metabolism and toxicity of drugs (Wormhoudt et al. 1999; Hengstler et al. 1998).

It becomes evident that organs other than liver, such as lung (Yost 1999; Zhang et al. 2006), kidney and intestine (Roediger and Babidge 1997; Paine and

Thummel 2003; Kaminsky and Zhang 2003; Shin et al. 2009), skin (Oesch et al. 2007), brain (Dutheil et al. 2009), and placenta (Syme et al. 2004), can also contribute to the metabolism of xenobiotics (De Kanter et al. 1999) and partly to organ specific toxicity.

Another important matrix for the metabolism of xenobiotics is blood. In addition to in vitro studies in whole blood, serum or plasma prepared from blood from humans or animals is used (Williams 1987). Under the enzymes present in blood, serum esterases have the most significant effect on drugs. These include cholinesterase (ChE), serum arylesterase (SA), carboxylesterase (CE), and red blood cell (RBC) esterases. These enzymes play a role in both activation of prodrugs and deactivation of drugs (Williams 1987). Recent examples of marketed prodrugs are adefovir, tenofovir, valganciclovir, olmesartan, parecoxib, tamiflu, famciclovir, and ximelagatran (Los et al. 1996; Bernardelli et al. 2002; Boyer-Joubert et al. 2003; Li et al. 1998; Vere-Hodge et al. 1989; Balimane et al. 2000; Clement et al. 2003; Powell et al. 1993). The stability in blood is also of special importance for the administration of peptides due to the presence of endo-, carboxy-, and aminopeptidases (Powell et al. 1993).

In addition to the potential of liberating the active drug upon absorption, orally applicable prodrugs require a sufficient stability in the gastrointestinal tract which is most importantly pH-dependent chemical stability (Balbach and Korn 2004) as well as stability against GI esterases as pepsin and pancreatin. Enzymatic or bacterial degradation of prodrugs in the GI tract can be studied in vitro, e.g., in Caco-2 cells concomitant to permeability experiments (see also Chap. 27, "Absorption: In Vitro Tests - Cell Based"), ex vivo (see also Chap. 28, "Absorption: In Vitro Tests - Non Cell Based"), or in vivo.

42.2 In Vivo Biotransformation Studies

PURPOSE AND RATIONALE

In vitro studies can only give a limited, “mechanistic” picture of biotransformation in animals or humans. The quantitative importance of each individual metabolite needs to be assessed in vivo. Samples collected from in vivo studies give rise to comprehensive metabolite identification work (Watt et al. 2003; Clarke et al. 2001) which is also required from a regulatory point of view (Baillie et al. 2002). Due to the labor-intense nature of these studies and the need of applying radiolabeled compounds in order to get a complete picture of biotransformation, these studies are performed during preclinical and clinical phase of drug development. Of particular importance is the collection of human metabolism data from the human ADME study using radiolabeled drug (Krone et al. 2011) to identify relevant human metabolites and to compare their exposure between human and animal species used in toxicological studies and to assess their pharmacological activity.

PROCEDURE

Samples for a biotransformation investigation are typically collected concomitant to mass balance and radiokinetic studies in animal and human employing radiolabeled test compound (Iyer et al. 2001, 2003; Lantz et al. 2003; Hayakawa et al. 2003; Huskey et al. 2004; Cui et al. 2004; Cook et al. 2003). Plasma prepared from blood, urine, and feces samples serve as a basis. Additional matrices (e.g., tissues and bile) might complete the picture. Before analysis, samples, possibly after pooling, are processed in most instances to enhance sensitivity and to separate matrix components interfering with the analytical procedure, e.g., proteins. Protein precipitation is normally applied to plasma followed by a concentration step if necessary. Sample processing is mandatory for feces and tissue homogenates and is typically done by extraction with mixtures of organic solvents like acetonitrile or methanol with buffer in different ratios followed by evaporation of the extracts. Urine can be analyzed directly without processing if sample concentration is not needed.

In addition to generation of metabolite profiles of the original samples, information on glucuronic acid conjugates or sulfates (Walle et al. 1983) present as phase II metabolites can be gained by enzymatic digestions of complete samples or isolated metabolite peaks.

Urine and feces homogenates might serve as a basis for structure elucidation of metabolites by LC-MS/MS directly or—if necessary—by more detailed NMR/MS investigation after isolation of the metabolites by preparative chromatography.

EVALUATION

Samples are analyzed by a suitable chromatographic system, typically HPLC with online radiodetection. Metabolite profiles in plasma and tissues are given as percent of radioactivity present in total. Profiles in urine, bile, and feces are given as percent of the dose administered.

MODIFICATION OF THE METHOD

Different analytical methodologies adapted to the particular test compound and its metabolites are used which have to be optimized case by case and cannot be generalized. Whereas high-performance liquid chromatography (HPLC) is a method of choice for many pharmaceuticals, also other techniques like gas chromatography (GC), e.g., for profiling of steroids (Holland et al. 1986), or capillary electrophoresis (CE) might play a role. In recent years, the application of microplate scintillation counter for 96-well plates (TopCount) revolutionized the practice in offline radiodetection to enhance sensitivity and speed in analyzing low radioactivity level samples as an alternative to online radiodetection or offline radiodetection using the classical approach of liquid scintillation counting (Nassar et al. 2004b; Kiffe et al. 2003; Boernsen et al. 2000). Accelerator mass spectrometry (AMS) might serve as an offline radiodetector for samples with low radioactivity content.

CRITICAL ASSESSMENT OF THE METHOD

Despite the elaborate effort necessary for using radioisotopes, mainly carbon-14, metabolic profiling studies still play a dominant role in this field. Only quantification on the basis of radiodetection gives a reliable profile of structurally unknown metabolites formed from a given drug within a complex endogenous matrix. A quantitative comparison of metabolites by means of LC-MS/MS is only possible if the respective metabolites are known and available for calibration.

Application of hyphenated techniques, in particular LC-MS/MS, in combination to radiodetection or as a sole device in analysis of studies employing nonlabeled test compounds gives rise to rapid structural information (Watt et al. 2003; Clarke et al. 2001). However, uncertain extraction yield of metabolites has to be considered. The dominating role of LC-MS/MS is not reached by LC-NMR coupling despite of advances in this technique (Dear et al. 2000b). Other techniques applied in this context comprise improvements of hyphenated MS techniques like capillary liquid chromatography (Sandvoss et al. 2004), or ion exchange liquid chromatography-MS for charged polar molecules (Dear et al. 2000a).

In most instances, classical approaches in isolation of metabolites followed by MS and NMR analyses are still necessary to obtain the definitive structural information. Complex structures of metabolites require often multiple NMR experiments in addition to an initial one-dimensional ^{1}H NMR experiment for final structure elucidation.

Techniques applying test compounds labeled with stable isotopes are applied as well (Browne et al. 1993). However, they have not found broad acceptance in substituting radioisotopes in this field due to their restrictions in quantification of unknown metabolites.

Of particular interest is the generation of metabolite profiles across species to assess the sufficient exposure of human metabolites in animal species used in toxicological studies. Alternatives to the classical approach of a series of radioactive animal and human studies are proposed based on nonradioactive analyses (Gao et al. 2010).

Accelerator mass spectrometry (AMS) offers the possibility to perform metabolite profiling concomitant to microdosing or microtracer studies in humans applying ultralow amounts of radioactivity (Smith 2011; Garner 2000; Garner et al. 2000; Combes et al. 2003). At least for a limited number of representative samples, AMS might serve as an expensive offline radiodetector for HPLC eluates as well.

EXAMPLE

Iyer et al. (2001) investigated the metabolism of [^{14}C] omapatrilat in humans with samples collected during a clinical study. Plasma samples were prepared from blood spiked with or without methyl acrylate to trap compound-free sulfhydryl groups, which was important for this particular compound. Samples were pooled over the 12 subjects enrolled in the study. Urine was pooled over time to give a 0–24 h pooled urine sample

representing 92% of the radioactivity excreted in urine and a 0–168 h sample. Feces were not analyzed.

For sample processing, pooled plasma samples (1 and 6 h, 2 mL) were mixed with acetonitrile (6 mL), vortexed vigorously, and centrifuged. The precipitates were again extracted with acetonitrile (2x), and the supernatants from previous extraction were combined. The pooled extracts were evaporated at room temperature under a stream of nitrogen, and the residues were reconstituted in HPLC mobile phase. A portion of the sample was used for radioactivity determination, and the remaining sample used for HPLC profiling.

Pooled 0- to 24-h and 0- to 168-h human urine samples were concentrated on an Oasis HLB 3.0-mL cartridge. The cartridge was loaded with pooled urine (3 mL) and washed sequentially with water containing 0.1% acetic acid (2 × 3 mL, pH 3.2) and methanol (2 × 3 mL). Liquid scintillation counting of the water and the methanol extracts showed quantitative recovery of radioactivity in the methanol fractions. The methanol extracts were combined, evaporated to dryness under a stream of nitrogen, and dissolved in HPLC mobile phase.

Selected urine samples were digested for cleavage of conjugates. For this, a solution of β-glucuronidase (0.2 mL, 2,104 U) in water was added to a solution of 0- to 24-h pooled human urine (1.0 mL) in 0.2 M sodium acetate buffer (1.0 mL, pH 4.8). The mixture was incubated at 37°C in a water bath for 24 h. In addition, control experiments were done in the absence of the enzyme (negative control), positive control in the presence of phenolphthalein glucuronide (1 mg), and incubation in the presence of the β−glucuronidase inhibitor 1,4-saccharolactone (10 mg). A 0.2 M glycine buffer (8.0 mL, pH 10.5) was added at the end of the incubation to the positive control. The amount of phenolphthalein generated was quantified against a phenolphthalein standard curve with a UV-visible spectrophotometer operating at 550 nm. All other samples were centrifuged for 5 min in a bench top microcentrifuge and stored at −20°C until further analysis.

Plasma and urine samples were profiled using a suitable HPLC system under specific conditions (gradient, column). Readout was done offline by fraction collection of the HPLC run followed by liquid scintillation counting. Biotransformation profiles were prepared by plotting the baseline corrected radioactivity against time after injection.

For metabolite isolation, 1.5 L of pooled urine was applied to a XAD-2 resin column first. The ethyl acetate extract obtained containing 85% of the radioactivity was applied upon evaporation to semi preparative HPLC on a Zorbax RX C18 column (9.4 × 250 mm, 5 μm) using gradient elution. Fractions obtained were further separated by isocratic elution on the semipreparative column. The metabolite fractions obtained were finally purified by preparative thin-layer chromatography. Liquid chromatography/mass spectrometry (LC/MS) and LC/MS-MS analysis was applied to the isolated metabolite fractions for structure characterization.

42.3 Perfused Organs

PURPOSE AND RATIONALE

In comparison to other in vitro systems for studying drug metabolism, metabolism studies with isolated organs allow a definitive conclusion about the contribution of a given organ to in vivo drug metabolism. Metabolism studies in perfused organs give the best correlation to the in vivo situation since all metabolic pathways and cofactors are available. In comparison to in vivo animal studies, experiments in isolated organs can be performed under precisely defined conditions such as composition of the perfusion media or perfusion rate. Since the liver is the most active organ for drug metabolism, liver perfusion studies are frequently used. Additionally, tissue preparation for perfusion studies in heart (e.g., Enser et al. 1967; Scheuer and Olson 1967), lung (e.g., Baciewicz et al. 1991; Kaneda et al. 2001), kidney (Nizet 1975; Newton and Hook 1981), brain (e.g., Thompson et al. 1968), and intestine (e.g., Pang et al. 1985; Cong et al. 2001) has been published.

Concentration of the drug and related metabolites is determined using appropriate analytical methods such as HPLC, LC-MS, or LC-MS/MS techniques. The use of a radiolabeled drug allows more easy and precise recognition of the drug and related metabolites.

PROCEDURE

It is described in Chap. 35, “Distribution - In Vivo - Perfused Organs”.

42.4 Organ Slices

PURPOSE AND RATIONALE

The slice technique was already introduced by Otto Wartburg in 1923 and commonly used in in vitro liver research until isolated hepatocytes and isolated perfused liver preparation were introduced and optimized (Krumdieck et al. 1980; Olinga et al. 1998). Previous methods of slicing using the Stadie-Riggs (Stadie and Riggs 1944), Vibratome (Smith et al. 1985), or hand-made slice technique (Forster 1948) suffered on a rapid preparation of thin tissue slices of uniform thickness and dimension under conditions that minimize trauma to the live tissue (Krumdieck et al. 1980).

Since the introduction of the Krumdieck slicer (Krumdieck et al. 1980) and a new incubation system for slices (Smith et al. 1985), tissue slices are commonly used in drug metabolism and toxicity studies.

PROCEDURE

Cylindrical piece of tissue of about 12 mm in diameter is placed into the Krumdieck microtome and cut by means of a sharp punch. Slices are released into circulating buffer. The slice thickness is set by the screw-adjustable rest and is usually between 160 and 640 µm. The variability of the slice weight increases with increasing slice thickness (Krumdieck et al. 1980). Afterward, the slices were placed on the inside walls of stainless steel roller-equipped steel mesh scintillation vials containing 2 mL Waymouth's 752/1 media supplemented with 10% fetal calf serum and gentamicin (84 µg/mL). Vials were capped with elastic rubber septa (300 µM) to allow gas exchange and placed in an incubator set at 37°C with constant aeration (O_2:CO_2 = 95:5). The vials were rotated at 10 rev/min and culture media replaced every 12 h (Smith et al. 1985). Incubation of NCE is done in media in comparison to a solvent control (Dogterom 1993).

EVALUATION

Thickness and viability of the slices (e.g., morphology, ATP content) are investigated in parallel. Metabolic capacity of various enzymes is ensured by positive and negative controls during the incubation procedure. Concentration of the drug and related metabolites is determined using appropriate analytical methods such as HPLC, LC-MS, or LC-MS/MS techniques. The use of a radiolabeled drug allows more easy and precise recognition of the drug and related metabolites.

MODIFICATION OF THE METHOD

Vandenbranden et al. (1998) used additional antibiotics to reduce bacterial impurities during long-term cultivation.

The slicing technique can be adapted to various organs and allows tissues specific comparison of metabolism and toxicity within animals and humans. Stefaniak et al. (1988) used the method for metabolism studies in lung. Therefore, lung trachea or bronchiole (rat/human) was cannulated, and lungs were instilled with 1.5% (w/v) low melting agarose solution containing 0.9% (w/v) NaCl at 37°C and allowed to gel on ice. Tissue cylinders with an 8-mm diameter were cut as described from Krumdieck et al. (1980). Ruegg et al. (1987) adapted the method to investigate cell-specific toxicity in kidney cells.

CRITICAL ASSESSMENT OF THE METHOD

The use of liver slices as an in vitro tool for drug metabolism has various advantages compared to isolated hepatocytes such as faster and easier preparation, the presence of different cell types, and the maintenance of an intact tissue architecture with cell-cell and cell-matrix interactions (except the first cell layers which are always damaged because of the slicing

procedure), so that even in very good slices, normally no more than approximately 80% of the cells are intact (De Graaf et al. 2002). In general, the complete cellular machinery is available. Since mostly all organs are applicable to the slice technology, organ-selective drug toxicity or the relative contribution of the organs to the total body clearance can be investigated.

Organ slices are applicable to long-term cultures; viability up to 72 h has been described for rat liver slices (Fisher et al. 1995). On the other hand, investigation of enzyme activity revealed changes in the metabolic capacity of phase I and phase II enzymes in long-term cultures (Vandenbranden et al. 1998). De Kanter and Koster (1995) established a general method for cryopreservation of slices. Postthaw viability, especially phase I and phase II biotransformation activity, maintained for at least 4 h (De Graaf et al. 2002). Generally, cryopreservation allows a more universal use of liver slices since the method becomes independent from the availability of tissue, especially for human tissue. In addition, using slices from the same donor simplifies a comparison of compounds in the early stage of drug discovery.

42.5 Primary Hepatocytes

PURPOSE AND RATIONALE

Isolated hepatocytes provide a convenient link between the complex architecture of the intact organ and subcellular fractions. The latter approach suffers from lack of relevance to the in vivo situation, while the former one, as close as possible to the liver in vivo, suffers from complex methodology and limited use for multiple compounds (Mandan et al. 2002; Gómez-Lechón et al. 2008).

Cryopreserved hepatocytes in suspension were successfully applied in short-term metabolism studies and as metabolizing system in mutagenicity assays (Hengstler et al. 2000b), providing qualitative metabolic information and quantitative pharmacokinetic parameters from key animal species and human at the early stage of drug discovery and drug development. Culturing hepatocytes in a sandwich configuration between collagen and Matrigel or on collagen alone have been studied and used in a broad variety of assays that requires prolong culturing such as clearance/metabolism studies, induction, inhibition, or hepatotoxicity studies (Hewitt et al. 2007).

PROCEDURE

Hepatocytes—either freshly prepared or cryopreserved—are commercially available or prepared in-house if intact liver can be accessed. Isolation of the animal hepatocytes follows after a two-step collagenase perfusion of the liver via the vena porta in situ (Seglen 1976) or via several blunt-end cannulae inserted into vessels available on the cut surface of

pieces of human liver obtained from resection. Liver cells are gently scraped out into suspension buffer and washed twice to three times by centrifugation to remove cell fragments and nonvital cells. Hepatocytes are used immediately or cryopreserved for further use according to published cryopreservation procedures (De Kanter and Koster 1995; Li 2007).

Isolation of hepatocytes according to the standard operation procedures mentioned below results generally in a viability of the hepatocytes ≥80%. Incubation with NCE is performed in various drug concentrations and incubation time point(s).

EVALUATION

Viability of the hepatocytes is usually determined by trypan blue exclusion rate. Viability over incubation time can be determined by LDH retention or albumin secretion (Gebhardt et al. 2003). For metabolism purposes, positive controls with well-known phase I and/or phase II metabolism are incubated in parallel to NCEs to assure metabolic capacity of the hepatocytes, e.g., ethoxyresorufin, ethoxycoumarin, testosterone for phase I metabolism, and 4-hydroxybiphenyl, 4-methylumbelliferone, 1-chloro-2,4-dinito-benzene, and 2-naphthol for phase II metabolism (Gebhardt et al. 2003). Concentration of the drug and related metabolites is determined using appropriate analytical methods such as HPLC, LC-MS, or LC-MS/MS techniques. The use of a radiolabeled drug in combination of LC/MS techniques allows an easier and precise recognition of the drug and related metabolites.

MODIFICATION OF THE METHOD

Since enzyme activities of hepatocytes in suspension decrease markedly with longer incubation time, hepatocytes in culture are required if longer incubation time is necessary, particularly phase II metabolism. To achieve longer incubation times, cultivation of freshly isolated or cryopreserved hepatocytes in culture on monolayer (Maslansky and Williams 1982; Wang et al. 2002; Pichard et al. 2006; Klieber et al. 2010), sandwich culture on variable matrices (e.g., Maurel (1996), Kern et al. (1997), Wang et al. (2002)), in coculture (Hengstler et al. 2000a, b; Gebhardt et al. 2003), or in bioreactors (perfusion culture system or 96 well bioreactor) (e.g., Bader et al. 1998; Wang et al. 2002; Gebhardt et al. 2003) are described. Immobilization of liver cells in alginate beats has facilitated commercialization of isolated hepatocytes (Guyomard et al. 1996; Rialland et al. 2000) but has not succeeded in a broad acceptance.

For elucidating the specific enzyme responsible for a certain metabolic step occurring in hepatocytes, specific inhibitors are useful. Selective or total inhibitors are used for cytochrome P450s in particular for CYP1A2, CYP2C9, CYP2D2, and CYP3A4 using furafylline, sulfaphenazole, quinidine, and ketoconazole and aminobenzotriazole (ABT) as total CYP inhibitor at low concentrations (1, 10, 3, 3, and 1,000 μM). Furafylline is a well-known suicide inhibitor which needs to be added prior to the incubation (Donato and Castell 2003; Newton et al. 1995; Rettie et al. 1995; Birkett et al. 1993). Also antibodies raised against specific enzymes are used for studying the involvement of these enzymes in the biotransformation. These are mainly in use for cytochrome P450s (e.g., Wang and Lu 1997) due to their commercial availability. An interesting advancement in the application of intact hepatocytes in the evaluation of metabolic stability is the incubation of the test article and hepatocytes in 100% human serum, therefore providing an experimental condition similar to humans in vivo (Li 2007). It has been reported that in vivo hepatic clearance can be predicted more accurately from data obtained with hepatocytes incubated in serum than from data obtained in the absence of serum using rat hepatocytes (Blanchard et al. 2004) and human hepatocytes (Blanchard et al. 2005). The combination of human hepatocytes and 100% human serum may represent a more physiologically relevant experimental model and eliminates the need to consider plasma protein binding and intracellular concentration for the prediction of in vivo metabolic clearance.

CRITICAL ASSESSMENT OF THE METHOD

Metabolism studies in hepatocytes might be a good compromise between perfused livers and subcellular fractions such as microsomes, since the complete cellular machinery is available. Isolation (and cultivation) of hepatocytes is still time- and lab-intensive and needs to be optimized for livers of every different animal species (De Graaf et al. 2002). Nevertheless, some pitfalls have to be taken in account:

A modulation in metabolic capacity and transport internalization of hepatocytes in suspension and in long-term cultures has been described (Hengstler et al. 2000a, b; Olinga et al. 1998). The loss of cofactors

such as NADPH are probably the reason for a stronger decrease of metabolic capacity of phase I and phase II metabolism in cryopreserved hepatocytes compared to fresh hepatocytes or liver homogenate (Hengstler et al. 2000b), whereas other groups suspect the absence of microcirculation for the downregulation of detoxification genes and loss of functional activity including a variety of P450 isoenzymes (Vinci et al. 2011). An increase of metabolism of cryopreserved hepatocytes of benzo[a]pyrene equally to freshly isolated hepatocytes was reported after Percoll centrifugation (Hengstler et al. 2000b). Hence, Percoll centrifugation is recommended before using cryopreserved hepatocytes in metabolism studies. Due to the variability of the enzyme activity with time, the maximum incubation time in suspension should be limited up to 4–8 h (Hengstler et al. 2000b; Olinga et al. 1998). Under specific culture conditions, hepatocytes retain their polarity (Swift et al. 2010).

Since fresh human liver samples are not available to many laboratories, cryopreserved hepatocytes from commercial sources are a good alternative. Various studies have shown that kinetic profiles are similar in cryopreserved and fresh hepatocytes, and CYP3A atypical kinetic phenomena are displayed in cryopreserved hepatocytes as well (Hewitt et al. 2007). Good prediction of in vitro clearance of 41 drugs by cryopreserved human hepatocytes was shown in 4 independent studies with drugs being CYP and UGT substrates (Browne et al. 1993; Hewitt et al. 2007). Pooled cryopreserved hepatocytes—similar as pooled microsomes—are available that reflects the “average donor” as well as cryopreserved hepatocytes from individuals from special subpopulations (e.g., donors with 2D6 and 2C9 polymorphic enzymes) which can be used for later screening approaches or detailed metabolism studies for regulatory documents. Since a couple of years, cryopreserved hepatocytes, which attach and form a confluent layer after cryopreservation which is used, e.g., for longer lasting induction studies are available from commercial sources as well (Pichard et al. 2006).

A direct comparison of drug clearances in freshly isolated rat hepatocyte suspensions and cultures revealed that the measured in vitro clearance for high-turnover compounds was lower for conventional monolayers compared to suspensions whereas conventional cultures gave a higher estimation for low turnover such as S-warfarin (Griffin and Houston 2005). Thus, hepatocytes in culture may be more suitable for predicting the Clint of low clearance compound (Blanchard et al. 2004).

As quality control, hepatocytes should be characterized using marker substrates for the major metabolizing enzymes in parallel to the investigations with new/unknown drugs.

EXAMPLE

42.5.1 Isolation of Human Hepatocytes

The isolation of human hepatocytes, previously reviewed (Li 2007), is described according to Hengstler et al. (2000b).
Preparation of buffer solutions

Suspension buffer

- 620 mL glucose solution (9 g/L D-glucose)
- 100 mL KH buffer (60 g/L NaCl, 1.75 g/L KCl, 1.6 g/L KH_2PO_4 adjusted to pH 7.6 with NaOH)
- 100 mL HEPES buffer (60 g/L HEPES adjusted to pH 7.6, without carbogen equilibration)
- 150 mL amino acid solution (0.27 g/L L-alanine, 0.14 g/L L-aspartic acid, 0.4 g/L L-asparagines, 0.27 g/L L-citrulline, 0.14 g/L L-cysteine, 1 g/L L-histidine, 1 g/L L-glutamic acid, 1 g/L L-glycin, 0.4 g/L L-isoleucine, 0.8 g/L L-leucine, 1.3 g/L L-lysine, 0.55 g/L L-methionine, 0.65 g/L L-ornithine, 0.55 g/L L-phenylalanine, 0.55 g/L L-proline, 0.65 g/L L-serine, 1.35 g/L L-threonine, 0.65 g/L L-tryptophan, 0.55 g/L L-tyrosine, 0.8 g/L L-valine. Dissolve the amino acids that cannot be dissolved at neutral pH by addition of 10 N NaOH and thereafter adjust pH to 7.6 by 37% HCL).
- 5 mL insulin solution (2 g/L insulin dissolved in 1 N NaOH, adjusted to pH 7.6 by 1 N HCl)
- 8 mL $CaCl_2$ solution (19 g/L $CaCL_2 \times 2H_2O$)
- 4 mL $MgSO_4$ (24.6 g/L $MgSO_4 \times 7H_2O$)
- 2 g BSA/L; dissolved in the mixture of the abovementioned solutions

Buffer A

- 498 mL washing buffer (8.3 g/L NaCl, 0.5 g/L KCl, 2.4 g/L HEPES, adjusted to pH 7.4 with 4 N NaOH)

- 2 mL EGTA solution (47.5 g EGTA/L; dissolved by addition of NaOH, adjusted to pH 7.6 by HCL)

Buffer B
- 498 mL washing buffer (8.3 g/L NaCl, 0.5 g/L KCl, 2.4 g/L HEPES, adjusted to pH 7.4 with 4 N NaOH) Collagenase buffer (Buffer C)
- (3.9 g/L NaCl, 0.5 g/L KCl, 2.4 g/L HEPES, 0.7 g/L $CaCl_2 \times 2\ H_2O$, adjusted to pH 7.2 with 4 N NaOH), prewarm to 37°C before use
- Dissolve 100 mg collagenase[1] in 200 mL of buffer C immediately before perfusion

Human liver samples, e.g., from liver resection or nontransplantable organs should be immediately transferred into ice-cold suspension buffer (resected tissue can be stored in ice-cold suspension buffer for at least 4 h). Liver samples of approximately 100 g should be cut off in such a way that they only present one cut surface. Perfuse with buffer A for 20 min at 37°C (3 drops/s). Perfusion should be performed by several blunt-end cannulae inserted into vessels of the cut surface. The number of the cannulae depends on the number of large vessels available on the cut surface. Perfuse with buffer B for additional 20 min at 37°C. Thereafter, perfuse with collagenase buffer for 30 min in a circulating way at 37°C. Transfer the tissue into a large Petri dish with suspension buffer; scrape liver cells gently out with spatula. Filter the liver cell suspension through gauze and centrifuge for 5 min at $50\times g$. Wash twice with suspension buffer, centrifuge again, and resuspend the final pellet in 30 mL suspension buffer. Determine trypan blue exclusion rate after a 1:1 dilution of the hepatocyte suspension with trypan blue solution (4 g/L trypan blue). A similar procedure is described for the isolation of rat hepatocytes (Hengstler et al. 2000b).

A standard operation procedure for the isolation of rat hepatocytes is published from Gebhardt et al. (2003).

42.5.2 Cryopreservation

The cryopreservation of hepatocytes is described according to Hengstler et al. (2000b).

Adjust hepatocytes to 3 Mio cell/mL in suspension buffer in an Erlenmeyer flask. Incubate for 30 min at 37°C during gentle shaking and carbogen equilibration. Determine the volume (original volume) and centrifuge the suspension for 5 min at $50\times g$ at 4°C. All further steps are performed at 4°C. Discard a volume equal to two-thirds of the original volume from the supernatant and resuspend the cell pellet in the remaining suspension buffer (one-third of the original volume) by shaking gently. Add ice-cold suspension buffer containing 12% (v/v) of DMSO to the cell suspension up to 50% of the original volume, resulting in a DMSO concentration of 4% and approximately 6 Mio/mL hepatocytes. After 5 min on ice, add suspension buffer containing 16% (v/v) of DMSO up to the original volume of the cell suspension, resulting in a DMSO concentration of 10% and 3 Mio/mL hepatocytes. After 5 min in ice, transfer the hepatocyte suspension to cold cryovials with 1.5 mL/vial. Start the freezing program within 5 min. The time period between the second addition of DMSO and initiation of the cryopreservation should not exceed 10 min. The freezing procedure should be performed as follows (can be performed by any computer-controlled freezing machine):

- Cooling in 10 min down to 0°C
- 8 min at 0°C
- In 4 min down to −8°C
- In 0.1 min down to −28°C
- In 2 min down to −33°C
- In 2 min up to −28°C
- In 16 min down to –60°C
- In 4 min down to −100°C

The temperature in the chamber and in one cryovial should be monitored by a chart record to control whether crystallization heat was sufficiently compensated. Transfer the cryovials into liquid nitrogen immediately after the freezing program has been finished.

42.5.3 Thawing

Thawing of hepatocytes is described according to Hengstler et al. (2000b).

Thaw the frozen hepatocytes quickly by gentle shaking in a 37°C water bath. The hepatocytes should thaw but not become warm. Transfer the hepatocyte suspension into an ice-cold Erlenmeyer flask immediately after

[1]Selection of an adequate batch of collagenase is the key critical step for successful isolation of human hepatocytes. Whereas the majority of all collagenases allow successful isolation of rat hepatocytes, selection of a good batch for human liver is more critical. Mostly, the collagenase concentration has to be optimized for an individual batch of collagenase.

thawing and dilute DMSO gradually by the addition of ice-cold not carbogen-equilibrated suspension buffer, 0.5-, 1-, 2-, and 3-fold of the volume of the thawed hepatocyte suspension. Suspension buffer should be added dropwise, and hepatocytes should be on ice for 3 min before the next dilution step takes place. After centrifugation at 50×*g* for 5 min at 4°C and resuspension in 10 mL suspension buffer, the hepatocytes can be purified by Percoll centrifugation.

42.5.4 Percoll Centrifugation

The Percoll centrifugation of hepatocytes is described according to Hengstler et al. (2000b).

Add the following into an ice-cold 50-mL Falcon tube:

- 10 mL of hepatocytes in suspension buffer (max. 20 Mio cells)
- 22 mL of suspension buffer (without carbogen equilibration)
- 18 mL Percoll solution

Mix gently and centrifuge at 250×*g* for 20 min at 4°C. The pellet contains intact hepatocytes. Resuspend the cell pellet in suspension buffer and wash twice in suspension buffer (centrifugation at 50×*g* for 5 min at 4°C).

42.5.5 Incubation of NCEs with Hepatocytes in Suspension

Transfer 1 mL of suspension buffer containing 1 Mio hepatocytes (fresh or cryopreserved) into glass vials (the diameter of the hepatocyte suspensions in the glass vial should be at least twice its height). Transfer the glass vials into a shaking water bath or in an air-conditioned rotating incubator (37°C, approximately 40 rpm). Add NCE in the appropriate concentration and incubate up to 2 h (Gebhardt et al. 2003), 4 h (Olinga et al. 1998), or 8 h (Hengstler et al. 2000b), respectively. Organic solvent should be minimized as much (≤0.2% of DMSO or ≤1% methanol or acetonitrile) as possible to circumvent inhibitory effects of the solvents (Busby et al. 1999). The reaction is stopped by adding ice-cold acetonitrile and a sharp centrifugation step afterward. The supernatant is directly applied to HPLC or LC/MS analytics for quantification of the remaining compound and related metabolites. Note, activities of xenobiotic-metabolizing enzymes decrease within the incubation time (Hengstler et al. 2000b).

42.6 Homogenates

PURPOSE AND RATIONALE

Metabolism studies in tissue homogenate are probably one of the oldest methods and already published as early as in 1930s (Potter and Elvehjem 1936). Drug metabolism studies in homogenate are usually used to investigate potential species-species difference early in the drug metabolism research in view of selecting the appropriate species for toxicology studies. In comparison to subcellular fractions, e.g., S9 or microsomes, tissue homogenate contains most of the enzymes and sometimes cofactors necessary for function.

PROCEDURE

The tissue is homogenized at low temperature in buffer media using a mincer or a mixer such as a Waring blender or Ultra-Turrax followed by grinding in a tissue grinder equipped with a motorized, serrated Teflon pestle to produce a uniform suspension, which is immediately used or deep-frozen until use. Incubation with NCE is performed in various drug and cofactor concentrations with different incubation time point(s) and extraction procedures.

EVALUATION

Concentration and structure characterization of the drug and related metabolites are usually determined with HPLC, LC/MS, or LC/MS/MS techniques. The use of a radiolabeled drug in combination with LC/MS techniques allows an easier and more precise recognition of the drug and related metabolites.

MODIFICATION OF THE METHOD

Numerous applications using liver homogenates are published with variable drug and cofactor concentration, incubation time points, and workup procedures.

Kinetic but also dynamic responses are investigated in various other tissue homogenates such as lung (e.g., Zhang et al. 1996; Manautou et al. 1992), kidney (e.g., Gergel et al. 1992; Knudsen et al. 1996), and brain (Yagen et al. 1991; Aragon et al. 1992; Hornykiewicz 2002).

CRITICAL ASSESSMENT OF THE METHOD

Due to interindividual variation of the animals and differences in the enzyme panel of each individual, a quantitative comparison of two different compounds seems to be difficult. The same is true for reproducibility. Determination of the protein concentration should be performed and kept constant in the incubation.

EXAMPLE

Tissues were immediately frozen on dry ice after sacrifice until use. The tissue is homogenized at 0–4°C in a fivefold volume (tissue wt/buffer vol) of 0.1 M potassium phosphate buffer containing 5% sucrose, pH 7.4 using a 15 s spin in a Waring blender followed by grinding in a tissue grinder equipped with a motorized, serrated Teflon pestle, to produce uniform suspension. The suspension was immediately used or deep-frozen until use (Norton et al. 1992). Incubation with NCE is usually performed in 1 mL suspension and at a drug concentration of 1 μM or 10 μM and glucose-6-phosphate dehydrogenase, glucose-6-phosphate, 0.4 mM TPN, and $MgCl_2$ (3.5 U/mL, 1 mM, 0.4 mM, and 10 mM, respectively) for 30 min at 37°C (Norton et al. 1992). Reaction was stopped by acidifying, and the drug and related metabolites are extracted with organic solvent.

According to Norton et al. (1992), the drug BW1370U87 was incubated in 1 mL suspension and at a drug concentration of 1 or 10 μM and glucose-6-phosphate dehydrogenase, glucose-6-phosphate, 0.4 mM TPN, and $MgCl_2$ (3.5 U/mL, 1 mM, 0.4 mM, and 10 mM, respectively) as cofactors for 30 min at 37°C. Reaction was stopped by adding 0.1 mL of 1 N HCl, and the drug and related metabolites are extracted with methyl-3°-butyl ether. Iley et al. (1999) demonstrated the biotransformation of various tertiary amidomethyl ester prodrugs at a concentration of 200 μM in 300 μL liver homogenate using the following cofactor concentrations: 6.25 mM glucose-6-phosphate, 1.25 mM $NADP^+$, 6 mM $MgCl_2$, and 2.5 U/mL glucose-6-phosphate dehydrogenase at 37°C. The reaction was stopped at various time points by adding ten volumes of acetonitrile (ice-cold) and centrifuged. 3-Methylcholanthrene-induced rat liver homogenates were used to study the metabolism of (+)-trans-benzo[a]pyrene at a concentration of 20 μM and various volumes of rat homogenate at 37°C (Sindhu and Kikkawa 1995). The incubation medium consisted of 50 mM Tris–HCl, pH 7.4 containing 150 mM KCl, 5 mM $MgCl_2$, and 0.5 mM NADPH in a total volume of 1 mL. After various time points, the reaction was stopped by adding H_2O-saturated ethyl acetate. For additional application, see also Zhang et al. (1996), Otsuka et al. (1996), Guillouzo (1995), Poon et al. (1995), or Lan et al. (1989).

42.7 9,000*g* Fractions

PURPOSE AND RATIONALE

Since liver is the most important organ for metabolism investigations, the procedures described here focus on liver 9,000*g* fractions exemplarily. 9,000*g* supernatants (S9 fractions) contain both microsomal and cytosolic proteins in a significant lower concentration compared to microsomes based on total protein content. 9,000*g* fractions are commercially available and more easily to prepare than microsomes since 9,000*g* centrifugation is an intermediate step in the preparation of microsomes (Fig. 42.3). In combination with the high storage stability, S9 fractions also give rise to high-throughput applications using S9 fractions. 9,000*g* liver fractions from a variety of species are available from various commercial suppliers.

PROCEDURE

The 9,000*g* fraction might either be of commercial source or prepared individually according to literature (Testa and Jenner 1976; Wrighton and Stevens 1992; Jones et al. 1998; Linget and du Vignaud 1999; Li 2004). The microsomal protein is reconstituted in phosphate buffer pH 7.4 for the incubation at a definite protein concentration (usually 2 mg/mL). The reaction requires reduced β-nicotinamide adenine dinucleotide phosphate (NADPH) as a cofactor for electron donation or an NADPH-generating system consisting of $NADP^+$, glucose-6-phosphate (G6P), and glucose-6-phosphate dehydrogenase (G6PD). Magnesium chloride is used for stimulation. Test compounds are added in solution using dimethyl sulfoxide most often as solubilizer (final concentration <0.5%). Incubation is carried out at 37°C over a definite incubation time (usually up to 1 or 2 h). To stop the reaction, ice-cold acetonitrile or aqueous trifluoroacetic acid containing a definite amount of internal standard is added in equal amounts or up to three volumes depending on the sensitivities of the analytics used. Subsequently, precipitated protein is removed by centrifugation or filtration.

EVALUATION

Samples obtained are analyzed by chromatographic means, e.g., LC-MS/MS and HLPC using UV detection or radiodetection, if radiolabeled substrates are applied. Metabolic stability as final result is given as percent remaining after incubation by dividing peak area of parent compound in the sample by the area of the time 0 sample and multiplication by 100. Also evaluation of parent and metabolites detected is possible for generating a metabolic profile, in particular using radiolabeled compounds. Determination of a full enzyme kinetics (V_{max}, K_m) is possible using various time points and concentrations.

MODIFICATION OF THE METHOD

Depending on the matter of interest in use of 9,000*g* fractions, modifications in use of cofactors are necessary. With respect to microsomal proteins, an NADPH-regenerating system has to be present to cover cytochrome P450-dependent metabolism, UDPGA as a cofactor for glucuronidation in combination with alamethicin as a modifier. Indeed these cofactors are in use in most instances as by Wittman et al. (2000, 2001), Rajanikanth et al. (2003), Epperly et al. (2001), Mae et al. (2000), and Hewawasam et al. (2002). Incubation time and substrate concentrations are highly subject to modifications.

Besides applications in studying the metabolism of compounds, the S9 liver fractions of human or aroclor-induced rat are in use as “metabolic activation” of the Ames test for mutagenicity of chemicals, in most instances without addition of phase II cofactors (Maron and Ames 1983). S9 fractions are also used for activation in reporter gene assays (Sumida et al. 2001).

CRITICAL ASSESSMENT OF THE METHOD

Due to the presence of both microsomal and cytosolic enzymes present in 9,000*g* fractions, these preparations offer the advantage of the most complete picture of biotransformation compared to other subcellular fractions (Plant 2004; Brandon et al. 2003) if cofactors in the appropriate concentrations are added. On the other hand, metabolically active enzyme concentration related to total protein concentration is significantly lower compared to microsomal preparations causing lower turnover of a substrate in general. Because of these characteristics, the 9,000*g* fraction is applied to a lesser extent in accelerated-throughput applications for screening of metabolic stability compared to microsomes.

The same considerations as for other subcellular systems with respect to solvent influences have to be considered in tests in 9,000*g* fractions because organic

solvents deactivate cytochrome P450 isozymes and other concentration dependently (Busby et al. 1999; Easterbrook et al. 2001). Solvent influences are lowest for methanol and acetonitrile (<10% inhibition at 0.3% solvent), but higher for ethanol and DMSO. Therefore, as low as possible solvent amounts should be used.

EXAMPLE

A standard procedure is taken from Mandagere et al. (2002): Substrates are incubated at 37°C and pH7.4. The reaction mixture consists of 4 mL of a 5 mg protein/mL suspension of liver S9 (equivalent to approximately 1 mg/mL of microsomal protein in the final reaction mixture), 4 mL of an NADPH-generating cofactor (6.4 mM glucose-6-phosphate, 1.1 mM NADP, and 1.3 mM MgSO4), 0.32 mL of glucose-6-phosphate dehydrogenase, 7.58 mL of 0.1 N K2HPO4, and 0.1 mL of substrate (6–8 μg/mL) such that the concentration was 10 μM in the final reaction volume of 16 mL. Aliquots are taken at 1, 3, 5, 10, 15, 30, and 60 min and snap frozen for deactivation of enzymes. Samples are stored at −70°C prior to analysis. Note that no cofactors for phase II metabolism were applied in the protocol.

42.8 Microsomes

PURPOSE AND RATIONALE

Liver microsomes are a widely used test system in studying metabolic stability and profiles both of large number of compounds in the early part of the value chain during drug discovery and development (Brandon et al. 2003). Commercial availability and the ease of preparation (Testa and Jenner 1976; Raucy and Laskor 1991; Wrighton and Stevens 1992; Jones et al. 1998; Linget and du Vignaud 1999; Li 2004) of the microsomal liver fraction in combination with the capability for automation of the incubation give rise to accelerated-throughput applications. High storage stability (Meier et al. 1983; Pearce et al. 1996; Yamazaki et al. 1997) also provides the possibility to generate a human liver bank (Von Bahr et al. 1980) in order to study the huge interindividual differences in enzyme activities especially in the human population. The latter is applied in the correlation analysis to study metabolic pathways in the context of enzyme typology (Beaune et al. 1986).

PROCEDURE

Procedures in use are numerous and depend strongly on the objective of the application. Microsomes from almost all organs of interest can be applied from commercial source or prepared separately from organ pieces. A comprehensive overview on preparation of subcellular fractions is shown in Fig. 42.3 (Ekins et al. 1999). The microsomal protein is reconstituted in phosphate buffer pH 7.4 for and used in incubation at a definitive protein concentration (usually up to 1 mg/mL). The reaction requires reduced β-nicotinamide adenine dinucleotide phosphate (NADPH) as a cofactor for electron donation or an NADPH-generating system consisting of glucose-6-phosphate (G6P) and glucose-6-phosphate dehydrogenase (G6PD). Magnesium chloride is used for stimulation. Test compounds are added in solution using dimethyl sulfoxide most often as solubilizer (up to 0.5% final concentration). Incubation is carried out at 37°C over a defined incubation time (usually up to 1 h). To stop the reaction, ice-cold acetonitrile or aqueous trifluoroacetic acid containing a definitive amount of internal standard is added in equal amounts or higher, depending on the sensitivity of the analytics used. Subsequently, precipitated protein is removed by centrifugation or filtration.

EVALUATION

Samples obtained are analyzed by chromatographic means, e.g., LC-MS/MS and HLPC using UV detection or radiodetection, if radiolabeled substrates are applied. Metabolic stability as final result is given as percent remaining after incubation by dividing peak area of parent compound in the sample by the area of the time 0 sample and multiplication by 100. Also evaluation of parent and metabolites detected is possible for generating a metabolic profile, in particular using radiolabeled compounds. Determination of full enzyme kinetics (V_{max}, K_m) is possible using various time points and drug concentrations.

MODIFICATION OF THE METHOD

Numerous modifications are in place at each lab regarding incubation conditions like substrate and protein concentration, incubation time, cofactor use and concentration, sequence of the different pipetting steps, etc. (e.g., Kling et al. 2003; Mitsuya et al. 2000; Diana et al. 1995). These modifications depend on the purpose of the method, e.g., as a high-throughput screen in early drug discovery or as a tool to characterize a development compound in vitro for regulatory files. For screening purposes, a high and low turnover compound should be added as quality control in each run. Besides these modifications on the biological part of the assay, specific protocols on pipetting robots and conditions used for evaluation by LC-MS/MS also in combination with the instrumental equipment available are applied which are typically not published. Besides LC-MS/MS, also LC-UV (Shearer et al. 2002; Stratford et al. 1999) and capillary electrophoresis (Clohs et al. 2002) are described.

Typically the reaction is started by addition of NADPH (Plobeck et al. 2000; Stratford et al. 1999) or the NADPH-regenerating system (Bloomer et al. 2001; Wei et al. 2000).

MacKenzie et al. (2002) added 5 μM $MnCl_2$ in addition to $MgCl_2$.

Linget and du Vignaud (1999) incubated in the presence of 3% bovine serum albumin to assist dissolution of compounds with poor solubility.

For extrapolation of in vitro metabolism data to in vivo, more detailed in vitro investigations are necessary as a first step. In this either enzyme kinetics is determined to calculate K_m and V_{max} and finally the intrinsic metabolic clearance as the quotient of both (Houston 1994a, b; Iwatsubo et al. 1996). Alternatively, the in vitro $t_{1/2}$ method is used (Obach et al. 1997; Obach and Reed-Hagem 2002; Jones and Houston 2004).

In order to cover glucuronidation reactions in incubations in microsomal fractions, several modifications have been applied in order to optimize conditions. These comprise longer incubation times than necessary for oxidative reactions by cytochrome P450s, and use of modifiers, both to overcome the latency in activity due to the diffusional barriers of the endoplasmatic reticulum (Coughtrie and Fisher 2003; Csala et al. 2004). Modifiers used are detergents or the pore-forming peptide alamethicin (Fisher et al. 2000). Also disruption of cells by sonication is applied (Ethell et al. 1998).

For elucidating the specific enzyme responsible for a certain metabolic step occurring in liver microsomes, the addition of enzyme-specific inhibitors is useful. If suicide inhibitors are used, preincubation of the inhibitor is needed. Selective or total inhibitors are used for cytochrome P450s in particular (Donato and Castell 2003; Newton et al. 1995; Rettie et al. 1995; Birkett et al. 1993). Also antibodies raised against

specific enzymes are used for studying the involvement of these enzymes in the biotransformation. These are mainly in use for cytochrome P450s (e.g., Wang and Lu 1997) due to their commercial availability.

CRITICAL ASSESSMENT OF THE METHOD

The high batch-to-batch variability of enzyme activities affords usage of pooled microsomes if metabolic stability has to be screened. Individual donors are used only for specific applications like correlation analysis. Since no cytosolic enzymes are present, the screening in liver microsomes might sometimes lead to misleading results if compared to in vivo data. On the other hand, the enzyme activities are higher in microsomal preparations than in 9,000*g* fractions giving rise to higher metabolic turnover (Brandon et al. 2003). However, this might lead also to overestimation of metabolic instability in microsomes compared to systems like hepatocytes or liver slices (Sidelmann et al. 1996).

The same considerations as for other subcellular systems with respect to solvent influences have to be considered in tests in 9,000*g* fractions because organic solvents deactivate cytochrome P450 isozymes and other concentration dependently (Busby et al. 1999; Easterbrook et al. 2001). Solvent influences are lowest for methanol and acetonitrile ($<10\%$ inhibition at 0.3% solvent), but higher for ethanol and DMSO. Therefore, as low as possible solvent amounts should be used. Published applications of microsomal stability tests use DMSO amounts of up to 1% which clearly can lead to enzyme-specific inhibition.

EXAMPLES

42.8.1 Example 1: High-Throughput Application for Metabolic Stability Tests

Di et al. (2003) described in detail an automated application on a Packard Multiprobe robot for high-throughput screening. The following final concentrations are applied:

1.3 mM NADPH

3.3 mM glucose-6-phosphate

3.3 mM $MgCl_2$
0.4 U/mL glucose-6-phosphate dehydrogenase
1 mM EDTA
88 mM phosphate buffer, pH 7.4
0.5 mg/mL microsomal protein
1 μM test compound
0.2% DMSO

The incubation is performed in 96 multititer plates for 0 and 5 min. The pipetting steps for the 5-min incubation plate are:

1. 990 μL of dilution buffer was added to each well of the 2-mL deep well dilution plate.
2. 10 μL of sample stock (0.5 mM) was added to the corresponding well of the dilution plate and mixed by aspiration/dispensation three times at high speed to form the diluted sample.
3. 100 μL of NADPH cofactor (10.938 mL of phosphate buffer, 1.609 mL of regenerating solution A, and 0.322 mL of solution B) was added to each well of the incubation plate.
4. 50 μL of each diluted sample was added to the 1-mL deep well incubation plate in duplicate and warmed at 37°C for 10 min.
5. 100 μL of the prewarmed microsomes (see previous section) was added to each well of the incubation plate.
6. The plate was incubated off the robot at 37°C, 70 rpm for 5 min on a shaker (Armalab, Bethesda, MD).
7. At the end of the incubation, the plate was immediately returned to the Packard robot, and 500 μL of cold acetonitrile was added to each well. The plate was gently mixed on a vortexer (VWR, So. Plainfield, NJ).

Subsequently, precipitated protein is removed by centrifugation.

The supernatants obtained are analyzed by LC-MS/MS with compound-specific methods.

A general generic LC comprises of application of a trapping cartridge to improve efficiency and peak shape and subsequent elution of the trapped components with a high amount of organic modifier. The following analytical conditions are used:

Column: Keystone Aquasil C18 10 × 2.1 mm, 5 μm, guard cartridge
Mobile phase: Loading = 0.1% formic acid/water, elution = 0.1% formic acid (95% acetonitrile/water)
Flow rate: optimization = 0.3 mL/min, 0.8 min, loading = 3.0 mL/min, 5 s, flash/analysis = 1.0 mL/min, 0.5 min
Gradient: isocratic
Injection volume: 20 μL
Detection: electrospray (positive or negative mode), multiple reaction monitoring

A backup generic LC method is in place for compounds failed by method 1 using the conditions as follows:

Column: Keystone Aquasil C18 50 × 2.1 mm, 5 μm, column
Mobile phase: A = 0.1% formic acid/water, B = 0.1% formic acid/acetonitrile
Flow rate: 0.8 mL/min
Gradient: 0.1 min/10%B, 2.5 min/90%B, 4.0 min/90% B, 4.1 min/10%B, 5.5 min/10%B
Injection volume: 20 μL
Detection: atmospheric pressure chemical ionization (positive or negative mode), selected ion mode

Final results are given as percent remaining after incubation by dividing peak area of parent compound in the 5-min sample by the peak area of the time 0-min sample, multiplied by 100.

42.8.2 Example 2: Enzyme Mapping Studies by Use of P450 Isozyme Selective Inhibitors

An example for applying specific inhibitors for cytochrome P450 isozymes in incubations with human liver microsomes is given by Wójcikowskia et al. (2004). Objective of the study was to elucidate the enzymes involved in the metabolism of perazine.

Human liver microsomes from three patients were used to optimize the conditions of perazine metabolism. On the basis of the obtained results, perazine metabolism in liver microsomes was studied in respect of the linear dependence of product formation on the time and concentrations of protein and substrate. Microsomal protein, 500 μg, was resuspended in 500 μL of 20 mM Tris/HCl buffer (pH = 7.4). For inhibition studies, 25 μM perazine was chosen as a therapeutic concentration in the liver, which did not saturate the enzyme. Perazine was incubated with liver microsomes and the specific CYP inhibitors: 2 μM a-naphthoflavone (a CYP1A2 inhibitor), 10 μM sulfaphenazole (a CYP2C9 inhibitor), 5 μM ticlopidine (a CYP2C19 inhibitor), 10 μM quinidine (a CYP2D6 inhibitor), 200 μM DDC (a CYP2A6 + CYP2E1 inhibitor), and 2 μM ketoconazole (a CYP3A4 inhibitor). After 3-min preincubation at 37°C, the reaction was initiated by adding NADPH to a final concentration of 1 mM. After 15-min incubation, the reaction

was stopped by adding 200 μL of methanol. Perazine and its metabolites were analyzed by HPLC. The reduction of formation of the two main metabolites formed by *N*-demethylation and sulfoxidation was determined in comparison to control incubations without inhibitor.

42.9 Cytosol

PURPOSE AND RATIONALE

Since liver is the most important organ for metabolism investigations, the procedures described here focus on liver cytosol exemplarily. Liver cytosol fraction contains soluble phase I and phase II enzymes which play an important role in drug metabolism (Brandon et al. 2003). These are alcohol and aldehyde dehydrogenases, epoxide hydrolases, sulfotransferases, glutathione *S*-transferase, *N*-acetyl transferases, and methyl transferases. Therefore, in cytosolic preparations, these biotransformation steps can be studied. Cytosolic fractions are commercially available or easy to prepare, alternatively.

PROCEDURE

In a typical procedure to study sulfation reactions (Tabrett and Coughtrie 2003), the reaction mixtures consist of a 6.25 mM potassium phosphate buffer (pH 7.4), containing 60 μM adenosine 3′-phosphate 5′-phosphosulfate (PAPS) as a cofactor, 75 μg liver cytosolic protein, and 0.125–100 μM substrate (4-nitrophenol in the example cited here). Reaction is started by the addition of PAPS and incubated for 10 min at 37°C. PAPS not utilized in the reaction is precipitated with 200 μL 0.1 M barium acetate, 200 μL 0.1 M barium hydroxide, and 200 μL 0.1 M zinc sulfate and centrifuged for 5 min at 14,000*g*.

EVALUATION

Samples obtained are analyzed by chromatographic means, e.g., LC-MS/MS and HLPC using UV detection or radiodetection, if radiolabeled substrates are applied. Metabolic stability as final result is given as percent remaining after incubation by dividing peak area of parent compound in the sample by the area of the time 0 sample and multiplication by 100. Also evaluation of parent and metabolites detected is possible for generating a metabolic profile, in particular using radiolabeled compounds. Determination of a full enzyme kinetics (V_{max}, K_m) is possible using various time points and concentrations.

MODIFICATION OF THE METHOD

Conditions for cytosolic incubations depend on the aim of the assay, e.g., to cover specific enzymatic activity present in the cytosol. For this purpose, it is essential to fortify the incubation medium with the specific cofactor for the reaction—if needed (Ekins et al. 1999). β-Nicotinamide adenine dinucleotide (NAD) is needed for alcohol and aldehyde dehydrogenases, flavin adenine dinucleotide (FAD) for polyamine oxidase, and β-nicotinamide adenine dinucleotide phosphate (NADPH) for dihydropyrimidine dehydrogenase. Phase II reactions depend on PAPS (sulfotransferases), glutathione (glutathione *S*-transferases, Raney et al. 1992; Slone et al. 1995), acetyl-coenzyme A (*N*-acetyltransferases), or *S*-adenosylmethionine (methyltransferases). NADPH as a cofactor has to be added if cytosolic reductases are the aim of interest (Inaba and Kovacs 1989).

Obach et al. (2004) set up a method for inhibition studies in cytosol using phthalazine as a substrate of aldehyde oxidase. In this system, 0.05 mg protein/mL was used in 25 mM potassium phosphate buffer pH7.4 containing 0.1 mM ethylenediaminetetraacetic acid. Incubation is terminated after 2.5 min.

Chen et al. (1999, 2003) used cytosol prepared from various sections of the human intestine to study the occurrence and distribution of sulfotransferases in the gastrointestinal tract. They fortified the cytosol with PAPS. They utilized the sulfuryl group transfer from p-nitrophenol sulfate to PAPS to generate PAPS for measurement of the phenol sulfotransferase activity by measurement of the colored product p-nitrophenol. Cytosolic incubation were stopped by addition of Tris buffer, pH 8.7.

Antibodies against SULT can be incorporated into the assay (Lewis et al. 2000; Thomas et al. 2003).

CRITICAL ASSESSMENT OF THE METHOD

The conduct of stability/profiling studies in liver cytosol is most often fine-tuned to the specific biotransformation reaction which is intended to be studied (Favetta et al. 2000; Frandsen and Alexander 2000; Long et al. 2001). A generalized procedure, e.g., with fortification of the cytosol with all relevant cofactors to cover the entire cytosolic enzyme activities, is uncommon. This might also be due to the fact that utilization of cytosol as a screening tool for metabolic stability is rather rare (Linget and du Vignaud 1999) and may only come into consideration if an in vitro-in vivo correlation cannot be established on the basis of microsomal tests. On the other

hand, the enzyme activities of NAT, SULT, and GST are higher in cytosol preparations than in 9,000*g* fractions, giving rise to better cover the metabolites derived by these routes (Brandon et al. 2003).

EXAMPLE

In an automated assay developed by Linget and du Vignaud (1999), incubations were performed using 2.5 μM substrate and cytosolic protein concentrations between 0.26 and 2.6 mg/mL. Incubations were done on a 215 Gilson liquid handler. The assay was set up for the screening of glutathione adducts. Therefore, 1,2 epoxy-3-(*p*-nitrophenoxy) propane was used as a model substrate, and 1 mM glutathione was added. Substrate was pipetted as a solution in 0.1 M Tris HCL buffer containing 5 mM of magnesium chloride and 3% bovine serum albumin. The BSA was added to assist dissolution of compounds with poor solubility. Incubations are done on a vibrating device. Samples are taken after incubation times of 0, 1, 2, 3, 4, and 5 min. At each of these time points, an aliquot of the incubation mixture was transferred from the incubation tube into a well in a 96 deep well plate containing an equal volume of acetonitrile for quenching by protein precipitation followed by centrifugation of the plates. Supernatants were analyzed by HPLC for metabolic screening. Half-life and rate were determined for intra- and interassay variability showing standard deviations of less than 5%.

42.10 Recombinant Enzymes

PURPOSE AND RATIONALE

Recombinant enzymes are used to elucidate the enzymes involved in certain biotransformation steps and to determine the relative contribution if more than one enzyme is involved (Rodrigues 1999; Friedberg et al. 1999; Brandon et al. 2003; Donato et al. 2003). This is particularly of importance for metabolic steps which are catalyzed by polymorphic enzymes. In combination with correlation analyses from data obtained with individual human liver microsomes and inhibition experiments in human hepatocytes and/or liver microsomes employing either specific chemical inhibitors or

antibodies, a solid statement on the enzymes involved in the metabolism of a drug can be obtained in many instances.

PROCEDURE

Experimental conditions are similar to those applied in human liver microsomal incubations. In case of human P450 isozymes, microsomal protein is derived from CYP-transfected insect cells (Supersomes^{TM}, Baculosomes^{TM}) or bacteria (Bactosomes^{TM}). The microsomal protein is reconstituted in phosphate buffer pH 7.4 for the incubation. The reaction requires reduced β-nicotinamide adenine dinucleotide phosphate (NADPH) as a cofactor for electron donation or an NADPH-generating system consisting of glucose-6-phosphate (G6P) and glucose-6-phosphate dehydrogenase (G6PD). Magnesium chloride is used for stimulation. Test compounds are added in solution using dimethyl sulfoxide most often as solubilizer in as low as possible amounts. Incubation is carried out at 37°C over incubation time of up to about 1 h. To stop the reaction, ice-cold acetonitrile or aqueous trifluoroacetic acid containing a definite amount of internal standard is added in equal amounts or higher depending on the sensitivity of the analytics used. Subsequently, precipitated protein is removed by centrifugation or filtration.

EVALUATION

Samples obtained are analyzed by chromatographic means, e.g., LC-MS/MS and HLPC using UV detection or radiodetection, if radiolabeled substrates are applied. Metabolic stability as final result is given as percent remaining after incubation by dividing peak area of parent compound in the sample by the area of the time 0 sample and multiplication by 100. Also evaluation of parent and metabolites detected is possible for generating a metabolic profile, in particular using radiolabeled compounds. Determination of a full enzyme kinetics (V_{max}, K_m) is possible using various time points and concentrations.

MODIFICATION OF THE METHOD

Commercially available (BD Gentest, Invitrogen, Cypex) are a wide variety of cytochrome P450 isozymes including allelic variants expressed in insect or mammalian cells. They comprise of uridine diphosphoglucuronosyl transferases (UGTs), flavin monooxygenases (FMOs), monoamine oxidases (MAOs), microsomal epoxide hydrolases, arylamine N-acetyltransferases (NATs), glutathione transferases (GSTs), and sulfotransferases (SULTs). According to the isozyme to be studied, specific cofactors have to be incorporated: an NADPH-regenerating system for P450 isozymes and FMOs, uridine diphosphoglucuronic acid (UDPGA) for UGTs in combination with alamethicin as a modifier to assist membrane transport (Ethell et al. 2003; Kuehl and Murphy 2003), acetyl-coenzyme A for the cytosolic *N*-acetyl transferases, glutathione for GSTs, and PAPS for SULTs. If radiolabeled cofactors are available ([^{3}H]GST, [^{14}C]UDPGA), their use facilitates in some instances the detection of the metabolites formed even from nonlabeled substrates.

CRITICAL ASSESSMENT OF THE METHOD

Besides expression in insect cells and bacteria (*Escherichia coli*), a variety of other expression systems are used like mammalian cells, V79 hamster cells, and systems in yeast (Friedberg et al. 1999 and references cited therein). High expression level and/or high yields in producing cells are achieved in baculovirus and *E. coli*. Therefore, these systems are nowadays in broad application in the industrial environment, also because of their commercial availability.

Supersomes are available containing cDNA-expressed cytochrome b5 or not. Since insect cell microsomes do not contain significant amounts of cytochrome b5, the incorporation of this enzyme increases the respective cytochrome P450 activity.

The availability of allelic variants gives rise to genotyping studies with recombinant enzymes (Coller et al. 2002).

Organic solvents deactivate cytochrome P450 isozymes and other concentration dependently (Busby et al. 1999). Moreover, this effect is different between the isoforms and depends also on the solvent used. Solvent influences are lowest for methanol and acetonitrile (<10% inhibition at 0.3% solvent), but higher for ethanol and DMSO. Therefore, as low as possible solvent amounts should be used.

EXAMPLE

42.10.1 Example 1

The example for applying cDNA-expressed P450 isozymes is given by Wójcikowskia et al. (2004). Objective of the study was to elucidate the enzymes involved in the metabolism of perazine.

Microsomes from baculovirus-infected insect cells expressing CYP1A1, CYP1A2, CYP2A6, CYP2B6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4 (Supersomes™) were obtained from Gentest. All the Supersomes™ were coexpressed with human P450 reductase.

CYP2E1 was additionally coexpressed with the human cytochrome b-5. Microsomal protein, 500 µg, was resuspended in 500 µL of 20 mM Tris/HCl buffer (pH = 7.4). To study perazine metabolism in Supersomes™, the incubations were carried out at the neuroleptic concentration of 750 µM (3 K_m) allowing to achieve the velocity of reaction of about V_{max} to show the maximum ability of cDNA-expressed enzyme to metabolize perazine. After 3-min preincubation at 37°C, the reaction was initiated by adding NADPH to a final concentration of 0.1 mM. After 2 h incubation, the reaction was stopped by adding 200 µL of methanol. Perazine and its metabolites were analyzed by HPLC.

42.10.2 Example 2

A fully automated assay for the determination of the intrinsic metabolic clearance in cytochrome P450 isozymes has been developed by McGinnity et al. (2000) using the major drug-metabolizing human hepatic cytochrome P450s (CYP1A2, -2C9, -2C19, -2D6, and -3A4) coexpressed functionally in *E. coli* with human NADPH-P450 reductase, to predict the CYP isoform(s) involved in the oxidative metabolism of NCEs.

CYP CL_{int} determination assays were performed by a robotic sample processor (RSP) (Genesis RSP 150; Tecan, Reading, UK). The primary stock of all probe substrates was prepared manually in dimethyl sulfoxide or acetonitrile at 100-fold final incubation concentration. The final concentration of organic solvent in the incubation was 1% v/v. At this concentration, dimethyl sulfoxide has been shown to reduce the activities of CYP2C9/19. All substrates were incubated at 3 µM except tolbutamide (CL_{int} calculated by determining V_{max} and K_m), ibuprofen (10 µM), and testosterone (10 µM). The RSP was programmed to add chilled quenching solvent (100 µL of acetonitrile) to 96-well refrigerated blocks, and compound stocks were then prediluted in 100 mM potassium phosphate buffer, pH 7.4. *E. coli* membranes and microsomes prepared from baculovirus coexpressing individual CYPs and NADPH reductase were added to incubation tubes (100 pmol of CYP/mL final concentration)

located in a 96-well heated block (37°C). An aliquot was removed to produce a 0-min time point, and the assay was initiated via addition of NADPH (1 mM final concentration). Aliquots (50 μL) were removed at 5, 10, 15, and 20 min and quenched in acetonitrile, frozen for 1 h at −20°C, and afterward centrifuged at 3,500 rpm for 20 min. The supernatants were removed and transferred into HPLC vials using the RSP. Test compounds used for the validation of the method (diltiazem, testosterone, dextromethorphan, propranolol, metoprolol, diazepam, tolbutamide, ibuprofen, verapamil, omeprazole) were analyzed by HPLC under compound-specific conditions.

42.11 Blood, Plasma, and Serum

PURPOSE AND RATIONALE

Mainly due to esterase activities, many drugs reveal degradation in blood (Williams 1987). In some instances, namely, if a prodrug concept (Huryn et al. 2004) is applied, e.g., for enhancing the absorption of a drug, cleavage of the ester prodrug in blood is intended for liberation of the pharmacologically active compound. Therefore, stability studies in blood are important. In most instances, these studies are performed in plasma or serum derived from human and/or animal blood. However, also red blood cells are accountable for metabolic activity.

PROCEDURE

In a typical procedure, the drug to be investigated is spiked to serum or plasma in a concentration of 25 μM and subsequently incubated at 37°C over a time of up to several hours (typically 5 min to 1 h). After addition of acetonitrile, denatured proteins are removed, and the supernatant is analyzed appropriately.

EVALUATION

Samples obtained are analyzed by chromatographic means, e.g., LC-MS/MS and HLPC using UV detection or radiodetection, if radiolabeled substrates are applied. Metabolic stability as final result is given as percent remaining after incubation by dividing peak area of parent compound in the sample by the area of the time 0 sample and multiplication by 100. Also evaluation of parent and metabolites detected is possible for generating a metabolic profile, in particular using radiolabeled compounds.

MODIFICATION OF THE METHOD

It can be appropriate to coincubate the compound of interest in the presence of inhibitors of serum esterases, e.g., sodium fluoride, physostigmin, or ecothiophate iodide (Chien and Tang-Lieu 1990; Quon et al. 1993). In case of carboxy- or aminopeptidase cleavage of peptides, specific peptidase inhibitors like amastatin, bestatin, phenylmethylsulfonyl fluoride, 1,10-phenanthroline, or ethylenediaminetetraacetic acid (EDTA) are useful (Lee and Stavchansky 1995).

An esterase-like activity of human serum albumin (HSA) might also contribute to the serum instability of esters which can be studied in buffer preparations containing albumin (Ohta et al. 1987).

Quon et al. (1985) investigated the stability of esmolol in blood, plasma, red blood cells, and purified enzymes (human serum pseudocholinesterase, human and dog serum albumin, acetyl choline esterase, carbonic anhydrases A and B, and human hemoglobin). Udata et al. (1999) studied the hydrolysis of propranolol ester prodrugs in purified acetylcholine esterase.

Some authors reported the use of serum or plasma diluted to 80% with buffer or less instead of the native matrix (Di-Stefano et al. 2001; Mahfouz et al. 1999; Scriba 1993).

CRITICAL ASSESSMENT OF THE METHOD

In general, serum as well as plasma reflects the enzymatic status in blood in a similar manner. However, it may become relevant that the coagulation cascade is suppressed during preparation of plasma by addition of citrate, heparin, or EDTA, whereas in serum, those enzymes are present in nonphysiological concentrations. Since these enzymes, e.g., thrombin, reveal proteolytic activity (Lafleur et al. 2001), this has to be considered if studying the stability of peptides.

Stability tests in plasma and serum are fixed component in the validation procedures of bioanalytical assays (see also Chap. II.P of this book: Chaps. 31 “Bioanalytical Assays LC-MS/MS”, 32 “Bioanalytical Assays:RIA/EIA”, and 33 “Bioanalytical Assays - Toxicokinetics”).

Besides modifications of time and concentrations, incubations in serum or plasma appear to be rather simple and reliable in predicting the in vivo relevance of the in vitro data.

EXAMPLE

An example for an automated stability test in plasma is described by Linget and du Vignaud (1999). Incubations are performed on a 215 Gilson liquid handler. Incubation was done at substrate concentrations of 50 μM on 96 deep well plates. Each incubation tube contained 375 μL of a 200 μM test compound solution (in 0.1 M Tris buffer with 3% BSA, added to assist dissolution of compounds with poor solubility) and 1125 μL of plasma. Samples are taken after incubation times of 0, 1, 2, 3, 4, and 5 min. At each of these time points, an aliquot of the incubation mixture was transferred from the incubation tube into a well in a 96 deep well plate containing an equal volume of acetonitrile for quenching by protein precipitation followed by centrifugation of the plates. Supernatants were analyzed by HPLC for metabolic screening.

43.1 Pharmacogenomics of Drug Transporters

43.1.1 Introduction

The role of membrane transporters for the pharmacokinetic (PK) and pharmacodynamic (PD) properties of a drug is becoming evident in many aspects. Membrane transporters are major determinants for the absorption, distribution, and elimination of many drugs or at least of their more hydrophilic metabolites. Thereby, the overall effect of transporters is thoughtlessly underestimated, if only the systemic concentration of a drug is monitored clinically. The role of drug transporters on cellular and tissue distribution, especially with regard to the brain, the heart, the liver, the kidney, and other peripheral tissues seems to be of much higher importance. Unfortunately, the clinical investigation of tissue distribution phenomena requires the development of new techniques like PET (positron emission tomography), but already today, there is a clinical example of ^{11}C-verapamil crossing the blood-brain barrier in the presence of a strong P-gp inhibitor (Eyal et al. 2010, pp. 579–585). Another impressive example is a significant and growing body of data showing a correlation between long-term response to imatinib chemotherapy in CML patients with functional OCT1 activity in the cancer cells (Engler et al. 2011, pp. 608–611) (imatinib is described as substrate of OCT1). More examples like this, illustrating the importance of transporters for cellular or tissue exposure, will be experienced in the near future with the development of PET-labeled transporter probe substrates and approaches of personalized medicine. The understanding of the role of pharmacogenetics in drug metabolism expanded greatly in the 1990s. This is mainly

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_47, © Springer-Verlag Berlin Heidelberg 2013

due to technological improvements in gene scanning and gene variant identification. The number of variant alleles identified for genes coding for drug metabolizing enzymes (DMEs) considerably increased in the early 2000s, and continues to increase. The clinical consequences – or at least genotyping-phenotyping relationships – of DME polymorphisms have not been demonstrated for all variants. Only those DME allele variants will be mentioned for which significant changes in enzyme activity have been found using probe drugs.

Two large superfamilies, the SLC (solute carrier) family and the ABC (ATP-binding cassette) family, have been classified. Presently, 378 different members belong to the SLC family classified in 51 subfamilies (http://www.bioparadigms.org). Most of the SLC members are uptake transporters mediating the transport of nutrients, vitamins, and other endo- or xenobiotics into the cell. The ABC transporter family consists of 49 members divided into 7 subfamilies (Dean et al. 2001, pp. 1156–1166). All ABC transporters share a conserved catalytic domain for ATP hydrolysis and couple the unidirectional efflux of a substrate to the hydrolysis of ATP. By this energy-dependent efflux mechanism, the ABC transporter can protect the cell from toxic compounds. For this reason, ABC transporters are highly discussed as one resistance mechanism of cancer cells to chemotherapeutics. From these, altogether 427 transporter proteins seven and nine transporters are selected by the ITC consortium White Paper (including FDA representatives) (Giacomini et al. 2010, pp. 215–236) and the EMA drug-drug interaction draft guidance (April 2010), respectively, as most relevant in the drug development process today. OATP1B1, OATP1B3, OAT1, OAT3, and OCT2 are uptake transporters from the liver and the kidney, identified by both groups, while the biliary uptake transporter OCT1 is requested by the EMA only. In addition to the well-established efflux transporters P-gp (ABCB1) and BCRP (ABCG2), the EMA has identified BSEP as a source of clinical pharmacodynamic interactions. In recent years, only a handful of single-nucleotide polymorphisms (SNPs) in transporter proteins are identified as clinically relevant, but due to the emerging interest in personalized medicine, the total number is expected to increase very fast. Thousands of SNPs are listed in the NCBI-SNP database (http://www.ncbi.nlm.nih.gov/projects/SNP) and with a focus on drugs at the Pharmacogenetics Knowledge Base (http://www.pharmgkb.org/). With the next-generation sequencing projects of about 1,000 complete genomes, our knowledge will expand dramatically in the near future (Kaiser 2008, p. 395; Siva 2008, p. 256). This part will focus on clinically relevant SNPs in the 7/9 drug transporters only; for further insights in the numerous SNPs of the transporters, it will be referred to original publications and reviews.

43.1.1.1 SLC Transporter Family

OATP1B1

OATP1B1 (SLCO1B1) is predominantly expressed in the basolateral membrane of human hepatocytes. Interestingly, no directly related isoform of human OATP1B1 (and also OATP1B3) is expressed in mouse or rat, questioning the significance of these preclinical species for substrates of these transporters – nevertheless, a broad substrate overlap between the species was observed. Besides endogenous substances like bile acids, thyroid hormones, and bilirubin conjugates, many highly prescribed drugs are identified as substrates of OATP1B1 with statins like atorvastatin, rosuvastatin, pitavastatin, and pravastatin as most relevant ones today. Furthermore, cardiovascular drugs from the sartane family, anticancer drugs, antibiotics, HIV protease inhibitors, some toxins, and more are identified as substrates in vitro. A comprehensive overview of OATP1B1 substrates, inhibitors, and also the importance of the transport protein for the hepatic uptake of anions is summarized in Niemi et al. (2011, pp. 157–181).

Genotyping

About 41 nonsynonymous variants are described for the SLCO1B1 gene today (Niemi et al. 2011, pp. 157–181), and for some of them, a decreased activity was proven in vitro (Tirona et al. 2001, pp. 35669–35675). The common SNP c.521T > C, also known as, *5 allele has become very prominent due to pronounced clinical effects described later. In vitro, a reduced membrane expression of the protein was predicted. The c388A > G variant is another prominent SNP found in the gene of OATP1B1, and it is remarkable that c388A > G and c.521T > C together form four well-known haplotypes *1A (c388A – c521T), *1B (c388G – c521T), *5 (c388A – c521C), and *15 (c388G – c521C). The functional consequences of these haplotypes have been studied extensively with mixed results, maybe due to different expression systems and/or probe substrates, but *15 and *5 are clearly identified as haplotypes with

reduced activity in vitro (Iwai et al. 2004, pp. 749–757; Kameyama et al. 2005, pp. 513–522; Nozawa et al. 2005, pp. 434–439;. Ho et al 2006a, pp. 1077–1084, 2006b, pp. 1793–1806; Katz et al. 2006, pp. 186–196; Tsuda-Tsukimoto et al. 2006, pp. 2646–2656; Deng et al. 2008, pp. 424–433). Haplotype *1B seems to be correlated with some increased activity of the transporter, but results are very controversial (reviewed in Niemi et al. (2011), pp. 157–181; Deng et al. (2008), pp. 424–433). More SNPs also leading to a stop codon or located in the promoter region of the SLCO1B1 gene were identified with very low incidence. The combined frequency of the low activity *5 and *15 haplotypes is 15–20% in Europeans and 10–15% in Asians.

Clinical Effects

Many studies with, to some extent, unexpected results have demonstrated the clinical relevance of SNPs in the SLCO1B1 gene and are comprehensively summarized in Niemi et al. (2011), pp. 157–181, Deng et al. (2008), pp. 424–433. Most importantly, the c521T > C variant leads to a remarkable increase in the AUC of statins like rosuvastatin (1.7-fold), pravastatin (1.9-fold), atorvastatin (2.1-fold), and simvastatin acid (3.1-fold), while the most hydrophobic statin fluvastatin was not significantly affected (1.2-fold) (Pasanen et al. 2006, pp. 873–879; Niemi et al. 2006, pp. 356–366). Due to these results, it was speculated that carriers of the *5 and *15 SNP might be on higher risk for statin-induced myopathy, a concentration-dependent skeletal muscle toxicity and a rare, but serious adverse reaction in statin therapy. In a remarkable genome-wide association study, this was confirmed for simvastatin but only for the highest dose of 80 mg/day (Pasanen et al. 2006, pp. 873–879). A second study confirmed the higher risk of the c521T > C SNP also for milder forms of simvastatin, atorvastatin, and pravastatin induced adverse events (Voora et al. 2009, pp. 1609–1616). In 2009, even a dose adjustment for statin therapy according to a SNP analysis in patients was suggested (Niemi 2010, pp. 130–133). Furthermore, there are some good indications that the c521T > C SNP also effects the AUCs of meglitinide like repaglinide and nateglinide clinically, although it is not proven in vitro that these drugs are OATP1B1 substrates (Niemi et al. 2005, pp. 468–478; Zhang et al. 2006, pp. 567–572; Kalliokoski et al. 2008a, pp. 937–942, 2008b, pp. 311–321, 2008c, pp. 818–825).

OATP1B3

OATP1B3 (SLCO1B3) is also expressed nearly exclusively in the basolateral membrane of human hepatocytes. OATP1B1 and OATP1B3 are homolog proteins and share a broad overlap of substrates with differences in the transport kinetics. Some specific substrates for OATP1B3, especially the octapeptide cholecystokinin, were identified. As OATP1B1 and OATP1B3 are the main liver-specific anion transporters for many drugs, it will be very useful to evaluate to which proportion of OATP1B1 and OATP1B3 a drug is transported into the liver to predict pharmacokinetic properties and possible interactions.

Genotyping and Clinical Effects

In vitro data on SNPs in SLCO1B3 are limited and partly contradicting. Experimental results about localization and transport function were substrate and cell line dependent (Letschert et al. 2004, pp. 441–452). In vivo data from clinical trials are also rare and do not show conclusive results to demonstrate the impact of haplotypes of OATP1B3 clinically. In a study with 92 adult Caucasian cancer patients, six variants of the SLCO1B3 gene (334T > G (*2), 439A > G (*3), 699G > A (*4), 767G > C (*5), 1559A > C (*6), and 1679T > C (*7)) were analyzed and did not show a correlation with the docetaxel clearance (Baker et al. 2009, pp. 155–163). In a second study with the related taxane paclitaxel, the SNPs 334T > G and 699G > A analyzed in a cohort of 90 cancer patients were also not correlated with a changed plasma clearance (Smith et al. 2007, pp. 76–82).

OAT1 and OAT3

OAT1 (SLC22A6) and OAT3 (SLC22A8) are expressed at the basolateral membrane of the kidney tubular cells and are responsible for the uptake of mostly hydrophilic small organic anions into the organ as the first step of active renal secretion. OAT1 and OAT3 share partly overlapping substrate specificities for endogenous substrates and drugs like captopril, olmesartan, furosemide, several β-lactam antibiotics, antivirals, and NSAIDs. Furthermore, OAT3 shares some substrates with the hepatic OATP family like pravastatin and rosuvastatin. Properties of the members of the OAT family are comprehensively reviewed (VanWert et al. 2010, pp. 1–71; Burckhardt and Burckhardt 2011, pp. 29–104).

Genotyping

Several nonsynonymous SNPs were described in the OAT1 gene, comprehensively reviewed in Srimaroeng et al. (2008, pp. 889–935). For the 149G > A (R50H), in vitro transport was unaltered for p-aminohippurate, ochratoxin A, and methothrexate (Fujita et al. 2005, pp. 201–209), while affinities for adefovir, cidofovir, and tenofovir were significantly higher. Clinical consequences are not described until today. The SNP 1361G > A (R454Q) identified in African-Americans leads to a nonfunctional transporter in vitro, but surprisingly adefovir clearance was not altered clinically (Fujita et al. 2005, pp. 201–209). Several nonsynonymous SNPs were identified in the coding region of the SLC22A8 gene, encoding OAT3 (Nishizato et al. 2003, pp. 554–565; Erdman et al. 2006, pp. F905–F912; Urban et al. 2006, pp. 223–230). In Japanese, 1166C > T (A389V) had no remarkable influence on the pravastatin clearance compared to wild type (Nishizato et al. 2003, pp. 554–565). Others SNPs like 913A > T (I305F) showed altered transport of probe substrates estrone-3-sulfate and/or cimetidine in vitro (Erdman et al. 2006, pp. F905–F912). Three SNPs were identified as loss of function mutations (445C > A, R149S; 715C > T, Q239X; and 779T > G, I260R) with a possible impact on the excretion of drugs, while clinical data are missing until today.

OCT1 and OCT2

OCT1 (SLC22A1) and OCT2 (SLC22A2) organic cation transporters are predominantly expressed at the basolateral membrane of the liver and the kidney, respectively. The proteins are also expressed in many other cells and tissues (reviewed by Koepsell et al. (2007, pp. 1227–1251)). OCT1 and OCT2 mediate the uptake of organic cations into hepatocytes and kidney proximal tubular cells, respectively, thereby mediating the first step of hepatic and renal metabolism and/or secretion. Again, substrate specificity of the two related transporters is highly overlapping with some distinct differences. Endogenous substrates for OCTs are monoamine neurotransmitters, choline, creatinine, and guanidine, while the most prominent pharmaceutical transported by OCTs is the antidiabetic drug metformin. Metformin response is thought to be influenced by the uptake into the liver by OCT1, while OCT2 is involved in the active renal secretion of the drug. In addition, the histamine H2 antagonist cimetidine, some antivirals, and the antiarrhythmic quinidine are described as substrates for OCTs.

Genotyping and Clinical Effects

Due to the high clinical variability of metformin response and the rare, but severe occurrence of lactic acidosis during metformin treatment, genetic variabilities in SLC22A1 and SLC22A2 genes are highly discussed as an obvious explanation. Numerous studies were performed with partly contradictory data summarized comprehensively in a review by Zolk et al. (Zolk 2011).

By in vitro models, six common naturally occurring SNPs in the SLC22A1 gene were shown to translate into proteins with reduced or eliminated functions (61R > C, 189S > L, 220G > V, 401G > S, 420del, and 465G > R) (Shu et al. 2007, pp. 1422–1431). Some or all of these SNPs were analyzed in three clinical studies in healthy volunteers and patients with mixed results. In the first report by Shu et al. (2007, pp. 1422–1431) with healthy volunteers, the glucose response of metformin was lowered for individuals carrying one of the four alleles with reduced function (61R > C, 401G > S, 420del, 465G > R). This effect could not be confirmed in additional studies with patients. Zhou et al. (2009, pp. 1434–1439) analyzed the two most common SNPs (61R > C, 420del) with no effect on metformin response, and in two additional studies, the six SNPs were not associated with a change in metformin response (Shikata et al. 2007, pp. 117–122; Becker et al. 2009, pp. 242–247). To complicate the story even more, Gambineri et al. observed in a prospective study that carriers of the four SNPs (61R > C, 401G > S, 420del, 465G > R) showed no change in metformin response regarding glucose tolerance, but an impaired insulin response (Gambineri et al. 2010, pp. E204–E208). Many SNPs, but mostly with very low frequencies, were identified in the SLC22A2 gene. Only the SNP c808G > T (270A > S) with a frequency of about 15% was analyzed clinically in several studies with slightly different results summarized in Zolk et al. (Zolk 2011). This SNP influenced the pharmacokinetics of metformin clearance by about 40% reduction of the clearance but only in homozygote carriers.

43.1.1.2 ABC Transporter Family

BCRP (ABCG2)

The BCRP (breast cancer resistance protein) is an efflux transporter and expressed in numerous tissues and cell lines. At the apical membrane of the small intestine and at the blood-brain barrier, the protein limits the oral bioavailability and penetration of drugs into the brain, respectively. This efflux function of the transporter is also described at the blood testis/ placental tissue barrier. In the sinusoidal membrane of hepatocytes and the apical membrane of kidney tubular cells, the transport protein is responsible for the active secretion of drugs into bile and urine, respectively. Therefore, the transporter influences pharmacokinetic properties of substrates at the absorption and excretion level. The protein was first discovered in a breast cancer cell line as the major factor mediating drug resistance and has then been identified in many cell lines derived from malignant tissues of various origins. The BCRP protein is characterized by a very broad substrate specificity for a variety of anticancer drugs but also several nonchemotherapeutics like the statins rosuvastatin and pitavastatin, antibiotics like ciprofloxacin and other drugs like cimetidine, leflunomide, sulfasalazine, and glyburide. Poguntke et al. give an extensive review of in vitro and in vivo knowledge regarding the BCRP protein (Poguntke et al. 2010, pp. 1363–1384).

Genotyping and Clinical Effects

Numerous SNPs have been identified in the ABCG2 gene. At least one SNP c.421C > A, with a common allele frequency of 10–15%, 25–30% and 0–5% in the Caucasian, Asian, and African-American population, respectively, is related to a reduced function of the transporter by a decreased expression rate. Therefore, the SNP should affect pharmacokinetic properties of ABCG2 substrates, and indeed the AUC of HMG-CoA reductase inhibitors was markedly increased by 144% for rosuvastatin, 111% for simvastatin lactone, and 72% for atorvastatin, while, e.g., non-BCRP substrate pravastatin was unaffected (Keskitalo et al. 2009a, pp. 1617–1624, 2009b, pp. 197–203). Sulfasalazine, a BCRP substrate with a very low intestinal absorption and oral bioavailability, showed a dramatic 110-fold increase in AUC in ABCG2 knockout mice (Zaher et al. 2006, pp. 55–61), while clinical studies were contradictory. Urquart et al. documented a 2.5-fold increase in sulfasalazine AUC in human subjects with the c.34GG/c.421CC genotype indicating an influence on sulfasalazine plasma exposure (Urquhart et al. 2008, pp. 439–448). A second study with 36 healthy volunteers failed to reproduce this result (Adkison et al. 2010, pp. 1046–1062).

P-gp (MDR1, ABCB1)

Like BCRP, P-gp is an efflux transporter and expressed in numerous tissues and cell lines with a very similar expression pattern and function at the apical membrane of the small intestine, at the blood-brain barrier, at the sinusoidal membrane of hepatocytes, and at the apical membrane of kidney tubular cells. P-gp is also characterized by a very broad substrate specificity for a variety of anticancer drugs, but also several nonchemotherapeutics from many different indication areas, like digoxin, quinidine, verapamil, cyclosporine, atorvastatin, levofloxacin, loperamide, and many more.

Genotyping and Clinical Effects

About 100 SNPs have been identified in the coding region and many more in the complete gene. A silent polymorphism 3435C > T, sometimes in combination with other SNPs (like 2677G > T/A and 1236G > T), was analyzed comprehensively in many clinical studies with the probe substrates digoxin and talinolol and furthermore with various drugs from different therapeutic areas (protease inhibitors, immunosuppressants, antihistamines, anticonvulsants, and cytostatics) summarized in Cascorbi (2011, pp. 261–283). For all compounds, positive and negative correlations were observed. Thus today, no particular SNP in the gene is identified as a predictor of individual pharmacokinetics of P-gp substrates.

BSEP (ABCB11)

The bile salt efflux pump (BSEP) is expressed solely in the canalicular membrane of human hepatocytes and is responsible for the hepatic excretion of bile salts and thereby a major driver for the enterohepatic circulation of bile salts. BSEP is not described as a typical drug transporter today, but the inhibition of BSEP by drugs or endogenous compounds like steroid metabolites leads to an acquired form of liver diseases, namely,

drug-induced cholestasis and intrahepatic cholestasis of pregnancy, respectively. A common genetic variant of BSEP (c1131T > C) is identified as a susceptibility marker for acquired cholestasis comprehensively reviewed (Stieger and Geier 2011, pp. 411–425; Pauli-Magnus et al. 2010, pp. 147–159).

43.1.1.3 Recommendations for All Drug Transporters

It is becoming preclinical practice that especially for BCS and/or BDDCS class 3 and 4 drugs, the substrate specificity of drug transporters is analyzed for the drug itself and active metabolites. Even the pharmacokinetic behavior of BCS/BDDCS class 2 compounds is partly influenced by transporters (Wu and Benet 2005, pp. 11–23). If a drug is identified as substrate of a specific transporter, it is highly recommended to analyze subjects in clinical studies for the SNPs identified in the genes from phase I to phase III clinical trials. It is very likely that patients will benefit from this in many aspects, not only from a safety perspective, but also in the mind-set of personalized medicine. Special populations will be identified which will, e.g., profit more from a medication, are nonresponders, are on a higher or lower risk, or need dose adjustments. This becomes even more obvious as it is expected that the impact of drug transporters on cellular and tissue distribution (at the target site!) is of much higher importance than on "simple" pharmacokinetic properties. As SNP analysis today by high-throughput methods is fast and inexpensive, it should be considered to analyze the SNPs of all identified drug transporters on a routine basis in selected clinical trials – safety, tolerability, and effectiveness of new drugs will benefit.

43.2 Pharmacogenomics in Drug Metabolizing Enzymes

The understanding of the role of pharmacogenetics in drug metabolism expanded greatly in the 1990s. This is mainly due to technological improvements in gene scanning and gene variant identification. The number of variant alleles identified for genes coding for drug metabolizing enzymes (DMEs) considerably increased in the early 2000s, and continues to increase. The clinical consequences – or at least genotyping-phenotyping relationships – of DME polymorphisms have not been demonstrated for all variants. In the following text, only those DME allele variants will be mentioned for which significant changes in enzyme activity have been found using probe drugs. Complete information on CYPs alleles can be found at www.imm.ki.se/CYPalleles and Phase I and Phase II DMEs at www.pharmgkb.org/index.jsp.

43.2.1 Phase I Enzymes

43.2.1.1 CYP1A2

PURPOSE AND RATIONALE

CYP1A2 is involved significantly in the metabolism of several drugs (imipramine, clozapine, fluvoxamine, olanzapine, theophylline, acetaminophen, propranolol, tacrine) as well as in diet components (methylxanthines), endogenous substrates (estrogens), numerous aryl, aromatic and heterocyclic amines, and polycyclic aromatic hydrocarbons. It is inducible, notably by cigarette smoking, diet habits such as consumption of cruciferous vegetables (e.g., broccoli, watercress, collard greens, Brussels sprouts, mustard) and of charbroiled meats, some drugs (omeprazole, phenytoin, rifampicin), and is a target enzyme for the development of some cancers. Up to now, at least 23 CYP1A2 alleles have been detected. Probe drugs for CYP1A2 phenotyping are caffeine and theophylline. For safety concerns and drug availability, the preferred probe is caffeine. Caffeine 3-demethylation is mediated by CYP1A2 and accounts for 80% of caffeine clearance. Caffeine is also a probe drug for N-acetyltransferase and xanthine oxidase (Kalow and Tang 1993).

PROCEDURE

Phenotyping: A fixed or weight-adjusted dose of caffeine (solution, tablet, coffee) ranging from 1 to 3 mg/kg is administered. Diet requirements have to be respected (stable xanthine-free diet avoiding beverages like coffee, tea, cola, chocolate, no food component with CYP1A2-inducing properties) during the test period. As smoking is known to induce CYP1A2, control of stable smoking status is mandatory.

There are two commonly used and robust methods for phenotyping. The first one measures caffeine (1,3,7-methylxanthine) and its N-demethylated metabolite 1,7-dimethylxanthine (paraxanthine) in a plasma or saliva sample collected within 5–7 h post-caffeine dosing (Fuhr and Rost 1994). The second one uses the assay of the metabolites 1-methylurate (1U), 1-methylxanthine (1X), and 5-acetylamino-6-formylamino-3-methyluracil (AFMU) and 1,7-dimethylurate (17U) levels in urine collected at least for 8 h post-dosing (Campbell et al. 1987; Rostami-Hodjegan et al. 1996).

Commonly used methods for caffeine and metabolite(s) assay in plasma or urine involve an extraction step followed by HPLC with UV detection (Krul and Hageman 1998; Rasmussen and Bosen 1996; Schreiber-Deturmeny and Bruguerolle 1996). Urine needs to be acidified (pH 3.0–3.5) before sample freezing.

Genotyping: Reduced activity has been reported for CYP1A2*1C and CYP1A2*1F alleles in smoking subjects. Induction of CYP1A2 activity has been associated with these alleles, but the effect of CYP1A2*1F mutation on CYP1A2 activity has not been confirmed (Nordmark et al. 2002). In Caucasians, frequency of the CYP1A2*1C and CYP1A2*1F variants is about 1% and 33%, respectively (Sachse et al. 2003).

EVALUATION

Metabolic ratios (MRs) used are plasma 17X/137X and urinary (1U + 1X + AFMU)/17U.

In controlled conditions, in nonsmoking young and elderly subjects, intraindividual and interindividual variability in 17X/137X MR was about 17% and 47%, respectively, with no effect of age (Simon et al. 2003). A 70-fold range in MR has been observed in smoking and nonsmoking female Caucasian subjects using the urinary MR (Nordmark et al. 1999). Up to 200-fold differences were found using the urinary test. Lower variability is expected using the plasma caffeine test.

Higher CYP1A2 activity in men versus women has been reported, though inconsistently, and in children. Higher MR is usually observed in smokers versus nonsmokers, when population sample size is large. Pregnancy and oral contraceptives intake were found to decrease CYP1A2 activity (Abernathy and Todd 1985; Caubet et al. 2004; Kalow and Tang 1993). CYP1A2 activity was found lower in colorectal patients versus controls (Sachse et al. 2003).

Large variability in CYP1A2 activity explains that its distribution has been described unimodal, bimodal, or trimodal. Poor metabolizers (characterized with a MR <0.12) have been identified in a Chinese population and represented about 5% of the population tested, whereas PMs could represent 5–10% of Caucasian populations and 14% in Japanese population (Ou-Yang et al. 2000).

CRITICAL ASSESSMENT OF THE METHOD

Numerous studies have shown good correlation between the 17X/137X plasma MR and caffeine systemic clearance, and plasma MR is considered more

robust than the urinary one, since this last one can be affected by the effect of urinary flow on metabolite renal clearances.

Currently, no relationship between CYP1A2 genotype characteristics and CYP1A2 activity, as assessed by the caffeine test, has been usually found. Some associations have been found in specific genetic and environmental conditions (Han et al. 2001). Non-well-controlled conditions for urine sample collection, the effects (induction) linked to environmental factors, may overcome the role of CYP1A2 polymorphism, which can explain the paucity of clear associations between CYP1A2 genotyping and phenotyping.

Further investigations are needed to characterize the effect of variants (SNPs, haplotypes) on CYP1A2 activity.

MODIFICATIONS OF THE METHOD

Recent drug assay development involved LC-MS methods (Caubet et al. 2004; Kanazawa et al. 2000). A less practical breath test, using ^{13}C or ^{14}C labeled caffeine, can also be used (Kalow and Tang 1991).

43.2.1.2 CYP2C9

PURPOSE AND RATIONALE

CYP2C9 is involved significantly in the hydroxylation of about 16% of drugs (Schwarz 2003), including drugs with narrow therapeutic index such as anticoagulants (warfarin, acenocoumarol, phenprocoumon active S-enantiomers), and anticonvulsivants (phenytoin, hexobarbital), as well as numerous antidiabetic agents (i.e., tolbutamide, glibenclamide, glipizide), antihypertensive drugs (losartan, irbesartan), nonsteroidal

anti-inflammatory agents (i.e., diclofenac, ibuprofen, celecoxib), and diuretic (torsemide) and anti-rheumatoid agents (leflunomide).

A couple of CYP2C9 variants – mainly CYP2C9*2 and CYP2C9*3 – code for in vivo decreased activity, and two – CYP2C9*6 and CYP2C9*15 – have been reported to be associated with no activity. In Caucasian populations, CYP2C9*2 and CYP2C9*3 are encountered in 20–25% of subjects, while these genotypes have been found in less than 5% of East Asian subjects (Rosemary and Adithan 2007).

Probe drugs used for CYP2C9 phenotyping are tolbutamide, warfarin, phenytoin, and losartan. Diclofenac, flurbiprofen, Phenprocoumon, and torsemide have also been used. For safety concerns, the current preferred probe is tolbutamide, despite some risk of hypoglycemia.

PROCEDURE

Phenotyping: The method measures tolbutamide, its CYP2C9-formed 4′-hydroxylated metabolite, and the subsequent carboxytolbutamide metabolite of hydroxytolbutamide, formed by dehydrogenase enzymes. The urinary excretion of these two metabolites represented more than 85% dose of administered tolbutamide (Veronese et al. 1990, 1993).

Subjects receive a single oral 500 mg tolbutamide tablet in usual Phase I standard controlled conditions, with care to be paid to blood glucose. Urine is collected from drug intake to 8 or 24 h post-dosing.

The assay of tolbutamide and its metabolites is usually performed using HPLC and UV or fluorescence detection (Csillag et al. 1989; Veronese et al. 1990; Kirchheiner et al. 2002a; Hansen and Brosen 1999).

Genotyping: About two-third of Caucasian subjects express the wild genotype C9*1/*1. C9*1/*2 and C9*1/*3 heterozygote variants are expressed in 15–25% and 7–16% of Caucasian subjects, whereas the frequency of other variants is lower: 0.5–2.5%, 1–3%, and <1–1.5% for C9*2/*2, C9*2/*3, and C9*3/*3 variants, respectively (Scordo et al. 2001; Lee et al. 2002a; Schwarz 2003). More than 95% of Afro-American subjects express the wild genotype C9*1/*1 (Lee et al. 2002b). In Asian populations, CYP2C9*1/*3 is expressed in 2–8% subjects, but CYP2C9*2 is absent or extremely rare (Rosemary and Adithan 2007; Schwarz 2003; Xie et al. 2002). Overall, it has been estimated that 0.2–1% and 2–3% of Caucasian and Asian population could be qualified as poor metabolizers (PMs), respectively (Meyer 2000).

EVALUATION

The urinary metabolic ratio (MR, hydroxytolbutamide + carboxytolbutamide)/tolbutamide is generally used. There is a large interindividual variability in MRs in subjects with the same genotype. Different studies performed with different probe drugs (Yasar et al. 2002a; Kirchheiner et al. 2002b, 2003b; Lee et al. 2002c; Miners and Birkett 1998; Morin et al. 2004), highlighted that a PM status could be given to subjects who are homozygous for CYP2C9*3, or expressing CYP2C9*2/*3 variant, but intermediate situations – from extensive to slow metabolizer status – may vary not only among different allele combinations but also with the probe drug used.

Oral contraceptives were found to inhibit CYP2C9 activity using losartan for phenotyping (Sandberg et al. 2004).

CRITICAL ASSESSMENT OF THE METHOD

The tolbutamide test has the most convincing ability to discriminate between genotype variants and pharmacokinetics. There could be an analytical issue linked to the urine assay precision, as the urinary concentrations of the parent drug are very low in comparison with those of its metabolites.

To date, the CYP2C9*3 variant has been the only one found influencing significantly drug pharmacodynamics for warfarin, acenocoumarol (Sandberg et al. 2004; Morin et al. 2004; Versuyft et al. 2003), glipizide, and glyburide (Kirchheiner et al. 2002b) or drug side effects (Sevilla-Mantilla et al. 2004). Unconstant results were found regarding tolbutamide effects (Kirchheiner et al. 2002a; Shong et al. 2002). For anticoagulants, the possession of CYP2C9*2 and CYP2C9*3 variants was associated with decreased warfarin dose requirement in patients and an increased risk of adverse events such as bleeding (Daly and King 2003). An African-American subject with only the CYP2C9*6 variant exhibited serious phenytoin side effects associated with a marked impaired elimination of the drug (Kidd et al. 2001).

The variability of CYP2C9 activity observed among ethnic groups cannot be explained with our current knowledge on CYP2C9 variant alleles distribution (Xie et al. 2002).

MODIFICATIONS OF THE METHOD

Losartan (25 mg dose) has been proposed as a safer alternative to tolbutamide. The determination of losartan/E3174 (oxidized metabolite) ratio in 0–8 h urine or in plasma at 6 h post-dosing have been proposed (Yasar et al. 2002b; Sekino et al. 2003). However, in a comparative study in 16 subjects, a better correlation between genotyping and phenotyping was found with tolbutamide, as compared to losartan or flurbiprofen, though there was no subject with the C9*2/*3 or C9*3/*3 variants (Lee et al. 2003).

Recently, a 125 mg tolbutamide dose has been validated, with proposal of the use of just one blood sample collected 24 h post-dosing. Its safer use needs the drug to be assayed using LC-MS/MS methodology (Jetter et al. 2004).

43.2.1.3 CYP2C19

PURPOSE AND RATIONALE

CYP2C19 contributes to the metabolism of about 8% of drugs (Rogers et al. 2002), including *S*-mephenytoin, proton pump inhibitors (omeprazole, lansoprazole, pantoprazole), tricyclic antidepressants

(amitriptyline, imipramine, clomipramine, citalopram), benzodiazepines (diazepam, flunitrazepam), torsemide, fluvastatin, and proguanil. Two main variants – CYP2C19*2 and CYP2C19*3 – are coding for in vivo nil activity, as well as for CYP2C19*4, *5, *6, *7, and *8 variants. About 15–20% Asians, 4–7% Black Africans, and 3% Caucasians are PMs (Scordo et al. 2004).

Probe drugs used for CYP2C19 phenotyping are mephenytoin, omeprazole, and proguanil. The most currently used probe drug is omeprazole.

PROCEDURE

Phenotyping: The method measures omeprazole and its CYP2C19-formed 5-hydroxylated metabolite in plasma.

Subjects receive a single oral 20 or 40 mg omeprazole capsule in usual Phase I standard controlled conditions. Plasma can be collected from drug intake up to 24 h post-dosing, or only one plasma sample is collected at 2 or 3 h post-dosing.

The assay of omeprazole and its metabolite is usually performed using HPLC and UV detection (Lagerstrom and Persson 1984; Ieri 1996; Yim et al. 2001; Tybring et al. 1997) or LC-MS/MS assay (Kanazawa et al. 2002).

Genotyping: The two alleles CYP2C19*2 and CYP2C19*3 account for quite all PMs in Asians (>99%) and Black Africans, but defective alleles have not been fully characterized in 10–15% Caucasians. The CYP2C19*2 allele is the most frequent in Asian populations (30% in Chinese), as well as in Black Africans (about 17%) and in Caucasians (about 15%) (Xie et al. 2001). The CYP2C19*3 accounts for about 25% of inactive forms in Orientals and is extremely rare in Caucasians (Scordo et al. 2004; Rosemary and Adithan 2007).

EVALUATION

The AUC or plasma ratio of omeprazole to 5-hydroxyomeprazole is used.

As expected, homozygous PM subjects have lower metabolic activity as compared to heterozygous PM subjects, and potential interethnic difference has been noticed within a genotype (Yin et al. 2004).

Decreased CYP2C19 activity has been observed with oral contraceptives containing ethinylestradiol (Tamminga et al. 1999; Laine et al. 2000).

CRITICAL ASSESSMENT OF THE METHOD

Omeprazole hydroxylation rate correlates with S-mephenytoin hydroxylation rate, which was initially the CYP2C19 probe drug (Andersson et al. 1990; Chang et al. 1995; Balian et al. 1995). The alternate pathway – conversion of omeprazole to its sulfone derivative –, which is mediated via CYP3A4, does not influence the CYP2C19 pathway of omeprazole (Balian et al. 1995).

Time-dependent kinetics of omeprazole limits its use for phenotyping during chronic therapy (Gafni et al. 2001). CYP2C19 phenotyping with omeprazole may be affected by age, liver disease, and omeprazole therapy (Kimura et al. 1999).

Interethnic differences observed with different CYP2C19 substrates for subjects with same genotype have been attributed to differences in substrate specificity or enzyme isoforms (Bertilsson et al. 1992). The clearance of omeprazole is higher in Caucasian extensive metabolizers (EMs) than in Oriental EMs, due to a higher proportion of heterozygous EMs in this latter population (Ishizaki et al. 1994).

MODIFICATIONS OF THE METHOD

It has been proposed to use omeprazole for both CYP2C19 and CYP3A4 phenotyping (Gonzalez et al. 2003).

43.2.1.4 CYP2D6

PURPOSE AND RATIONALE

CYP2D6 is involved significantly in the metabolism of drugs mainly used in CNS (antidepressants, i.e., imipramine, paroxetine, citalopram; neuroleptics, i.e., haloperidol, risperidone) or cardiovascular (β-adrenoceptor blockers, i.e., metoprolol; antiarrhythmics, i.e., propafenone, flecainide) disorders. Significant interethnic and interindividual intraethnic differences in CYP2D6 activity have been found: 5–10% Caucasians, 6–8% Afro-Americans, and only 1% Asians have reduced CYP2D6 activity, and exhibit the PM phenotype. Expression of CYP2D6 has been shown to be polymorphic with up to now more than 80 genetic variants detected for the encoding gene, with more than 15 encoding for inactive enzyme. Probe drugs for CYP2D6 phenotyping are dextromethorphan, debrisoquin, sparteine, and metoprolol. For safety concerns and drug availability, the preferred probe is dextromethorphan (Schmid et al. 1985).

PROCEDURE

Phenotyping: The method measures dextromethorphan DM and its O-demethylated metabolite, dextrorphan DX, which is formed by CYP2D6. DM and DX, and other metabolites, are excreted in urine, mainly as glucuronide conjugates.

Subjects receive a single oral 10 to 30 mg dextromethorphan (generally hydrobromide salt syrup) dose. Urine is collected from drug intake to 8 h post-dosing. Other collection times (0–6, 0–10, 0–12, or 0–24 h) can be used, but short collection intervals might lead to increased intrasubject variability.

Urine is first hydrolyzed with β-glucuronidase. Then, different methods can be used involving DM and DX extraction, followed either by HPLC and fluorescence detection (Chladek et al. 1999; Hoskins et al. 1997) or capillary gas chromatography (Wu et al. 2003).

Genotyping: The incidence of alleles coding for inactive enzymes varies between populations: three "population specific" alleles are CYP2D6*4 in Caucasians, *10 in Asians, and *17 in Africans (Bertilsson et al. 2002). CYP2D6*3, *4, *5, *6 are the main inactive alleles producing the PM phenotype in Caucasians with CYP2D6*4 most commonly associated with the PM phenotype. By far the most frequent null allele – not encoding a functional protein product – is CYP2D6*4 with a frequency of 20–25% in Caucasians (Zanger et al. 2004). The frequency of the *17 allele – associated with decreased enzyme activity – is high in Black Africans and in Black Americans but practically absent in Caucasian populations (Bapiro et al. 2002; Gaedigk et al. 2002; Zanger et al. 2004). Four potential subgroups – ultrarapid metabolizers (UMs), extensive metabolizers (EMs), intermediate metabolizers (IMs), and poor metabolizers (PMs) – have been defined based on the genotype-phenotype relationships.

In Caucasian subjects, it has been recommended for "routine test" to genotype for alleles *1, *3, *4, *5, *6 which allow to detect 86–100% of poor metabolizers

(Sachse et al. 1997). To assign correct phenotype in nearly 100% subjects, *9 and *10 variants should also be determined.

EVALUATION

Subjects with a DM/DX metabolic ratio (MR) >0.3 are poor metabolizers. Subjects with DM/DX <0.03 are extensive metabolizers. Those with 0.03 < MR < 0.3 are intermediate metabolizers.

No difference or slightly higher CYP2D6 activity in females has been found when comparing to male subjects (Hägg et al. 2001; McCune et al. 2001).

Relationship between phenotyping and genotyping is investigated by plotting log MRs versus CYP2D6 allele combinations (Chou et al. 2003).

CRITICAL ASSESSMENT OF THE METHOD

The method is widely used due to easy and safe administration. High intrasubject variability limits the test for discriminating between EMs and UMs (Zanger et al. 2004).

The method is not appropriate in patients with renal impairment, due to reduced renal excretion of DM glucuronide metabolites. Sparteine has been recommended as a probe for this population and to discriminate between the four phenotypes UM, EM, IM, and PM. The DM/DX MR does not allow for consistent differentiation between CYP2D6 extensive metabolizers with one or two active alleles.

MODIFICATIONS OF THE METHOD

Assays have been developed to determine DM and DX in plasma or saliva (Bolden et al. 2002; Hu et al. 1998; Chladek et al. 2000; Härtter et al. 1996). The use of saliva or plasma for CYP2D6 phenotyping has been developed for subject convenience, or for the development of single point methods to be easily incorporated in the "cocktail methods." Good correlation between metabolic ratios calculated from plasma, saliva samples, and those obtained from urine has been observed.

43.2.1.5 CYP3A

PURPOSE AND RATIONALE

CYP3A is the predominant P450 subfamily (CYP3A4, CYP3A5, CYP3A7, CYP3A43) in the human liver and contributes significantly to the metabolism of many (at least 50%) drugs in numerous therapeutic classes. CYP3A4 is the major P450 present notably and predominantly in the liver and small intestine, and interindividual variability in the level of its expression is very high – 20-fold or more – (Shimada et al. 1994). CYP3A5 shares rather similar tissue distribution with CYP3A4, but it is preferentially expressed in the lung. It represents generally a few percentage of total CYP3A as compared to CYP3A4 (exceptions are esophagus and prostate, specific for CYP3A5, and kidney in which CYP3A5 is predominantly expressed). CYP3A4 and CYP3A5 exhibit overlapping substrate specificity, and there is currently no specific CYP3A5 probe drug. CYP3A7 is primarily the major fetal CYP3A enzyme.

Most of drugs biotransformed with CYP3A are also P-glycoprotein substrates (noticeable exceptions are midazolam and nifedipine). CYP3A and P-glycoprotein contribute substantially to the first-pass elimination of highly cleared CYP3A substrates when orally administered. However, CYP3A4 and P-glycoprotein activities are not coordinately regulated in the liver and in the intestine (von Richter et al. 2004).

Currently, 40 and 24 alleles have been identified for CYP3A4 and CYP3A5, respectively. Expression of CYP3A5 varies greatly among individuals (Lamba et al. 2002).

Due to multiple confounding factors, such as those involved in endogenous expression of CYP3A regulatory factors, numerous exogenous factors (environment, diet), the interplay between CYP3A and transporters in regulating drug disposition, the establishment of consistent relationships between CYP3A genotype and phenotype is actually a challenge (Wilkinson 2004). Currently, the value of CYP3A genotyping in drug development is far from being clinically useful.

The most used and validated probe drugs for CYP3A phenotyping are midazolam and ^{14}C-erythromycin (Watkins 1994). Alfentanyl, alprazolam, dapsone, dextromethorphan, lidocaine, nifedipine, omeprazole, quinine, and verapamil have also been used but less frequently, and CYP3A specificity for some of them has been questioned. The "endogenous" 6β-hydroxycortisol test (measurement of 6β-hydroxycortisol: cortisol ratio in urine) is only useful for detecting CYP3A induction and may be influenced by renal CYP3A activity.

Due to intraindividual differences in liver and intestinal CYP3A activity, phenotyping test results are related to the probe drug route of administration.

PROCEDURE

Phenotyping: *Midazolam test*: Midazolam is primarily metabolized to 1′-hydroxymidazolam by CYP3A. It is rapidly and completely absorbed after oral administration (Gorski et al. 1998). It is the probe of choice to assess intestinal and hepatic or hepatic CYP3A activities only, after oral (Thummel et al. 1996) or intravenous administration, respectively.

Oral test doses are 2, 5, or 7.5 mg (as a solution). IV doses are 0.015, 0.025, or 0.05 mg/kg, or 1 or 2 mg per subject, as a 2- to 30-min infusion.

Blood samples are collected over a 6-h period. Numerous GC, GC/MS, HPLC/UV, or LC/MS methods have been developed for plasma midazolam assay (see Lepper et al. (2004) and Frison et al. (2001)).

^{14}C-erythromycin breath test or ERMBT: CYP3A4 catalyzes the N-desmethylation of [^{14}C N-methyl] erythromycin. The test consists of the measurement of a single breath expired $^{14}CO_2$ collection obtained at 20 min following the IV administration of a 0.03 mg dose of ^{14}C-erythromycin (2–4 μCi administered) (Watkins 1994). This test is used for assessing hepatic CYP3A activity.

Genotyping: Allelic CYP3A4 gene variants are rare. No impact of the presence of the most common CYP3A4*1B mutation (with a frequency ranging from 0% in Chinese and Japanese to 45% in Afro-Americans) on midazolam, erythromycin, or nifedipine clearance has been evidenced. Most significant mutations are observed for CYP3A5 and CYP3A7. Further information on polymorphic expression of CYP3A5 and CYP3A7 can be found in the review by Lamba et al. (2002).

EVALUATION

A complete pharmacokinetic profile is required to assess midazolam clearance and is therefore more invasive than the ERMBT; however, the latter requires specific logistics for radiolabeled material use.

The midazolam or ERMBT phenotype tests are used for dose individualizing of narrow therapeutic index CYP3A-metabolized drugs such as anticancer agents. The ratio 1′-hydroxymidazolam/midazolam has generally been found not useful for phenotyping.

Within a population of similar demographic and health characteristics, a fourfold to sixfold range in the metabolic clearance of a CYP3A-drug substrate is usual, with common individual outliers exhibiting high or low activity (Lamba et al. 2002).

CRITICAL ASSESSMENT OF THE METHOD

Midazolam clearance has been found to correlate with hepatic CYP3A levels (Thummel et al. 1994) as well as ERMBT results (Lown et al. 1992). However weak, inconstant or lack of correlations between midazolam and ERMBT test results have been observed, which could be explained by binding to different CYP3A active sites. In addition, contrary to the midazolam test, the ERMBT does not capture CYP3A5 activity.

An ethnic difference – that could be drug specific – in CYP3A4 activity has been observed for few CYP3A4 substrates (alprazolam, nifedipine), with a lower clearance in Asians than in Caucasians (Xie et al. 2001).

CYP3A4 and CYP3A5 genotyping tests could not explain sufficiently the interindividual variability observed in midazolam pharmacokinetics (Eap et al. 2004a).

MODIFICATIONS OF THE METHOD

The combined use of IV midazolam and oral ^{15}N-midazolam or of the ERMBT and oral midazolam tests have been proposed to assess simultaneously the contributions of liver and intestine in CYP3A activity (Gorski et al. 1998; McCrea et al. 1999). The administration of orally given midazolam followed by an intravenous administration has also been validated (Lee et al. 2002c). A low oral 75 μg oral dose has recently been proposed, but it needs validation on a large scale (Eap et al. 2004b).

Modifications of the ERMBT have been described to improve its predictability in drug clearance estimations in cancer patients (Rivory et al. 2000).

A single blood sample for midazolam assay at 4 h post-dose has been reported as good estimator for IV or oral midazolam clearance determination (Lin et al. 2001).

43.2.1.6 Other CYPs

This section summarizes succinctly the current knowledge on some other CYPs, the role of which in drug metabolism and the impact of genetics on it have been more recently investigated as compared to other CYPs.

CYP2A6

CYP2A6, primarily expressed in the liver, is the major CYP (the sole at usual low concentrations) involved in nicotine oxidation, and is also involved in the metabolism of carcinogen or procarcinogen compounds (such as nitrosamines and aflatoxins). A couple of drugs is metabolized by CYP2A6: chlormethiazole, coumarin, disulfiram, halothane, valproic acid, and others (Oscarson 2001). CYP2A6 PMs are less than 1 in Caucasians but up to 20% in Orientals (Oscarson 2001; Raunio et al. 2001; Xu et al. 2002). The most "in vivo deficient" alleles for PM status are CYP2A6*2 and CYP2A6*4, rather common in Orientals (15% in Chinese, 20% in Japanese). The important role of CYP2A6 in nicotine metabolism was shown in an epidemiological study revealing that the CYP2A6 genotype was a major determinant for smoking behavior and susceptibility to tobacco-related lung cancer (Fujieda et al. 2004).

Phenotyping has been performed in some countries with coumarin (not available in all countries), despite some limitations with data accuracy obtained with the analytical methods used (Pelkonen et al. 2000; Cok et al. 2001). The test assesses the amount of 7-hydroxycoumari (free and conjugated) in urine after ingestion of 2–5 mg coumarin by the subjects. Nicotine has also been used as the probe drug for CYP2A6 in vivo activity testing. Recent investigations using pilocarpine as probe demonstrated that PM status was associated with two inactive CYP2A6 alleles, CYP2A6*4A, CYP2A6*7, CYP2A6*9, or CYP2A6*10 (Endo et al. 2008).

CYP2B6

CYP2B6 has been estimated to represent 1–10% of the total hepatic CYP content. It catalyzes bupropion hydroxylation, and S-mephenytoin N-demethylation and is involved in the metabolism of cyclophosphamide, ifosfamide, mianserin, efavirenz, artemisinin, and propofol (Turpeinen et al. 2006). CYP2B6*6 has been associated with reduced bupropion clearance in vitro (Hesse et al. 2004) but not in vivo; whereas, a moderate clearance increase was observed with CYP2B6*4 (Kirchheiner et al. 2003b). Multiple gene polymorphisms have resulted in phenotypic null alleles (Lang et al. 2004). Pharmacokinetics of the anti-HIV drug efavirenz has been associated with CYP2B6-G516T polymorphism (Saitoh et al 2007).

Bupropion (150 mg dose) has been proposed for phenotyping, but it is recommended to administer body weight-adjusted doses (Faucette et al. 2000). Efavirenz may also be a valuable probe for CYP2B6 (Ward et al. 2003).

CYP2C8

CYP2C8 is involved in the metabolism of arachidonic acid, all-trans retinoic acid, paclitaxel, amiodarone, amodiaquine, repaglinide, rosiglitazone, torsemide, troglitazone, and zopiclone. Most of these drugs are also metabolized by CYP3A4. Recently, the potential contribution of CYP2C8 to the metabolism of NSAIDs in addition to the well-known CYP2C9 role has been highlighted for ibuprofen (Garcia-Martin et al. 2004). The CYP2C8*3 allele (present in 13% and 2% of Caucasians and Afro-American subjects, respectively) has been shown in vitro deficient for paclitaxel and arachidonic acid metabolism (Dai et al. 2001; Bahadur et al. 2002). For the antidiabetic repaglinide, unexpected in vivo lower exposure was observed in subjects with CYP2C8*1/*3 genotype, without any pharmacological consequences (Niemi et al. 2003). For ibuprofen, reduced clearance of the R(-) enantiomer was related to CYP2C8*3 allele, and reduced clearance of the S(+) enantiomer was influenced by CYP2C8*3 and CYP2C9*3 alleles. In subjects homozygous or double heterozygous for these variants (8% of 130 subjects evaluated), the clearances of ibuprofen were only 7–27% of the clearances observed in subjects with no CYP mutations. A strong association between CYP2C8*3 and CYP2C9*2 occurrence has been characterized in a large Swedish population, highlighting linkage between CYP2C8 and CYP2C9 polymorphisms (Yasar et al. 2002c).

Further in vitro/in vivo investigations are needed to assess the relationship between CYP2C8 (and CYP2C9) polymorphisms and drug metabolic clearance, in order to address the clinical relevance of CYP2C8 genotyping.

CYP2E1

CYP2E1, an ethanol-inducible CYP, activates some procarcinogens like nitrosamines, is involved in the metabolism of endogenous substrates (steroids, bile acids), alcohols, xanthines, volatile chemicals (toluene, benzene, halocarbons) but of few drugs (chlorzoxazone, etoposide, dapsone, high-dose acetominophen) (Lieber 1997). Seven alleles, 13 genetic mutations have been described, but no genotyping-phenotyping relationships have been well established to date. Based on safe use and CYP selectivity (though CYP1A1, CYP1A2 have been found involved in its biotransformation in vitro), chlorzoxazone is the only in vivo probe drug to phenotype CYP2E1 activity toward assessment of its 6-hydroxylation (Ono et al. 1995; Lucas et al. 1999; Ernstgard et al. 2004). Due to dose-dependent metabolism, the dose should be preferably administered on a milligram/kilogram basis (10 mg/kg rather than the common 250 or 500 mg doses). Relatively low intraindividual variability in chlorzoxazone metabolism has been observed. Measurement can be done in urine or in plasma, after enzymatic hydrolysis of

6-chlorzoxazone glucuronide, using HPLC and UV detection or LC/MS/MS methods (Frye and Stiff 1996; Frye et al. 1998; Scoot et al. 1999). The use of plasma metabolite ratio determined with only one plasma sample – at 2 h post-dosing – has been recently validated.

43.2.2 Phase II Enzymes

With the exception of N-acetyltransferases (detailed below), there are few deficiencies in Phase II drug metabolism enzymes that have resulted in clinically significant effects. Each Phase II enzyme class is most often a superfamily of enzymes, and usually there is large interindividual and interethnic variability in drug conjugations, and overlapping substrate specificity exists for numerous isoenzymes. Despite the crucial role of conjugation enzymes in xenobiotic metabolism, the functional significance of enzyme polymorphism is only known for few substrates. Therefore, with the exception of the caffeine and TPMT tests (see below), no probe test drug has been yet investigated for in vivo phenotyping and validated to assess phenotyping-genotyping relationships. Nevertheless, some important aspects of enzyme polymorphism on the pharmacokinetics of drugs with narrow therapeutic index are summarized below.

43.2.2.1 N-Acetyltransferases

PURPOSE AND RATIONALE

N-acetyl transferases Type I (NAT1) and Type II (NAT2) catalyze N- and O-acetylation reactions involved in the metabolism of drugs containing arylamino, hydroxyl, sulfhydryl groups and hydrazine structure, and also in environmental carcinogens (such as those present in tobacco smoke, or in diet such as charcoal-broiled food) (Weber and Hein 1985). Pending on the drug, and on the interplays between CYPs and N-acetylases (and other Phase II conjugation enzymes) in xenobiotic metabolism, the impact of subject status "poor acetylator" or "rapid acetylator" on drug activity and/or toxicity may vary, and then is drug specific. NAT1 and NAT2 exhibit a high degree (81%) of amino-acid sequence homology and also share common substrates (Meisel 2002), but coding genes loci are regulated independently. Main NAT2 drug substrates are isoniazid, sulfonamides, procainamide, hydralazine, acebutolol, aminogluthetimide, and dapsone.

Para-aminosalicylic and para-minobenzoic acids are considered specific substrates for human NAT1, and sulfamethazine, isoniazid, procainamide, and dapsone are considered specific substrates for human NAT2 (Butcher et al. 2002). NAT1 is considered as ubiquitously distributed in the body, whereas NAT2 is expressed in the liver and the intestinal mucosa.

Polymorphic N-acetylation was first described for isoniazid in the 1950s and is the first example of interindividual pharmacogenetic variability. Until 2007, about 30 and more than 50 variant alleles have been described for NAT1 and NAT2, respectively. At http://N-acetyltransferasenomenclature.louisville.edu overviews on the NAT alleles can be found. The presence of some NAT1 variants, as well as NAT2 variants, has been linked to increased susceptibility to some cancers (notably bladder and colon cancers), and NAT2 polymorphism associated with some drug-induced diseases such as lupus erythematosus (hydralazine, procainamide), Stevens-Johnson or Lyell syndromes (sulfonamides).

Significant interethnic and geographic differences in NAT2 activity have been found. Slow acetylators represent 40–70% Caucasians and 10–20% Asians. High acetylation capacity has been reported in 5% Caucasians (Meyer and Zanger 1997).

Probe drugs for NAT-1 phenotyping is PAS, and for NAT-2 phenotyping are caffeine, sulfamethazine, procainamide, and isoniazid or dapsone. In vivo testing for NAT2 has been proved to be useful for drug monitoring to avoid potential side effects generally observed in slow metabolizers (the exception was the anticancer agent amonafide, with myelotoxicity observed in rapid acetylators). The most used test to identify rapid and slow acetylators is the caffeine test, which is described thereafter, though the N-acetylation step takes place after the N-desmethylation of caffeine by CYP1A2 followed by the biotransformation into an unstable intermediate.

PROCEDURE

Phenotyping: Caffeine is metabolized by CYP1A2, NAT2, and xanthine oxidases. The methods could involve the measurement of 5-acetyl-formylamino-3-methyluracil (AFMU), 5-acetyl-amino-3-methyluracil (AAMU, degradation product of AFMU), 1-methylxanthine (1MX), and 1-methyluric acid (1MU) in 0–8, 0–12, 0–24 h urine of subjects orally given 200 mg or 2–3 mg/kg caffeine after a xanthine-free regimen. The common metabolic ratio used is AFMU/1MX, but the AFMU/(AFMU + 1MX + 1MU) is more discriminating (Relling et al. 1992; Rostami-Hodjegan et al. 1996) and should be used when xanthine-oxidase inhibitors may be present (Fuchs et al. 1999). Other ratios such as AFMU/(1MX + 1MU), or AAMU/1MX, AAMU/(AAMU + 1MX + 1MU) have been validated (Tang et al. 1991; Nyeki et al. 2002).

The most common methods to assay caffeine and its metabolite in urine used HPLC with UV detection (Grant et al. 1984; Krul and Hageman 1998) or mass spectrometry (Baud-Camus et al. 2001).

Genotyping: Mutations of NAT2*5, NAT2*6, NAT2*7, NAT2*14, and NAT2*17 alleles are associated with a slow acetylation phenotype for homozygous subjects (Butcher et al. 2002).

There are large differences among ethnic groups regarding alleles' frequency. High frequency (>28%) of NAT2*5 alleles has been observed in Caucasians and Africans, and of NAT2*7 in Asians (>10%) and of NAT2*14 in Africans (>8%), this last one being <1% in Caucasians and Asians (Meyer and Zanger 1997).

EVALUATION

Caffeine test: Subjects with a AFMU/1MX ratio <0.55 or a AFMU/(AFMU + 1MX + 1MU) ratio <0.26 are slow acetylators (Fuchs et al. 1999). Higher activity has been observed in black as compared to white subjects (Relling et al. 1992), and a gender effect has generally not been observed (Kashuba et al. 1998).

CRITICAL ASSESSMENT OF THE METHOD

Depending on the probe drug used and on the experimental method, two or three acetylator types can be described: slow, intermediate, and rapid, the intermediate one being not always distinguished from the rapid one. Phenotype distribution has been considered as a continuous variable (Meisel 2002). Due to slow postnatal maturation of the acetylation enzymatic systems, the acetylation status is evolving in newborns and infants and depends on the probe drug used (Rane 1999).

Good relationships between genotyping and phenotyping tests have been reported (Meisel et al. 1997; Kita et al. 2001).

The urinary caffeine test is not based on assays of specific substrates and products of NAT2 ("including" other metabolism pathways involving at least xanthine-oxidases) and is affected by diet habits, xanthine-oxidase inhibitors such as allopurinol (Fuchs et al. 1999), or other drugs (Klebovitch et al. 1995). NAT activities are affected by anti-inflammatory drugs. Of note, acetominophen is an inhibitor of NAT2 in vivo (Rothen et al. 1998).

Discordances between caffeine and dapsone phenotyping data and between NAT2 phenotyping status and genotyping have been observed in acutely ill patients infected with HIV (O'Neil et al. 2000), which may be due partly to nondetection of rare NAT2 alleles (Alfirevic et al. 2003).

MODIFICATIONS OF THE METHOD

Some recent references for other used NAT2 phenotyping tests can be found for dapsone in Alfirevic et al. (2003), O'Neil et al. (2000), Queiroz et al. (1997), for sulfamethazine in Hadasova et al. (1996) and Meisel et al. (1997), and for procainamide in Okumura et al. (1997) and Mongey et al. (1999).

43.2.2.2 Uridine Diphosphate Glucuronosyltransferases

Glucuronidation is a potent detoxification pathway. The uridine diphosphate glucuronosyltransferases (UGTs) are involved in the biotransformation of endogenous substances (bilirubin, biliary acids, steroid hormones) and numerous drugs and carcinogens. Currently, 20 functional UGTs have been characterized with activity mainly expressed in the liver and GI tract. There are three subfamilies: UGT1A, UGT2A, and UGT2B, with distinct but broad overlapping substrate specificity existing for the different isoforms of each family. UGT1A1 is the most abundant UGT in the liver. Human diseases related to deficient UGT1A1 alleles are the well-characterized inherited unconjugated hyperbilirubinemias, including the Gilbert's syndrome which affects 6–12% of Caucasian subjects. Exhaustive reviews on roles, tissue patterns of expression, and pharmacogenomics of UGTs can be found in papers from Tukey and Strassburg (2000), Fischer et al. (2001), Guillemette (2003), and Wells et al. (2004).

A decreased clearance has been observed for some drugs metabolized by glucuronidation in patients with Gilbert's syndrome. A clinically significant impact of UGT polymorphism has to date is only demonstrated for some anticancer agents: clearly for irinotecan and with contradictory results for flavopiridol (Zhai et al. 2003). UGT1A1 and UGT1A9 are involved in the glucuronidation of the active metabolite SN-38 of irinotecan. The presence of the deficient UGT1A1*28 variant (most frequent variant as compared to UGT1A9 variants) has been clinically linked to a decrease in SN-38 glucuronidation rate and to an increased occurrence of serious side effects, mainly severe diarrhea and neutropenia (Ando et al. 1998; Innocenti et al. 2004; Iyer et al. 2002; Paoluzzi et al. 2004). Variants of UGT1A7 were reported to affect SN-38 glucuronidation but only in vitro (Villeneuve et al. 2003). Other factors, such as polymorphism in drug transporter P-glycoprotein and renal excretion, may play a role in the complex disposition pattern of irinotecan.

43.2.2.3 Methyltransferases

There are at least four enzymes catalyzing S-, N-, and O-methylation using S-adenosylmethionine, but only thiopurine methyltransferase (TPMT) polymorphism has been found to have important clinical consequences. To date, no endogenous substrate of TPMT is known. TPMT is involved in the metabolism of mercaptopurine, azathioprine, and thioguanine, narrow therapeutic index drugs in use for treatment of patients with neoplasia or autoimmune disease, or of transplant recipients. About 0.3% of Caucasian subjects have no detectable enzyme activity and 10% intermediate activity (McLeod and Evans 2001). Four alleles TPMT*2, TPMT*3A, TPMT*3B, and TPMT*3C account for 80–95% of Caucasians with intermediate or low enzyme activities. Patients with low inherent TPMT activity are at great risk for severe potentially life-threatening myelosuppressive toxicity with treatment by the above-mentioned drugs, whereas subjects with very high activity might be underdosed (Zhou 2006). Patients with two nonfunctional variant TPMT alleles should receive 5–10% of drug standard doses. TPMT genotyping has proved its usefulness in individualizing mercaptopurine dose in patients and can replace the phenotyping test: measurement of the erythrocyte enzyme activity, based on the in vitro conversion of 6-mercaptopurine to 6-methylmercaptopurine or 6-thioguanine to 6-methylthioguanine (Innocenti et al. 2000; Evans 2004). A cutoff concentration of 45.5 nmol thioguanine/gHb.h^{-1} for this TPMT phenotyping test has been proposed for assessing the need of the genotyping test (Wusk et al. 2004).

43.2.2.4 Glutathione S-Transferases and Sulfotransferases

Glutathione and sulfatation conjugations are important pathways for generally detoxifying endogenous substrates and xenobiotics (Commandeur et al. 1995). However, some produced metabolites (i.e., mercapturic acids, O-sulfo conjugates) are toxic by different mechanisms, often by reaction with DNA and other cellular nucleophils.

Eight classes of glutathione-S-transferases (GSTs) have been described. The role of the glutathione pathway and the impact of enzyme polymorphism have been highlighted for detoxification and some disease susceptibility, and routine phenotyping of some GSTs exists for clinical safety measurement, but currently there is not yet evidence of genotyping or phenotyping usefulness for drug dosage adjustment (Hayes and Strange 2000; Tetlow et al. 2004). GSTs are involved in the detoxification of chemotherapeutics, including platinum derivatives. Polymorphisms in the GSTP1 genotype might become a powerful tool to predict oxaliplatin-induced cumulative neuropathy (Lecomte et al. 2006).

Soluble sulfotransferases are involved in the sulfonation of endogenous substrates (notably steroids, neurotransmitters, eicosanoids) and numerous xenobiotics (i.e., acetaminophen, organic-platin anticancer agents). The presence of some sulfotransferases variants could be associated with some cancer risk. Phenotyping tests have been developed for some forms (SULT1A, SULT1A3) by measuring platelet sulfotransferase activity (Glatt and Meinl 2004).

PURPOSE AND RATIONALE

Characterization of physicochemical properties attained strong interest in the pharmaceutical research area and is now a standard method. One of the key challenges is to develop a pharmaceutical active ingredient into a drug, which combines biological activity with an appropriate physicochemical profile. Poor solubility in aqueous media is one of the major hurdles in the drug development process. Many promising drug candidates have failed simply due to inadequate solubility. The impact of solubility in drug discovery on biological assays, dosing and formulation, and intestinal absorption is discussed by Kerns et al. (2008).

A poor solubility can be overcome if a compound has an appropriate high permeability through a cell membrane. Passive permeability through a membrane has been correlated with the lipophilicity of a compound in many cases (Lipinski et al. 1997). Generally speaking, high lipophilicity will ease passive cell permeation but may result in poorly soluble compounds. To find here a compromise belongs to the art of drug discovery.

Another important physicochemical parameter is pKa, which describes the ionization state of a compound at a given pH. The ionization state of a compound in the different components of the gastrointestinal system (stomach, jejunum, ileum, and colon) is crucial for the understanding of drug absorption (Dressman et al. 1998). Ionized compounds have in general better solubility, but passive permeation through the membrane is limited (Comer and Tam 2001).

All these parameters have been long investigated in drug discovery but were part of the later stage of the

DOI 10.1007/978-3-642-25240-2_48, © Springer-Verlag Berlin Heidelberg 2013

process. Nowadays, the characterization of physicochemical properties moved also in the lead-finding phase of drug discovery (Kibbey et al. 2001). Thus, screening assays had to be developed able to give comparably accurate data and a throughput to characterize hundreds of compounds a day (Kerns et al. 2008).

44.1 Solubility Assays

PURPOSE AND RATIONALE

Solubility assays gain still growing attention in drug discovery because many pharmaceutical active compounds can be adjusted to in vivo testing just with cosolvents. Furthermore, in vitro assays may also lead to false results simply for precipitation of a compound in the assay media. Solubility assays vary in one main point: they are performed from either solids or stock solutions. A nomenclature has been established in the literature, which tries to distinguish between these methods. Determinations from stock solutions are often called "kinetic solubility," whereas "thermodynamic solubility" stands for solubility of solids (Kerns 2001). Thermodynamic solubility takes the crystal lattice forces into account. Batch-to-batch variations and polymorphism of investigated compounds are neglected in early stage of discovery but may become a key focus in later stage. Ritonavir is a prominent example (Law et al. 2001).

Stock solutions—already prepared by central logistic centers—have the advantage of standard start conditions, which are additionally similar to conditions found in biological assays. They allow a high throughput because the time delaying sample preparation is already done.

44.1.1 Determination of Solubility by Hyphenated HPLC Methods

PURPOSE AND RATIONALE

The range of solubility assays has to be <0.001 mg/ml up to >10 mg/ml in some cases. In vivo tests (orally or intravenous) need sufficient solubility of a compound in physiological or buffered solution. "True" data is also needed in compound optimization, where solubility is one of the parameters to be improved. Classification in poor, medium, or good solubility is often not sufficient. Hyphenated HPLC methods have been a long tradition in quantification and characterization of compounds in analytical sciences. Many reviews and handbooks cover this field (Unger 1994; Lunn and Schmuff 1997). The detection of the compounds is done with UV, mass spectroscopy, and light scattering or by nitrogen detection. In addition to the quantification of the solubility, impurities and side products are detected. Furthermore, buffer instability can be determined.

PROCEDURE

As described in the general introduction for solubility assays, there is a difference between kinetic and thermodynamic solubility. Thermodynamic solubility needs solid material of good quality, whereas kinetic solubility relies on organic stock solutions. The sample preparation is therefore different (Kibbey et al. 2001).

The procedure for determining solubility follows standard quantification methods with hyphenated HPLC. 0.5–1 mg of solid is weighed in a microvial, and 250 μl of buffer is poured over the solid. The vial is shaken for 24 h at 25°C. After shaking, the suspension is centrifuged and the supernatant is filtered. An aliquot (1–10 μl) of the supernatant is injected in a HPLC system. Eluents are generally acetonitrile and water containing 0.5% trifluoric acid or 0.5% formic acid. Both eluents are mixed via gradient device from 5% acetonitrile to 95% acetonitrile content. Separation is obtained on a reversed-phase column. The same aliquot of a standard is injected in a following run if one

point calibration is done (Pan et al. 2001). Better accuracy but longer evaluation time is needed if a five-point calibration is done covering a range from 0.1 μg/ml up to 2,000 μg/ml. Gradient time is set either to have higher throughput (fast gradient) or better chromatographic resolution.

The quantification is done via a calibration curve where the compound is weighed as standard and dissolved in an appropriate organic solvent (in most cases acetonitrile/water). The throughput of this method is 20 compounds a day.

If the standard stock solution is delivered from a centralized stock solution, the throughput can be increased significantly. Solubility obtained from organic stock solutions leads to kinetic solubility data (see also Sect. 44.1.2).

An aliquot of 30 μl is transferred in 250 μl buffer. The solution is shaken for 24 h at 25°C. If precipitation occurs, the sample is centrifuged and filtrated. The following procedure is the same as for the solubility from solids described above. The achieved throughput is mainly limited by the gradient time. Pan et al. (2001) investigated the effect of filtration on the quantification of solubility. They recommend polytetrafluoroethylene (PTFE) as the filter material of choice. In their compound set, they found 98% recovery after filtration.

Quantification of the compounds is done via different detection modes such as:

UV or photodiode array (PDA)
Mass spectroscopy (MS)
Nitrogen detection (CLND)
Light scattering (ELS)

or a combination of them (Guttman et al. 2004). Evaluation of the compound structure before quantification is necessary because not all compounds have, for instance, a chromophore (UV detection) or nitrogen (CLND).

EVALUATION

High-throughput methods use one-point calibration. The quantification of the solubility (c_{sol}) is done via the peak areas under the curves (AUC) of standard and measurement. For one-point calibration,

$$c_{sol} = \frac{AUC_{sol}}{AUC_{st}} * c_{st}.$$

Identification of the compound is done via either the retention time or the mass of the peak, which is to be quantified. If the chromatographic resolution is not good enough to separate impurities or degradation product, the measurement has to be repeated with longer gradient times or longer reversed columns.

CRITICAL ASSESSMENT OF THE METHOD

In the early stage of drug discovery, the main variance of solubility data is in most cases linked to batch-to-batch variations of a synthesized compound. Most batch-to-batch variations are related with different side-product profile or purity, and differences in the crystallinity. In extreme cases, oily, amorphous, or crystalline batches may be obtained for one compound. These effects superimpose errors coming from the experimental conditions.

Very poor soluble and very good soluble compounds will give an AUC far different from the standard injection. This may leave the linear range of the calibration. They are quantified therefore far more accurately with 5-point calibration, which covers a wide concentration range. Very good soluble compounds should be diluted to reach the linear range of the AUC/$c_{analyte}$ curve.

Very poor soluble compounds are in most cases lipophilic. They tend to stick to the used filter systems or used plastic devices, which leads to compound loss. Thus, very poor soluble compounds may be underestimated due to the sample preparation (Pan et al. 2001).

Each detection system has its own limitations. Compounds with no chromophore are not UV active for instance and may be quantified with ELS. A short analysis of the compound class is therefore needed to prepare and interpret the solubility experiments. Direct quantification of the sample without any external calibration is possible if a nitrogen detector is used. Throughput is higher and a standard injection is not necessary.

If a compound with high solubility exceeds the buffer capacity, it may change the pH of the buffer system. This is not realized without any pH control, which could be difficult to control in a standardized and miniaturized environment. This methodology fails for compounds without nitrogen or with nitrogen-nitrogen double bonds.

MODIFICATIONS OF THE METHOD

To achieve high-quality data with low sample amount, a commercial pSOL instrument (pION, Woburn, MA)

can be used. It delivers with a pH metric approach a solubility pH profile with 100 µg of solid compound. The throughput is 4–6 compounds a day.

TREGA describes a protocol for pH-adjusted measurements (TREGA). They need very accurate data for their idea of an computational program, simulating drug absorption in the gastrointestinal system. Five times 30–50 mg of compound are weighed in 10-ml vials. The vials are filled with 8 ml of buffer covering a pH range between 2 and 8. The vials are shaken for 8 h and the pH is controlled. If necessary, the pH is adjusted. The pH adjustment is done with HCl and NaOH. After pH adjustment, the compounds are shaken for additional 2 h. The pH adjustment is done until saturation solubility is achieved and the pH is stable. The experiment is tedious and reduces the throughput to a couple of compounds a day.

Kerns et al. (2008) reported a method where solid compounds are weighed into a Mini-UniPrep™ filter chamber. 0.45 aqueous buffer is added and the chamber is shaken for 24 h at room temperature. After automatic filtration, the supernatants are directly injected in a HPLC instrument. The throughput is reported to be 50 compounds a day per HPLC instrument.

An enhancement of this method is reported by Zhou et al. (2007). The so-called high-throughput equilibrium solubility (HT-Eq sol) assay starts from DMSO stock solutions but dries the compounds by evaporation. This avoids the time-limiting step of manual weigh-in, but results in the loss of the crystalline form. A comparable technique was used in the PASS assay Alsenz et al. (2007); here, the compound is handled as a suspension in heptane to achieve automated liquid handling. After drying the compound, the crystal lattice is not changed and the solubility measurement can start in a very small scale (96-well PCR plates). The readout is done by a fast UPLC method, resulting in a total throughput of 600 measurements per week.

Dressman reviewed the methodologies used for simulating biofluids. These methodologies focus on the solubility behavior and dissolution rate in solvents, which mimic the fluids in the gastrointestinal system like Fessif and Fassif. These dissolution tests are invented for better prediction of in vivo performance of drug products. They are barely comparable with solubilities in buffered aqueous media and have a limited throughput of a couple of compounds a day.

44.1.2 High-Throughput Solubility Assays

PURPOSE AND RATIONALE

In vitro testing of drug candidates and combinatorial chemistry lead to an increase of lipophilic compounds with poor solubility (Lipinski et al. 1997). Poor solubility itself may lead to poor oral availability of a potential drug. The growing demand for solubility data in lead phase of drug discovery is answered by a variety of simple solubility assays, which allow the classification of a compound without real quantification (see Chapter "Solubility Assays"). One of the easiest ways to detect saturation in a solvent is the

turbidity of the solution if precipitation occurs. The turbidity caused by precipitation of a poorly soluble compound can be detected by a couple of detection methods (Van de Hulst 1981; Hongve and Akesson 1998). Lipinsky describes the first methodology, which uses UV as detection method and is able to screen hundreds of compounds a day with one instrument.

PROCEDURE

Lipinsky dissolved compounds in DMSO at a concentration of 10 µg/ml. Complete dissolution is controlled by eye. One microliter of this solution is added into a cuvette containing 2.5 ml pH 7 phosphate buffer. Mixing of the system is controlled via an integrated mixing device. The temperature is kept constant between 22°C and 25°C. Stepwise one-microliter portions are added to the mixing chamber. After each step, an equilibrium time of 5 min is allowed before turbidity is analyzed. These steps are repeated up to 14 times, covering a range of <5 to >65 µg/ml. If precipitation occurs, the addition of compound is stopped after further two consecutive additions. The volume percent aqueous DMSO does not exceed 0.67%.

EVALUATION

Precipitated particles lead to an increase in UV absorbance due to light scattering. Lipinsky used a diode array UV (Hewlett Packard HP8452) at 600–820 nm for their experiment. UV absorbance (y-axis) vs. µl DMSO plots (x-axis) is used to detect the precipitation point. A strong increase in the slope of the curve indicates precipitation. Precipitation defines the maximum solubility level in this experiment. The method allows a classification between poor, moderate, and good soluble compounds. Poorly soluble compounds have in this scheme a solubility less than 10 µg/ml, whereas good solubility is defined as solubility higher than 65 µg/ml.

CRITICAL ASSESSMENT OF THE METHOD

The method has been used and modified by different authors (Bevan 2000; Green et al. 2004) and is today a standard solubility assay in industry. Advantages are the simplicity of the experiment and the low sample consumption. Impurities of the samples (which are common in the early drug discovery) are not detected and could lead to false-positives if the mixture has a better solubility as the pure material. False-negatives are observed if impurities have lower solubility as main material. Growing DMSO content alters the solubilizing properties of the aqueous media. Up to 5% DMSO content is seen as appropriate for a solubility ranking. It does reflect also the situation in many biological assays where the DMSO content is up to 5% (Lipinski et al. 1997). However, the quality of the data allows a ranking of compounds in poor/medium/good soluble compounds.

The method does underestimate compounds with slow dissolution rate. To minimize the risk of a wrong assessment, control measurements with other methods (preferably HPLC methods, see Sect. 44.1.1) are recommended. This could be done with one or two members of a compound class.

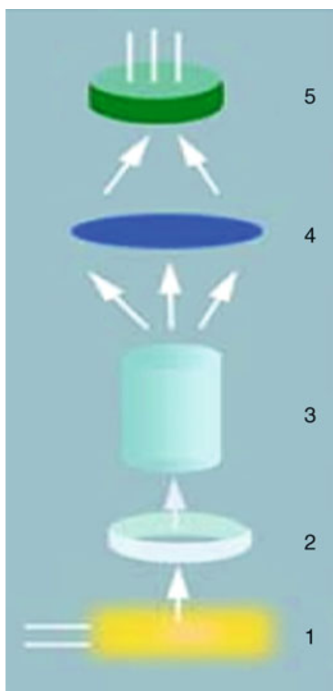
MODIFICATIONS OF THE METHOD

Bevan introduced a high-throughput alteration of the method. He used 10 mM DMSO stock solutions for a precipitation assay. In many biological assays, 10-mM DMSO stock solutions are the standard stock solutions from which aliquots are added to the various assays. 10-mM DMSO stock solutions are readily available, and the sample preparation can be minimized.

The assay itself is performed in a 96-well plate. DMSO stock solution is diluted 20-fold in PBS (0.01 M, pH 7.4). The diluted solution is again serially diluted 10 times with 5% DMSO/95% PBS across the 96-well plate in order to keep 5% DMSO content stable. The solubility assay is performed with two replicates for each compound; thus, eight compounds can be measured per plate. Detection of the precipitation is done with a helium/neon laser nephelometer (BMG Labtechnologies, Offenburg, Germany). The instrument lases at 632.8 nm, whereas the laser beam passes the well in a vertical and concentric path. The instrument detects just linear light from the source. A clear solution gives no signal (Sketch 44.1).

Precipitation leads to light scattering which is detected. The following solubility classifications are used: poor solubility (<10 mg/ml), medium solubility (10–100 mg/ml), and good solubility (>100 mg/ml).

The method can be faster if the liquid handling is done by an automated system. Many vendors have integrated nephelometer in their systems. An example is shown by Dehring et al. (2004). Here a Tecan platform was used together with the nephelometer.



Sketch 44.1 Principle of nephelometric detection

Consequent time optimization from liquid handling to data evaluation by adapted software leads to a total measurement time from protocol setup to data analysis from 6 to7 h for 96 compounds.

The methodology is now also adopted for 384-well plate format (Green et al. 2004). The data obtained by this method have good correlation with data obtained for 96-well plate format. The batch-to-batch variability is 5%. The quality of the well plates has a high influence on the obtained data. Even microscopic scratches may pretend precipitation. Pan et al. (2001) investigated different well plate types. His recommendation is to use Costar clear bottom white plates. Clear polypropylene Cliniplate (LabSystems) has also good quality but provided lesser signal enhancement.

Fligge and Schuler integrated an automated 384-well kinetic solubility method by nephelometry into the early validation LCMS process used for new compounds. Most pharmaceutical companies use a fast LCMS run for purity determination of a freshly synthesized compound delivered by their stock room as a DMSO solution. Here no additional sample logistic for the solubility measurement is necessary; the solubility value to rank a compound is available together with a purity report.

Avdeef introduced an alternative approach to measure kinetic solubility. Aliquots of DMSO stock solutions are pipetted robotically in incubation well plate, which contains an aqueous buffer. The concentration of the test compound should be between 50 and 150 μM in order to keep the DMSO content below 0.5%. After a time of incubation, the plate is filtered and the solved compound is quantified with a UV plate reader. The method is fast and robust and reported to be reliable (Kerns and Chen). Two hundred to 300 compounds can be measured a day. Additionally, pH-solubility profiles can be set up easily (Kibbey et al. 2001).

44.2 Determination of pKa

PURPOSE AND RATIONALE

The pKa is the dissociation constant for a given medium. It is a parameter which indicates the ionization state at a given pH and describes the acidity of a compound in a special medium. In drug discovery, it is a valuable parameter for SARs but also helps in the interpretation of pH-solubility profiles. For an acid:

$$\text{pKa} = -\log 10\ \text{Ka}\ (\text{Ka is the ionization constant})$$

$$\text{HA} = \text{H}^+ + \text{A}^-\quad \text{Ka} = [\text{H}^+][\text{A}^-]/[\text{HA}]$$

$$\text{pKa} = \text{pH} + \log[\text{HA}]/[\text{A}^-]$$

In practice, the pKa is the pH where 50% of the compound is ionized.

Molecules can have more than 1 pKa depending on the number of ionizable centers. In pharmaceutical research, the ionization state between pH 2 (stomach) and 8 (pH in colon) is most interesting. A review by Taylor covers the effects of the different protonization/ionization forms of a molecule on pharmacokinetic and pharmacodynamic properties. Molecules are less soluble in aqueous media but more permeable through membranes in their neutral form.

Today most pKas are determined by classical titration with UV (Albert) or potentiometric (Sirius GLpKa) detection. These methods could be coupled with multiwavelength spectrophotometer detection (Sirius, D-PAS). Tam et al. (1998) compared both methodologies and found good correlation between them.

PROCEDURE

The classical potentiometric approach (Sirius, GLpKa) can be coupled with multiwavelength detection, thus gaining enhanced sensitivity with decreased sample consumption.

Multiwavelength spectrophotometer detection is based on the change of the ionization state of a molecule. A change of the ionization state leads to a change of the electron density, which directly leads to an increase or decrease of UV absorbance – monitored by spectroscopic detection. The titration is performed with KOH or HCl across a pH range of 1.8–12.2. HCL and KOH solutions are prepared for the titration according Avdeef. The aqueous medium for compound solutions can be chosen individually. An ionic strength of 0.15 potassium chloride is recommended. The D-PAS uses an automated titration system coupled with fiber optic dip probe, a UV light source, and a photodiode detector. Spectral changes, which arise during the titration, are captured at concentrations down to 10^{-5} to 10^{-6} M.

The titration intervals can be set individually via the instrument software. The compound is solved in the measurement cell at a concentration of 10–100 μM, whereby the pH adjustment by automated titration of the system has an accuracy of 0.02 pH units. Tam suggests in their report titration steps of 0.1 pH units and to perform 25–35 pH readings and absorption spectra measurements during each titration.

Poorly soluble compounds can be measured with cosolvents as methanol, octanol, or DMSO at different concentrations. Their true water solubility can be extrapolated by the Yasuda-Shedlovsky method.

EVALUATION

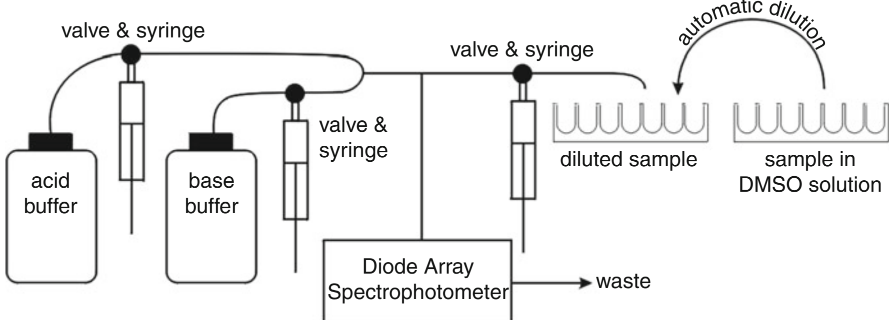
The instrument software computes the operational pH readings to the pH value by a multiparameter equation reported by Avdeef. The pKa values are calculated from the pH values and the absorption data of different wavelengths. The calculation is done by target factor analysis (Allen et al. 1998).

The Yasuda-Shedlovsky method pKa + log $[H_2O] = (A/\varepsilon) + B$ is used for the extrapolation of molecules with poor aqueous solubility measured within aqueous buffer containing different percentages of organic cosolvent. ε is the dielectric constant of the cosolvent mixture, $[H_2O]$ for the molar concentration of water, whereas A and B represent slope and intercept of the plot. pKa + $[H_2O]$ is plotted against 1/ε.

CRITICAL ASSESSMENT OF THE METHOD

The method shows very good correlation to pKas obtained by classical titration (Allen et al. 1998) or the literature (Lide and Frederikse 1996). Weak UV absorbance also limits the determination of pKas far away from a chromophore. A range of three bonds is considered tolerable (Tam et al. 1998). Poor UV absorbance may be enhanced by rise of the analyte concentration. If poor solubility of a compound may prevent the compound concentration to increase, then the use of cosolvents is recommended.

Furthermore, it has to be considered that side products or hydrolysis of the analyte in the pH profile can



Sketch 44.2 High-throughput pKa determination

give rise to false-positives. Thus, a quality control step before is recommended.

MODIFICATIONS OF THE METHOD

Comer and Tam (2001) developed a high-throughput pKa assay (SGA profiler, Sirius Analytical) which is able to measure the pKas of up to 200 compounds between pH2 and pH12. Compounds are dissolved in DMSO to give 10-mM stock solutions. Five to 20 µl of the stock solution is transferred in a deep well plate and is diluted with 2 ml of water. Up to 96 compounds can be measured per plate. The dilution is injected in a flow pH gradient, which is produced by mixing two buffer solutions containing mixtures of weak bases and acids. These mixtures have low absorbance in the UV above 250 nm. The flow gradient passes a diode array spectrometer covering 280–800 nm (Sketch 44.2).

Evaluation is done with the instrument software. The software calculates the change in UV absorbance at 30 different wavelengths in order to calculate the pKa. Since the pH gradient of the combined mixtures is linear over a wide range, the pH is a linear function of time. The pKas are calculated from the change of UV absorbance at multiple wavelengths as a function of time.

Up to 70% of all samples can be taken into account for a measurement, since most compounds in drug discovery have a chromophor and/or are nitrogen containing. The sample consumption is very low. Poor solubility of an analyte in the used buffer system is major hurdle of the method. If a compound precipitates during the measurement, dramatic UV changes are observed. If the compound is not soluble in water at all, it will precipitate in the mother plate. Thus, no UV change will be observed due to lack of compound. This will lead to false-negative results.

In order to measure a wider range of compounds, the traditional pH titrimetric methods (Jander and Blasius 1995) are still of good use. In the pH metric method, the sample is titrated in a pH range of choice with acid or base. The titration is monitored with a pH electrode. The pKas can be calculated from the shape of the titration curve. In order to get good resolution, small pH intervals are titrated, thus limiting the throughput of the method and leading to an increase in sample consumption. For validation and reference measurement this method is still the method of choice.

Small sample consumption combined with data of high accuracy can be obtained with capillary electrophoresis. Miller et al. (2002) demonstrated that pH-dependent capillary electrophoresis can be used for the titration of pKas. The work based on earlier contributions of Gluck et al. Analogous to the pH metric method, capillary electrophoresis is performed at a variety of different pHs. The mobility of the sample is measured and can be plotted in a pH/mobility curve. pKas are derived from the shape of the curve. Jia showed that capillary electrophoresis can be used in medium throughput for a broad range of pharmaceuticals.

Early works from Kibbey have been meanwhile customized to give commercially available equipment for high-throughput pKa measurements by CE (e.g., pKa Pro™, Advanced Analytical Technology). These systems have the advantage of standardized buffer systems – once the main problem for reliable pKa values by CE (Rafols et al. 2008). Henchoz et al. (2009) give a good summary of the methodology.

44.3 Lipophilicity

PURPOSE AND RATIONALE

Lipophilicity of a compound is associated with many physicochemical and physiological properties, e.g., permeability through a membrane. Lipophilicity is described in most cases as partition between two phases (hydrophilic and hydrophobic). Hansch was one of the first who examined the relevance of partition coefficients for the explanation of structural activity relationships.

The partition coefficient (P) is defined as the ratio of the equilibrium concentrations of a dissolved substance in a two-phase system consisting of two largely immiscible solvents, classically octanol and water.

In the case n-octanol and water:

$$P_{ow} = c_{n-octanol}/c_{water}$$

The partition coefficient itself is a constant. It is defined as the ratio of concentration of compound in aqueous phase to the concentration in an immiscible solvent, *as the neutral molecule*. The partition coefficient (P) therefore is the quotient of two concentrations and is usually given in the form of its logarithm to base 10 (logP). The logP will vary according to the conditions under which it is measured and the choice of partitioning solvent.

However, logD is the log distribution coefficient at a particular pH. It does take into account the equilibrium between ionized and not ionized species with the two solvents:

$$\text{Distribution Coefficient, D} = [\text{Unionized}]_{(o)}/[\text{Unionized}]_{(aq)} + [\text{Ionized}]_{(aq)}$$

$$\text{LogD} = \log_{10}(\text{Distribution Coefficient})$$

LogD at pH 7.4 is often quoted to give an indication of the lipophilicity of a drug at the pH of blood plasma. There are meanwhile 100,000 logP and logD values available, thus making it a valuable tool for comparison.

44.3.1 Lipophilicity by Octanol/Aqueous Shake Flask

PURPOSE AND RATIONALE

In order to determine a partition coefficient, equilibrium between all interacting components of the system must be achieved, and the concentrations of the substances dissolved in the two phases must be determined. Octanol and water are standard solvents for the equilibrium experiments. They are readily available and allow equilibrium experiments with good repeatability and reproducibility.

PROCEDURE

Two large stock bottles (2 l) of high-purity analytical grade n-octanol or water are saturated with a sufficient quantity of the other solvent. Both solvents are shaken for 24 h on a mechanical shaker. They are allowed to stand for 2 days to permit the phases to separate. In order to determine logP, a buffer system is chosen which has >2 pKa units above the pKa of the compound if the compound is a base. For acidic compound, the pKa has to be <2 pKa units below. Neutral compounds can be examined in water.

In order to determine $\log D_{7.4}$, appropriate phosphate buffer has to be chosen. After shaking for 4 h, two equal volumes of the phases are placed in a centrifugation tube. An aliquot of the test compound is added. The centrifuge tube is rotated 100 rotations in 5 min 180° about the transverse axis. In order to separate the phases, the samples are centrifuged at room temperature. They are standing for at least 1 h to ensure phase separation and constant temperature. An aliquot of each solvent compartment is then quantified with an appropriate method. Examples of analytical methods are:

Photometric methods
Gas chromatography
High-performance liquid chromatography

EVALUATION

For the determination of the partition coefficient, it is necessary to determine the concentrations of the test substance in both phases. The total quantity of substance present in both phases should be calculated and compared with the quantity of the substance originally introduced.

The logP and logD values are calculated from the ratio of their presence in the two components:

$$P_{ow} = c_{n-octanol}/c_{water}$$

CRITICAL ASSESSMENT OF THE METHOD

The measuring range of the method is determined by the limit of detection of the analytical procedure. This should permit the assessment of values of $\log P_{ow}$ in the range of −2 to 4 (occasionally when conditions apply, this range may be extended to $\log P_{ow}$ up to 5) when the concentration of the solute in either phase is not more than 0.01 mol/l.

The test temperature should be kept constant (±1°C) and lie in the range of 20–25°C. The method is restricted to samples of high purity and where plenty of compounds are available.

The throughput of the methods is limited due to the sample preparation and tedious experimental setup. It gives high-quality data, which can be used for cross validation of methods and reference data.

MODIFICATIONS OF THE METHOD

Hitzel reported a high-throughput variation of the method. They adopted the shake flask experiment to well plate format. Octanol, buffer, and compounds are transferred in the well plate by a liquid-handling system (Beckman Biomek 2000). The plate is sealed and shaken on reciprocal shaker for 30 min. The plate is centrifuged afterward, and aliquots of the aqueous and organic phase are analyzed via fast-gradient high-throughput chromatography. The correlation of the method with manual shake flask experiments in Eppendorf vials was excellent according to the authors.

Dohta et al. (2007) describe a promising attempt to increase the throughput of logD measurements by automated sampling which turned out to be difficult due to octanol contamination of the water phase. Nevertheless, they got good correlation to literature data and a significantly increased throughput.

44.3.2 Lipophilicity by Partition Chromatography

PURPOSE AND RATIONALE

Partition P of a compound between octanol phase (lipophilic) and water (hydrophilic) phase is one of the most commonly used parameters to express lipophilicity. The logarithmic value of P logP is the most common lipophilicity parameter. Strictly spoken, logP is the partition parameter of the neutral compound. Thus, in most cases, the logD is the measured parameter of choice (partition of neutral and charged molecule between buffered solution at a given pH and octanol). Besides shake flask experiments (see Sect. 44.3.1), chromatography is one of the major methods to determine lipophilicity data. Chromatography is readily available and easy to use. Nevertheless, one gets no exact partition coefficient, but you can find good correlation with shake flask measurements. The throughput of chromatographic methods is far higher than that of the traditional shake flask experiments (Valko et al. 1997).

PROCEDURE

The partition of the compound between stationary phase (in most cases octadecane bonded on silica) and mobile phase is used as surrogate parameter for lipophilicity. The retention time of the analyte correlates with the lipophilicity of the compound.

In order to get direct octanol-water partitioning, it is essential to immobilize octanol at the stationary phase (Mirrlees et al. 1976; Unger et al. 1978). The coating is achieved with repeated injections of pure octanol with a buffered eluent saturated with octanol. The octanol-coated columns have lengths of 1 cm (for logD 0–4.5) and 25 cm (for logD 0–1.5). The mobile phase is octanol-saturated 10-mM phosphate/KCl buffer (pH 7.4). Saturation of the buffer with octanol is achieved by shaking 1 l of octanol with 20 ml of octanol. The resulting octanol-saturated buffer is filtered. For high logD determination, up to 30% methanol is added.

20 µl of a 10-mM compound solution in DMSO is injected in the HPLC. The 1-cm column is used for high logD with a flow rate of 10 ml/min, whereas the compounds with low lipophilicity (logD < 1.5) are characterized with the 25-cm column at a flow rate of 2 ml/min. In order to avoid octanol loss on the column due to the DMSO, the direction of injections is reversed with every sample.

EVALUATION

The capacity value k’ (retention time – column dead time) is used for the calculation of the logD. For this purpose, a standard set of compounds with known $logD_{7.4}$ is used for calibration of the system.

$LogD_{7.4}$ for the standards is plotted against logk’. The linear equation

$$logD_{7.4} = a\ logk' + b$$

is used for the determination of $logD_{7.4}$. In order to determine logP, a buffer system is chosen which has >2 pKa units above the pKa of the compound if the compound is a base. For acidic compound, the pKa has to be <2 pKa units below.

CRITICAL ASSESSMENT OF THE METHOD

The method gives high-quality data with very good correlation with traditional shake flask (Slater et al. 1994)-derived logDs. The method is not suited for compounds with very low lipophilicity logD < -1 because for them no retention on the stationary phase is achieved. The other limitation is compounds with a lipophilicity >4.5. Due to the long retention time, the peaks become not detectable any more. Furthermore, the method is limited to compounds with chromophores. The throughput of the method is about 20–40 compounds a day.

MODIFICATIONS OF THE METHOD

An isocratic octanol-saturated 0.02 MOPS buffer in water is used from Minick et al. for chromatographic extrapolation of logD. They use an octyl (C8)-bonded stationary phase and vary the methanol content of the buffer. The methanol free log k’ is derived via extrapolation. This methodology is well suited for

compounds with high lipophilicity but also needs a chromophore due to the UV detection of the instrument setup.

Lombardo et al. use also different octanol concentrations in their isocratic method. They use a LC-ABZ column (Pagliara et al. 1995). This method is capable of covering a wide lipophilicity range with good correlation with $logP_{ow}$. Alternative detection methods such as mass spectrometry, ELS, or nitrogen detector are in most cases not appropriate due to the octanol-saturated aqueous media. An alternative is the use of standard HPLC reversed-phase gradient systems (Valko et al. 1997). These systems do not represent true octanol-water partitions, but are also good lipophilicity parameters by themselves.

Valko et al. have developed chromatographic methods, which are based on established reversed-phase methods with acetonitrile water gradients. The lipophilicity is characterized as a so-called chromatographic hydrophobicity index (CHI), which approximates the percentage of acetonitrile necessary for equal distribution between mobile and stationary phase. The method is able to provide hundreds of CHIs parallel to the quality control of compounds via RP/HPLC.

The next chapter will focus on alternative partition coefficients to P_{ow}.

45.1 Introduction

Drug efficacy and response are a function of drug concentration over time. In clinical pharmacokinetic studies, aspects of drug absorption, distribution, metabolism, and excretion over time are assessed. In the early clinical development, the pharmacokinetics of a drug is studied in healthy subjects followed by studies in patient population(s) with the aim to find the relevant dose in the target population(s). Particular pharmacokinetic studies in special populations assess the necessity of a dose adjustment from the planned/established clinical dose for patients.

In the following chapters, typical clinical pharmacokinetic studies are presented with results and conclusions, along with special emphasis on the individual study rationale, objective, design, and evaluation technique. In addition, a critical assessment of the method, as well as potential modifications and alternatives, is presented.

For the purposes of simplicity, the description of each study is limited to the collection, handling, and interpretation of pharmacokinetic data although clearly safety (and pharmacodynamic) parameters were also studied.

The protocols were developed with consideration of the current good clinical practices and conducted in compliance with the protocol that had received prior independent ethics board approval.

The principles and practices concerning the clinical conduct with particular emphasis on ethical aspects are stated in guidelines (International Conference on Harmonization E6 R1 2002; International Conference on Harmonization E8 1998). These principles have their origins in "The Declaration of Helsinki" (The Declaration of Helsinki 2008).

Design and conduct of the clinical studies are presented in the examples below; all were in conformance with these principles. Subjects were included only after an informed consent was given. All studies were part of a sound clinical development plan of the sponsor.

The protocols were subject to critical review, and it was assured that the information they contain is consistent with the actual risk-benefit evaluation of the investigational product. The respective internal review boards of the sponsor had approved them before finalization.

Assays used for bioanalytical measurements were validated, as the complete evaluation, assessment, and reporting of these clinical pharmacokinetic studies followed international and scientific quality standards.

45.2 Exploratory Assessment of Drug Dose Linearity/Proportionality and its Use for Study Optimization

PURPOSE AND RATIONALE

The first tolerability studies in early clinical development always provide pharmacokinetic (PK) data over a considerable dose range. Especially the explorative first-in-man study with escalating single doses or an explorative proof-of-principle study with escalating multiple doses provides a valuable basis for an exploratory assessment of dose linearity/proportionality of drugs in humans. In addition, such an assessment can directly help within the same study to optimize the dose selection and dose progression. Already in this early phase of the development, these data are going to support exposure-response relationships and thus a potential submission (US FDA Guidance for Industry Exposure-Response Relationships 2003; ICH E4 1994).

Information on dose linearity/proportionality in humans is required during later development if the dosage form is to be modified (EU CPMP 1999), and especially if several strengths are in use (US FDA Guidance for Industry Bioavailability and Bioequivalence Studies for Orally Administered Drugs 2003) or bioequivalence has to be supported (US FDA Bioequivalence Guidance 2006; EU CPMP 2010).

A priori however, animal data can provide hints with respect to the likelihood of observing a nonlinear relationship of the administered dose and

the resulting exposure as reflected by PK parameters. But even if doses were compared on a “per kg” basis, animal studies might be misleading due to the different physiology and extrinsic factors in animals and man.

Dose linearity/proportionality typically is assessed based on exposure-related PK parameters measured in the systemic circulation (blood), like the AUC for a specified time interval, or sometimes also based on the peak values (C_{max}), but can also be estimated based on PK parameters which are expected to be dose independent, like clearance (CL), (terminal) half-Life ($t_{½z}$), or volume of distribution (V). And for a drug, which is mainly eliminated via the renal route, this assessment of dose proportionality can also be based on the amounts of drug excreted in urine over a specified time or extrapolated to infinity. In both cases, it is important to use an assay with a sensitivity sufficient to quantify the amounts of drug completely.

PROCEDURE

The design of an exploratory assessment of dose linearity/proportionality during the conduct of a first-in-man study for candidate drug (XYZ1234) is presented below. For the purposes of simplicity, the description is limited to the collection, handling, and interpretation of pharmacokinetic data although clearly safety parameters are in the main focus.

45.2.1 Protocol Outline

Single oral dose-escalation study, to study safety, tolerability, pharmacokinetics, and pharmacodynamics of XYZ1234 in healthy male subjects (first-in-man study).

45.2.1.1 Secondary Objective

One of the secondary objectives of the study was to determine the pharmacokinetics (PK) of ascending single oral doses of XYZ1234.

45.2.1.2 Study Design

The study had a single-center, double-blind, placebo-controlled, randomized, single oral dose-escalation study design. Eight healthy male volunteers per dose step were to be randomized and treated with up to two of the following escalating dose steps: 10-, 25-, 50-, 100-, 200-, 300-, and 400-mg XYZ1234, or placebo, with a washout period of at least 2 weeks between the treatments. Six subjects in each dose step were randomized to XYZ1234 and two subjects to placebo.

Starting with the lowest dose, each of the subsequent doses was administered only if the preceding dose was safe and well tolerated. The decision to proceed to the next higher dose was based on the full range of safety parameters and pharmacokinetic data.

Eligible subjects entered the study unit the evening before study drug administration and were to be assessed for their baseline characteristics on the morning of the day of drug administration. After each oral dose, subjects remained in the study unit for 48 hours (h).

45.2.1.3 Inclusion Criteria

Healthy male volunteers, aged between 18 and 45 years, inclusive.

45.2.1.4 Treatments

In this study, a clear, colorless solution of varying concentrations of active substance XYZ1234 was used to provide the same dosing volume for the solution in each dose step. The escalating, double-blind doses of XYZ1234 oral solutions were administered at doses of 10, 25, 50, 100, 200, 300, and 400 mg or placebo.

The decision to proceed to the next higher dose was taken based on the full range of safety parameters and the bioanalytical data (with pharmacokinetic parameters for the last-but-one dose step, which had to be available and acceptable for the next planned dose step, based on an adequate extrapolation). This could result in the planned higher dose step(s) being skipped or, conversely, to additionally include a dose below the starting dose of 10 mg. The doses to be administered might have to be modified (decreased or interim steps be defined) as needed according to the ongoing benefit/risk assessment during the conduct of the study. The dose progression was to be continued until the maximum tolerated dose had been attained, or if derived from bioanalytical data, other findings were to be expected which prohibited further dose increases (e.g., prohibitive nonlinearity or the AUC being too large compared to the AUC from toxicology).

45.2.1.5 Pharmacokinetic Data

Concentrations of XYZ1234 in urine and plasma were determined and used for calculation of the PK parameters.

If feasible and adequate, an explorative investigation on potential metabolites in plasma and urine was to be performed.

EVALUATION

Due to the small sample size, all variables were only presented descriptively for the different bioanalytical data and pharmacokinetic parameters calculated.

Individual plasma concentrations of XYZ1234 were tabulated together with standard descriptive statistics. Individual and median profiles were presented graphically.

45.2.1.6 PK Parameters

If possible, the following PK parameters were to be determined based on plasma concentrations of XYZ1234 using noncompartmental or, if adequate, compartmental procedures: at least maximum concentration (C_{max}), time to maximum concentration (t_{max}), area under the concentration-time curve from time of drug administration to t hours ($AUC_{(0-t)}$), area under the concentration-time curve from time of drug administration extrapolated to infinity (AUC_{inf}), terminal elimination half-life ($t_{½z}$), mean (residence) time (M[R]T), as well as relative total oral clearance (CL/f) and relative volume of distribution during the terminal phase (Vz/f).

For urine data, the individual and mean fractional and cumulative urinary excretions of XYZ1234 were calculated; the cumulative excretion profiles were represented graphically; fractional and total urinary excretion ($Ae_{(t2-t1)}$; $Ae_{(0-48\ h)}$), urinary recovery (% of administered dose), and renal as well as nonrenal clearance (CL_R, CL_{NR}) were determined.

Explorative dose proportionality was to be investigated in parallel to the progress of the dose escalation using dose-normalized values (on a dose per body weight basis) for AUC, C_{max}, and Ae [characterized by an additional suffix "$_{_norm}$"] and/or by adequate regression analyses of all parameters. Predictions for the next dose steps were to be derived based on these findings.

CRITICAL ASSESSMENT OF THE METHOD

As rationale for selection of the dose range, doses providing a pharmacological effect (active doses) and doses being at the upper dose limit (NOAEL doses) were used. The dose progression was to be continued until the MTD was attained or—derived from bioanalytical data—until other prohibitive findings (prohibitive nonlinearity, area under the plasma concentration-time curve (AUC) exceeding that AUC from the toxicological studies) arose.

The described evaluation provides a tool, also called "online PK," which allows adjusting the dose in this "first-in-man" study on a very flexible basis. Consequently, already in the study protocol, this flexible dose scheme is described. The main prerequisite is, besides an adjustable dosing form, an immediate shipping and evaluation of the bioanalytical samples.

On an explorative basis, the relationship of concentrations resulting from the different doses can be conveniently studied using an evaluation as described in this chapter. Typically, this evaluation is part of the first study in humans (which is always a single-dose study) but could also be applied for early multiple-dose studies in analogy.

As mentioned earlier, this type of supportive study provides explorative data related to dose linearity/proportionality. In the context of the described study, these data are then used to predict the exposure for further planned dose steps, (inside) and especially outside the dose range investigated so far.

At least, if a notable nonlinear effect is seen by this explorative evaluation, then a more elaborate study will need to be performed.

MODIFICATIONS OF THE METHOD

Typically, a dose-proportional increase of exposure (AUC) cannot be expected if a concentration-dependent mechanism of distribution and elimination exists. Especially the renal clearance of a drug quite often is concentration dependent if a strong binding to blood constituents (proteins, cells) plays a major role. In those cases, it is recommendable to use free fractions of the drug instead, in order to find a parameter independent from the total concentrations, which then might be predictive for dose proportionality.

If a pivotal investigation of dose linearity/proportionality becomes necessary, a dedicated study has to be conducted. It typically will be a study where the subjects get at least three different doses in a randomized, intraindividual crossover. The dose steps should cover the clinical recommended dose range and—if possible—should also include the maximum tolerated dose; they ideally should increase in a geometric progression.

Table 45.1 Synopsis of key PK parameters: AUC_{inf}, C_{max} (including dose normalization to 100 mg), and the terminal half-life

		AUC_{inf} [µg*h/mL]				C_{max} [µg/mL]				$t_{1/2z}$ [h]		
Dose Step (mg)	N	Mean	CV %	Median	Med/100 mg	Mean	CV %	Median	Med/100 mg	Mean	CV %	Median
10	4	0.056	70.9	0.054	0.535	0.034	65.7	0.035	0.350	1.3	69.5	0.8
25	6	0.208	57.7	0.199	0.794	0.109	49.7	0.111	0.442	2.1	51.2	1.8
50	5	0.353	61.7	0.426	0.852	0.107	60.4	0.116	0.232	4.2	74.6	2.4
100	5	1.129	47.3	1.278	1.278	0.252	55.0	0.223	0.223	4.9	44.1	4.0
200	5	2.840	94.8	1.430	0.715	0.424	47.1	0.347	0.174	14.0	82.6	8.1
300	6	4.828	56.4	4.544	1.515	0.472	50.9	0.448	0.149	12.2	52.6	11.0
400	6	4.486	65.1	4.495	1.124	0.434	89.7	0.272	0.068	7.4	39.0	7.1

However, this registration study should at best be performed when the therapeutic dose range is clearly established, and the final drug formulation is available.

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a high level summary of the data from the study described above under *Procedure* is presented below. It should be noted that in this specific example study for the first application in man, only a liquid formulation was available, which—due to low solubility of the drug—generated notable inter- (and intra-) individual variability.

45.2.1.7 Results

Only at the higher 200- and 300-mg doses, XYZ1234 could be detected in plasma 48 h after administration. Following the lower doses of 10 and 25 mg, the last quantifiable concentration was detected after 3 and 4 h, respectively. The quantification-limit of the analytical method might have impeded somewhat the reliability of the PK parameters obtained for the two lowest doses (10 and 25 mg). For example, the low values of the calculated $t_{1/2z}$ for these two doses (see Table 45.1) probably resulted from not having quantifiable concentrations at time points following 3 and 4 h p.a., with the consequence of having smaller $AUC_{inf,\ norm}$ values for the lower doses (see Fig. 45.1) and a further increase up to the 300-mg dose. This is also the reason why in this case linearity was not studied with the usual statistics (bioequivalence criteria for a dose-2/dose-1 ratio). AUC_{inf} nevertheless exhibited, in average, a dose proportionality; the 95 % confidence range includes the origin of the coordinates (see Fig. 45.2).

Total relative plasma clearance (CL/f) was found to decrease for the reasons mentioned above, leveling off at the 100-mg dose.

C_{max_norm} gradually declined to the 400-mg dose. C_{max} does not always increase linearly with dose; however, this finding might indicate that the rate of oral absorption is declining with increasing doses. AUC_{inf_norm} declined at the 400-mg dose; however, the median values for the nonnormalized AUC_{inf} were almost identical for the 300- and 400-mg doses (see Table 45.1). This might indicate that the extent of absorption is maximal and is leveling off at the 300-mg dose.

Comparing the data from the seven dose groups synoptically, it can be seen that the dose-normalized exposure [AUC_{inf}] shows much less differences for the medians than the dose-normalized peak values [Cmax] (see Table 45.1). The variability [CV %] is greater than 50 % for nearly all of these observations.

As described, the assessment of the dose linearity/proportionality is hampered in this case by the fact that for the lower doses the profile is not complete assessable, that obviously at the highest dose the resorption is limited, and that the used suboptimal formulation

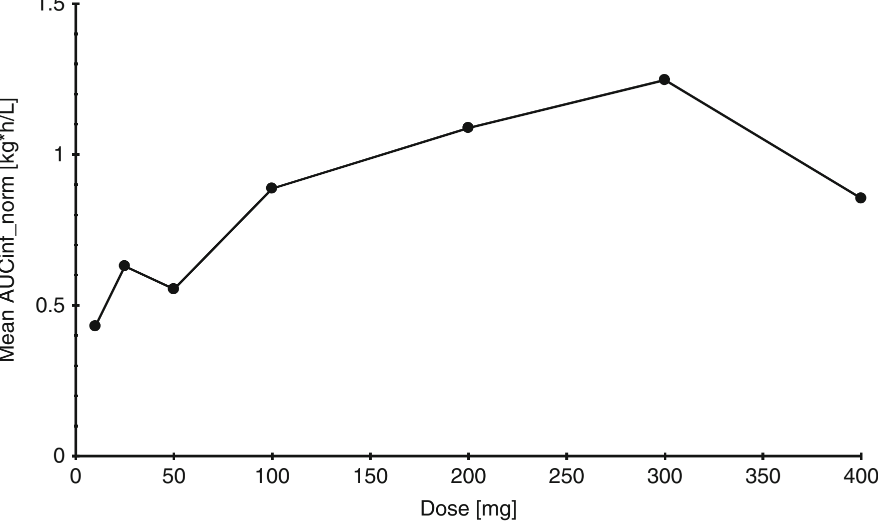

Fig. 45.1 Relationship of "dose per body weight"-normalized AUC_{inf} values for XYZ1234 versus dose

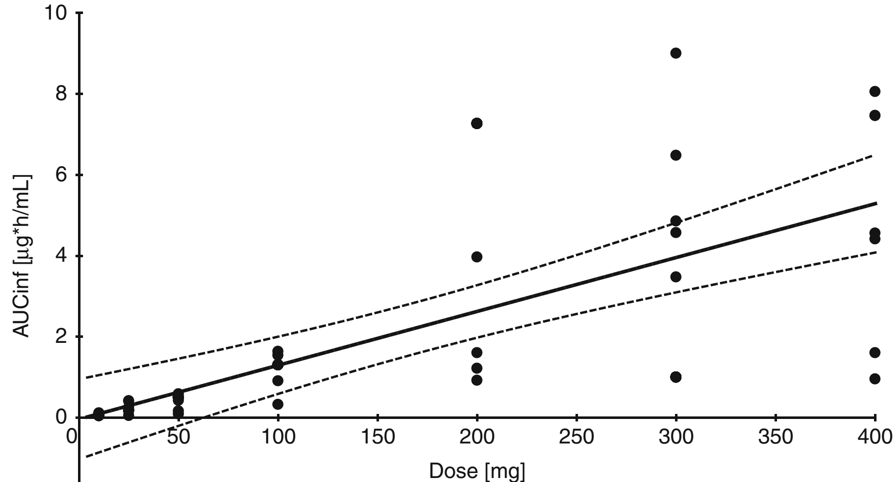

Fig. 45.2 Relationship of observed AUC_{inf} values for XYZ1234 plasma profiles versus dose, with linear regression (*bold line*) and the 95 % confidence range (*dashed line*)

generates a lot of variability. Nevertheless, the example shows that even in this case, predictions to support dose escalation were possible and were even very helpful in that specific study.

45.3 Exploratory Evaluation of Time-Invariant Steady-State Pharmacokinetics

PURPOSE AND RATIONALE

The first tolerability studies early in clinical drug development always provide pharmacokinetic (PK) data over a range of doses, mostly with a single-dose approach. In situations where an explorative proof-of-principle study with escalating multiple doses in patients is needed as the GO/NO GO criterion for further development, the assessment of steady-state conditions in a highly standardized, i.e., a healthy, population has proven to provide meaningful data. Under specific circumstances, information from these studies has a pivotal character for a submission (US FDA Guidance for Industry 2003; ICH E4 1994). The definition of dose linearity/proportionality of drugs in humans after repeated dosing has a crucial impact on the design of large-scale studies in patient settings, including special patient populations (see other contributions in this section).

PROCEDURE

The design of an exploratory assessment of dose linearity/proportionality during the conduct of a multiple-dose study for candidate drug (XYZ123) is presented below. In this case study, a drug was investigated that had shown a terminal half-life of about 24 hours (h) in single-dose trials. In the first clinical studies with different solid formulations, high inter- and intrasubject variability was observed in plasma concentrations and derived pharmacokinetic variables. Data from a study that compared a new formulation to a conventional one and to an oral solution showed that intrasubject variability was markedly reduced. As in that study only one dosage strength had been tested, here different dosage strengths were administered to assess dose linearity/proportionality at steady state.

45.3.1 Protocol Outline

Pharmacokinetics, safety, and tolerability of multiple oral doses of 25-, 50-, and 75- or 100-mg XYZ123 given once daily over 7 days as capsules in healthy men in an open-label study.

45.3.1.1 Primary Objective

To assess pharmacokinetics of multiple oral doses of 25-, 50-, and 75- or 100-mg XYZ123 given once daily over 7 days as capsules.

45.3.1.2 Study Design

Open-label study with three treatment groups, with multiple oral doses of 25 mg (treatment group I) and 50 mg (treatment group II) once daily immediately after intake of a standard breakfast in a parallel-group design. Safety information and bioanalytical data were reviewed to determine the dose for treatment group III (multiple oral doses of 75- or 100-mg XYZ123).

45.3.1.3 Inclusion Criteria

Caucasian men between 30 and 65 years of age, with body mass indices of 18–29 kg/m^2. Volunteers were healthy, nonsmoking, and not receiving regular medication.

45.3.1.4 Treatments

Treatment A: Multiple oral doses of 25-mg XYZ123 as capsules, given once daily immediately after intake of a standard breakfast for 7 days.

Treatment B: Multiple oral doses of 50-mg XYZ123 as capsules, given once daily immediately after intake of a standard breakfast for 7 days.

Treatment C: Multiple oral doses of 75- or 100-mg XYZ123 as capsules, given once daily immediately after intake of a standard breakfast for 7 days.

45.3.1.5 Pharmacokinetic Data

Derived from concentrations of XYZ123 in plasma and urine before and at predefined times after dosing.

EVALUATION

All bioanalytical data, derived PK data, and safety data were listed and descriptive statistics calculated. Individual and median data were plotted. The log-transformed PK parameters AUC and C_{max} were analyzed for dose proportionality. The PK parameters $AUC_{(0–24)}$ and C_{max} were also descriptively analyzed for accumulation ratio.

CRITICAL ASSESSMENT OF THE METHOD

For the definition of the lowest dose, exposure data from animal pharmacological effect models and from single-dose studies in man were used. In addition, information from a food screen and on the elimination half-life were applied for the design of the study: the marked effect of a high-fat high-calorie breakfast on the exposure of XYZ123 resulted in a standard continental breakfast on each dosing day. An elimination half-life of almost 24 h lets one expect that steady state is reached after 5 days of once-daily dosing. To confirm the latter expectation, predose and 12-h postdose plasma concentrations were analyzed on days 2–7. An algorithm for the selection of the highest dose was predefined on the basis of "online" safety and bioanalytical data, i.e., C_{max}.

MODIFICATIONS OF THE METHOD

If the active moiety of a drug (parent or metabolite(s)) exhibits half-lives that are greater than 2 days, the evaluation of steady-state conditions might become problematic in a study with healthy subjects due to long dosing periods. In these situations, the insertion of PK profiling days in patient studies might prove to be helpful. Whereas in single-dose studies a crossover design might be the proper choice to assess intraindividual variability, a parallel-group or sequential design has been preferred in multiple dose settings.

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a summary of the pharmacokinetic results obtained from the study described above under "Procedure" is presented below.

45.3.1.6 Results

The primary objective of this study was to investigate the pharmacokinetics of XYZ123 after multiple dosing for 7 days at three dose levels. Pharmacokinetic profiles were derived both on day 1 (up to 23.5 h post dose) and on day 7 (up to 119.5 h post dose), with same sampling time points relative to dose, and samples were also taken on days 2–6 to monitor the approach to steady state.

Mean C_{max} and $AUC_{(0–24)}$ (= AUC_τ) both on day 1 (C_{max}: 0.46, 1.16, and 3.29 µg/mL; AUC_τ: 7.12, 16.37, and 39.85 µg*h/mL) and on day 7 ($C_{max,ss}$: 0.91, 2.31, and 5.95 µg/mL; $AUC_{\tau,ss}$: 14.17, 33.55, and 74.48 µg*h/mL) increased with increasing dose although the increases were marginally higher than strict dose proportionality would predict: the deviation from linearity was, however, minor. The median time to reach maximum plasma concentration was 6 h on both profile days and at all doses. The terminal phase half-life of XYZ123 on day 7 was quite constant with mean values between 19 and 23 h: a slight reduction in half-life (accompanied by a reduced terminal phase volume of distribution) was observed at the higher doses.

The extent of exposure to XYZ123 in this study generally increased in a dose-proportional fashion over the dosing range of 25–100 mg, although there was a slight trend to higher values at the higher doses. Times to reach maximum concentration were constant at all doses and after both single and multiple dosing: terminal phase half-lives were also fairly constant at all doses after multiple dosing. After 7 days of repeated dosing, the observed accumulation of XYZ123 (based on AUC_τ and C_{max}) showed a factor of about 2, agreeing well with the theoretical expectation: this suggests linear pharmacokinetic behavior of XYZ123 between single and repeated dosing.

Median $C_{max,ss}$ values of 0.79, 2.3, and 5.0 µg/mL at 6 h post dose were observed: slightly higher increases were apparent than strict dose proportionality would predict.

From the mean trough concentrations of XYZ123 on days 2–7, it is apparent that steady-state conditions were attained at all doses after 7 days of repeated dosing, in line with the observed terminal phase half-life of the compound.

Descriptive statistics for the primary pharmacokinetic parameters of XYZ123 on days 1 and 7 are shown in the text tables below (Table 45.2).

The mean data for $C_{max,init}$ (and to a lesser extent $AUC_{\tau,\ init}$) on day 1 confirm the descriptive observation already made that the increases with increasing dose were slightly higher than strict dose proportionality would predict. Median $T_{max,\ init}$ was very constant (6 h) throughout the dose range studied (Table 45.3).

Table 45.2 Pharmacokinetic parameters of XYZ123 (Day 1)

PK parameter	MEAN (geometric mean): Day 1		
	Treatment A (25 mg)	Treatment B (50 mg)	Treatment C (100 mg)
$C_{max,init}$ (µg/mL)	0.46 (0.45)	1.16 (1.12)	3.29 (3.14)
$T_{max,init}$[a] (h)	6.0[a]	6.0[a]	6.0[a]
$AUC_{\tau,init}$ (µg[a]h/mL)	7.12 (6.97)	16.37 (15.87)	39.85 (38.59)

$AUC_{(0–inf),ss}$ (µg[a]h/mL)	27.55 (26.85)	58.60 (56.88)	116.20 (110.55)
$t_{1/2,ss}$ (h)	23.28 (22.86)	20.40 (20.21)	18.76 (18.18)
$V_{z,ss}$ (L)	61.35 (59.22)	45.04 (44.34)	37.92 (36.24)

[a]Median values reported

Table 45.4 XYZ123 PK parameters—dose proportionality

Parameter	Comparison	Estimated ratio	Expected ratio if dose proportional	95 % CI
AUC_{τ} (μg*h/mL)	50:25 mg	2.362	2.000	1.97, 2.84
	100:25 mg	5.197	4.000	4.33, 6.24
	100:50 mg	2.200	2.000	1.83, 2.64
$AUC_{(0\text{–}inf)}$ (μg*h/mL)	50:25 mg	2.119	2.000	1.69, 2.66
	100:5 mg	4.118	4.000	3.28, 5.17
	100:50 mg	1.943	2.000	1.55, 2.44
$AUC_{(0\text{–}t)}$ (μg*h/mL)	50:25 mg	2.254	2.000	1.79, 2.85
	100:25 mg	4.439	4.000	3.51, 5.61
	100:50 mg	1.969	2.000	1.56, 2.49
C_{max} (μg/mL)	50:25 mg	2.544	2.000	2.07, 3.13
	100:25 mg	6.442	4.000	5.24, 7.92
	100:50 mg	2.532	2.000	2.06, 3.11

The analysis of the dose adjusted values confirms the faster than linear increase of $C_{max,init}$, $C_{max,ss}$, and $AUC_{(0\text{–}24),init}$ with increasing dose.

The same trend for $C_{max,ss}$ and $AUC_{\tau,ss}$ was observed on day 7 as on day 1, i.e., slightly higher than dose-proportional increases were recorded; $AUC_{(0\text{–}t),ss}$ and $AUC_{(0\text{–}inf),ss}$ on the other hand showed increases very closely related to the increases in dose. As for the single-dose data, $T_{max,ss}$ remained very stable over the dose range investigated, with median values of 6 h. There was an indication for slightly reduced terminal phase half-life times at the higher doses which may explain the reduced differences in $AUC_{(0\text{–}t),ss}$ and $AUC_{(0\text{–}inf),ss}$. This was also accompanied by a lower volume of distribution associated with the terminal phase at the higher doses (Table 45.4).

Dose proportionality could be shown for the dose-dependent parameters $AUC_{(0\text{–}inf)}$ and $AUC_{(0\text{–}t)}$ and all the three possibilities of treatment comparisons (B vs. A, C vs. A, C vs. B). The 95 % confidence interval contains all of the expected ratios.

For the parameter $AUC_{(0\text{–}24)}$, only the expected ratio of the comparison of C and A is not contained in the confidence interval. So dose proportionality could be shown for the two other comparisons.

For the parameter C_{max}, dose proportionality could not be shown for all of the three comparisons. The three expected comparisons are not contained in the confidence intervals.

A comparison of geometric mean values for C_{max} and AUC_{τ} between day 7 and day 1 indicates ratios of approximately 2 at all dose levels: the ratios are given in the following table (Table 45.5).

Table 45.5 Observed accumulation ratios of geometric mean parameters for XYZ123

	Mean (geometric mean): Day 7: Day 1		
Ratio	Treatment A (25 mg)	Treatment B (50 mg)	Treatment C (100 mg)
$C_{max,ss}/C_{max,init}$	1.98	1.99	1.81
$AUC_{\tau,ss}/AUC_{\tau,init}$	1.99	2.05	1.87

These results agree well with the theoretical accumulation anticipated according to the formula:

Accumulation $A_I = 1/1\text{–}2^{-\varepsilon}$ where $\varepsilon = \tau/t_{1/2}$ and τ is the dosing interval.

Thus, for a dosing interval of 24 h and a half-life close to 24 h, the predicted accumulation factor is 2, close to the observed value found in this study. This is a good indication for linear kinetic behavior of XYZ123 between single and repeated dosing.

The peak-to-trough ratio (data not shown) increased with dose, reflecting the higher than dose-proportional increase in $C_{max,ss}$.

The course of the median trough plasma concentrations (Fig. 45.3) shows a saturation beyond day 5, which is an indicator for reaching the steady state.

45.4 Special Populations: Exploratory Profiling of the Impact of Gender, High Age, and Food Intake on Drug Disposition

PURPOSE/RATIONALE

In early clinical development, the early steps before entering into larger patient studies are typically an explorative first-in-man study with escalating single doses in healthy volunteers, an explorative proof-of-principle study with escalating multiple doses in healthy volunteers, and then a proof-of-concept with escalating multiple doses in a population as close as possible to the target population for the phase IIb/III development program. Additional supportive studies are required to justify the fastest possible broadening of the population in the proof-of-concept study and thus to accelerate patient recruitment into the larger patient studies. Over and above this industry need, the

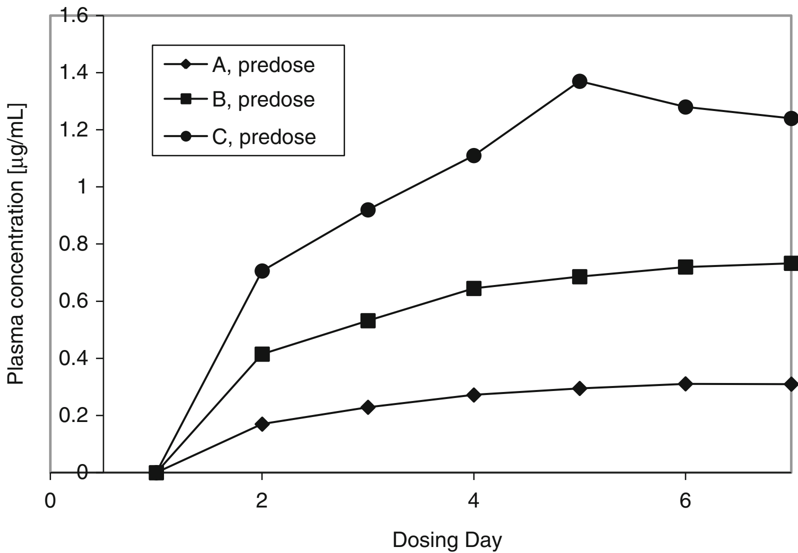

Fig. 45.3 Median XYZ123 trough plasma concentrations Treatment A: multiple oral doses of 25-mg XYZ123 daily (as one capsule) Treatment B: multiple oral doses of 50-mg XYZ123 daily (as two capsules) Treatment C: multiple oral doses of 100-mg XYZ123 daily (as four capsules)

principles of ICH and US Federal Drug Agency (FDA) guidance (US FDA 1978, 1989, 1993; ICH-E7 1994) also require that the pharmacokinetics and safety of a candidate drug are studied in the range of populations likely to receive the drug during the clinical development and later, once the drug is marketed.

The principles of US FDA and European Agency for the Evaluation of Medicines Products (EMEA) guidance also recommend an early profiling of food effects on bioavailability to help guide and select the formulations for further development (US FDA Guidance for Industry 2003; EMEA CPMP/EWP/560/95 1997).

Experience has shown that the exploratory profiling of the impact of gender, high age, and food intake (in the form of a food screen for worst-case food effects) on drug disposition (pharmacokinetics) and safety can be conveniently done in one study with the design described in this chapter. If a notable effect of these parameters is seen, then confirmatory studies need to be performed.

A priori animal data can provide hints with respect to the likelihood of observing some impact of gender, high age, and food intake on candidate drug pharmacokinetics.

The observation of gender-related differences in drug pharmacokinetics in multiple-dose animal studies is one hint that a gender effect might be expected, although gender effects observed in rodent should be viewed with caution. Data from in vitro metabolism assays based on liver factions from men and women could also suggest gender-related differences in metabolism.

Animal studies indicating that the drug candidate is primarily eliminated renally and/or physicochemical characteristics making a renal elimination likely are flags suggesting the need to profile candidate drug pharmacokinetics in elderly—since some degree of renal impairment is often observed this population.

Animal studies reporting an effect of food intake on drug pharmacokinetics, although suggestive, tend to be of low predictivity. This lack of predictivity can be explained by the different physiology and feeding behaviors in animals and man. Thus, if oral dosing is planned, since compliance with dietary restrictions could be an issue in outpatient studies, a screen for notable food effects in man should be included early during clinical development. Food effects are generally greatest when drug product is administered immediately after a meal is ingested. The nutrient and caloric content of the meal can also influence drug availability differently in different drugs, whereby meals that are high in calories and fat content are more likely to result in an effect. The time to dosing and fluid intake can also influence drug disposition.

PROCEDURE

The design of a study providing the suggested exploratory profiling of the impact of gender, high age, and food intake on the pharmacokinetics of candidate drug (Drug XYZ) in a single clinical study is presented below. For the purposes of simplicity, the study

description is limited to the collection, handling, and interpretation of pharmacokinetic data although other parameters were also studied.

In this explorative study, candidate drug is given immediately after ingestion of a high-calorie/high-fat meal (US FDA Guidance for Industry 2003). Since the impact of different food compositions and times to food intake are not tested, this aspect of the study is referred to as a food screen.

45.4.1 Protocol Outline

Explorative pharmacokinetics of Drug XYZ (200 mg, given as tablets), including a food screen, in younger and elderly, obese, but otherwise healthy, adults.

45.4.1.1 Objectives

Primary: The primary objective of the study was to investigate and compare the pharmacokinetics of Drug XYZ, including a food screen, in younger adult and elderly obese, but otherwise healthy, men and women.

Secondary: The secondary objective of the study was to assess the safety of single doses of Drug XYZ in younger and elderly obese, but otherwise healthy, adults.

45.4.1.2 Study Design

A single-center, open-label, randomized, balanced, single-dose, two-treatment (fed vs. fasted), two-period crossover design. In one trial period, subjects were dosed after fasting (= fasted trial period), and in the other trial period, subjects were dosed after consuming a high-fat breakfast (= fed trial period). Subjects were randomized to the sequence of trial periods. The wash-out period between trial periods was at least 5 days which approximated to >10 Drug XYZ apparent terminal half-lives.

45.4.1.3 Number of Subjects

Twenty-four (24) subjects (12 men/12 women, per gender 6 younger adult subjects, 6 elderly subjects) were recruited.

Due to the variability in the pharmacokinetic parameters seen in earlier studies, no formal sample size justification was given for 12 subjects per population. However, according to the guidance for industry by the US FDA, 12 subjects is the typical minimum sample size for a bioavailability comparison (US FDA 1978); even in a pilot study, “a sufficient number of subjects (e.g., 12) need to complete the study” (US FDA Guidance for Industry 2003). This was fulfilled here for each of the strata: male, female, younger, elderly.

45.4.1.4 Inclusion Criteria

The following inclusion criteria were met: Adults aged between 18 and 45 years (young adults) and aged 65 years or older (elderly); With body mass index (BMI) of 30 and < 40 kg/m^2; Women who are either post-menopausal or surgically sterile or willing to use pre-scribed barrier contraceptive methods; Who are healthy for the purpose of the study and not receiving regular medication in the month preceding the study; With normal findings in the physical examination, unless the investigator considers an abnormality to be clinically irrelevant; Who are non-smoking or light smokers; Elderly subjects with creatinine clearance of >50 mL/min; young adults with creatinine clearance of >80 mL/min.

45.4.1.5 Treatments

A single-dose of Drug XYZ (200 mg) was given orally as tablets. In the fasted trial period, subjects remained fasted until 2 h after dosing. In the fed trial period, subjects were dosed orally after consuming a high-fat breakfast whose composition conformed to US FDA guidance (US FDA Guidance for Industry 2002).

45.4.1.6 Pharmacokinetic Data

Plasma concentrations of Drug XYZ, before and at predetermined times post dose, were measured.

Concentrations of Drug XYZ in urine collected over the profiling period were measured. Volumes of urine collected over each profiling period were recorded.

The volume of urine collected over 24 h and the concentration of creatinine were determined to allow the subjects’ creatinine clearance to be calculated.

EVALUATION

The data pertinent to the assessment of the explorative profiling of issues related to age, gender, and the impact of food intake when dosing from study described above was evaluated as follows:

Due to the investigational nature of this study and the small sample size, all variables were only presented descriptively. Where appropriate, individual data were presented together with descriptive statistics.

Descriptive pharmacokinetic parameters (standard parameters including peak concentrations (C_{max}), time of C_{max} (T_{max}), area under the curve (AUC) between time 0 and time t where t = 24 h post dose (AUC_{0-t}), AUC after extrapolation to infinity ($AUC_{0-\infty}$), apparent terminal half-life ($t_{1/2_z}$)) for plasma Drug XYZ were calculated using a noncompartmental analysis employing a linear/log trapezoidal method as implemented in WinNonlin® (Pharsight Corp.) protocols. For urine Drug XYZ data, the descriptive pharmacokinetic parameters included fractional/cumulative urinary excretion, and renal clearance of Drug XYZ was calculated using SAS® for Windows™ protocols.

If appropriate, pharmacokinetic parameters were compared descriptively between age groups (with/without stratification), between genders (with/without stratification), and between fasted and fed subjects (with/without stratification and individually). Although not intending to show bioequivalence, the 90 % confidence intervals (CI) for the differences in the log-transformed exposure measurements were calculated.

CRITICAL ASSESSMENT OF THE METHOD

The impact of gender, high age, and food intake on candidate drug pharmacokinetics and safety can be conveniently done in one explorative study with the design described in this chapter. Typically, this study would run shortly after key data are available from the first-in-man study and employs a dose in the upper third of the dose range tested in the first-in-man study. The highest safe dose from the first-in-man study is not usually chosen unless a notable safety margin is given because food intake can cause substantial increases in exposure.

As the clinical development progresses, the dose chosen in this study may prove to be higher or lower than the actually required therapeutic dose. Similarly, the drug formulation available at this early time point may differ from that eventually marketed. These differences may have a notable influence on the magnitude of food effect seen. In the experience of the author, the observed food effects ranged from a 50 % reduction in AUC to a 20-fold increase in AUC when different oral formulations of the same drug were dosed immediately after the same high-fat/high-calorie food.

As mentioned earlier, this type of supportive study provides explorative profiling. If a notable effect of these parameters is seen, then suitable confirmative studies will need to be performed. However, these studies should ideally be performed when the therapeutic dose range and the final drug formulation are known.

Although the impact of gender and high age on the pharmacokinetics of the developmental drug can be studied based on single-dose data as described, the use of steady-state data is required if there is reason to believe that the pharmacokinetics of the drug studied are not accurately predictable from single-dose data.

MODIFICATIONS OF THE METHOD

The type of study described in this chapter provides explorative profiling of issues related to age, gender, and the impact of food intake when dosing. If appropriate, the same principle could be applied to address other variables, for example, to investigate the impact of different types of food composition and/or time of food ingestion using a relatively small population. Typically, this type of evaluation would be extended during the later clinical development by performing a population pharmacokinetic/pharmacodynamic assessment of the impact of gender and high age on the drug disposition during the phase II/III studies.

The most common impact of high age is via a reduced renal and/or hepatic function. In the example given, the study inclusion criteria deliberately allow the inclusion of elderly subjects with mildly impaired renal function, i.e., subject presenting creatinine clearances of >50 mL/min. No measures were taken to ensure that the number of enrolled elderly volunteers with normal and mild renal impairment was balanced. Such measures would have allowed an explorative insight into the impact of mildly impaired renal function at the expense of delaying recruitment since the recruitment of healthy elderly with mild renal impairment is more complicated. If renal elimination is believed to play a notable contribution to developmental drug elimination, then the complication of recruitment may be warranted.

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a high level summary of the pharmacokinetic results obtained from the study described above under *Procedure* is presented below.

45.4.1.7 Results: Pharmacokinetics

The data from study described above, as summarized in Tables 45.6 and 45.7 and Fig. 45.4 below, can be summarized as follows:

- A trend was seen in all analyzed groups toward a slightly lower Drug XYZ plasma C_{max} under fed conditions than after fasting. Drug XYZ plasma C_{max} was also reached later under fed conditions than after fasting in all analyzed groups.
- From 6 h post dose until at least 48 h post dose, the Drug XYZ plasma concentrations (median values) were slightly higher in the elderly than in young adults and also slightly higher in female than in male subjects, both under fed and under fasting conditions.

Table 45.6 Summary of key Drug XYZ PK parameters: young versus elderly, fasted versus fed

		All PK subjects ($n = 24$)		Young ($n = 12$)		Elderly ($n = 12$)	
Parameter	Statistic	Fasting	Fed	Fasting	Fed	Fasting	Fed
C_{max} (μg/mL)	Geometric mean	1.23	0.96	1.24	0.87	1.22	1.06
	Range	0.73–2.50	0.58–1.96	0.75–1.72	0.58–1.39	0.73–2.50	0.66–1.96
		Geometric mean ratio (90 % CI: upper-lower)		–		–	
		0.7816 (0.6969–0.8767)					
T_{max} (h)	Median	1.0	3.0	1.0	3.0	1.0	3.0
	Range	0.5–2.0	1.0–5.0	0.5–2.0	1.0–4.0	1.0–2.0	1.0–5.0
$AUC_{0-\infty}$ (μg.h/mL)	Geometric mean	9.26	8.99	7.80	7.44	11.0	10.86
	Range	3.52–34.61	3.63–40.06	3.52–14.89	3.63–17.0	6.03–34.61	3.94–40.06
		Geometric mean ratio (90 % CI: upper-lower)		–		–	
		0.9714 (0.8985–1.0502)					
$t_{1/2_z}$ (h)	Geometric mean	12.4	12.0	12.0	11.4	12.7	12.8
	Range	6.8–30.2	6.7–39.4	8.6–18.5	8.5–17.0	6.8–30.2	6.7–39.4

Table 45.7 Summary of key Drug XYZ PK parameters: male versus female

		Male ($n = 12$)		Female ($n = 12$)	
Parameter	Statistic	Fasting	Fed	Fasting	Fed
C_{max} (μg/mL)	Geometric mean	1.31	0.95	1.15	0.97
	Range	1.03–1.60	0.66–1.52	0.73–2.50	0.58–1.96
T_{max} (h)	Median	1.0	3.0	1.0	3.0
	Range	0.5–2.0	1.0–5.0	1.0–2.0	1.0–5.0
$AUC_{0-\infty}$ (μg.h/mL)	Geometric mean	8.12	7.46	10.55	10.84
	Range	3.52–34.61	3.63–32.86	6.03–30.62	5.30–40.06
$t_{1/2_z}$ (h)	Geometric mean	11.5	11.1	13.3	13.1
	Range	6.8–22.3	6.7–25.4	9.7–30.2	8.7–39.4

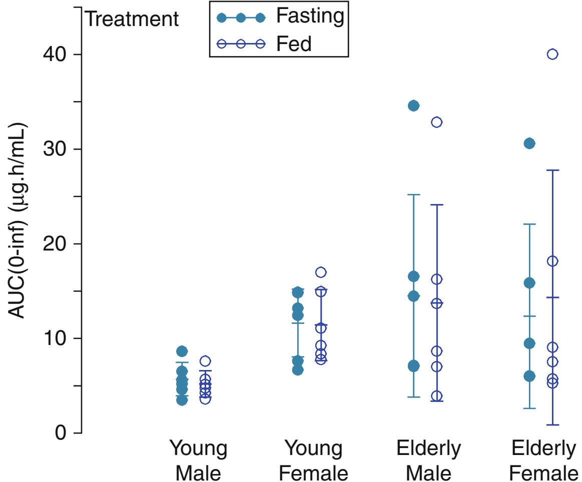

Fig. 45.4 Individual $AUC_{0-\infty}$ values per stratum, with arithmetic mean ±1 SD

- Urinary excretion of unchanged Drug XYZ was low: 48 h after administration, approximately 1 % of the administered dose was excreted unchanged. There was a trend in all analyzed groups toward a slightly lower cumulative Drug XYZ excretion in urine under fed than under fasting conditions. Cumulative excretion seemed slightly higher in the elderly than in the younger adults and in women than in men, both under fed and under fasting conditions.
- Drug XYZ showed delayed absorption due to food intake. The overall geometric mean Drug XYZ plasma C_{max} was 1.23 mg/L under fasting and 0.96 mg/L under fed conditions. Overall median T_{max} was 1 h under fasting and 3 h under fed conditions. Similar differences in C_{max} and T_{max} under fasting and fed conditions were seen in all populations analyzed.
- Overall, no differences were seen in AUC parameters and elimination half-life under fasting and fed conditions.
- A trend was seen toward a smaller $AUC_{0-\infty}$ in the young than in the elderly (geometric mean after fasting, 7.8 and 11.0 mg.h/L, respectively) and in the male than in the female subjects (geometric mean after fasting, 8.12 and 10.55 mg.h/L, respectively).
- There was a trend toward a shorter $t_{1/2_z}$ value in the young than in the elderly (geometric mean after fasting 12.0 and 12.7 h, respectively) and in the male than in the female subjects (geometric mean after fasting 11.5 and 13.3 h, respectively).
- An exploratory analysis was performed using a four-factor ANOVA model, with treatment, period, and sequence as fixed factors and subject within sequence as random factor. The results from the ANOVA were used to calculate the back-transformed 90 % confidence intervals (CI) for the differences between the fed and fasted condition in the log-transformed exposure measurements (C_{max}, AUC_{0-t} and $AUC_{0-\infty}$). For C_{max}, the difference between fasting and fed conditions was found to be statistically significant while this was not the case for the AUC parameters.

45.5 Profiling of Drug Absorption, Distribution, Metabolism, and Elimination in Man: The Hadme Study

PURPOSE/RATIONALE

The aim of this kind of study is to characterize the absorption, distribution, metabolism, and elimination of the investigational product in humans (hADME study) following an administration of the compound in a radiolabeled form. The use of a radiolabel allows identifying metabolites, which were not known beforehand, and characterizing them. In addition, using a radiolabel is—in most cases—the only way to establish a complete balance of the drug and its metabolites, which is required to validate the completeness and predictivity of the results.

A typical hADME study includes an overall balance of excretion of the administered radioactivity (mass balance), protein binding, and metabolic profiles in plasma, urine, and feces and, if possible, the determination of descriptive pharmacokinetic parameters for the radioactivity, the parent compound, and the identified metabolites in plasma and in urine. If feasible and adequate, structures of the observed metabolites will be elucidated.

Knowledge of the absorption, distribution, metabolism, and elimination in man, beyond being a prerequisite for assessing the consequences of dosing in target patient population in phase II studies, will also aid the prediction of potentially relevant drug-drug interactions and of high-risk populations for dosing with the investigational drug.

Presently, there are no official, general guidelines for this kind of study available; the different aspects are covered instead by dedicated guidelines, for example, metabolism, related to drug interaction (US FDA 1997a, 1999a; EU CPMP 1997), or for the related preclinical studies (EU EUDRALEX 3BS11a 1994), or only in a high level form (EU EUDRALEX 3CC3a 1988). The general use of radioactive-labeled drugs in clinical studies is described in a separate FDA regulation (US FDA 2010).

Nevertheless, hADME studies using radioactive-labeled drugs became recently of special interest based on the guidelines on metabolites in safety testing (US FDA 2008; International Conference on Harmonization M3 (R2) 2009). In the FDA guidance document, it is stated: *Human* in vivo *metabolism studies usually have been performed relatively later in drug development, but we strongly recommend* in vivo *metabolic evaluation in humans be performed as early as feasible*. There are slight differences between the ICH and the FDA documents, related to the reference data deciding on the need of metabolite testing, which as consequence might allow the use of alternative (nonradioactive) methods.

This type of hADME studies using radioactive-labeled drug should be run unless phase I studies show that ≥90 % of the dose is excreted unchanged in urine. In this case, a hADME study may not be required. For those drugs, a urine assay should be the prerequisite for phase I trials, and then mass balance may be established in trials where quantitative urine collections are performed. If phase I data indicate that "cold mass balance," i.e., ≥90 % recovery in urine, cannot be obtained, a hADME study has to be scheduled for the development program.

PROCEDURE

The design of a typical hADME study for a candidate drug (XYZ1234) is presented below. For the purposes of simplicity, the description is limited to the collection, handling, and interpretation of pharmacokinetic data although clearly safety parameters are also studied.

45.5.1 Protocol Outline

Absorption, distribution, metabolism, and elimination of XYZ1234 in healthy men following oral administration of ^{14}C-XYZ1234 (100 mg, 4 MBq) as solution.

45.5.1.1 Objective

Primary objective: To investigate the absorption, distribution, biotransformation, and elimination of XYZ1234 in healthy men following oral administration of ^{14}C-XYZ1234. This includes (1) overall balance of excretion of the administered radioactivity (mass balance); (2) metabolic profiles in plasma, urine, and feces; (3) if possible, structures of the observed metabolites; (4) determination of descriptive pharmacokinetic parameters for XYZ1234 and its active metabolite (XYZ5678) in plasma and in urine; and (5) characterization of protein binding in plasma.

45.5.1.2 Study Design

A single-center, open-label, single-dose study design. Subjects did enter the clinical site on the morning 1 day before dosing and remained at the study site at least 7 days after dosing. In case radioactivity measurement showed that recovery in the excreta (urine plus feces) was still below 95 % of the administered dose on day 7 or that the activity in the last plasma sample was still above 1 Bq/mL, then the subjects were requested to stay in the clinic until one of the levels had reached the mentioned limits. The maximum prolongation of the stay in the clinical center was 14 days post dosing. If necessary, after that time, the subjects had to continue daily collection of urine and feces at home until the radioactivity in the excreta samples reached definite threshold criteria (1 Bq both per mL of urine and per homogenate of 100-mg feces, respectively).

45.5.1.3 Sample Size/Population

Six white men aged between 45 and 65 years, with body mass indices (BMI) of 19–29 kg/m^2.

45.5.1.4 Treatments

After overnight fasting, a single oral dose of ^{14}C-XYZ1234 (100 mg, 4 MBq) administered as solution.

45.5.1.5 Pharmacokinetic Data

- Radioactivity administered orally and radioactivity recovered in whole blood, plasma, urine, feces, and expired air
- Concentrations of XYZ1234 and its active metabolite (XYZ5678) in plasma and urine
- Metabolic profiles: number of, and radioactivity attributable to, specific peaks in analyses

(chromatograms) of the radioactivity in plasma, urine, and feces
- Structures of observed metabolites (if possible)
- Protein binding in plasma (in vitro only)

EVALUATION

Where appropriate, individual data were presented together with the descriptive statistics.

If measured radioactivity for plasma, blood, and urine was related to the weight of a sample, the result was converted to the volume of the sample in order to generate the values as concentrations comparable to the "normal" bioanalytical data.

In the case of urine for this conversion, a constant specific weight of 1.02 g/mL is assumed for all subjects. In the case of plasma and whole blood for this conversion, a constant specific weight of 1.03 g/mL (plasma) and of 1.05 g/mL (whole blood), respectively, is assumed for all subjects. In the case of the radioactivity measurements, results are then also listed in terms of measured radioactivity per mL sample and as "concentrations" (i.e., given in μg equivalents per mL sample (μg-eq/mL)), representing the sum of original compound and/or radiolabeled metabolites.

Due to the small sample size, all variables were only presented descriptively for the different bioanalytical data and pharmacokinetic parameters calculated: number of relevant observations, geometric mean, geometric standard deviation, arithmetic mean, standard deviation, coefficient of variation, median, minimum, and maximum.

CRITICAL ASSESSMENT OF THE METHOD

The required information can be generated in this explorative study with a design described as above. The threshold criteria to stop collecting urine and feces (as described under "study design") guarantee that the combined daily excretion reached a value below 0.1 % of the administered dose. Further collection would not significantly contribute to the overall balance and has to be outweighted to the burden of the subject involved. Using fixed specific weights per matrix for the calculation of concentrations in the respective—originally weighted—samples (urine, plasma, and blood) had proven to be superior to an individual determination of the specific weights: the variability of the results was reduced without a hint for any reduction of the accuracy of the resulting concentration values.

This study could already be conducted after key data are available from the first-in-man study but should use a dose in the upper third of the range of therapeutic doses and a formulation similar to the therapeutic one. The latter cannot always be realized, but just using an oral solution of the radiolabeled drug will, only in rare cases, allow to support all objectives of the study mentioned. These type of hADME studies are increasingly being performed as early as possible in the clinical development (Deroubaix and Coquette 2004), in order to support the assessment of the consequences of dosing in the target patient population, or special populations in order to support the prediction of potentially relevant drug-drug interactions and high-risk populations for dosing with the investigational drug, and to generate the information on human metabolites early enough in order later not to compromise the long-term safety studies in animals and to prevent the need of repeating them. These advantages of conducting the study early have to be balanced against possible uncertainties related to the therapeutic dose and the formulation during early development; timing of the hADME study has therefore to be decided on a project-specific basis.

MODIFICATIONS OF THE METHOD

The example shown comprises protein binding in vitro only (predose samples), since the parent compound in plasma was known to massively exceed all metabolites. If this is not the case, in addition, samples to determine the protein binding ex vivo are required. Depending on the kind of measurement (radioactivity vs. specific), these samples then can indicate a general hint for protein binding across all labeled molecules (weighted by their occurrence in plasma), if only the ex vivo radioactivity is determined, or can provide protein binding data for metabolites, if a specific assay is available.

This type of hADME study always will have an explorative character and typically comprise less than the normal minimum of 12 subjects for a PK study. If the compound is expected to show different and unpredictable ADME characteristics in special populations, then it might be necessary to include these populations in addition to normal, healthy subjects. Or if other conditions might influence ADME in a not predictable manner (e.g., food effects), then it might even be necessary to run the study in a crossover design. The inclusion of females (being

not of childbearing potential) was discussed several times, but it seems to be a rare exception for hADME studies.

Further on, if nonlinearities are observed for the ADME characteristics, instead of a single dose, multiple-dose studies may be needed, where the radiolabeled drug is administered under steady-state conditions.

hADME studies preferentially use compounds labeled with C-14; labeling with H-3 provides, in many cases, less stability and requires a "wet/dry" comparison of the samples during analytics in order to detect free tritiated water. Similar precautions and tests for the in vivo stability of the label are necessary if other nuclides are used as radiolabel.

A promising alternative to the conventional radioanalytical measurement of C-14 in hADME studies is accelerated mass spectrometry (AMS), which can operate as a detector for C-14 with an increase of sensitivity by a factor of 1,000 (Garner 2000). This technique is complex and presently not used routinely. In addition, as an alternative, the last-generation, high-sensitivity liquid scintillation beta counters show an increase of sensitivity by a factor of 10–20 (Deroubaix and Coquette 2004). In those cases where the dosimetric calculations indicate that a traditional dose (2–4 MBq) would result in an unacceptable radiation burden (e.g., due to an intensive and long-lasting binding to melanopherous tissues), then both techniques can certainly provide useful alternatives, since using these radioanalytical tools would allow to administer much lower doses of the radionuclide.

If the drug development has to be done exclusively in compromised patients (some anticancer, anti-AIDS drugs) which may make a comprehensive hADME trial using a radioactive drug difficult to conduct, then other means of establishing mass balance and metabolism information may have to be negotiated.

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a high level summary of the pharmacokinetic results obtained from the study described above under *Procedure* is presented below.

45.5.1.6 Results

1. *Balance of excretion*: On average, 34.6 % of the administered radioactivity was excreted in urine and 60.6 % was excreted in feces. No quantifiable radioactivity was found in expired carbon dioxide. The total excretion averaged 95.2 % after 17 days. The urinary excretion of the parent drug averaged 8.85 % of the dose and the urinary excretion of the metabolite XYZ5678 averaged 11.7 %. There was still 14.1 % of the drug that was eliminated in the urine in a form different than XYZ1234 or XYZ5678, as one or several other metabolites.
2. *Metabolic profile*: The metabolites in urine with the largest contribution were the demethyl product (P7) (26 %) and the hydroxylated isomers (P3, P4) (19 % and 6 %). An unidentified metabolite with a molecular weight of 450 g/mol (P5) represented 19 % followed by the unchanged product (P9) (joint contribution of ca. 18 %).

   The contribution of each peak to the total radioactivity in feces was calculated, and the results showed that the metabolites in feces with the largest contribution were the hydroxylated isomers (P3, P4; 38 % and 11 %, respectively) and unknown "450 g/mol" metabolite (P5) (24 %), while the unchanged drug (P9) was found with a contribution of 7 %.

In plasma, XYZ1234 remained mainly unchanged. Only trace levels of the demethyl compound XYZ5678 (P7), glucuronide (P6), and the unidentified "450 g/mol" metabolite (P5) were found.

3. *Structure of metabolites*: The parent Drug XYZ1234 had three main metabolites: XYZ5678, 2-OH XYZ1234, and XYZ1234 glucoside. The XYZ5678 had a metabolite 2-OH XYZ5678.
4. *Pharmacokinetic parameters in plasma and urine*: ^{14}C-XYZ1234 solution was rapidly absorbed from the gastrointestinal tract. The peak radiocarbon concentration in plasma averaged 1.61 μg-eq/mL and occurred between 0.5 and 4 h. $AUCinf_{inf}$ of plasma radiocarbon was, on average, 36.9 μg-eq.h/mL. Elimination of radiocarbon was characterized by a mean half-life of 20.5 h.

   Whole blood concentrations represented approximately 80 % of the plasma concentrations. C_{max} = 1.33 μg-eq/mL, $AUCinf_{inf}$ = 32.7 μg-eq.h/mL. The mean half-life, 20.2 h, was very close to the plasma half-life. There was radioactivity in the red blood cells, and it declined with an elimination half-life similar to the half-lives in plasma and whole blood radiocarbon concentrations.

   The peak concentration of XYZ1234 averaged 1.54 μg/mL and was reached between 0.5 and 4 h after dosing. $AUCinf_{inf}$ averaged 37.2 μg.h/mL. The elimination half-life (19.8 h) was similar to the half-life observed for radiocarbon.

   The renal clearance of XYZ1234 averaged only 4 mL/min, this being small compared to the nonrenal clearance, which was tenfold higher (42 mL/min). Whereas the renal clearance of the metabolite XYZ5678 averaged 144 mL/min.

   The C_{max} of XYZ1234 and XYZ5678 summed was 99 % of the C_{max} of radiocarbon pharmacokinetic in plasma. The t_{max} for radiocarbon and for XYZ1234 was similar, the t_{max} of XYZ5678 appearing a few hours later. The difference in average urinary excretion between the sum of XYZ5678 and XYZ1234, and the radiocarbon, showed that 14.1 % of the drug was eliminated in the urine in a form different than XYZ1234 or XYZ5678, as one or several other metabolites. This was also confirmed by the metabolic profiles.
5. *Plasma protein binding*: The mean protein binding was 91.3 %; no major interindividual differences occurred.

45.6 Assessment of the Relative and/or Absolute Bioavailability of Drugs

PURPOSE/RATIONALE

The assessment of a drug's bioavailability (BA) is the most important information on its PK. Consequently, numerous guidelines primarily focus on this issue as from the exposure efficacy as well as safety for the patient is deduced (US FDA 2002, 2003a, b, c; ICH E4 1994; EU CPMP 1999, 2001, 2003).

Bioavailability is defined as the rate and extent by which the active moiety becomes available at the site of action. Because neither concentrations nor amounts can generally be determined at the site of action, plasma/serum concentrations are used as a surrogate to determine the rate and extent of bioavailability. Provided that the pharmacokinetics of the drug considered is linear and time invariant, the area under the curve (AUC) is a measure for the fraction of the dose available according to Dost's law of corresponding areas. Absolute bioavailability is deduced from the comparison of an extravascular and an intravascular administration, for example, AUC_{PO}/AUC_{IV}. Relative bioavailability compares the exposure following two different extravascular application forms.

Bioavailability is defined for a formulation, not for a drug.

Bioavailability studies quantify rate and extent of absorption. They compare the efficiency of the disposition of several drug formulations, for example, immediate release versus extended release or capsule versus tablet or tablet A versus tablet B, etc., or they compare the disposition of different routes of administration, for example, oral versus subcutaneous or oral versus intravenous. According to the definition, a comparison to the intravenous bolus injection yields the "absolute" bioavailability.

Bioavailability figures should always be given for the active moiety of a drug.

The criterion of bioequivalence applies if there is a similarity in bioavailability (statistically proven) that is unlikely to result in clinically relevant differences in efficacy and/or safety.

The bioavailability of a drug formulation is best described by C_{max}/T_{max} (rate) and area under the systemic concentration-time curve AUC (extent).

Details on the design of and the interpretation of data from bioavailability studies are given in (US FDA 2002, 2003a, b, c; ICH E4 1994; EU CPMP 1999, 2001, 2003).

PROCEDURE

The design for an absolute bioavailability study for Drug XYZ123 is presented below. For the purposes of simplicity, the description is limited to the collection, handling, and interpretation of pharmacokinetic data although safety parameters were also in the focus.

45.6.1 Protocol Outline

A phase I, open-label, randomized, crossover study to investigate the bioavailability, safety, tolerability, and pharmacodynamics following single oral administration of XYZ123 as capsule and single intravenous administration of XYZ123 in healthy men.

45.6.1.1 Primary Objective

To characterize the bioavailability of XYZ123 drug substance (25 mg) as a capsule formulation following a single oral administration in fasting conditions in healthy male adult volunteers using 10 mg of intravenously administered XYZ123 as reference formulation.

45.6.1.2 Study Design

This was an open-label, single-dose, randomized, 2-period crossover study with a minimum washout period of 7 days. Each treatment group received treatment A (10-mg XYZ123, intravenously administered) and treatment B (25-mg XYZ123 as capsule, orally administered), once each under fasting conditions.

45.6.1.3 Inclusion Criteria

Healthy male subjects, aged 18–45 years (inclusive), with a body mass index between 18 and 27 kg/m^2 (inclusive), normal or clinically irrelevant abnormal findings (in the opinion of the investigator) in the medical history and physical examination, laboratory values, ECG, blood pressure and pulse rate, negative serology (HIV antibody, hepatitis B surface antigen, hepatitis C antibody), and urine screen for drugs of abuse.

45.6.1.4 Treatments

Regimen A (reference treatment):

Intravenous (IV) administration of XYZ123 (10 mg, administered over 30 min)

Regimen B (test treatment):

Oral (PO) administration of XYZ123 (25 mg, as a capsule formulation)

45.6.1.5 Pharmacokinetic Data

Concentrations of unconjugated XYZ123 and cysteine (CYS)-conjugated XYZ123 in plasma were measured predose and at predetermined times up to 48 h post dose.

The primary analysis examined pharmacokinetic parameters calculated from plasma concentrations of CYS-conjugated XYZ123 using noncompartmental techniques. The secondary analysis examined the pharmacokinetic parameters of unconjugated XYZ123.

EVALUATION

The primary analyses consisted of characterizing the bioavailability of oral XYZ123 using intravenous XYZ123 as the reference. Determination of bioavailability was to be based on the plasma concentrations of CYS-conjugated XYZ123. Descriptive statistics and formal statistical analysis were used to summarize and analyze the pharmacokinetic parameters of unconjugated XYZ123 and CYS-conjugated XYZ123 in all evaluable subjects.

The secondary analyses consisted of assessing the safety, tolerability, and pharmacodynamic responses after administration of XYZ123 and XYZ123 in plasma and urine using descriptive statistics.

CRITICAL ASSESSMENT OF THE METHOD

For the oral route of administration, the dose was selected according to the experience from the FIM study, where this dose was safe and well tolerated and was in the dose-proportional range. The dose for the intravenous route of administration was adjusted according to the results from animal bioavailability studies where the absolute bioavailability was in the range of 50 %.

Bioavailability/bioequivalence studies are usually conducted in healthy subjects. Although the inclusion of women is now being encouraged, in this study, only men were enrolled. The study was the second clinical trial in this project.

As the bioequivalence rules are clearly defined, the study population must ensure a high level of

Table 45.8 Summary of the pharmacokinetic parameters in plasma

Treatment	C_{max} (ng/mL)	T_{max}[a] (h)	AUC_{last} (ng.h/mL)	AUC_{0-inf} (ng.h/mL)	$t_{½}$ (h)
XYZ123 (unconjugated)					
10 mg IV	49.5 (30.4–96.7)	0.50 (0.50–0.58)	81.8 (42.7–149.2)	207.4[b] (85.1–602.4)	85[b] (36–165)
25 mg PO	15.1 (8.8–24.3)	1.00 (0.50–4.00)	85.0 (60.5–136.4)	215.9[b] (127.8–337.8)	94[b] (61–192)
Conjugated XYZ123					
10 mg IV	280.8 (198.0–420.6)	0.50 (0.50–0.75)	367.1 (256.5–1344.5)	nd	nd
25 mg PO	98.1 (45.9–209.9)	1.50 (1.00–4.00)	317.1 (139.0–704.7)	nd	nd

nd not determined

[b]$n = 14$

standardization, sometimes limiting the extrapolation to patient settings. Typical enrolment criteria are

- Nonsmoking males between 18 and 45 years
- Normal for weight and BMI
- (Clinically) healthy
- Not using any medication
- Massive dietary and general restrictions
- No hypersensitivities
- No history or presence of any condition that might interfere with the absorption, distribution, metabolism, or elimination of the drug under investigation

MODIFICATIONS OF THE METHOD

In this example, an oral formulation has been compared to an intravenous one, aiming at "absolute" bioavailability. More often, the relative bioavailabilities of different oral formulations are assessed in BA studies. The reference formulation in these studies usually is either a marketed (solid) product or an oral solution.

If the drug under investigation has a toxic potential, BA studies have to be conducted in the patient setting the drug is intended for use.

Deviations from the a.m. high level of standardization might become necessary depending on the properties of the compound.

Almost all clinical study types described in this section deal in any way with bioavailability and/or bioequivalence questions. Specifics are mentioned there.

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a high level summary of the pharmacokinetic results obtained from the study described above under *Procedure* is presented below. Due to the anticipated mode of action of the drug (blood pressure lowering) in this example, instead of an intravenous bolus injection, an intravenous infusion over 30 min was chosen.

45.6.1.6 Results: Pharmacokinetics

A summary of the pharmacokinetic parameters in plasma is presented in Table 45.8.

After oral treatment with 25-mg XYZ123, plasma concentrations of the parent compound were low as a result of a rapid metabolization into the first metabolite XYZ123. For unconjugated and conjugated XYZ123, C_{max} was reached on average 1–1.5 h after oral treatment, after which a rapid initial elimination phase and a slow terminal elimination phase were observed, with a terminal elimination half-life of 3.5–4 days (unconjugated XYZ123). This long half-life led to a small carryover effect in Period 2 for unconjugated

Table 45.9 Results of bioavailability analysis

Analyte	Parameter	Treatment ratio (PO/IV)	90 % CI
Conjugated XYZ123	AUC_{last}	0.38	0.33, 0.43
Unconjugated XYZ123	AUC_{0-inf}	0.47	0.38, 0.59
Unconjugated XYT123	AUC_{last}	0.45	0.43, 0.47

Note: Data were dose corrected

XYZ123. Due to the relatively high lower limit of quantitation (LLQ) of the assay for conjugated XYZ123, the terminal elimination phase for this analyte could only be observed for one subject. The concentrations of conjugated XYZ123 in plasma were 5–10-fold higher than of unconjugated XYZ123. The AUC_{last} (both analytes) and AUC_{0-inf} (unconjugated XYZ123 only) were similar after treatment with XYZ123 25 mg PO and XYZ123 10 mg IV (Table 45.9).

In summary, the calculated bioavailability on basis of the AUC_{last} of conjugated XYZ123 was 38 %. However, this could be a slight underestimation of the bioavailability since this AUC_{last} could only be determined until 6 h post dose. A calculation of the bioavailability on basis of the AUC_{last} or AUC_{0-inf} of unconjugated XYZ123 yielded a slightly higher bioavailability of 45–47 %.

45.7 Drug–Drug Interaction Studies

PURPOSE/RATIONALE

During preclinical developments, numerous flags can arise which indicate that the drug under study has the potential to interact, i.e., its pharmacokinetics or pharmacodynamics can be altered, by concomitant medications, dietary factors, and/or social habits such as tobacco or alcohol in the target population (US FDA 2006b and references therein). Regulatory guidance suggests that if appropriately performed in vitro studies indicate the lack of such an interaction, then a specific clinical study is not compulsory. However, if the claim "No clinically relevant interaction with Drug X" is desired in the product label, then a confirmatory clinical study is compulsory even if in vitro studies indicated the lack of an interaction (EMEA CPMP/EWP/560/95 1997; CPMP/EWP/560/95/Rev. 1 2010).

When discussing interactions, it is important to differentiate between "detectable" and "clinically relevant" interactions. It is accepted that for compounds with a wide therapeutic margin, pharmacokinetic drug interactions may have little clinical relevance. An interaction is considered clinically relevant when the therapeutic and/or toxicity of a drug is changed to such an extent that a dosage adjustment or medical intervention may be required or when concomitant use of two interacting drugs could occur when both are used as therapeutically recommended (EMEA CPMP/EWP/560/95 1997; CPMP/EWP/560/95/Rev. 1 2010).

The basis of an interaction can be pharmacokinetic, pharmacodynamic, or a combination thereof. Pharmacodynamic interactions may be caused by a wide variety of mechanisms; hence, detailed guidance for pharmacodynamic studies is limited, and the study design must be chosen on a case-by-case basis.

During drug development, both aspects for the involvement of the developmental drug in a potential drug-drug interaction has to be considered: their potential as ***victim***, which means they are the object of a drug-drug interaction, or their potential as ***perpetrator***, which means they are the cause of the drug interaction. The scope of mechanisms causing pharmacokinetic interactions may include alterations in one or more of the absorption, distribution, metabolism, and elimination processes (EMEA CPMP/EWP/560/95 1997; CPMP/EWP/560/95/Rev. 1 2010). The alterations may reflect effects of the developmental drug on the pharmacokinetics of the potential interaction partner and vice versa.

Extensive guidance has been published by regulatory agencies on in vitro and in vivo drug-drug interactions studies and how the results obtained can impact the drug dosing and labeling (US FDA 2006b; EMEA CPMP/EWP/560/95 1997; CPMP/EWP/560/95/Rev. 1 2010; US FDA 1997a). Some of the limitations of this guidance are discussed in a recent review that also provides a summary of current industry practice (Bjornsson et al. 2003). However, there is clearly a need for a further harmonization of study designs and marker substrates employed and in the manner in which the data obtained is interpreted, for example, by the development of classification systems. In addition, while existing guidance mainly covers P450-mediated drug interactions, the importance of other mechanisms such as transported has been recognized and should

also be addressed. Recently, increased interest in drug transporters and research in this area has revealed that drug transporters play an important role in modulating drug absorption, distribution, and elimination. Acting alone or in concert with drug-metabolizing enzymes, they can affect the pharmacokinetics and pharmacodynamics of a drug. This commentary will focus on the potential role that drug transporters may play in drug-drug interactions (see Zhang et al. 2006).

Typically, drug-drug interaction studies include some form of comparison of the bioavailability of some marker substrate, for the example given below of ethinylestradiol, when dosed with or without concomitant dosing with the investigational drug, in this example Drug XYZ. Ethinylestradiol is one active component of oral contraceptives and thus a very common concomitant medication for Drug XYZ whose target population is largely younger women. From earlier in vitro and animal in vivo studies, Drug XYZ was known to be potent inducer of both phase I and phase II metabolizing enzymes, including those enzymes reportedly involved in the clearance of ethinylestradiol. Since a clinically relevant drug-drug interaction between Drug XYZ and oral contraceptives would impact the product label and probably also impact the market value of the drug, the study described below was performed.

PROCEDURE

The design of a typical drug-drug interaction study is presented below. For the purposes of simplicity, the description of this example is limited to the collection, handling, and interpretation of data pertinent to the assessment of potential pharmacokinetic and pharmacodynamic interactions, although other parameters were also studied.

45.7.1 Protocol Outline

Effects of repeated once-daily Drug XYZ doses on the safety, pharmacodynamics, and pharmacokinetics of ethinylestradiol after dosing with monophasic oral contraceptives containing ethinylestradiol in healthy overweight or obese women.

45.7.1.1 Objectives

Primary: The primary objective of the study was to study the effects of repeated once-daily Drug XYZ doses on the pharmacokinetics of ethinylestradiol after dosing with monophasic oral contraceptives containing ethinylestradiol in healthy overweight or obese women.

Secondary: The secondary objective of the study was (1) to assess whether Drug XYZ affects the contraceptive effect of the oral contraceptives containing ethinylestradiol as reflected by changes in serum progesterone and 17-β-estradiol levels and (2) to evaluate the safety, tolerability, and pharmacokinetics of repeated once-daily oral doses of Drug XYZ.

45.7.1.2 Study Design

Single-center, double-blind, randomized crossover study in young healthy overweight or obese women. Subjects crossed over with respect to Drug XYZ or placebo that was given double-blinded. The study ran over two menstrual cycles.

Cycles 1 and 2 involved dosing with either Drug XYZ or matching placebo on days 6–20, dosing with the subjects normal ethinylestradiol containing oral contraceptive on days 8–28, hospitalization on days 19–21, and visits to the study site (lunch times) on days 1 (cycle 1 only), 6, 12, 16, 24, and 28.

Day 1 was the first day of the stop week, i.e., the first day after completing the previous cycle: (menstruation generally starts on day 2 or 3, dosing with the oral contraceptive starts on day 8). Sexually active subjects used double barrier contraception during cycles 1 and 2 and for 28 days after completing cycle 2. Subjects were advised to continue use of these measures for at least 28 days after completing cycle 2. Dropouts were not to be replaced.

45.7.1.3 Number of Subjects

Based on published variability in pharmacokinetic studies of ethinylestradiol in lean subjects, taking confidence intervals of 80–125 %, residual variance ranged between 10 % and 33 %. Based on these residual variance values, calculated samples sizes ranged between 6 and 30 (subjects). For example, based on a residual variance value of 17.5 %, a sample size of 14 was calculated.

The chosen sample size reflects (1) the formal sample size calculation (using a residual variance value of 17.5 %) based on the pharmacokinetics of ethinylestradiol in lean subjects; (2) published sample sizes in other studies of this type of study ranged

between 12 and 34; (3) that this study will include overweight and obese subjects, a population who have been suggested to show a higher variability in their pharmacokinetics and in their menstrual cycles; and finally (4) the plan not to replace dropouts.

Based on the planned analysis of variance on log-transformed data, 90 % confidence intervals for AUC ratio's ethinylestradiol + Drug XYZ and ethinylestradiol alone, 20 subjects complete the study as planned.

45.7.1.4 Inclusion Criteria

The following inclusion criteria were met: women aged between 18 and 35 years; with body mass index (BMI) of $25.0 \leq 35.0$ kg/m^2; who are either postmenopausal or surgically sterile and willing to use prescribed barrier contraceptive methods; who—apart from being overweight or obese—are healthy for the purpose of the study and not receiving regular medication in the month preceding the study (with the exception of oral contraceptives); who are using monophasic contraceptives containing ethinylestradiol as the estrogen compound; who present normal gynecological histories and normal, regular menstrual cycles (within the previous 12 months); without contraindications for treatment with oral contraceptives; who are not pregnant or lactating; with normal findings in the physical examination, unless the investigator considers an abnormality to be clinically irrelevant for the study; who are nonsmoking or light smokers.

45.7.1.5 Treatments

Cycles 1 and 2: Oral administration of (1) the subjects normal oral contraceptive once daily (mornings before breakfast) on days 8–28 of each cycle and (2) Drug XYZ or matching placebo, once daily (mornings before breakfast) on days 6–20 of each cycle (15 doses in total).

45.7.1.6 Pharmacokinetic/Pharmacodynamic Data

Plasma concentrations of ethinylestradiol (EE) on day 20 in cycles 1 and 2.

Plasma concentrations of Drug XYZ, before and at predetermined times post dose, were measured on days 6, 12, 16, 20, 24, and 28 in cycles 1 and 2.

Serum concentrations of 17-β-estradiol and progesterone on days 6, 12, 16, 20, 24, and 28 in cycles 1 and 2.

EVALUATION

The data pertinent to the assessment of potential pharmacokinetic and pharmacodynamic interactions from study described above was evaluated as follows:

Where appropriate, individual data were presented together with descriptive statistics including mean, standard deviation, standard error of the mean, coefficient of variation (in %), median, minimum, maximum, and the number of relevant observations.

Where applicable, pharmacokinetic parameters (C_{max}, T_{max}, AUC_{0-24}, $t_{½}$) were calculated using a noncompartmental analysis employing a linear/log trapezoidal method.

Plasma EE: Descriptive statistics and comparison of plasma EE concentrations in cycles 1 and 2. Analysis of variance on log-transformed data, 90 % confidence intervals for AUC ratio of EE + Drug XYZ and EE alone ($AUC_{EE+Drug\ XYZ}/AUC_{EE}$).

Analysis of variance was performed on the log-transformed AUC_{0-24} of ethinylestradiol to estimate intrasubject variability. The intrasubject variability was subsequently used to estimate the 90 % confidence interval of the $AUC_{EE+Drug\ XYZ}/AUC_{EE}$ ratio.

Plasma drug XYZ: Individual plasma concentrations were tabulated together with standard descriptive statistics for each variable.

Serum progesterone: Descriptive statistics and comparison of serum progesterone concentrations in cycles 1 and 2. Descriptive comparison of the proportion of subjects who ovulated while receiving Drug XYZ and contraceptive concomitantly and the proportion of subjects who ovulated while receiving contraceptive alone. Ovulation was assumed if serum progesterone levels exceeded 1.4 ng/mL on day 20 of a menstrual cycle. Individual and mean/median profiles were presented graphically.

Serum 17-β-estradiol: Descriptive statistics and comparison of serum 17-β-estradiol concentrations in cycles 1 and 2. Individual serum concentrations of 17-β-estradiol were tabulated.

CRITICAL ASSESSMENT OF THE METHOD

The study described above could have been powered to study effect of Drug XYZ on pharmacodynamic effects of ethinylestradiol, in this case, to study effects on ovulation.

The study described above did not study interactions with other active components of oral

contraceptives whose pharmacokinetics could also be altered by concomitant dosing with Drug XYZ.

The study described above did not study whether or not the observed effects on the pharmacokinetics of ethinylestradiol were reversible, and if so, the time course thereof.

The lack of prior knowledge of the time course of any Drug XYZ–mediated induction of phase I and II metabolizing enzymes complicated the interpretation of the data obtained from the example study. Based on previous clinical studies, the Drug XYZ dosing regimen was chosen to ensure that enzyme induction was maximal at the time shortly before ovulation. However, it was not known whether or not the observed enzyme induction would fade after prolonged exposure to Drug XYZ, or whether on rechallenge, the same magnitude of enzyme induction would be seen, or if the observed induction was reversible.

This example however followed the recommended basic profiling sequence, i.e., in vitro profiling, confirmation of the in vitro observation in animals, explorative profiling in man. The example study would typically be followed by further profiling of this drug-drug interaction potential with other substrates, representing a range of concomitant medication in the target patient population, for example, using population pharmacokinetic approaches and definitive studies designed to support clear labeling statements.

MODIFICATIONS OF THE METHOD

The following general issues and approaches should be considered (for a more detailed discussion, see references (US FDA 1997a, 2006b; EMEA CPMP/EWP/560/95 1997; CPMP/EWP/560/95/Rev. 1 2010). In the following discussion, the term *substrate* (S, in our example ethinylestradiol) is used to indicate the drug studied to determine if its exposure is changed by another drug, which is termed the *interacting drug* (I, in our example Drug XYZ). Depending on the study objectives, the substrate and the interacting drug may be the developmental drugs or approved products.

45.7.1.7 Study Design

Clinical drug-drug interaction studies are generally designed to compare substrate levels with and without the interacting drug, and thus many of the principles applying to comparative bioavailability studies also apply here. Because a specific study may consider a number of questions and clinical objectives, no one correct study design for studying drug-drug interactions can be defined.

The following considerations may be useful when choosing a study design:

- Interpretation of findings from these studies will be aided by a good understanding of dose/concentration and concentration/response relationships for both desirable and undesirable drug effects. In certain instances, reliance on endpoints other than pharmacokinetic measures/parameters may be useful.
- The inhibiting/inducing drugs and the substrates should be dosed so that the exposure of both drugs is relevant to their clinical use.
- The time at steady state before collection of endpoint or pharmacokinetic observations depends on whether inhibition or induction is to be studied. Inducers can take several days or longer to exert their effects, while inhibitors generally exert their effects more rapidly. Thus, if induction is to be assessed, a more extended profiling period after attainment of steady state for the substrate and interacting drug may be necessary.
- When attainment of steady state is important, long half-lives of the substrate, interacting drugs, and/or their metabolites should be considered.
- When a substrate and/or an interacting drug are to be studied at steady state, documentation that near steady state has been attained is important.
- Studies can usually be open label (unblinded), unless pharmacodynamic endpoints subject to bias are part of the assessment of the interaction.
- For a rapidly reversible inhibitor, administration of the interacting drug either just before or simultaneously with the substrate on the test day might be the appropriate design to increase sensitivity.

45.7.1.8 Study Population

Clinical drug-drug interaction studies may generally be performed using healthy subjects on the assumption that findings in this population should predict findings in the target patient population. Safety considerations, however, may preclude the use of healthy subjects. In certain circumstances, inclusion of patients from the targeted patient population may offer certain advantages, including the opportunity to study pharmacodynamic endpoints.

45.7.1.9 Choice of Substrate and Interacting Drugs

Substrates for a developmental drug (Developmental drug is the Perpetrator): When testing inhibition, the substrate selected should generally be one whose pharmacokinetics is markedly altered by coadministration of known specific inhibitors of the affected enzyme systems (i.e., a very sensitive substrate should be chosen). If the initial study is positive for inhibition, further studies with other substrates representing a range of substrates based on the likelihood of coadministration may be useful. If the initial study is negative with the most sensitive substrates, it can be presumed that less sensitive substrates will also be unaffected.

Developmental drug as substrate (Developmental drug is the Victim): When testing a developmental drug for the possibility that its metabolism is inhibited or induced (i.e., as a substrate), selection of the interacting drugs should be based on a priori knowledge of the enzyme systems that metabolize the developmental drug. The choice of interacting drug should then be based on known, important inhibitors of the pathway under investigation. If the study results are negative, then absence of a clinically important drug-drug interaction for the metabolic pathway could be claimed.

45.7.1.10 Route of Administration

For a developmental drug used as either an interacting drug or substrate, the route of administration should generally be the one planned for in-product labeling.

45.7.1.11 Dose Selection

For both the substrate and interacting drug, testing should maximize the possibility of finding an interaction. For this reason, the maximum planned or approved dose and shortest dosing interval of the interacting drug (as inhibitors or inducers) should be used. Doses smaller than those to be used clinically may be needed for substrates on safety grounds and may be more sensitive to the effect of the interacting drug.

45.7.1.12 Sample Size and Statistical Considerations

For both developmental drugs and approved drugs, when used as substrates and/or interacting drugs in drug-drug interaction studies, the desired goal of the analysis is to determine the clinical significance of any increase or decrease in exposure to the substrate in the presence of the interacting drug. Assuming unchanged PK/PD relationships, changes may be evaluated by comparing pharmacokinetic measures of systemic exposure that are most relevant to an understanding of the relationship between dose (exposure) and therapeutic outcome.

Results of drug-drug interaction studies should be reported as 90 % confidence intervals about the geometric mean ratio of the observed pharmacokinetic measures with (S + I) and without the interacting drug (S). Confidence intervals provide an estimate of the distribution of the observed systemic exposure measure ratio of S + I versus S alone and convey a probability of the magnitude of the interaction.

When a drug-drug interaction is clearly present, the sponsor should be able to provide specific recommendations regarding the clinical significance of the interaction based on what is known about the dose–response and/or PK/PD relationship for either the investigational agent or the approved drugs used in the study.

The sponsor may wish to make specific claims in the package insert that no drug-drug interaction is expected. In these instances, the sponsor should be able to recommend specific *no effect* boundaries, or clinical equivalence intervals, for a drug-drug interaction. No effect boundaries define the interval within which a change in a systemic exposure measure is considered not clinically meaningful.

EXAMPLE
To illustrate the type of data that can be obtained using the discussed study, a high level summary of the data from the study described above under *Procedure* is presented below.

45.7.1.13 Results

The data pertinent to the assessment of potential pharmacokinetic and pharmacodynamic interactions from study described above, as given in Table 45.10 below, can be summarized as follows:

In this study, nine different brands of oral contraceptives were used. The dose of ethinylestradiol per pill most commonly taken was 30 μg (by 17 subjects) and ranged from 20 to 50 μg across all subjects, 24 subjects who completed the study as planned.

Pharmacokinetics: When EE was administered in combination with Drug XYZ, arithmetic mean $t_{1/2}$ and T_{max} values were comparable for both treatments. Geometric mean C_{max} and $AUC_{0–24}$ values were approximately 20–30 % lower, respectively, than when EE was administered with placebo. For $AUC_{0–24}$, the lower and upper limits of the 90 % CI were below the predefined 90 % CI of 0.8–1.25. Therefore, a pharmacokinetic interaction between Drug XYZ and EE can be concluded. The mechanism for this statistically significant reduction in systemic exposure to EE is unknown; however, since Drug XYZ is known to induce CYP 1A2 in man, and CYP 1A2 and phase II enzymes in animals, the observed effect could reflect a metabolic interaction between Drug XYZ and EE.

Pharmacodynamics: Serum progesterone and 17-β-estradiol levels are considered reliable indicators for the occurrence of ovulation. Since progesterone and 17-β-estradiol levels were comparable for both treatments, and progesterone serum concentrations did not exceed 1.4 ng/mL (as defined in this study, progesterone concentrations above 1.4 ng/mL on day 20 of a menstrual cycle indicated ovulation) for both treatments, it was concluded that Drug XYZ administration did not affect the contraceptive effect of ethinylestradiol-based oral contraceptives and that no ovulation occurred in any of the subjects.

45.8 Profiling the Effect of Food on Drug Bioavailability

PURPOSE/RATIONALE
Drugs intended for oral administration have to pass through the gastrointestinal tract before they can enter the bloodstream and eventually reach their target site of action. Often already profiled using a food screen in the first-in-man study, the assessment of the influence of food intake on the bioavailability of a drug belongs to the most important steps when describing the drug pharmacokinetics in early clinical development. The outcome of such food screens or formal food interaction studies has a considerable impact on the design of ensuing studies and forms the basis for later labeling recommendations as well as for the package insert (US FDA Guidance for Industry 2002).

Food can alter the bioavailability of drugs either by direct physical or chemical interaction or by the physiological response. Such effects are most prominent when the drug product is administered shortly after a meal. The composition of such a meal should lead to the greatest possible physiological reaction. Consequently, a high-fat, high-calorie breakfast after overnight fasting is recommended. Details on the composition of such a meal and the design of those studies can be found in US FDA Guidance for Industry (2002) and EU CPMP (1999).

The effects of food intake include the physiological effects of food itself, as well as physicochemical interactions between food and the drug under investigation.

Table 45.10 Summary statistics of pharmacokinetic parameters for ethinylestradiol

	EE + placebo				EE + Drug XYZ			
Parameter	*n*	Arithmetic mean	CV (%)	Geometric mean	*n*	Arithmetic mean	CV (%)	Geometric mean
$\mathbf{C_{max}}$ (pg/mL)	24	98.3	39	91.1	24	79.4	43	72.5
$\mathbf{AUC_{0–24}}$ (pg.h/mL)	24	933	34	879	24	672	32	637
	Treatment ratio and 90 % confidence interval of EE $AUC_{0–24}$ (EE + Drug XYZ over EE + placebo) 0.73 (0.68–0.78)							
$\mathbf{t_{½}}$ (h)	24	22	27	21	24	21	28	20
$\mathbf{T_{max}}$ (h)	24	1.2	55	–	24	1.2	54	–

For the latter, the categories of the biopharmaceutical classification system (BCS) become important (Amidon et al. 1995). A comprehensive excellent review of the determinants of food effects on clinical pharmacokinetics can be found in Singh (1999).

PROCEDURE

The design of an exploratory food interaction bioavailability study with Drug XYZ123 is presented below. In this given project, the food interaction study was initiated in parallel to a hADME study just after completion of the first-in-man study. In this study, the collection, handling, and interpretation of pharmacokinetic data were in the focus.

45.8.1 Protocol Outline

Study of the effect of food on the pharmacokinetics of film-coated tablets (3 × 200 mg) of XYZ123 in healthy men.

45.8.1.1 Primary Objective

To assess the effect of food on the pharmacokinetics of 600-mg XYZ123 in healthy men.

45.8.1.2 Study Design

An open, randomized, four-period crossover study. There were four sequence groups of five subjects each. Each sequence group received the treatments A, B, C, and D (different time intervals between food intake and medication) in different sequential order (Williams design). Washout periods were at least 4 days.

45.8.1.3 Inclusion Criteria

Healthy men aged between 40 and 65 years. Body weights within −15 % and +10 % of the normal weight according to Broca.

45.8.1.4 Treatments

Treatment A: Single dose of 3 × 200-mg XYZ123 on an empty stomach (overnight fasting) and start of high-fat-food intake 4 h later.

Treatment B: Single dose of 3 × 200-mg XYZ123 together with high-fat food (drug administration 15 min after start of high-fat-food intake).

Treatment C: Single dose of 3 × 200-mg XYZ123 2 h after start of high-fat-food intake.

Treatment D: Single dose of 3 × 200-mg XYZ123 on an empty stomach (overnight fasting) 1 h before start of high-fat-food intake.

45.8.1.5 Pharmacokinetic Data

Concentration of XYZ123 in plasma before and at predefined times after dosing.

EVALUATION

Descriptive statistics of all variables.

Analysis of variance (ANOVA) with treatment, subject (nested within sequence), and period as main factors was performed for C_{max} and AUC_{0-inf}. The 90 % confidence intervals of the point estimates of the ratio of C_{max} and AUC_{0-inf} and of the difference between treatments for t_{max} were determined. Pairwise comparisons to treatment A were made, with treatment A versus treatment B being the primary comparison.

CRITICAL ASSESSMENT OF THE METHOD

The information originating from preceding studies is needed for the proper design of a food interaction study: safety and tolerance data has to be considered as well as the PK results including a food screen. The terminal half-life of the drug or its active metabolite(s) will provide the basis for the washout periods. Single-dose linearity/proportionality will help to define the dose. Safety and tolerance data will justify the dose. The PK comparison in a food screen (FIM study, see below) will influence the sample size.

It depends on the target indication, for example, acute or chronic use, and on the intended dosing regimen, for example, once, twice, or thrice daily, whether a given food effect is acceptable for justification of further development or if it defines the “knockout.”

The study design described here is a quite complex approach. A simplification would limit the study conditions to both extremes: a high-fat, high-calorie breakfast starting 0.5 h before the drug administration versus fasting overnight (at least 10 h) + at least 4 h after drug administration.

MODIFICATIONS OF THE METHOD

There is a tendency to include a so-called food screen already in a FIM study. The limitation of such an approach is the nonavailability of information mentioned in the previous chapter. On the other hand,

Table 45.11 Summary of the pharmacokinetic parameters in plasma

	PK parameter (geometric mean + range)				
Treatment	C_{max} (μg/mL)	t_{max}[a] (h)	$t_{½}$ (h)	AUC_{0-inf} (μg.h/mL)	CLtot/F (L/h)
A (*n* = 19)	4.51	0.75	2.78	11.0	51.4
Food 4 h after dosing	(2.00–8.02)	(0.25–2.50)	(2.05–4.98)	(4.96–17.0)	(33.4–115)
B (*n* = 19)	3.60	1.50	2.77	11.4	49.8
Food with dosing	(1.72–8.57)	(0.75–6.00)	(1.78–4.22)	(5.62–19.0)	(29.9–101)
C (*n* = 19)	3.52	1.50	3.10	9.89	57.4
Food 2 h before dosing	(2.02–5.57)	(0.75–2.50)	(1.86–5.98)	(4.12–17.3)	(32.9–138)
D (*n* = 19)	5.41	0.50	3.05	11.8	48.3
Food 1 h after dosing	(2.98–8.65)	(0.50–1.50)	(2.40–4.45)	(6.13–18.2)	(31.2–92.7)

[a]For t_{max}, the median + range is presented

changes in the formulation during the drug development phase, a switch from an immediate-release to an extended-release formulation might necessitate a repetition.

Only if the conditions for a waiver apply, a food interaction study is not needed for a submission package. Under all other circumstances, where drug products are administered orally for systemic exposure, this kind of study is a must. And it must be conducted with the drug product that is intended for the market authorization.

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a summary of the pharmacokinetic results obtained from the study described above under *Procedure* is presented below.

45.8.1.6 Results: Pharmacokinetics

The XYZ123 concentration-time profiles show that food caused a delay in drug absorption and a lower peak concentration. This effect was most pronounced when food and medication were taken at the same time. A summary of the pharmacokinetic parameters in plasma is presented in Table 45.11.

Table 45.12 Summary of the point estimates of the treatment ratios or of the difference between treatments

PK parameter	Treatment	Point estimate of treatment ratio[a]	90 % CI
C_{max}	B/A	0.79	0.69–0.91
	C/A	0.78	0.68–0.89
	D/A	1.20	1.04–1.37
AUC_{inf}	B/A	1.03	0.94–1.12
	C/A	0.89	0.81–0.98
	D/A	1.07	0.97–1.17
t_{max}[a] (h)	B–A	1.13	0.88–1.63
	C–A	0.94	0.63–1.25
	D–A	0.00	−0.13–0.13

[a]Point estimate of the treatment difference (h) is presented for t_{max}

A summary of the point estimates of the treatment ratios or of the difference between treatments for XYZ123 is presented in Table 45.12. The AUC_{0-inf} was similar for all treatments. When compared to treatment A, the AUC_{0-inf} of the other treatments was within the 80–125 % equivalence limits.

The point estimates show that taking food 2 h before, or at the same time as receiving medication, delayed absorption and lowered the maximum plasma concentration. The relative bioavailability, however, was similar for all treatments. The lower limit of the 90 % CI for C_{max} was marginally outside the predefined equivalence range for treatment B and C, but C_{max} was within the equivalence range for treatment D.

The intake of a high-fat meal before or at dosing lowered the maximum plasma concentration (C_{max}) and increased the absorption time (t_{max}).

The relative bioavailability, however, was equivalent when medication was taken with food or under fasting conditions.

45.9 Exploratory Profiling of Enzyme Induction on Drug Disposition

PURPOSE/RATIONALE

Concomitantly administered drugs have the potential to interact, i.e., their pharmacokinetics or pharmacodynamics can be altered (US FDA 2006b and references therein). Regulatory guidance suggests that if appropriately performed in vitro studies indicate the lack of such an interaction, then a specific clinical study is not compulsory. However, if the claim "No clinically relevant interaction with Drug X" is desired in the product label, then a confirmatory clinical study is compulsory even if in vitro studies indicated the lack of an interaction (EMEA CPMP/EWP/560/95 1997; CPMP/EWP/560/95/Rev. 1 2010).

Drug-drug interactions mediated by enzyme induction are less common than those mediated by enzyme inhibition. Drug-drug interactions due to enzyme induction are also less likely to cause safety issues, except toxic if a toxic metabolite is formed by metabolite activation; however, they may affect the activity of the developmental drug itself and of concomitant medications. In this context, it is to mention that induction of CYP 3A4 by a developmental drug is frequently investigated for oral contraceptives, although they are not very sensitive substrates (US FDA 2006b).

Preclinical profiling for enzyme induction is complicated by the observation that, contrary to as seen for enzyme inhibition, the enzyme inductive potential of a drug in man is difficult to assess preclinically, especially in nonhuman systems. There are however numerous flags which can indicate that the drug under study has some activating effect on drug-metabolizing enzymes such as the cytochrome P450 isozymes (CYP) 1A2, 3A4, etc. These flags can include a drop in systemic exposure to developmental drug after multiple dosing, increases in animal liver weights after multiple dosing in toxicology studies, class characteristics, and positive signals in animal and human in vitro enzyme induction screens.

If one or more of these flags are observed, especially positive signals in human in vitro enzyme induction screens, then the in vivo inductive potential of the developmental drug is typically studied in suitable explorative clinical studies. Given the expectation that enzyme induction is more likely to cause a reduced efficacy of developmental drug itself and/or of concomitant medications than to cause safety issues, in the profiling of enzyme induction during early clinical development in man is typically included as secondary objective in other studies. Such explorative clinical studies employ non-indication-specific, but metabolically well-characterized, marker drugs or compounds. If a notable inductive potential is seen in these explorative clinical studies, then more specific studies with drugs with a narrow therapeutic index critical and/or frequent usage in the target population are usually performed.

PROCEDURE

The design of a study providing the suggested exploratory profiling of the effect of Drug XYZ on CYP 1A2- and CYP 3A4-mediated metabolism is presented in the *Protocol Outline* below. For the purposes of simplicity, the description is limited to the collection, handling, and interpretation of data pertinent to the assessment of potential drug-mediated effects on CYP1A2- and CYP3A4-mediated metabolism, although other parameters were also studied.

45.9.1 Protocol Outline

Safety, tolerability, and the effect on CYP 1A2- and CYP 3A4-mediated metabolism of single and repeated oral doses of 400-mg and 1,200-mg Drug XYZ or placebo in overweight or obese, but otherwise healthy, men.

45.9.1.1 Objectives

Primary: The primary objective of the study was to investigate in overweight or obese, but otherwise healthy, men: (1) the safety and tolerability of single and repeated oral doses of 400-mg and 1,200-mg Drug XYZ and (2) the effect of Drug XYZ on CYP1A2- and CYP3A4-mediated metabolism.

Secondary: The secondary objective of the study was to investigate the pharmacokinetics of Drug XYZ after single and repeated oral doses of 400-mg and 1,200-mg Drug XYZ in overweight or obese, but otherwise healthy, men.

45.9.1.2 Study Design

The study had a single-center, single- and repeated-dose, single-trial period, and double-blind design.

Subjects received single doses of 150-mg caffeine, once before starting treatment with Drug XYZ (day 1) and then again together with Drug XYZ dosing on day 10. In addition, subjects received a single daily dose of 400-mg and 1,200-mg Drug XYZ or matching placebo on day 2 and then again on days 4–10.

On days 1 and 10, CYP 1A2 activity was monitored using the plasma concentrations of caffeine and paraxanthine and CYP 3A4 activity was monitored using the urinary excretion of free cortisol and 6-β-hydroxy-cortisol (Rost and Roots 1994; Fuhr et al. 1996; Streetman et al. 2000; Kovacs et al. 1998; Tran et al. 1999).

The treatment period between trial periods was at least 10 days which approximated to >10 Drug XYZ apparent terminal half-lives.

45.9.1.3 Number of Subjects

The inclusion of eight (8) subjects was considered to be in line with common industry practice for this type of explorative study.

45.9.1.4 Inclusion Criteria

The following inclusion criteria were met: men aged between 18 and 55 years; with body mass index (BMI) of 25–35 kg/m^2; who—apart from being overweight or obese—are healthy for the purpose of the study and not receiving regular medication in the month preceding the study; with normal findings in the physical examination, unless the investigator considers an abnormality to be clinically irrelevant; who are nonsmokers.

45.9.1.5 Treatments

Single (day 2) and repeated (days 4–10) oral doses of 400-mg and 1,200-mg Drug XYZ or matching placebo after fasting. Single doses of 150-mg caffeine, once on day 1 and then again on day 10.

45.9.1.6 Pharmacokinetic Data

Plasma concentrations of Drug XYZ, caffeine, and paraxanthine, before and at predetermined times post dose, were measured.

Concentrations of Drug XYZ, 6-β-hydroxy-cortisol, and free cortisol in urine collected over the profiling period were measured. Volumes of urine collected over each profiling period were recorded.

The volume of urine collected over 24 h and the concentration of creatinine were determined to allow the subjects' creatinine clearance to be calculated.

EVALUATION

The data pertinent to the assessment of potential drug-mediated effects on CYP 1A2- and CYP 3A4-mediated metabolism from study described above was evaluated as follows: Due to the investigational nature of the study, and the small sample size, all variables were only presented descriptively. Where appropriate, individual data were presented together with descriptive statistics.

Plasma caffeine and paraxanthine: Descriptive pharmacokinetic parameters (standard parameters including peak concentrations (C_{max}), time of C_{max} (T_{max}), area under the curve (AUC) between time 0 and time t where t = 24 h post dose (AUC_{0-t}), AUC after extrapolation to infinity ($AUC_{0-\infty}$), apparent terminal half-life ($t_{1/2_z}$), and total clearance (CL)) for plasma caffeine and paraxanthine on days 1 and 10 were calculated using a noncompartmental analysis employing a linear/log trapezoidal method as implemented in WinNonlin® (Pharsight Corp.) protocols. Changes from baseline (day 10–day 1) in caffeine clearance and the area-under-the-curve (AUC) ratio paraxanthine/caffeine were presented individually and with corresponding descriptive statistics. The ratio of paraxanthine AUC/caffeine AUC was calculated.

Urinary 6-β-hydroxy-cortisol and free cortisol: The following pharmacokinetic variables were derived from urine concentration data for 6-β-hydroxy-cortisol and free cortisol on days 1 and 10 using SAS® for Windows™ protocols: amount excreted during each collection interval for 6-β-hydroxy-cortisol and free cortisol, total amount excreted (mg) during 12 h (Ae_{0-12}) and 24 h (Ae_{0-24}) for both compounds, the ratio of Ae_{0-24} of 6-β-hydroxy-cortisol/Ae_{0-24} of free cortisol, the ratio of Ae_{0-12} of 6-β-hydroxy-cortisol/Ae_{0-12} of free cortisol.

CRITICAL ASSESSMENT OF THE METHOD

Ideally, such a study should profile the dose dependence, the time dependence, and the reversibility of the enzyme induction. Also the enzyme substrates used as

markers for the enzyme activity should be drugs with a narrow therapeutic index used by the target population and/or frequent usage in the target population.

In the described study, the time dependence and reversibility of the enzyme induction were not studied. Also the enzyme substrate used as a marker for the CYP 1A2 activity was caffeine, which, although frequently encountered in the target population and commonly used as a marker for CYP 1A2 activity, is not a drug with a narrow therapeutic index used by the target population. The enzyme substrate used as a marker for the CYP 3A4 activity, urinary 6-β-hydroxy-cortisol, and free cortisol, although readily amenable to inclusion in studies, is not a drug and is also known to be a relatively insensitive marker for CYP 3A4 induction. Also urinary 6-β-hydroxy-cortisol and free cortisol do not differentiate between intestinal and liver CYP 3A4 activities. But on the other hand, since only endogenous markers are to be determined, this test can be implemented in the early development program without the need to conduct a dedicated study in order to generate a flag for CYP 3A4 induction early.

MODIFICATIONS OF THE METHOD

The design of studies profiling of enzyme induction is typically case specific since the time and dose dependence of enzyme induction differs between the enzyme (s) being induced and the drug causing the induction. There is no clearly defined regulatory guidance on enzyme induction studies beyond the recommendation that study designs should be science based.

It is generally accepted that the dosing regimen should minimally ensure that the anticipated therapeutic steady-state exposure is maintained (or exceeded) for some days since although some inducible enzymes respond rapidly, others require longer exposure before responding. Ideally, such a study should profile the dose dependence, the time dependence, and the reversibility of the enzyme induction. Also the enzyme substrates used as markers for the enzyme activity should be drugs with a narrow therapeutic index used by the target population and/or frequent usage in the target population.

The study described in this chapter provides explorative profiling of potential enzyme induction after dosing over 2 weeks at two dose levels and in comparison to placebo. This relatively comprehensive design reflects the combination of (1) the clear expectation that a clinically relevant enzyme induction would be observed based on numerous flags from preclinical studies and experience with other members of this chemical class characteristics for this drug, (2) the chance ability to build in the planned investigation into a tolerability study due to the use of innocuous (caffeine) or endogenous enzyme markers (urinary 6-β-hydroxy-cortisol/free cortisol), and (3) the opinion that a clinically relevant enzyme induction would have severely impacted the market value of a Drug XYZ and thus should be profiled as early as possible.

In practice, the explorative profiling of enzyme induction is even less elaborate than that performed for Drug XYZ because (1) it requires the use of enzyme substrates which are less amenable to inclusion in tolerability studies and (2) risk-benefit considerations do not justify studies a with a range of dose levels.

Instead, specific confirmatory clinical studies employing drugs with a narrow therapeutic index used by the target population and/or frequent usage in the target population are typically implemented in the late clinical development as part of the range of drug-drug interaction studies used to support the drug label.

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a high level summary of the data from the study described above is presented below.

45.9.1.7 Results: Pharmacokinetics

The data pertinent to the assessment of potential drug-mediated effects on CYP 1A2- and CYP 3A4-mediated metabolism from study described above, as given in Tables 45.13 and 45.14 below, can be summarized as follows:

- The mean $AUC_{0-\infty}$ for caffeine on day 10 was decreased by approx. 67 % and approx. 80 % when compared to day 1 for subjects treated with 400-mg and 1,200-mg Drug XYZ, respectively, and was more pronounced than for caffeine and paraxanthine mean AUC_{0-t} values, which also decreased substantially.
- Administration with placebo showed no notable change in caffeine or paraxanthine levels.
- On day 10, the mean caffeine clearance [dose/$AUC_{0-\infty}$] was increased by approx. threefold in subjects treated with 400-mg Drug XYZ and five-fold in subjects treated with 1,200 mg.
- All the caffeine/paraxanthine results suggest that Drug XYZ induced CYP 1A2 in humans and that the extent of induction was dependent on the dose administered.
- Given that a natural approx. 20-fold variation in CYP 1A2 activity has been reported in the literature, the observed induction was considered to be clinically irrelevant.
- The ratio of 6-β-hydroxy-cortisol/free cortisol excretion was about 11 for all treatments on both day 1 and 10, suggesting that there was no noticeable effect on CYP 3A4 activity.

Table 45.13 Mean (SD) plasma caffeine and paraxanthine pharmacokinetic variables (ng.h/mL) by treatment

Analyte variable Day	*N*	Treatment group Placebo	400 mg	1,200 mg
Caffeine				
AUC_{0-t}				
Day 1 (baseline)	8	26,626.1 (8,971.9)	16,261.7 (3,908.3)	21,977.9 (4,309.7)
Day 10	8	24,996.9 (5,393.2)	6,464.0 (2,052.7)	6,580.1 (1,493.6)
$AUC_{0-\infty}$				
Day 1 (baseline)	8	43,222.8 (23,538.3)	20,585.0 (8,236.6)	33,769.3 (11,680.6)
Day 10	8	37,447.4 (14,356.4)	6,776.0 (2,326.7)	6,793.7 (1,572.8)

Day 1 (baseline)	8	8,258.1 (2,036.8)	7,430.9 (1,166.8)	7,809.7 (2,228.7)
Day 10	8	8,886.6 (2,549.1)	5,624.1 (770.9)	6,054.2 (1,192.0)

45.10 Formulation Interactions

PURPOSE/RATIONALE

The reasons why individuals differ in their responsiveness to drugs in medical products are manifold including age, gender, genetics, disease, and concomitantly administered drugs.

The focus of interaction studies has changed from ad hoc observational studies to rationally designed studies. Depending on the structural and physicochemical characteristics and on animal and human in vitro data, selective in vivo studies are performed. Based on the results of such studies, the risk of clinically relevant interactions may be predicted. As a result, essential information on formulation interactions has become an integral part of the labeling document of a drug product.

Formulation interactions can be of many different kinds, such as formulation interactions with packaging

Table 45.14 Mean (SD) ratio of urinary 6-β-hydroxy-cortisol/free cortisol excreted by treatment

Analyte variable Day	*N*	Treatment group Placebo	400 mg	1,200 mg
Ratio 6-β-hydroxy-cortisol/free cortisol				
Ae_{0-12} Day 1 (baseline)	8	8.75 (2.3)	11.4 (7.9)	9.28 (3.7)
Ae_{0-24} Day 10	8	11.3 (2.0)	11.4 (4.7)	12.7 (6.1)

material (compatibilities), interactions between the active drug and excipient(s), or interactions between formulations (e.g., when mixing the drug product with other (parenteral) drug products). Details about how to deal with changes in components or composition of drug products are described in published regulatory guidances (US FDA 1995, 1997b, 1999b), while no formal guidance exists that in particular covers all types of formulation interactions. It is important to differentiate between detectable interactions and clinically relevant interactions. A clinically relevant interaction, for example, is the concomitant administration of two drugs that interact to such an extent that a dosage adjustment of either drug may be required. Details about clinically relevant (drug-drug) interactions and assessment of equivalence of formulations can be found (US FDA 2001; Steinijans and Hauschke 1997; CPMP/EWP/QWP/1401/98 2002; CPMP/EWP/560/95 1998).

Reasons for change of formulation include, but are not limited to, poor bioavailability of solid oral formulations, limitations in drug load for oral or parenteral formulations, profound food effect, too early/too late onset of action (absorption, distribution), too short/too long duration of action (metabolism, elimination), or high intra- and interindividual variability.

While formulation interactions often are subject to in vitro investigations, the chapter below presents a particular example of a clinical formulation interaction study (Frick et al. 2004): a potential interaction of a drug in medical practice frequently given concomitantly with another drug (i.e., both mixed in a syringe) was subject to a clinical study which is illustrated below. For the purposes of simplicity, the description is limited to the collection, handling, and interpretation of pharmacokinetic data although safety and pharmacodynamic parameters were also assessed.

PROCEDURE

The design of a typical formulation interaction study is presented below.

45.10.1 Protocol Outline

Pharmacokinetics of HMR1964 (insulin glulisine) syringe-mixed versus simultaneously injected 0.1 IU/kg HMR1964 (insulin glulisine) and 0.2 IU/kg NPH insulin in healthy subjects using the euglycemic clamp technique.

45.10.1.1 Objective

To investigate the pharmacokinetics of insulin glulisine following subcutaneous (s.c.) administration of insulin glulisine immediately premixed in a syringe with NPH insulin versus separate simultaneous injections of insulin glulisine and NPH insulin.

45.10.1.2 Design, Treatment, and Sample Size

This was a single-dose, randomized, open-label, two-way, crossover study. 0.1 IU/kg insulin glulisine and 0.2 IU/kg NPH insulin separate and simultaneous s.c. injections in the abdominal area or 0.1 IU/kg insulin glulisine and 0.2 IU/kg NPH insulin by s.c. injection in the abdominal area, immediately after being premixed in the syringe.

45.10.1.3 Population Treated

Thirty-two (32) healthy male subjects, aged 18–45 years, with body mass index between 18 and 26 kg/m^2, with a minimum body weight of 65 kg were treated.

Pharmacokinetic interaction studies are suggested to be performed in healthy individuals (Schall and Williams 1996). Furthermore, it was anticipated that any interaction, should it occur, would be present in this population.

EVALUATION

45.10.1.4 Statistical Procedures Pharmacokinetics

The interpretation of the pharmacokinetic variables C_{max}, AUCs, and MRT of insulin glulisine was based on 95 % confidence intervals, after ln-transformation of the data. These 95 % confidence intervals were calculated for the respective mean ratios of pair-wise treatment comparisons. In addition, the "test" treatment was compared to the "reference" treatment with respect to the pharmacokinetic variables using an ANOVA with subject, treatment, and period effects, after ln-transformation of the data. The subject sum of squares was partitioned to give a term for sequence (treatment by period interaction) and a term for subject within sequence (a residual term). Due to the

explorative nature of the study, no adjustment of the α-level was made for the multiple testing procedure.

The time to maximum insulin glulisine concentration (T_{max}) was analyzed by nonparametric analyses. Ninety-five percent nonparametric confidence intervals for the respective median difference in treatment ("test reference") were calculated according to (Steinijans and Diletti 1983). Pair-wise treatment comparison was made for the pharmacokinetic variables.

CRITICAL ASSESSMENT OF THE METHOD

45.10.1.5 Introduction

HMR1964 (INN: insulin glulisine) is a human insulin analogue for the treatment of Type I and Type II patients with diabetes mellitus. Combinations of insulin preparations that differ both in their time of onset and duration of action are used to optimally control blood glucose in patients with diabetes mellitus. The most commonly used insulin regimens include a long-acting insulin to provide basal insulin requirements and control fasting and preprandial blood glucose in combination with a short-acting insulin to control prandial blood glucose excursions. These two insulins are sometimes premixed in the syringe prior to injection. HMR1964 (insulin glulisine) has a more rapid onset and shorter duration of action than regular insulin when administered subcutaneously.

45.10.1.6 Study Rationale

The purpose of the study was to compare the time concentration profiles of syringe-premixed versus simultaneously, subcutaneously injected 0.1 IU/kg insulin glulisine and 0.2 IU/kg NPH insulin. This is intended to address the use of insulin glulisine in a basal bolus treatment regimen, when it might be injected together with NPH insulin to avoid the need for two separate injections, with the aim of determining whether mixing the two insulin preparations might compromise the rapid-acting properties of insulin glulisine.

45.10.1.7 Dosing Recommendation/ Therapeutic Dose Range

A single dose of 0.1 IU/kg HMR1964 (insulin glulisine) was chosen for this study as this dose is well within the range of recognized average prandial insulin dose in Type I and Type II patients with diabetes mellitus. Based on the primary pharmacokinetics of HMR1964 (insulin glulisine), a single-dose study was anticipated to be adequate.

MODIFICATIONS OF THE METHOD

45.10.1.8 Individual Bioequivalence

In contrast to the standard average bioequivalence approach for which the regulatory requirements (US FDA 2001; CPMP/EWP/QWP/1401/98 2002) have been internationally harmonized, this is not the case for the more recent concept of individual bioequivalence (Steinijans and Hauschke 1997). The main reason for introducing more complex replicate designs and bioequivalence criteria is the highly variable drugs for which the setting of suitable bioequivalence ranges poses a major problem and scaling of the bioequivalence criteria by the intrasubject variability has been suggested. The shortcoming of the present two-treatment, two-period (2 × 2) crossover design to detect subject-by-formulation interactions provides a second argument in favor of the more complex replicate designs. A unified approach of proposed statistical procedures for the replicate design has been given by Schall and Williams (1996).

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a high level summary of the data from the study described above under *Procedure* is presented below.

Thirty-two (32) healthy male subjects with demographics as described above completed the study according to the protocol.

The insulin glulisine concentration-time profiles are reflected in the following results:

The total systemic insulin glulisine availability as presented by $AUC_{(0\text{–clamp end})}$ was similar for the two modes of administration of insulin glulisine and NPH insulin, mixed in a syringe immediately before injection (treatment B) and the separate simultaneous injections (treatment A).

The maximum insulin glulisine concentration C_{max} was somewhat attenuated, being 27 % less, when insulin glulisine was premixed with NPH insulin as compared to the separate simultaneous administration. Nevertheless, the time to C_{max} did not differ between the two treatments with T_{max} values of 47 and 50 minutes (min).

The MRT of insulin glulisine was somewhat longer when insulin glulisine was premixed with NPH insulin (118 min) compared to their simultaneous administration (92 min), corresponding to an average increase of 27 %.

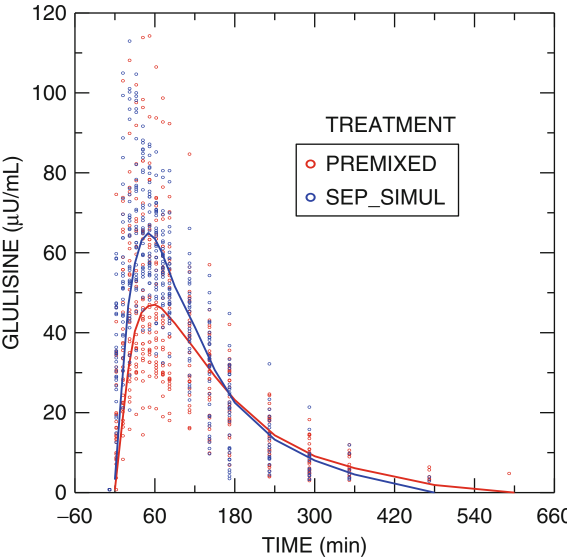

Fig. 45.5 Insulin glulisine concentration-time profiles: individual profiles (*dotted lines*) and the fitted average mean profiles (*solid line*)

In summary, the total insulin glulisine availability [AUC(0-clamp end)] was similar for the two modes of administration, and further, the time to maximum concentration [C_{max}] was not affected when insulin glulisine was mixed with NPH insulin with T_{max} values of 47 and 50 min. C_{max} was somewhat attenuated being 27 % less when insulin glulisine was immediately premixed with NPH insulin as compared to the separate simultaneous administrations of these study medications.

Overall, these data support the possibility of mixing of insulin glulisine with NPH insulin in a syringe immediately prior to administration (Fig. 45.5, Table 45.15).

45.11 Special Population: Subjects with Renal Impairment

PURPOSE/RATIONALE

A pharmacokinetic (PK) study in individuals with impaired renal function is recommended when renal impairment is likely to significantly alter the disposition of a drug/or its active metabolite(s) such that a dose adjustment may be needed. In the main, this is the case primary for drugs that are mainly eliminated (excretion and/or metabolism) by the kidneys and/or if a drug has

Table 45.15 Pharmacokinetic parameters of HMR1964 (insulin glulisine). Separate simultaneous (treatment A) versus immediately premixed (treatment B)

Variable	Geometric mean (arithmetic mean) ($N = 32$) Simultaneous (A)	Premixed (B)	Point estimate/(95 % CI)[a] Premixed (B)/simultaneous (A)
AUC$_{(0\text{–clamp end})}$ (μIU.min.mL^{-1})	9,261.79 (9,401.83)	8,251.20 (8,843.44)	89.1 % (78.1; 101.6 %)
C$_{max}$ (μIU/mL)	69.98 (71.80)	51.32 (55.39)	73.3 % (64.3; 83.6 %)
MRT (min)	92 (96)	118 (121)	127.3 % (120.3; 134.7 %)
T$_{max}$ (min)	47[b]	50[b]	3.9 min (−3.3; 12.4 min)[c]

[a]Point estimates and 95 % confidence intervals for the ratio of treatment means, based on ln-transformed data
[b]Median values
[c]Point estimates and 95 % confidence intervals for the respective median differences from nonparametric data analysis

a narrow therapeutic window. However, severe renal impairment may affect the disposition of a drug through diverse mechanisms; thus, also low renal clearance drugs may significantly be affected by renal impairment.

Most drugs are cleared by elimination of unchanged drug by the kidney and/or by metabolism in the liver. For a drug eliminated primarily via renal excretory mechanisms, impaired renal function may alter its pharmacokinetics (and pharmacodynamics) to an extent that the dosage regimen needs to be changed from that used in patients with normal renal function.

A study also should be considered when a drug or an active metabolite exhibits a combination of high hepatic clearance (relative to hepatic blood flow) and significant plasma protein binding. In this setting, renal impairment could induce a significant increase in the unbound concentrations after parenteral administration due to a decreased plasma protein binding coupled with little or no change in the total clearance (decrease in unbound clearance).

More details about when such studies may be or may not be important, and other aspects as study design and methods, can be found in (EMEA CHMP 2004; US FDA 1998). Although the most obvious type of change arising from renal impairment is a decrease in renal excretion, or possibly renal metabolism of a drug or its metabolites, renal impairment has also been associated with other changes, such as changes in absorption, hepatic metabolism, plasma protein binding, and drug distribution. These changes may be particularly prominent in patients with severely impaired renal function and have been observed even when the renal route is not the primary route of elimination of a drug. Thus, for most drugs that are likely to be administered to patients with renal impairment, pharmacokinetic characterization should be assessed in patients with renal impairment to provide rational dosing recommendations. It may not be feasible to conduct the study in patients with the condition for the intended use of the drug. An acceptable alternative is to use otherwise healthy subjects with different degrees of renal function. It may also be necessary to study the influence of dialysis on the pharmacokinetics of a drug. In this case, it is recommended to study this end-stage-renal-diseased subgroup separately from the renally impaired individuals, as different types of clinical study protocols are suggested to be applied for those undergoing dialysis and those who are not. Renally impaired individuals not undergoing dialysis are subject to the example that is discussed below.

It is also key to distinguish between *explorative* studies conducted during the investigational phase before the confirmatory safety and efficacy trials, aimed to give appropriate dosage recommendations for the patients with reduced renal function and *confirmative* studies (usually conducted in parallel to the confirmatory safety and efficacy trials) when assessing the influence of renal impairment on the pharmacokinetics of a drug, as, for example, study design and timing of study conduct may be different.

In summary, the primary goal of a study in individuals with impaired renal function is to determine whether the pharmacokinetics are altered to such an extent that the dose and/or dosing regimen of a drug should be adjusted from that established in the confirmatory safety and efficacy trials.

The following chapters present a particular study in renally impaired individuals with result illustration and conclusion. For the purposes of simplicity, the description is limited to the collection, handling, and interpretation of pharmacokinetic data although safety parameters were also studied.

PROCEDURE

The design of a typical renal impairment study is presented below.

45.11.1 Protocol Outline

Pharmacokinetics of HMR1964 (insulin glulisine) after subcutaneous injection of a single dose of 0.15 IU/kg in nondiabetic subjects with different degrees of renal function in an open, parallel-group, single-dose, multicenter study.

45.11.1.1 Objective

To investigate the pharmacokinetics of HMR1964 (insulin glulisine) in nondiabetic subjects with different degrees of renal function.

45.11.1.2 Design, Population, Treatment

Single-dose, open, three-parallel-group, study in nondiabetic subjects with different degrees of renal function (classified according to US FDA 1998). The renal function groups consisted of 8 individuals each and were comparable to each other with respect to age, gender, and weight. The creatinine clearance (CL_{cr}) was the measures of renal function.

Group 1 (normal renal function): $CL_{cr} > 80$ mL/min

Group 3 (moderate renal impairment): CL_{cr} 30–50 mL/min

Group 4 (severe renal impairment): $CL_{cr} < 30$ mL/min, but not requiring hemodialysis.

Individuals were allocated to these renal function groups based on the weighted average of the two pretreatment CL_{cr} values. Individuals received a single dose (0.15 IU/kg body weight) of HMR1964 (insulin glulisine) subcutaneously in the periumbilical abdomen. Blood for determinations of insulin in serum were taken according to the sampling schedule.

45.11.1.3 Inclusion Criteria

Nondiabetic men or women, aged between 18 and 75 years. The renally compromised individuals had to show a reasonably stable renal function in the previous 3 months (e.g., maximum change in CL_{cr} of approximately 15 mL/min, determined by urine and/or serum). Women either postmenopausal, surgically sterilized, or not pregnant and using adequate contraception.

EVALUATION

45.11.2 Statistical Procedures Pharmacokinetics

The relationship between renal impairment and the absorption and disposition of HMR1964 (insulin glulisine) was assessed by regressing pharmacokinetic parameters onto CL_{cr}. Regression parameter estimates ($\pm$ standard error) with confidence intervals and coefficients of correlation (Pearson) with p-values for test of difference from zero were reported. Scatter plots of the concentration-time profiles and pharmacokinetic parameters against creatinine clearance were produced.

Statistical methods were applied to the natural log (ln)-transformed pharmacokinetic parameters, except for T_{max} on which statistical methods on raw data were applied.

CRITICAL ASSESSMENT OF THE METHOD

45.11.2.1 Introduction

HMR1964 (INN: insulin glulisine) is a human insulin analogue for the treatment of Type I and Type II patients with diabetes mellitus. Combinations of insulin preparations that differ both in their time of onset and duration of action are used to optimally control blood glucose in patients with diabetes mellitus. The most commonly used insulin regimens include a long-acting insulin to provide basal insulin requirements and control fasting and preprandial blood glucose in combination with a short-acting insulin to control prandial blood glucose excursions. HMR1964 (insulin glulisine) has a more rapid onset and shorter duration of action than regular insulin when administered subcutaneously (Frick et al. 2003).

Preclinical studies suggest HMR1964 (insulin glulisine) does not differ from the established elimination pathways of endogenous human insulin.

45.11.2.2 Study Rationale

The purpose of this study was to characterize the impact of renal impairment on the absorption and disposition of HMR1964 (insulin glulisine) in nondiabetic subjects with different degrees of renal

function. A control group with normal renal function and similar demographics to the renally impaired subjects was included in this study, as suggested by the CPMP and FDA Guidance for Industry (EMEA CHMP 2004; US FDA 1998). This study was conducted after the investigational phase in parallel to the confirmatory safety and efficacy trials.

45.11.2.3 Population

In order to cover a wide range of renal function, individuals from renal function groups 1, 3, and 4 were enrolled. Individuals with mild impairment (group 2) are often much more difficult to recruit for phase I studies, as mostly not yet diagnosed. Yet those patients can be found in phase II/III studies quite frequently, allowing a population PK approach for mild renal impairment. As described above, individuals with end-stage renal disease are recommended to be studied separately.

For adequate representation of individuals with various degrees of renal impairment, equal numbers of individuals from each renal function group were recruited, and the renally compromised individuals had to show a reasonably stable renal function in the previous 3 months (e.g., maximum change in CL_{cr} of approximately 15 mL/min, determined by urine and/or serum) before study starts. This study followed an alternative approach (EMEA CHMP 2004; US FDA 1998) and used a nonpatient (i.e., otherwise healthy) population with different degrees of renal function with comparable demographic factors such as weight, age, and gender. Individuals were matched for body mass index (BMI) and age between the three renal function groups (BMI matched ± 20 % between renal function groups, and with age, between 18 and 75 years, matched ± 20 years between renal function groups) and a similar number of men and women were enrolled in each renal function group.

45.11.2.4 Dosing Recommendation/ Therapeutic Dose Range

A single dose of 0.15 IU/kg HMR1964 (insulin glulisine) was chosen for the individuals with renal impairment as this is a well-recognized average prandial insulin dose in Type I and Type II patients with diabetes mellitus. Based on the primary pharmacokinetics of HMR1964 (insulin glulisine), a single-dose study was anticipated to be adequate.

MODIFICATIONS OF THE METHOD

45.11.2.5 Reduced/Staged Study Design

In a reduced design, individuals at the extremes of renal function (normal and severely impaired individuals) are studied. The aim of such a study is to confirm that the pharmacokinetics is not altered to a clinically relevant extent. A prerequisite to this approach is a good reason to believe that renal impairment does not affect the PK to a degree sufficient to warrant dosage adjustment.

45.11.2.6 Full Study Design

In specific situations, it makes sense to study the PK also in groups with mild renal impairment, which as compared to the presented example would cover a GFR range of 50–80 mL/min.

45.11.2.7 Population PK

A population PK evaluation of patients from the safety and efficacy trials can be used to assess the impact of renal function on the disposition of a drug. Special care must be taken that patients with severe renal impairment are adequately represented in the population. The population PK approach assesses the impact of various covariates on the disposition of a drug. Nonlinear mixed effects modeling may be used to model the relationship between various covariates and pharmacokinetic parameters. CL_{cr} as a measure of renal function may be one of the covariates. This type of approach has its advantages as it involves assessment of the effect of renal impairment on the PK in the target population.

45.11.2.8 End-Stage-Renal-Diseased Individuals

Independently of a drug being eliminated by the renal route or not, the dialysis process can significantly alter the PK of a drug. Once significant fractions of a drug are removed by dialysis, the dosing regimen may need to be changed (e.g., supplementary dosing during/after dialysis). A study in individuals with end-stage renal disease also provides information about the value of dialysis as a countermeasure in case of overdose.

45.11.2.9 Crossover Study Design

In case of two study medications, a sound alternative to a parallel design would be the (complete) crossover study design.

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a summary of the PK results obtained from the study described above under *Procedure* is presented below.

A population as described above completed the study according to the protocol.

Table 45.16 Pharmacokinetics of 0.15 IU/kg insulin glulisine in subjects with renal impairment

	Geometric mean (CV %)		
	Normal ($n = 8$)	Moderate ($n = 8$)	Severe ($n = 8$)
$AUC_{(0-end)}$ (μIU. min.mL^{-1})	13,215 (31)	18,473 (19)	17,650 (19)
$AUC_{(0-5\ h)}$ (μIU.min. mL^{-1})	13,120 (29)	18,412 (19)	16,912 (16)
$AUC_{(0-2\ h)}$ (μIU.min. mL)	9,005 (24)	11,626 (26)	9,622 (17)
CL_{tot}/F (mL/min)	852 (20)	637 (20)	680 (14)
C_{max} (μIU/mL)	108 (30)	131 (29)	108 (15)
T_{max} (min)[a]	56 (29)	58 (18)	68 (22)

[a]Median values

Note: The apparent relative total clearance was calculated as $CL_{tot}/F = dose/AUC_{(0-5\ h)}$

There was no apparent relationship between PK parameters and degree of renal function, as there were no obvious differences in insulin concentration-time profiles (Fig. 45.6) between the three renal function groups. The PK properties of HMR1964 (insulin glulisine) were similar in subjects with decreased renal function covering a wide range of renal impairment.

In detail, there were no statistically significant correlations (Table 45.16) between renal function as measured by CL_{cr} and the parameters characterizing the rapid-acting properties of HMR1964 (insulin glulisine), $AUC_{(0-2\ h)}$, C_{max}, and T_{max} (Table 45.16). There were weak, though statistically significant,

correlations between renal function and parameters characterizing total exposure ($AUC_{(0\text{–}end)}$ and $AUC_{(0\text{–}5\ h)}$) and relative total clearance of HMR1964 (insulin glulisine) (CL_{tot}/F).

The predicted changes, which are within the conventional equivalence bounds, are too small to suggest any meaningful clinical consequences.

In conclusion, the rapid-acting insulin, HMR1964 (insulin glulisine), maintains its pharmacokinetic properties in subjects with decreased renal function covering a wide range of renal impairment (Jaros et al. 2004a, b).

As a consequence, no dose adjustments in patients with renal failure are warranted on the basis of intrinsic properties of HMR1964 (insulin glulisine).

45.12 Special Population: Subjects with Hepatic Impairment

PURPOSE/RATIONALE

A pharmacokinetic study in individuals with impaired hepatic function is recommended when hepatic impairment is likely to significantly alter the pharmacokinetics of a drug/or its metabolite(s) such that a dose adjustment may be required.

In liver disease, the likelihood of a pharmacokinetically relevant drug-disease interaction depends on the type of drug (extent of intra-/extrahepatic elimination, hepatic extraction ratio, protein binding) and the nature (flow, enzymatic capacity/reserve) and extent of the liver dysfunction. The likelihood of a pharmacokinetic relevant interaction with the need for dosage adjustment in individuals with impaired hepatic function depends on the changes in systemic exposure.

The majority of drugs is cleared hepatically through a variety of oxidative and conjugative metabolic pathways and/or through biliary excretion of unchanged drug or metabolites. In the main, alterations of these excretory and metabolic activities by hepatic impairment can lead to drug accumulation or, less often, to a failure to form metabolite(s). Liver disease may also alter kidney function, which can lead to accumulation of a drug and its metabolites even when the liver is not primarily responsible for elimination. Moreover, the specific impact of any disease on hepatic function is often poorly described and highly variable, particularly with regard to effects on the pharmacokinetics of a drug.

Hence, a study in individuals with impaired hepatic function may also be recommended if the liver is not the major organ for elimination, or if the drug has a narrow therapeutic window, or in case the metabolism is unknown and other information is missing.

It is also central to distinguish between explorative studies (conducted during the investigational phase before the confirmatory safety and efficacy trials, aimed to give dosage recommendations for patients with reduced hepatic function which otherwise would be treated with the planned clinical dose for patients with normal hepatic function) and confirmative studies (usually conducted in parallel to the confirmatory safety and efficacy trials) when assessing the influence of hepatic impairment on the pharmacokinetics of a drug, as, for example, study design and timing of study conduct may be different.

Measurements such as creatinine clearance have been used successfully to adjust dosing regimens for drugs eliminated primarily by the kidneys. Measures of hepatic function have been sought using endogenous substances affected by the liver, such as bilirubin and albumin, or functional measures such as prothrombin time, or the ability of the liver to eliminate marker substrates such as indocyanine green or galactose (Figg et al. 1995; Tang and Hu 1992). Clinical variables such as ascites or encephalopathy, nutritional status, peripheral edema, and histological evidence of fibrosis have also been used to categorize hepatic impairment (Albers et al. 1989; Pugh et al. 1973; Figg et al. 1995; Tang and Hu 1992; Zakim and Boyer 1996; Dickson et al. 1989; Wiesner et al. 1989; Maddrey et al. 1998; Carithers et al. 1978). Despite extensive efforts, no single measure or group of measures has gained broad clinical use. Yet, the most widely used scheme system to classify the degree of hepatic impairment is the Child-Pugh system (Albers et al. 1989; Pugh et al. 1973; Dickson et al. 1989).

More details about when such studies may or may not be important, and other aspects as study design and methods, can be found in (EMEA CHMP 2005; US 2003d).

In summary, a pharmacokinetic study in individuals with impaired hepatic function is recommended if the extent of hepatic metabolism is unknown, the hepatic metabolism/excretion accounts for >20% of the elimination of parent drug or metabolite(s), and for drugs with a narrow therapeutic window. The primary goal of such a study is to determine if the pharmacokinetic

is altered to an extent that the dose and/or dosing regimen of a drug should be adjusted from that established in the confirmatory safety and efficacy trials.

The following presents a particular clinical study with results and conclusions that was performed in two groups of individuals, hepatic impaired patients and healthy subjects.

For the purposes of simplicity, the description is limited to the collection, handling, and interpretation of pharmacokinetic (PK) data although clearly safety parameters are also studied.

PROCEDURE

The design of a typical hepatic impairment study is presented below.

45.12.1 Protocol Outline

To investigate the pharmacokinetics of XYZ123 in individuals with hepatic impairment in comparison with those in healthy subjects after multiple oral administration of 800-mg XYZ123 once a day for 7 days in an open, multicenter study.

45.12.1.1 Design, Population, Treatment

Open, nonrandomized, multicenter, repeated-dose study in two groups of individuals. Twelve (12) patients with hepatic impairment with a Child-Pugh score ≥5 and ≤ 14 (Table 45.17) and 12 healthy subjects matching for age, weight, and sex. Individuals received a repeated oral administration of 800-mg XYZ123 once a day for 7 days after a standard meal. Samples were collected according to the sampling schedule for determinations of XYZ123 and of its main metabolite XYZ456 in plasma and XYZ123 in urine. The unbound fraction of XYZ123 in plasma was determined by ultra filtration.

45.12.1.2 Inclusion Criteria

Patients with hepatic impairment: Twelve patients with hepatic impairment with a Child-Pugh score ≥5 and ≤14 (Table 45.17).

Healthy subjects: Twelve healthy subjects with approximately similar range of age and weight, and sex matched, were recruited in the same center as the patient he/she was matching. Age, weight, and sex were matched to those of the patient (individual age within 5 years, weight within 20 % of the matching patient). Women either postmenopausal, surgically sterilized, or not pregnant and using adequate contraception.

Table 45.17 The Child-Pugh classification (Albers et al. 1989; Pugh et al. 1973)

Assessment	Degree of abnormality	Score
Encephalopathy	None	1
	Moderate	2
	Severe	3
Ascites	Absent	1
	Slight	2
	Moderate	3
Bilirubin (mg/dL)	<2	1
	2.1–3	2
	>3	3
Albumin (g/dL)	>3.5	1
	2.8–3.5	2
	<2.8	3
Prothrombin time (seconds > control)	0–3.9	1
	4–6	2
	>6	3
Total score	Group	Severity
5–6	A	Mild
7–9	B	Moderate
10–15	C	Severe

EVALUATION

45.12.1.3 Statistical Procedures: Effect of Hepatic Impairment on PK Parameters

To compare PK parameters of XYZ123 and XYZ456 between the two groups, a one-way analysis of variance was used with group (patients with hepatic impairment and healthy subjects) as main effect in the model, after natural logarithmic transformation of the following pharmacokinetic parameters: C_{max}, AUC(0–24 h) on day 1 and day 7 and $t_{1/2,\lambda z}$ (on day 7 only) for XYZ123 and XYZ456 Ae(0–24 h), CL_R, $t_{1/2,\lambda 1}$ and fu for XYZ123 on day 1 and day 7, and Rac for XYZ123. The ratio of the adjusted means (patients with hepatic impairment/healthy subjects) was obtained by calculating the exponential of the difference of the adjusted means of natural log–transformed parameters. Ninety percent confidence intervals (CI 90 %) of the ratio were constructed using the mean square error (MSE) of the analysis of

variance. For the discrete variable t_{max}, the effect of hepatic impairment was assessed using Kruskall-Wallis nonparametric test.

Plots of pharmacokinetic parameters (C_{max}, AUC of XYZ123 and XZY456, CL_R of XYZ123) versus Child-Pugh score and treatment day were drawn.

CRITICAL ASSESSMENT OF THE METHOD

45.12.1.4 Background to the Example

Drug XYZ123 is rapidly and almost completely absorbed after oral administration. There is a substantial first pass effect, and the oral bioavailability after administration of the tablet is around 60 %. Food does not modify the bioavailability of XYZ123 tablet. In humans, XYZ123 is eliminated mainly by metabolism (70 % of the dose), the metabolites being mainly excreted in feces, and is also excreted unchanged in the urine (13 %) and feces (7 %). Some circulating metabolites have been identified: most of them are present at low concentrations with an AUC representing 2–13 % of that of XYZ123. The metabolites are not likely to contribute to the pharmacological effect. CYP3A4 is partially involved in the metabolism of XYZ123.

45.12.1.5 Study Rationale

The steady-state pharmacokinetics of XYZ123 are not predicted from single dose data, since XYZ123 pharmacokinetics exhibit some moderate time dependency. In healthy subjects a 1.5-fold accumulation was observed which was not predicted from single-dose data. The dosing regimen was based on the therapeutic dose (800 mg twice a day) with a 7-day duration being well within the duration of therapeutic treatment which varies from 5 to 10 days. Given the modest pharmacokinetic changes observed in phase I studies after single-dose administration, the exposure reached after repeated-dose administration should not be much higher than those obtained in healthy subjects and should be in the range of the well-tolerated exposure.

Thus, a multiple-dose study was performed in which all healthy and hepatic impaired individuals received the same dose. It was the aim to include 12 patients with various and well-distributed degrees of hepatic impairment (according to the Child-Pugh score) and 12 pair-matched (based on demographic characteristics) healthy subjects in order to have 10 patients and 10 subjects evaluable. The pharmacokinetics of XYZ123 in plasma (total and unbound) and in urine was assessed after the 1st dose and at steady state after the seventh dose. The pharmacokinetics in plasma of its main metabolite XYZ456 was also assessed.

MODIFICATIONS OF THE METHOD

45.12.1.6 Reduced Study Design

As individuals from the Child-Pugh category with mild impairment could have a normal hepatic function and for the majority of drugs, clinically insignificant differences are more likely to be observed in individuals with moderate and severe impairment, in a reduced design, just individuals with moderate hepatic impairment in combination with a control group are investigated. As a consequence of such a design, the findings in the moderate category would be applied to individuals with a mild Child-Pugh category, and dosing in the severe category would generally be a contraindication in the labeling document.

45.12.1.7 Population PK

A population PK evaluation of patients from the safety and efficacy trials can be used to assess the impact of altered hepatic function (as a covariate) on the PK of a drug. In each of the Child-Pugh category patients should adequately be represented, such that the population PK approach sound evaluates the impact of various covariates on the PK of the drug. Nonlinear mixed effects modeling may be used to model the relationship between various covariates and PK parameters. This type of approach has its advantages as it involves assessment of the effect of hepatic impairment on the PK in the target population. However, this approach may prove difficult in hepatic impairment due to the low prevalence of hepatic disease in the general population.

45.12.1.8 Statistical Procedures PK

Despite the fact that it is difficult to define a relationship between PK parameters and measures of hepatic function, the most appropriate statistical approach is to calculate geometric means and 95 % confidence intervals to compare the healthy and impaired groups (see "Example"). Investigation of the relationships between hepatic functional abnormalities and selected PK

parameters using linear and nonlinear models in order to derive dose recommendations is an appropriate alternative, yet, in spite of many constraints.

45.12.1.9 PK Results and Association with Measures of Hepatic Function

Past experience indicates that it has been difficult to develop a measure or group of measures of hepatic function that predict alterations in drug PK as the grounds for hepatic impairment are manifold (e.g., impaired hepatocellular function, impaired biliary excretion, decreased protein binding, consequences of shunting of blood passing the liver).

In contrast to renal impairment, no obvious marker exists for characterizing hepatic function with respect to predictions of drug elimination capacity. Therefore, dose recommendations may not be as accurate for hepatic impairment as for renal impairment.

Nonetheless, relationships between hepatic functional abnormalities (e.g., hepatic blood flow, serum albumin concentration, prothrombin time, or overall impairment scores such as Child-Pugh) and selected pharmacokinetic parameters (e.g., total body clearance, oral clearance, apparent volume of distribution, unbound clearance, or dose-normalized area under the unbound concentration-time curve) can also be should using linear and nonlinear models. A regression approach for continuous variables describing hepatic impairment and pharmacokinetic parameters is appropriate, with the understanding that some correlations will rely on categorical variables (e.g., Child-Pugh). Typically, modeling results would include parameter estimates of the chosen model and measures of their precision (standard errors or confidence intervals). Prediction error estimates are also desirable to assess appropriateness of the model.

45.12.1.10 Classification of Hepatic Impairment

An alternative to ensure that the individuals have an impaired metabolic capacity is to administer a metabolic probe (e.g., a CYP3A4 probe if the drug under investigation is a CYP3A4 substrate) to evaluate if the pharmacokinetics of the drug is altered.

Exogenous markers that have been used to assess different hepatic drug elimination mechanisms are, for example, antipyrine (Figg et al. 1995) and MEGX (lidocaine metabolite) (Testa et al. 1997), markers for the functional ability of the cytochrome P-450 oxidative pathway, or ICG (indocyanine blue) (Figg et al. 1995), a markers for hepatic blood flow, and galactose (Tang and Hu 1992). Such markers may be used in parallel to the Child-Pugh classification.

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a summary of the PK results obtained from the study described above under *Procedure* is presented below.

A population as described above completed the study according to the protocol (Tables 45.18, 45.19).

Table 45.18 Demography

Results—Study subjects and conduct			
Demography, creatinine clearance and Child Pugh score			
Parameter	Statistics	Patients with hepatic impairment	Healthy subjects
Number of subjects	N	13	13
Sex	Male	11	11
	Female	2	2
Age (years)	Mean [Min–Max]	52.2 [38–73]	51.8 [35–74]
Weight (kg)	Mean [Min–Max]	74.4 [54.5–104.7]	75.3 [62.2–101.0]
Height (cm)	Mean [Min–Max]	166.3 [152.4–180.3]	171.9 [154.9–184.0]
Creatinine clearance: (mL/min)	Mean [Min–Max]	112 [71–152]	93 [68–133]
Child Pugh score	Median [Min–Max]	7 [5–11]	NA

NA not applicable

The demographic characteristics were similar in both groups (Table 45.18). The median Child-Pugh score of patients with hepatic impairment was 7 with a range of 5–11 (Table 45.19).

Steady state was achieved after 2 days of dosing.

Figures 45.7 and 45.8 shows the mean plasma concentration of XYZ123 (Fig. 45.7) and of XYZ456 (Fig. 45.8) after single and repeated doses of XYZ123 (800 mg) once a day. The PK parameters of XYZ123 (Table 45.20) show that:

After single and repeated doses of XYZ123, mean C_{max} and AUC were similar in both groups. Maximum values observed in patients were similar or smaller than those observed in healthy subjects. Between subject variability (CV) was around 30 % for both groups except for patients on day 7 where it was lower with 20 %.

After single and repeated doses of XYZ123, the main elimination half-life ($t_{1/2,\lambda 1}$) and the terminal elimination half-life ($t_{1/2,\lambda z}$) (after repeated doses) were similar in both groups, as well as the between subject variability which was around 20 %.

After single dose of XYZ123, there was a 27 % and 25 % increase in Ae(0–24 h) and renal clearance, respectively, in patients compared to healthy subjects. These increases were not statistically significant probably due to the high between subject variability (around 50 %) observed in patients.

Table 45.19 Child-Pugh score and grade of hepatic impairment

Grade of hepatic impairment	A	B	C
Child-Pugh Score	5–6	7–9	10–15
Number of subjects	4	6	3
Observed Child–Pugh score [min–max]	5–6	7–9	10–11

min minimum, *max* maximum

At steady state, the difference between both groups was less marked with 10 and 16 % increases in Ae (0–24 h) and renal clearance when comparing patients to healthy subjects, again with values not statistically different between groups and a between subject variability still around 50 % in patients.

The accumulation ratio (Rac) was similar in both groups with the between subject variability in patients (43 %) higher than in healthy subjects (16 %).

The results showed that whatever the group, there was no statistically significant difference in unbound fraction of XYZ123 whether it was measured at t_{max} or $t_{12\ h}$. Since there was no time effect, the mean unbound fraction (fu) was calculated from fu C_{max} and fu $C_{12\ h}$ on day 1 and on day 7 for both groups.

Figure 45.9 indicates that in patients with hepatic impairment there was no trend toward any relationships between XYZ123 pharmacokinetic parameters and the Child-Pugh score.

The pharmacokinetic parameters of XYZ456 are summarized in Table 45.21 and show that:

After single and repeated doses of XYZ123, mean C_{max} and AUC of XYZ456 were approximately twice as low as in patients compared to healthy subjects. These differences were statistically significant. Between subject variability ranged from 50 % to 60 % in patients and from 20 % to 30 % in healthy subjects.

The terminal elimination half-life was 20 % lower in patients compared to healthy subjects. Probably the elimination half-life was not accurately determined in patients as XYZ456 concentrations were close to the lower limit of quantification. Thus, as the elimination has a biphasic profile, for patients, this elimination half-life probably corresponds to a mix of $t_{1/2,\lambda 1}$ and $t_{1/2,\lambda z}$.

Figure 45.10 indicates that in patients with hepatic impairment there was no trend toward any relationships between XYZ456 pharmacokinetic parameters and the Child-Pugh score.

[a]Ratio of the adjusted means (patients with hepatic impairment/healthy subjects)
[b]Significance of p-value from ANOVA table; NS: non significant, $^{*}0.01 < p \leq 0.05$, $^{**}0.001 < p \leq 0.01$, $^{***}p \leq 0.001$
[c]fu = (fu C_{max} + fu C12 h)/2
[d]Rac = AUC(0–24 h)–day 7/AUC(0–24 h)–day 1

In summary, the plasma pharmacokinetic profile of XYZ123 is similar to that achieved in healthy subjects with an alteration in one of the XYZ123 elimination pathways in patients with hepatic impairment. This was shown by a marked decrease in XYZ456 metabolite formation, though there was no clear relation between the extent of the decrease and the severity of hepatic impairment. There is a trend for a slight increase in XYZ123 renal clearance with no clear relation between the extent in renal clearance increase and severity of hepatic impairment. Furthermore, it is unlikely that the decrease in XYZ456 formation could modify the overall pharmacological activity as this metabolite is known not to contribute to a clinically relevant extent.

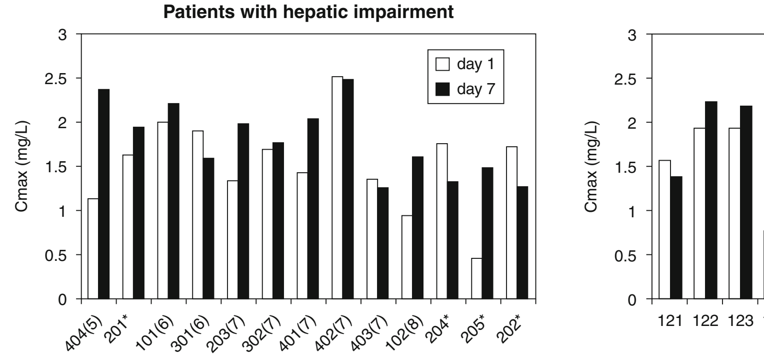
In conclusion, from a pharmacokinetic point of view, the dosage regimen of 800-mg XYZ123 once daily should not be modified in patients with hepatic impairment, provided that the renal function is not severely impaired.

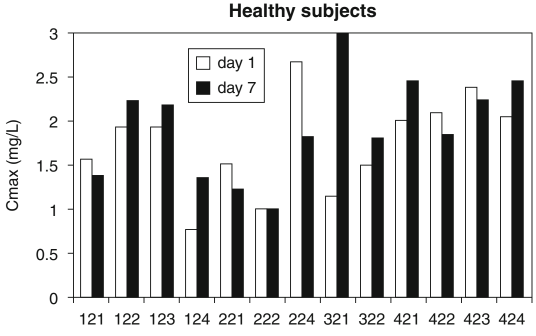
45.13 Special Populations: Profiling the Effect of Obesity on Drug Disposition

PURPOSE/RATIONALE

Regulatory guidance requires that the pharmacokinetics and tolerability of a candidate drug are studied in the range of populations likely to receive the drug during the clinical development and later, once the drug is marketed (US FDA 1978). Over and above this regulatory need, in some cases, an early switch to using special populations can be advantageous to a clinical development.

Obesity is associated with physiological changes that can alter the pharmacokinetic parameters of many drugs (Blouin et al. 1987). For example, increases in the apparent volume of distribution and total body clearance have been reported for the antibacterial agents vancomycin and





For patients with hepatic impairment, the subject number is followed by the Pugh score in brackets.

aminoglycosides (Bearden and Rodvold 2000). For drugs with non-body-weight-adjusted dosing, obese individuals may be notably underdosed and thus show lower efficacy. Since many of these effects are not simply predictable, appropriate profiling of drug pharmacokinetics/pharmacodynamics in obese individuals is essential for drugs targeting indications where the obesity is a prevalent concomitant illness.

European Agency for the Evaluation of Medicines Products (EMEA) and US Federal Drug Administration (FDA) guidance recommend that the pharmacokinetics of candidate weight control drugs are studied in obese (EMEA CPMP/EWP/281/96 (R1) (2007); US FDA 2007).

The good availability of individuals who are obese but are otherwise healthy makes the early profiling of drug pharmacokinetics/pharmacodynamics in healthy obese relatively easy. If no difference is observed between healthy obese and healthy lean individuals, then the recruitment of healthy lean subjects in many studies can be justified. In some cases, for example, when developing drugs for metabolic diseases (e.g., obesity, diabetes), the advantages of an early switch to obese individuals—a population closer to the final patient group than the typical healthy lean subject—early in drug development can justify this limited complication of the recruitment process.

PROCEDURE

The design of a study comparing the steady-state pharmacokinetic/pharmacodynamic profile of Drug XYZ in obese and nonobese healthy adults is presented below. Drug XYZ was developed for both subcutaneous (SC) and intravenous (IV) application routes. For the purposes of simplicity, the description is limited to the collection, handling, and interpretation of pharmacokinetic data pertinent to the assessment of the impact of obesity, although other parameters were also studied.

45.13.1 Protocol Outline

A phase I, open-label study of the effect of obesity on the pharmacokinetic/pharmacodynamic profile of subcutaneous and intravenous Drug XYZ.

45.13.1.1 Objectives

Primary: The primary objective of the study was to compare steady-state pharmacokinetic/pharmacodynamic profile of SC Drug XYZ between obese and nonobese healthy adults.

Secondary: The secondary objective of the study was to compare steady-state pharmacokinetic parameters after IV administration and absolute bioavailability of Drug XYZ between obese and nonobese healthy adults.

45.13.1.2 Study Design

The study had an open-label, two-way crossover randomized study. Two groups of obese and nonobese healthy volunteers were administered multiple doses of SC Drug XYZ to reach steady state (treatment A) and single IV dose of Drug XYZ (treatment B). The washout period between trial periods was at least 10 days which approximated to >10 Drug XYZ apparent terminal half-lives.

45.13.1.3 Number of Subjects

Twenty-five (25) obese adults and 25 adults age-, height-, and sex-matched nonobese. Estimations based on previous studies with nonobese showed that the inclusion of 24 subjects per strata (obese, nonobese) would give enough power to allow the detection of a >20 % difference in AUC of Drug XYZ at steady state with alpha $= 0.05$ and beta $= 0.10$. According to the guidance for industry by the US FDA, 12 subjects is the typical minimum sample size for a bioavailability comparison; even in a pilot study, "a sufficient number of subjects (e.g., 12) need to complete the study" (US FDA 2003b). This requirement was fulfilled here for each of the substrata obese male, nonobese male, obese female, and nonobese female.

45.13.1.4 Inclusion Criteria

The following inclusion criteria were met: adults aged between 18 and 55 years; obese with body mass index (BMI) of $30.0 \leq 39.9$ kg/m^2 (≥ 40.0 kg/m^2 on a case-by-case basis) or nonobese volunteers with BMI of $18.5 \leq 24.9$ kg/m^2; men who are willing to use prescribed barrier contraceptive methods; women who are either postmenopausal or surgically sterile and willing to use prescribed barrier contraceptive methods; who—apart from being obese—are healthy for the purpose of the study and not receiving regular medication in the month preceding the study; with normal findings in the physical examination, unless the investigator considers an abnormality to be clinically irrelevant for the study; who are nonsmoking or light smokers.

45.13.1.5 Treatments

Treatment A: Single (day 1) 1.5 mg/kg Drug XYZ dose given as an IV infusion over 6 hours (h).

Treatment B: Once daily 1.5 mg/kg Drug XYZ SC doses over 4 days.

45.13.1.6 Pharmacokinetic Data

Treatment A: Plasma concentrations of Drug XYZ, before and at predetermined times post dose after IV dosing on day 1. Treatment B: Plasma concentrations of Drug XYZ, before and at predetermined times after SC dosing on days 1 and 4.

A 24-h urine sampling was performed during the IV dosing period of the study that started on day 1 and ended on day 2. The volume of urine collected and the concentration of creatinine were determined to allow the creatinine clearance to be calculated.

EVALUATION

The data pertinent to the assessment of the impact of obesity on the disposition of the developmental drug from study described above was evaluated as follows:

Descriptive pharmacokinetic parameters (total clearance (CL or CL/F), mean residence time (MRT), volume of distribution (Vd or Vd/F), peak concentration (C_{max}), time of peak concentration (T_{max}), area under the curve between time 0 and the time of the last quantifiable concentration (AUC_{0-t}) and/or AUC for the dosing interval ($AUC_{0-\tau}$), apparent terminal half-life ($t_{1/2_z}$) after day 1, and $AUC_{0-\tau}$ after day 4) for plasma Drug XYZ were calculated using a noncompartmental analysis employing a linear/log trapezoidal method as implemented in WinNonlin® (Pharsight Corp.) protocols. The absolute bioavailability was calculated by comparison of day 1 data for treatments A and B.

Descriptive statistics (number of observations (n), mean, standard deviation, coefficient of variation in percent (CV %), or median and range) were calculated for each parameter. Statistical tests using SPSS software were as follows:

Homogeneity test of variance (Levene's test) for each dependent variable.

Independent *t*-test on log-transformed parameters: C_{max}, AUC_{0-t}, $AUC_{0-\tau}$, $t_{1/2_z}$ for plasma concentrations of Drug XYZ.

CRITICAL ASSESSMENT OF THE METHOD

The type of study described in this chapter provides profiling of the impact of obesity on the disposition of the developmental drug after dosing via two dosing routes. Although for Drug XYZ this approach was justified given the intention to market the Drug XYZ for both SC and IV applications, typically, however, only the proposed therapeutic dosing route would be tested.

Although the impact of obesity on the disposition of the developmental drug can most comprehensively be studied based on steady-state data as described, the use of single-dose data could also suffice provided there is reason to believe that the pharmacokinetics of the drug studied are accurately predictable from single-dose data.

MODIFICATIONS OF THE METHOD

The use of weight as covariate in PK studies showed to be not optimal for obese patients; therefore, increasingly adjusted weight descriptors are utilized, which assess the fat in the body differentially. These formulas differentiate between males and females and use patient's height or body mass index in addition. The use of a predicted normal weight (PNWT) (Duffull et al. 2004) seems to have advantages in obese patients.

The described supportive study was specifically designed and suitably powered to identify differences in Drug XYZ pharmacokinetics between obese and nonobese. Typically, this type of evaluation would be extended during the later clinical development by performing a population pharmacokinetic/pharmacodynamic assessment of the impact of obesity on the disposition of the developmental drug during the phase II/III studies.

If obesity is a not a prevalent concomitant illness in the targeted indication, then this type of study is unlikely to be performed. Instead, a population pharmacokinetic/pharmacodynamic assessment of the impact of obesity on the disposition of the developmental drug would be performed during the phase II/III studies. A suitably powered clinical study would only be performed if such population pharmacokinetic/pharmacodynamic assessments raised significant questions.

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a high level summary of the pharmacokinetic results obtained from the study described above under *Procedure* is presented below.

45.13.1.7 Results: Pharmacokinetics

The data from study described above, as given in Tables 45.22 and 45.23 below, can be summarized as follows:

- After 1.5 mg/kg SC dosing for 4 days, AUC_{0-t} for Drug XYZ was 16 % higher in obese subjects compared to nonobese subjects. This is explained by:
  - A similar, 100 % systemic absorption in both groups
  - A lower weight-adjusted clearance in obese subjects (see below)
- After SC dosing, absorption was slightly delayed in the obese (T_{max} 4 h vs. 3 h) and no difference in C_{max} values was observed after repeated SC dosing. The difference was therefore mainly attributed to the elimination phase. Steady state was reached on day 4 in both obese and nonobese subjects, with almost no unpredicted accumulation.
- After a 6-h IV infusion, Drug XYZ clearance and volume of distribution estimates were over 30 % higher in obese than in controls. On a weight-adjusted basis, these parameters were about 10 % lower in obese. MRT estimates were similar for both groups.
- Exposure (AUC) to Drug XYZ was significantly higher in obese subjects. This observation was explained as follows: while the total clearance (L/h) is much higher in obese subjects (i.e., higher total elimination capacity: 121 mL/min creatinine clearance in obese vs. 83 mL/min in nonobese), the clearance on a weight-adjusted basis was actually lower. Since the dose was weight adjusted, this leads to higher AUC estimates.
- The C_{max} is 15 % higher in obese, which can be explained by the fact that the distribution volume does not increase proportionally with weight either, similar to the argument for clearance.

45.14 Special Population: Pediatric Population

PURPOSE/RATIONALE

The number of medicinal products currently labeled for pediatric use is limited.

There is a general lack of pharmacokinetic (PK) and other clinical information to support the administration of many medicinal products to children which leads to a lack of appropriate dosage recommendations in this population. As a consequence, there is frequent off-

Table 45.22 Mean Drug XYZ pharmacokinetic parameters (CV %) on days 1 and 4 following 1.5 mg/kg SC 24-h dose of Drug XYZ in 24 nonobese and 24 obese healthy subjects

label use of licensed medicines in children. In 2006, the European Parliament and the Council of the European Union have issued a regulation on medicinal products for pediatric use, implementing a Pediatric Committee (PDCO) to overcome these gaps.

The disposition of a drug may differ considerably between adults and children as in the pediatric population the organs affecting the absorption, distribution, metabolism, and excretion of a drug are under continuous maturation, which at least is expected to lead to additional inter- and intraindividual variances in the PK of a drug in this population. To support the development of a pediatric formulation and especially in order to support the dosing recommendation in different age groups, PK studies should be performed. In case the systemic exposure of a drug is readily related to the pharmacological or therapeutic effect, PK results in the pediatric population can be used for extrapolation of efficacy data from studies performed in adults.

Current guidelines have recently been updated, proposing new pediatric rules and actually encouraging to investigate the safety and efficacy of a medicinal product in children, and also elucidate cases in which the drug blood concentration will become the basis of subsequent determination of the dosage schedule.

As the pediatric subgroup represents a vulnerable population, studies in children are endowed with specific challenges such as additional ethical (e.g., informed consent be obtained from the legal guardian) or clinical-technical (e.g., minimize the amount of blood drawn and the number of venipunctures) issues.

PK studies in the pediatric population are generally conducted in patients with the disease under investigation. This may lead to higher intersubject variability than studies in healthy subjects, but the data better reflect clinical use.

More details about when such studies may or may not be important, and other aspects as study design and methods, can be found in the literature below.

In summary, PK studies in the pediatric population should determine if the dosage regimen in the pediatric population is to be adjusted to achieve approximately the same level of systemic exposure that is safe and effective in adults.

The following chapters present a particular study in a pediatric population (children and adolescents) with result illustration and conclusion. For the purposes of simplicity, the description is limited to the collection, handling, and interpretation of PK data although safety and pharmacodynamic parameters were also studied.

PROCEDURE

The design of a typical pediatric study is presented below.

45.14.1 Protocol Outline

Pharmacokinetics of HMR1964 (insulin glulisine) and regular human insulin injected subcutaneously as a single dose in pediatric subjects with type I diabetes in a single-center, double-blind, randomized, two-way crossover study.

45.14.1.1 Objective

To investigate the pharmacokinetics of insulin glulisine and regular human insulin in pediatric type I diabetic subjects.

45.14.1.2 Design, Treatment, and Sample Size

Single-center, single-dose, double-blind, randomized, two-way crossover design; 20 pediatric type I diabetic subjects (10 per age class) of either gender. The two age classes were built by children aged between 5 and 11 years and adolescents aged between 12 and 17 years.

Pediatric patients received a single dose of 0.15 IU/kg body weight of HMR1964 (insulin glulisine) and regular human insulin administered subcutaneously in the periumbilical abdomen 2 minutes (min) before a standardized liquid meal. Volume and frequency of blood sampling for determinations of insulin in serum were minimized and were taken according to the sampling schedule.

45.14.1.3 Population Treated

Twenty type I diabetic pediatric subjects, of both age classes children and adolescents: 10 children (5 male and 5 female), between 7 and 11 years of age, with body mass indices between 16.4 and 22.7 kg/m^2, and 10 adolescents (4 male and 6 female), between 12 and 16 years of age, with body mass indices between 17.7 and 26.3 kg/m^2.

EVALUATION

45.14.2 Statistical Procedures Pharmacokinetics

The relationship between age and pharmacokinetics was assessed by analyses of variance (ANOVA) on AUCs, MRT, and C_{max} with adjustments for treatment, period, sequence, and subject within sequence effects by age class using the natural log–transformed values to compare treatments within age class. Point estimates and 95 % confidence intervals were calculated for the treatment ratios per age class.

ANOVAs with adjustments for age class, period, sequence, and subject within sequence effects were performed by treatment to compare age classes within treatment. Point estimates and 95 % confidence intervals were calculated for the age class ratios per treatment.

T_{max} was analyzed by nonparametric analyses. Ninety-five percent nonparametric confidence intervals for the respective median treatment and age class differences were calculated.

CRITICAL ASSESSMENT OF THE METHOD

45.14.2.1 Introduction

HMR1964 (INN: insulin glulisine) is a human insulin analogue for the treatment of type I and type II patients with diabetes mellitus. Combinations of insulin preparations that differ both in their time of onset and duration of action are used to optimally control blood glucose in patients with diabetes mellitus. The most commonly used insulin regimens include a long-acting insulin to provide basal insulin requirements and control fasting and preprandial blood glucose in combination with a short-acting insulin to control prandial blood glucose excursions. Insulin glulisine has a more rapid onset and shorter duration of action than regular insulin when administered subcutaneously.

Preclinical studies suggest that insulin glulisine does not differ from the established elimination pathways of endogenous human insulin.

45.14.2.2 Study Rationale

Insulin glulisine may be of particular use for children and adolescents who encounter more difficulties in adjusting their daily activities to fixed dosing meal intervals. Given immediately before a meal or thereafter to balance the actual carbohydrate intake may be of significant advantage, provided the rapid and short-acting nature of insulin glulisine also prevails in this patient population.

This study was conducted to investigate the pharmacokinetics of insulin glulisine and regular human insulin subcutaneously administered 2 min before a standard meal in pediatric type 1 diabetic patients from both age classes (10 children and 10 adolescent subjects) in order to verify the sameness of differences seen in adults.

45.14.2.3 Population

Twenty male and female pediatric type 1 diabetic patients from both age classes (10 children and 10 adolescents subjects) were treated.

45.14.2.4 Dosing Recommendation/ Therapeutic Dose Range

A single dose of 0.15 IU/kg insulin glulisine was chosen for the children following a dosing approach estimate on the basis of body weight. Based on the primary pharmacokinetics of insulin glulisine, a single-dose study was anticipated to be adequate.

MODIFICATIONS OF THE METHOD

45.14.2.5 Study Design Aspects

To study the plasma protein binding at least in newborns and infants is recommended, as the protein binding is reduced in the preterm and term infant at birth and in the first weeks of life. Also, the drug elimination capacity is reduced in this subgroup of very young children due to immaturity of both metabolic pathways and renal function.

Initial titrating doses may be estimated on the basis of body weight or surface area from an extrapolation of adult data.

45.14.2.6 Classification of Age Classes

Any classification of the pediatric populations into age categories is to some extent arbitrary.

Suggestions for categorization are presented in the literature below and are as follows:

Neonate: birth to 1 month
Infant: 1 month to 2 years
Child: 2–12 years
Adolescent: 12 years to 16–18 years

The pharmacokinetics of a drug in humans 16–18 years and older is expected to be similar to that of adults.

Depending on the intended use of a drug in the pediatric population, studies should be performed in all pediatric age groups to allow dose adjustment within an individual over time.

45.14.2.7 Population Pharmacokinetics

An alternate approach is the population pharmacokinetic approach or study. This approach relies on infrequent (sparse) sampling of blood from a larger population than would be used in a standard pharmacokinetic study to determine pharmacokinetic measures and/or parameters.

The population pharmacokinetic approach assesses the impact of various covariates on the pharmacokinetics of a drug. Nonlinear mixed effects modeling may be used to investigate the relationship between various covariates and pharmacokinetic parameters. Age or age group may be one of the covariates. This type of approach has its advantages as it involves assessment of the effect of age on the pharmacokinetics in the target population.

45.14.2.8 Crossover Study Design

In case of the comparison of two study medications, a sound alternative could be the (complete) crossover study design (see “Example”).

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a summary of the PK results obtained from the study described above under *Procedure* is presented below.

Twenty pediatric type I diabetic patients as described above completed the study according to the protocol; 19 subjects were evaluable for PK evaluation of regular human insulin treatment. The demographic data are depicted in Table 45.24.

The concentration-time profile of insulin glulisine differed considerably from regular human insulin (Fig. 45.11a, b, c), with initial fractional AUCs being higher after insulin glulisine than after regular human insulin, while the total AUC (AUC(0–6 h)) was only slightly larger. The C_{max} of insulin glulisine was higher by 71 % and reached earlier with a median T_{max} of 54 min compared to 66 min after regular human insulin. The MRT for insulin glulisine was distinctly shorter with 88 min compared to 137 min for regular human insulin, indicating the shorter residence of insulin glulisine in the systemic circulation (Table 45.25).

Contrasts between the concentration-time profiles of insulin glulisine and regular human insulin obtained in the population as a whole were also present in both age classes, children and adolescents (Table 45.26).

The two age classes, children and adolescents, presented an almost equal PK profile of insulin glulisine, displayed by point estimates close to 100 % with a slight trend toward higher exposure in adolescents (Table 45.27). Nevertheless, T_{max} and MRT were the same in each age class.

In contrast to the findings with insulin glulisine, the comparison between age classes for regular human insulin revealed on average 60 % higher exposure (AUCs and C_{max}) in adolescents (Table 45.28). Nevertheless, there were no substantial differences in T_{max} and MRT.

In summary, in pediatric type I diabetic subjects, equally in each age class children and adolescents, insulin glulisine was more rapidly absorbed than regular human insulin. The fractional AUCs were larger, and C_{max} was higher with an earlier T_{max} for insulin glulisine. MRT was distinctly shorter, indicating the shorter residence of insulin glulisine in the systemic circulation compared to regular human insulin.

Table 45.24 Demographic variables

	Arithmetic mean (range)					
	All subjects ($n = 20$)

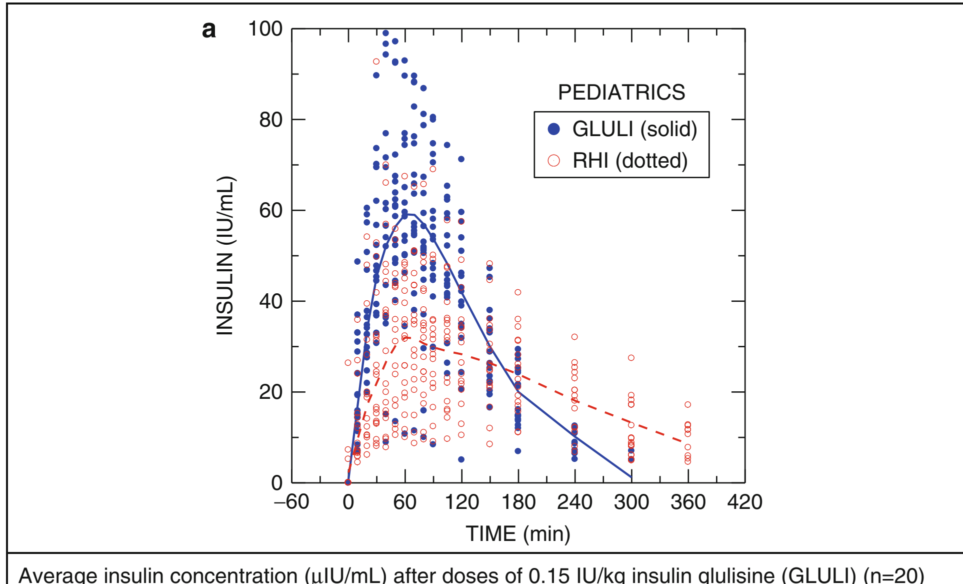
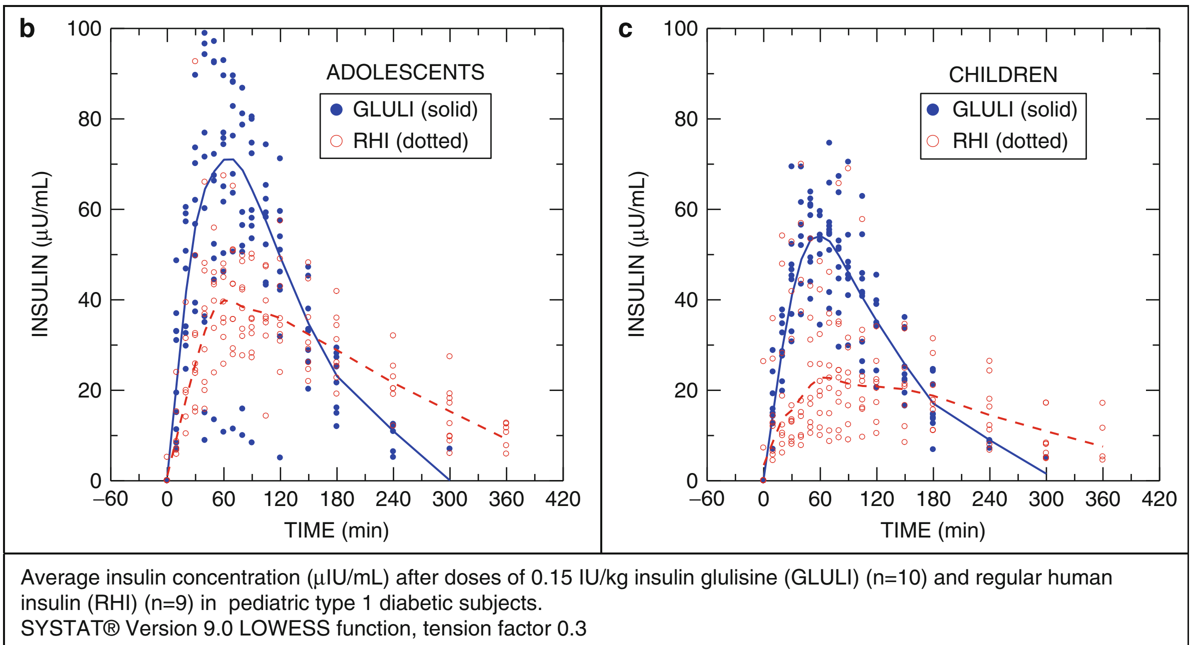
BMI (kg/m^2)	20.9 (16.4–26.3)		20.9 (16.4–26.3)		20.9 (17.6–24.5)	
	Children ($n = 10$)			Adolescents ($n = 10$)		
	All ($n = 10$)	Male ($n = 5$)	Female ($n = 5$)	All ($n = 10$)	Male ($n = 4$)	Female ($n = 6$)
Age (years)	10.1 (7–11)	10.2 (8–11)	10.0 (7–11)	14.7 (12–16)	15.5 (14–16)	14.2 (12–16)
Weight (kg)	40.0 (26.0–50.0)	39.1 (26.0–50.0)	40.8 (27.5–49.0)	64.2 (51.0–82.5)	72.7 (53.0–82.5)	58.6 (51.0–65.0)
BMI (kg/m^2)	19.4 (16.4–22.7)	19.2 (16.4–21.1)	19.7 (17.6–22.7)	22.4 (17.7–26.3)	23.1 (17.7–26.3)	22.0 (20.2–24.5)

Serum insulin concentrations – children and adolescents



Average insulin concentration (µIU/mL) after doses of 0.15 IU/kg insulin glulisine (GLULI) (n=20) and regular human insulin (RHI) (n=19) in pediatric type 1 diabetic subjects.
SYSTAT® Version 9.0 LOWESS function, tension factor 0.3

Serum insulin concentrations – children / adolescents



Average insulin concentration (µIU/mL) after doses of 0.15 IU/kg insulin glulisine (GLULI) (n=10) and regular human insulin (RHI) (n=9) in pediatric type 1 diabetic subjects.
SYSTAT® Version 9.0 LOWESS function, tension factor 0.3

Fig. 45.11 Children and adolescents

The two age classes, children and adolescents, presented an almost equal PK profile after insulin glulisine with a slight trend toward higher exposure in adolescents. In contrast, the comparison between age classes for regular insulin revealed on average 60 % higher exposure in adolescents.

In conclusion, in pediatric type I diabetic subjects, equally in each age class children and adolescents,

insulin glulisine was more rapidly absorbed and had a shorter residence in the systemic circulation compared to regular human insulin. Insulin glulisine displays pharmacokinetic properties in pediatric type 1 diabetic subjects, which classify insulin glulisine as a rapid-acting insulin analogue in this patient population with no specific dose adjustment warranted on the basis of intrinsic properties of HMR1964 (insulin glulisine).

45.15 Special Populations: Assessment of Ethnic and/or Genetically Determined Differences

PURPOSE/RATIONALE

Special populations become more and more important for clinical trials. It is requested to investigate the influence of organ dysfunctions (kidney, liver), of the underlying and concomitant illness, of gender/age, and also of ethnic differences (ICH-E5 1998). Increasing knowledge about population-determined PD and PK and especially about the genetic background of metabolic capacities raises more and more complex questions during drug development. In this chapter, the assessment of genetically determined (interethnic) differences will be discussed.

During recent years, genotyping of drug-metabolizing enzymes and transporters (DME + T), known to show a polymorph expression, gained more and more importance to predict phenotypes (US FDA 2005). This provides a helpful tool to predefine and select populations on risk and to investigate them specifically in a dedicated phase I study (for specific terminology, see EU CPMP 2002). If one of the known polymorph DME + T's is involved in the metabolism of the drug (or suspected to be), an explorative study—as described in this chapter—might be helpful during early development. Presently, the DME + T's with sufficiently established background knowledge to be considered as "validated" are CYP 2C9, CYP 2C19, CYP 2D6, NAT2, and MDR1, of further

interest became the UGTs. Genetic phenotyping is increasingly recommended for other kind of studies (EU 2010), and thus the investigation described in this chapter provides a tool to assess these influences.

PROCEDURE

The design of an exploratory profiling of the impact of polymorphism of CYP 2C19 on the pharmacokinetics of candidate drug (XYZ1234) in a single clinical study is presented below. Two control groups (both genders) were required, since the poor CYP 2C19 group consisted of males and females (due to the low prevalence in the European population).

For the purposes of simplicity, the description is limited to the collection, handling, and interpretation of pharmacokinetic data although clearly safety parameters are also studied.

45.15.1 Protocol Outline

Explorative assessment of the pharmacokinetics of XYZ1234 following a single oral 100-mg dose, given in a special micronized formulation in poor and extensive CYP 2C19 metabolizing healthy male and female subjects.

45.15.1.1 Objective

Comparative assessment of the pharmacokinetics (PK) of XYZ1234 following a single oral 100-mg dose in healthy male and female subjects, which are poor or extensive metabolizers for CYP 2C19 respectively.

45.15.1.2 Study Design

The study was performed open labeled in a single center in three parallel groups.

45.15.1.3 Number of Subjects

Eighteen subjects (6 poor CYP 2C19 metabolizers [2–4 of them males] and 12 extensive CYP 2C19 metabolizers [6 males and 6 females], if possible with matching body mass indices (BMI) and age distribution).

45.15.1.4 Inclusion Criteria

Healthy men or women aged between 18 and 60 years, with BMI of 19.5–29.5 kg/m^2. Screening must have determined the CYP 2C19 metabolizer status beforehand.

45.15.1.5 Treatments

XYZ1234 100 mg per os (orally, PO.) (in a special micronized formulation, under fasting conditions).

45.15.1.6 Pharmacokinetic Data

Concentrations of XYZ1234 in plasma and urine were measured before and at predetermined times up to 72 h (h) post dosing and were used to determine the PK data.

If feasible and adequate, an explorative investigation on potential metabolites in plasma and urine was to be performed.

EVALUATION

Due to the small sample size, all variables were only presented descriptively for the different bioanalytical data and PK parameters calculated.

This descriptive statistics will be presented by CYP 2C19 metabolizer status and where applicable by gender, including mean (arithmetic and/or geometric), standard deviation (usual and/or dispersion factor), standard error of the mean, coefficient of variation (in %), median, minimum, maximum, and number of observations.

For pharmacokinetics in plasma: Individual concentrations of XYZ1234 will be tabulated together with descriptive statistics and plotted. Median profiles will be presented graphically by CYP 2C19 metabolizer status and gender. Pharmacokinetic parameters (at least C_{max}, t_{max}, $AUC_{(0-t)}$ [t = 24 h, and "last > LOQ"], AUC_{inf}, $t_{½z}$, MT, as well as CL/f and Vz/f) will be determined based on plasma concentrations of XYZ1234 using noncompartmental procedures.

For urine data, the individual and mean fractional and cumulative urinary excretion of XYZ1234 will be calculated if feasible and adequate {$Ae_{(t2-t1)}$; $Ae_{(0-72\ h)}$, urinary recovery [% of administered dose], and renal clearance CL_R (fractional and total)}.

CRITICAL ASSESSMENT OF THE METHOD

In the actual development program, this study was needed to exploratively elucidate the influence of the CYP 2C19 phenotype before starting the first multiple-dose study due to the observation of a deviating pharmacokinetics in a poor CYP 2C19 metabolizing subject included in an earlier single-dose study (the first-in-man study). The described study had to clarify if this deviating PK for this subject is based on the status of being a "poor CYP 2C19 metabolizer" or was based on a further individuality of that specific subject (e.g., a different degree of resorption).

Since the prevalence of poor metabolizers for CYP 2C19 in a Caucasian population is only 2–5 %, the recruiting of those subjects became cumbersome, and the consequence for the design of the study was that some study details were more adjusted to the needs of those subjects as in a "normal" phase I study.

The formulation used in this study had proven to be superior to other formulations tested; as dose, 100 mg is selected (instead of the targeted 400 mg) in order to generate an additional safety margin for the case that the metabolizer status consistently influences the extent of exposure.

The impact of selected phenotypes on candidate drug pharmacokinetics and safety can be conveniently investigated in an explorative study with the design described in this chapter. Typically, this study would run shortly after key data are available, indicating the influence of polymorph DME + T. The dose should be adjusted (i.e., reduced, compared to the clinical dose) based on the expected degree of interaction.

But especially since a predicted phenotype based on genotyping data was used to define the study groups, this investigation cannot consider all the extrinsic and intrinsic factors influencing the real activity of enzymes and transporters. During the further clinical development additional (population) analyses, studies might be required to further elucidate the respective influence of the DME + T polymorphism and its consequences.

MODIFICATIONS OF THE METHOD

The design of study described in this chapter is relatively simple but nevertheless provides explorative profiling of issues related to DME + T polymorphism, and the same principle could be applied to address further influencing factors or populations. The more complicated part is to clearly define both relatively small test and control groups based on the DME + T properties or other characteristics.

Typically, this type of evaluation would be extended during the later clinical development by performing a population pharmacokinetic/pharmacodynamic assessment of the impact of genetically determined (interethnic) differences on the disposition of the developmental drug during the phase II/III studies.

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a high level summary of the data from the study described above under *Procedure* is presented below.

45.15.2 Results

Compared to the extensive metabolizers for CYP 2C19, the plasma profiles clearly differ for the poor CYP 2C19 metabolizers: the initial peak is higher and especially the elimination phase takes much longer. There is, in addition, an indication of a difference between the two control groups (females vs. males). Some profiles for the females show peaks similar to those seen for the poor metabolizers, and at least in one case, a similar long elimination phase was to be observed. Nevertheless in average the two control groups of extensive CYP 2C19 metabolizers are highly overlapping and clearly below the profiles for the poor CYP 2C19 metabolizers (see Fig. 45.12).

The peak values (C_{max} as median) are 0.95, 0.35, and 0.61 μg/mL for the poor metabolizers, the male extensive metabolizers, and the female extensive metabolizers, respectively. The differences in the overall exposure (AUC, extrapolated to infinity) are much more prominen, because of the intensive differences in the elimination phase. The median values were 8.83, 0.83, and 2.49 μg*h/mL for the poor metabolizers, the male extensive metabolizers, and the female extensive metabolizers, respectively. This difference is already obvious when comparing the exposure only over the first 24 h: the median values for $AUC_{(0–24\ h)}$ were 4.21, 0.83, and 1.38 μg*h/mL for the poor metabolizers, the male extensive metabolizers, and the female extensive metabolizers, respectively.

Also the half-life of the terminal phase strongly differed. The median values were 43.6, 4.6, and 18.5 h for the poor metabolizers, the male extensive metabolizers, and the female extensive metabolizers, respectively.

The PK parameters showed a significant variability in these small ($n = 6$) groups. In addition, the extrapolated portion of the exposure (AUC:%Extrap) is quite high for the poor metabolizers and also the extensive metabolizing females, indicating that (at least for the poor metabolizers) even the 72-h blood collection period was not sufficient, which in addition contributes to the variability of the PK data.

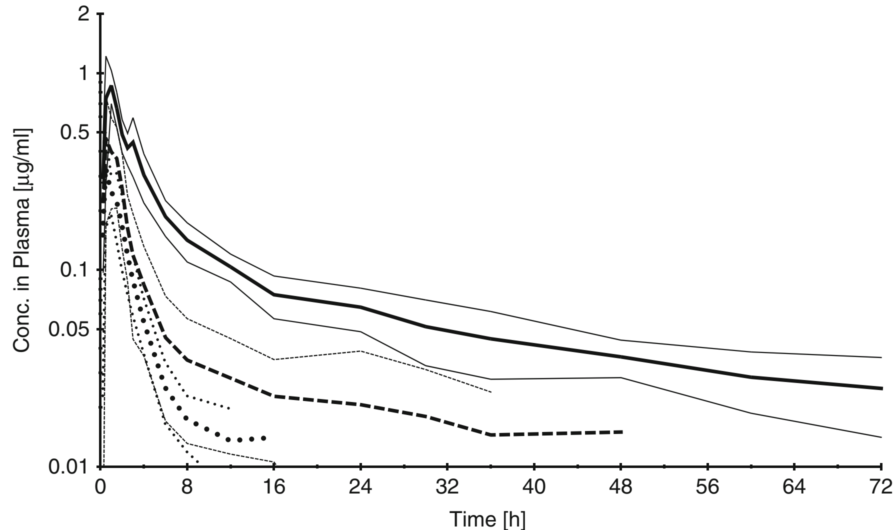

Fig. 45.12 Plasma concentration versus time profiles of XYZ1234 following a single oral 100-mg dose given to poor CYP 2C19 metabolizing male and female subjects (*straight lines*), to extensive CYP 2C19 metabolizing females (*dashed lines*), and to extensive CYP 2C19 metabolizing males (*dotted lines*), respectively. *Mean values (bold) and 90 % confidence interval*

45.16 Profiling of the Gastrointestinal Site of Absorption

PURPOSE/RATIONALE

For several reasons, it may be helpful to investigate the extent of absorption by determining the window for absorption in the gastrointestinal (GI) tract, for example:

- If the drug is intended to reach the colon, a drug loss in the small intestine is not desirable as this portion does not contribute to efficacy, but possibly to intolerance.
- The drug has a (too) short systemic half-life, and the feasibility for the development of an extended-release formulation has to be investigated.

In the present study, example the feasibility of the development of a slow-release formulation was evaluated. Guidelines on the design and conduct of such studies have not yet been published.

PROCEDURE

The design of an exploratory assessment of the absorption window for a high-clearance drug candidate is presented below. The aim of the present study was to compare the regional drug absorption from the proximal small bowel, the distal small bowel, and ascending colon with an immediate-release reference formulation, using pharmacoscintigraphy and remote release via the Enterion™ capsule to evaluate the feasibility of the development of an extended-release formulation.

45.16.1 Protocol Outline

Pharmacoscintigraphic evaluation of the regional drug absorption of XYZ123 in healthy men.

45.16.1.1 Primary Objective

To investigate the pharmacokinetics (PK) of an XYZ123 formulation (200 mg) following topical release in the proximal small bowel, distal small bowel, and colon via the Enterion™ capsule in healthy subjects and to compare to the PK of an XYZ123 immediate-release reference formulation (200 mg).

45.16.1.2 Study Design

Randomized four-way crossover design.

45.16.1.3 Inclusion Criteria

Healthy male subjects aged between 18 and 65 years.

45.16.1.4 Treatments

Regimen A: XYZ123 immediate-release formulation in tablet form (200 mg, reference)

Regimen B: XYZ123 formulation (200 mg) delivered to the proximal small bowel via the Enterion™ capsule

Regimen C: XYZ123 formulation (200 mg) delivered to the distal small bowel via the Enterion™ capsule

Regimen D: XYZ123 formulation (200 mg) delivered to the ascending colon via the Enterion™ capsule

45.16.1.5 Pharmacokinetic Data

Derived from concentrations of the parent drug XYZ123 in whole blood and of the active metabolite ABC4321 in plasma before and at predefined times after dosing (Regimen A) and following activation of the Enterion™ capsule (Regimens B, C, and D).

EVALUATION

PK data: The PK parameters of ABC4321 in plasma were determined by individual PK analyses. The individual and mean concentrations of ABC4321 in plasma were tabulated and plotted. PK variables were listed and summarized by treatment with descriptive statistics. An analysis of variance (ANOVA) including sequence, subject nested within sequence, period, and treatment effects was performed on the ln-transformed parameters (except t_{max}). The mean square error was used to construct the 90 % confidence interval for treatment ratios. The point estimates were calculated as ratio of the antilog of the least square means. Pair-wise comparisons to treatment A were made. Whole blood concentrations of XYZ123 were not used to perform PK analyses.

Scintigraphic data: The activation time post dose and the arrival, residence, and transit times of the capsule in different regions of the GI tract (i.e., dosing time subtracted from the actual clock time for each transit event) were derived from the scintigraphic images and tabulated for each treatment condition and for subjects. Descriptive statistics were performed where appropriate.

CRITICAL ASSESSMENT OF THE METHOD

The pharmacoscintigraphy of a drug vehicle from which the contents can be released via remote signal

was applied to early drug development in recent years with increasing frequency.

Via remote control of its current location, this capsule represents a reliable tool for immediate release at the GI location where the permeation capability of the drug substance should be assessed.

As the capsule can be "loaded" with the drug as powder, suspension, or solution, the physicochemical situations in the different parts of the GI tract can be mimicked.

An in vitro compatibility study ("leakage test") had been performed beforehand: (1) Three capsules were filled with powdered tablet formulation of XYZ123, containing 200 mg of the drug each. (2) Each capsule was transferred to simulated gastric fluid (SGF) and placed in a shaking water bath maintained at 37°C for 2 h. (3) After this 2-h incubation, each capsule was transferred to simulated intestinal fluid (SIF) and placed in a shaking water bath maintained at 37°C for 24 h. (4) Aliquots of SGF were taken at 1 and 2 h and aliquots of SIF were taken at 1 and 24 h and analyzed for XYZ123. (5) The content of the capsules was analyzed for XYZ123.

The leakage of powdered drug formulation (0.01 %) under simulated in vivo conditions was considered acceptable. The recovery of drug from the capsules was within the specification limits for the film-coated tablets.

In the study presented here, absorption from the colon was not reliable, thus making it nonfeasible to develop a formulation with a 24-h (h) release profile reducing the administration frequency to QD.

MODIFICATIONS OF THE METHOD

Other attempts to define the site of absorption were other kinds of vehicles as well as catheters. Three main perfusion methods have been employed in the small intestine: (1) a triple lumen tube including a mixing segment, (2) a multilumen tube with a proximal occluding balloon, and (3) a multilumen tube with two balloons occluding a 10-cm-long intestinal segment. A critical assessment of these perfusion techniques can be found in (Lennernäs 1998). Whereas vehicles inherit the advantage of minimal invasiveness, their transit through the GI tract depends on the individual physiology of the study subject. On the other hand, this is exactly the fate of a solid dosage form.

EXAMPLE

To illustrate the type of data that can be obtained using the discussed study, a summary of the pharmacokinetic and scintigraphy results obtained from the study described above under *Procedure* is presented below.

45.16.1.6 Results

PK data: PK parameters were calculated for all subjects for Regimens A (immediate release), B (proximal small bowel activation), and C (distal small bowel activation).

However, for Regimen D (ascending colon activation), out of the six subjects available, two subjects had plasma concentrations which were low and $AUC_{(0-\infty)}$ could not be calculated, and a further two subjects had $AUC_{(0-\infty)}$ of >20 % extrapolated from the last observation. Hence, for this parameter, contrasts for Regimen D should be interpreted cautiously. Mean $AUC_{(0-\infty)}$ values for regimens A, B, C, and D were 4.236, 4.175, 2.36, and 0.965 μg/mL*h, respectively. For the contrast Regimen B versus Regimen A, the ratio was 100.3 %: for the contrast Regimen C versus Regimen A, the ratio was 55.9 %; and for the contrast Regimen D versus Regimen A, the ratio was 27.8 %.

Table 45.29 Summary of pharmacokinetic parameters in plasma

Treatment/location		$AUC_{(0-\infty)}$ (μg/mL.h)	$AUC_{(0-t)}$ (μg/mL.h)	AUC ext (%)	C_{max} (μg/mL)	t_{max} (h)	$t_{½}$ (h)
Immediate release (Reference, A)	N	8	8	8	8	8	8
	Mean	4.236	4.168	1.96	2.0226	0.63	2.129
Proximal small bowel (B)	N	8	8	8	8	8	8
	Mean	4.175	4.111	1.68	1.3791	1.31	2.119
Distal small bowel (C)	N	8	8	8	8	8	8
	Mean	2.360	2.298	3.31	0.4563	2.38	2.686
Ascending colon (D)	N	4	5	4	5	5	4
	Mean	0.965	0.722	18.25	0.1020	3.50	7.22

Mean C_{max} values for regimens A, B, C, and D were 2.02, 1.38, 0.46, and 0.10 μg/mL, respectively. For C_{max} for the contrast Regimen B versus Regimen A, the ratio was 64.5 %: for the contrast Regimen C versus Regimen A, the ratio was 20.2 %; and for the contrast Regimen D versus Regimen A, the ratio was 4.0 %.

The t_{max} tended to increase through the regimen order of A (0.63 h) to B (1.31 h) to C (2.38 h) to D (3.50 h).

The $t_{1/2}$ was similar for Regimens A and B (2.1 h) and slightly longer for Regimen C (2.7 h). Half-life was longer for Regimen D (7.2 h) based on the four subjects for which this was calculated (Table 45.29).

Scintigraphic data: Gastric emptying of the Enterion™ capsule occurred on average at 1.15 h post dose for Regimen B, at 1.28 h post dose for Regimen C, and at 2.39 h post dose for Regimen D.

Small intestinal transit times for the Enterion™ capsule were on average 4.19 h for Regimen B, 4.69 h for Regimen C, and 4.11 h for Regimen D.

Colon arrival of the Enterion™ capsule occurred on average at 5.34 h post dose for Regimen B, at 6.25 h post dose for Regimen C, and at 6.49 h post dose for Regimen D.

Capsule recovery occurred on average at 23.86 h post dose for Regimen B, at 34.23 h post dose for Regimen C, and at 30.59 h post dose for Regimen D. This resulted in colonic transit times of 18.52 h for Regimen B, 25.11 h for Regimen C, and 24.53 h for Regimen D.

Enterion™ capsules were successfully activated in eight subjects for Regimen B, eight subjects for Regimen C, and seven subjects for Regimen D.

Gastrointestinal transit data: Two main parameters influence the gastric emptying of pharmaceutical formulations, the physical size of the dosage form and whether it is administered in the fasted or fed state. When the stomach is empty of food, i.e., in the fasted or interdigestive state, indigestible solids, such as large single unit dosage forms, will be emptied by the action of the migrating myoelectric complex (MMC) (Kelly 1980). The MMC is usually divided into four phases of activity (Bieck 1989), which recur approximately every 2 h. Phase III of the MMC is known as the "housekeeper wave" and acts to empty the stomach of swallowed saliva, cellular debris, and indigestible solids. If the formulation is administered just before a "housekeeper wave," then it may be rapidly emptied from the stomach. However, if the preparation is administered just after phase III activity, then it is probable that the Enterion™ capsule would not be emptied until the next "housekeeper wave" occurred some 2 h later.

The Enterion™ capsules demonstrated typical gastric emptying for the majority of subjects for preparations administered in the fasted state. The capsules left the stomach within 3 h of dosing in seven of the eight subjects for Regimen B (proximal small bowel activation), in seven of the eight subjects (eight subjects dosed on nine occasions) for Regimen C (distal small bowel activation), and in five of the seven subjects for Regimen D (ascending colon activation). This suggests that in the majority of individuals, the first cycle of phase III MMC activity was 100 % efficient. Gastric emptying occurred within 5 h of dosing in the majority of the remaining subjects, suggesting that the capsule was removed from the stomach by the second cycle of phase III MMC activity. An extended gastric residence time of 19.08 h was recorded for subject 3 (Regimen C). Extended gastric residence times have been observed previously with a radiotelemetry capsule (RTC), which is comparable in size to an Enterion™

capsule. The RTC did not empty from the fasted stomach within a 12-h study period, even though phase III contractions were noted at 4.5, 6.4, and 8.5 h post dose, therefore indicating a 2 hourly recurring MMC (Kelly 1980). The study demonstrated that the phase III contractions of the MMC were not always efficient at removing large nondisintegrating dosage forms from the stomach.

Mean small intestinal transit times for the Enterion™ capsule of 4.19 ± 1.19, 4.69 ± 1.71, and 4.11 ± 1.45 h for Regimens B, C, and D, respectively, are not unusual. There is always a high degree of intra- and intersubject variability observed in gastrointestinal tract data (Kelly 1980). These intestinal transit times are in general agreement with the 3 h (±1 h, range 1.3–6 h) previously reported for solutions, pellets, and tablets (Davis et al. 1986).

Colon arrival of the Enterion™ capsule occurred on average at 5.34 ± 1.13, 6.25 ± 1.88, and 6.49 ± 2.50 h post dose for Regimens B, C, and D, respectively. For many of the subjects, colon arrival occurred after the ingestion of food at 5 h post dose (lunch). The ingestion of a meal is known to stimulate colonic activity, and this is termed the gastrocolonic response (GCR). The GCR has been shown to play an important role in determining colon arrival of pharmaceutical preparations following an overnight fast or a light meal (Price et al. 1993a, b).

Capsule recovery occurred on average at 23.86 ± 6.39, 34.23 ± 28.85, and 30.59 ± 26.60 post dose for Regimens B, C, and D, respectively. This resulted in average colonic transit times of 18.52 ± 5.65, 25.11 ± 24.00, and 24.53 ± 25.12 h for Regimens B, C, and D, respectively. Colonic transit times of dosage forms ranging from 1 to 60 h have been reported (Hardy et al. 1985, 1987). The results for colonic transit for this study are therefore in good agreement with those previously reported.

The pharmacokinetics of XYZ123 formulations after release in different regions of the gastrointestinal tract reveal similar exposure for the proximal small bowel as compared to the immediate-release formulation, halved exposure for the distal small bowel, and only poor absorption from the ascending colon. Thus, colonic resorption cannot be relied on for the development of an extended-release formulation. Analysis of the scintigraphic data has confirmed release of the formulation at the target locations in the required number of subjects.

45.17 Special Situations for Drug Delivery: Modified-Release Formulations

PURPOSE/RATIONALE

One of the special situations for drug delivery is the assessment of the pharmacokinetic (PK) properties of a modified-release formulation. Modified-release products always gain importance if the PK/PD profile of a drug is not close to optimal for its target indication mostly because the (short) PK or efficacy half-life does not match the intended dosing frequency.

Details on the design, objectives, and interpretation of bioavailability studies on modified-release products can be found in (US 1997c, d, 2003a; EU CPMP 1999, 2003b).

PROCEDURE

The design of an exploratory bioavailability study on modified-release drug products is presented below. For the design of the study, information from a recent bioavailability study with other modified-release products, from a site-of-absorption study and from a Modeling and Simulation experiment was used.

45.17.1 Protocol Outline

Comparison of pharmacokinetics and safety of extended-release formulations of 600-mg XYZ123 with that of an immediate-release formulation—a single-center, open-label, crossover study in healthy men.

45.17.1.1 Primary Objective

To compare the PK characteristics of extended-release (ER) formulations of XYZ123 with the PK of an immediate-release (IR) formulation of XYZ123.

45.17.1.2 Secondary Objective

To assess the influence of food on the PK of ER formulations of XYZ123.

45.17.1.3 Study Design

The study was carried out in a single-center, open-label, single-dose, four period crossover study design with two independent treatment groups.

Single oral doses of 600-mg XYZ123 were given under fasting and under nonfasting conditions.

The order of treatments and of fasting and nonfasting conditions was randomized in a four-way crossover incomplete block design (treatment groups I and II). The washout periods between the administrations of study medication were at least 48 hour (h) each.

45.17.1.4 Inclusion Criteria

Healthy men aged 18–55 years and assessed as healthy based on findings in medical history, physical examination, blood pressure, pulse rate, and electrocardiogram (ECG) during screening.

45.17.1.5 Treatments

Treatment Group I

Treatment A: 600-mg XYZ123 (1 film-coated tablet containing 200 mg + 1 film-coated tablet containing 400 mg given together) as IR formulation under nonfasting (NF) conditions (reference)

Treatment B: 600-mg XYZ123 in ER formulation (LLL matrix tablet) under fasting (F) and NF conditions.

Treatment C: 600-mg XYZ123 in ER formulation (LLL bilayer tablet) under F and NF conditions.

Treatment Group II

Treatment A: 600-mg XYZ123 (1 film-coated tablet containing 200 mg + 1 film-coated tablet containing 400 mg given together) as IR formulation under nonfasting (NF) conditions (reference)

Treatment D: 600-mg XYZ123 in ER formulation (KKK matrix tablet) under F and NF conditions.

Treatment E: 600-mg XYZ123 in ER formulation (KKK bilayer tablet) under F and NF conditions.

45.17.1.6 Pharmacokinetic Data

Concentration of XYZ123 in plasma before and at predefined times after dosing.

EVALUATION

Bioanalytical data: Individual plasma concentrations of XYZ123 were tabulated together with standard descriptive statistics for each treatment. Individual and median profiles were presented graphically.

In vivo *dissolution data*: The individual hypothetical in vivo dissolutions for the four extended-release formulations administered under fasting and nonfasting conditions relating to XYZ123 were estimated by numerical deconvolution using the individual response to the immediate-release formulation given under nonfasting conditions as the weighting (impulse) function using a hidden function of the validated HOEREP-PC software.

Plateau time data: The additional pharmacokinetic characteristics, i.e., plateau times of XYZ123 (time above 200, 500, 800, and 1,000 ng/mL [h]) were calculated in the interval from administration ($t = 0$) to exactly 12 h thereafter from the plasma concentration-time data pairs and subjected to ANOVA. Points of intersection with a specific plateau concentration were obtained by linear interpolation.

PK data: PK parameters were determined based on plasma concentrations of XYZ123 using noncompartmental procedures.

Primary PK Measure: AUC_{0-inf}

Secondary PK Measures: $C_{12\,h}$, $AUC_{0-12\,h}$, AUC_{0-t}, AUC_{ext} [%], C_{max}, t_{max}, MRT, $t_{1/2\lambda z}$, t_{lag}.

The primary measure was subject to an analysis of variance (ANOVA) including sequence, subject nested within sequence (subject (sequence)), period, and treatment effects. According to the treatment groups and fasting conditions, there were five realizations of the variable treatment. The sequence effect was tested using the subject (sequence) mean square from the ANOVA as an error term. All other main effects were tested against the residual error (error mean square) from the ANOVA. The ANOVA was performed on ln-transformed data. The mean square error was used to construct 90 % confidence intervals for treatment ratios. The point estimates were calculated as ratio of the antilogs of the least square means and were expressed as percentages. The ANOVA was performed separately for subjects in treatment group I and subjects in treatment group II. Point estimates and confidence intervals were primarily calculated for the ratio of each ER formulation to the IR reference formulation. Additionally, the ratios fasting/nonfasting for each ER formulation were calculated.

The secondary pharmacokinetic measures were evaluated descriptively.

For t_{max} frequency, distribution tables were given for each group, formulation, and fasting/nonfasting condition.

CRITICAL ASSESSMENT OF THE METHOD

The study described here has a very complex design for its exploratory approach. It combines four different extended-release formulations, each tested under fasting and nonfasting conditions, and compares the

results to the immediate-release drug product as the reference formulation. The bilayer tablets combine an immediate-release component and an extended-release component in one vehicle. In this project, a close cooperation between the galenics department and the clinical pharmacokinetic function was mandatory. The in vitro/in vivo correlation was done by means of the deconvolution which is an appropriate surrogate to describe the in vivo dissolution.

MODIFICATIONS OF THE METHOD

Recommendations exist to conduct in vivo studies first in an animal species (preferably the pig) before going to man. This approach has limited validity because modified release is primarily defined by the absorption properties of a drug. As absorption is influenced by the general composition, the sums of the physicochemical properties, and the length and residence times of each section of the GI tract, no animal species is similar to man in this respect.

Repeated dosing studies are recommended if the drug product is intended for subchronic or chronic use.

US FDA (2003a) Guidance for industry exposure-response relationships—study design, data analysis, and regulatory applications, April 2003

EXAMPLE

To illustrate the amount of data that can be obtained using the discussed study type, an overview of the pharmacokinetic and the deconvolution results obtained from the study described above under *Procedure* is presented below.

45.17.1.7 Results: Pharmacokinetics

The primary objective of the present study was to investigate the pharmacokinetic characteristics of four ER formulations of XYZ123. Two LLL formulations (matrix and bilayer tablets, treatments B and C, respectively) and two KKK formulations (matrix and bilayer tablets, treatments D and E) were compared with the pharmacokinetic characteristics of an IR formulation (treatment A) in the nonfasting state. The secondary PK objective was to assess the influence of food on the pharmacokinetics of these ER formulations of XYZ123.

45.17.1.8 Extended-Release Characteristics (Primary Objective)

LLL tablets (treatments B and C) provided lower C_{max} values and lower relative bioavailability compared to the IR formulation (treatment A). A longer half-life was observed for treatment B (matrix tablets), under both fasting and nonfasting conditions, but for treatment C (bilayer tablets), the lower limit of the 90 % confidence was above 100 % only under fasting conditions.

KKK tablets (treatments D and E) provided lower C_{max} values with similar (though not higher) AUC values for treatment E (bilayer tablets) and similar AUC for treatment D—only under nonfasting conditions. Increased half-lives were recorded for treatments D and E, only under fasting conditions.

Higher $C_{12\ h}$ values and longer MRTs, both features important for ER formulations, were obtained for all LLL tablets, compared to treatment A. A similar but less pronounced effect was observed for KKK formulations, notably under fasting conditions. Only treatment C (LLL, bilayer) had significantly greater time values than treatment A for the time above 800 ng/mL.

The effect of the IR component within the bilayer tablets on the absorption profile was most markedly observed in the figures describing the hypothetical in vivo dissolution. The increase in amount absorbed was steeper for treatments C and E, especially under fasting conditions.

45.17.1.9 Effects of Food (Secondary PK Objective)

No effect of food was recorded on $AUC_{0-\infty}$ and MRT values for the bilayer tablets (treatments C and E), with marginal effect on their rate of absorption and on C_{max} values. The absorption rate of matrix tablets, as well as their C_{max} values, was more affected. $C_{12\ h}$ values presented food consumption effects for all formulations, however, to a larger extent for KKK than for LLL tablets.

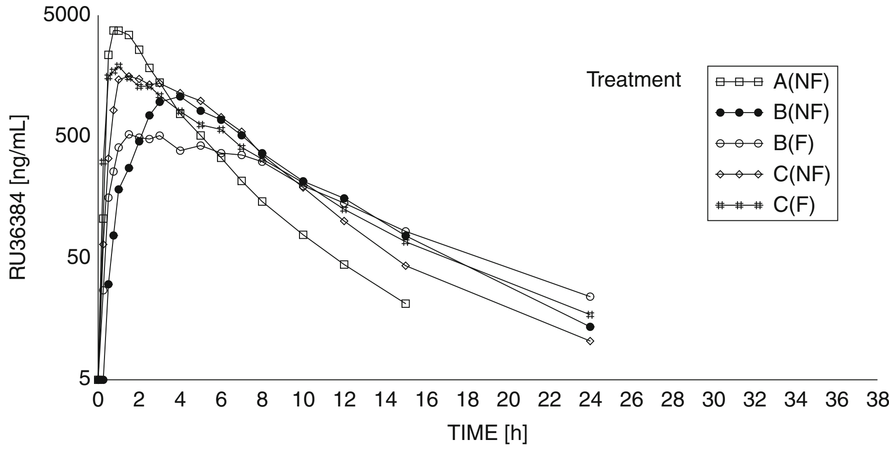

Fig. 45.13 XYZ1234 concentration in plasma versus time following treatments A(NF), B(NF), B(F), C(NF), and C(F) group I. Median plot—log-linear scale

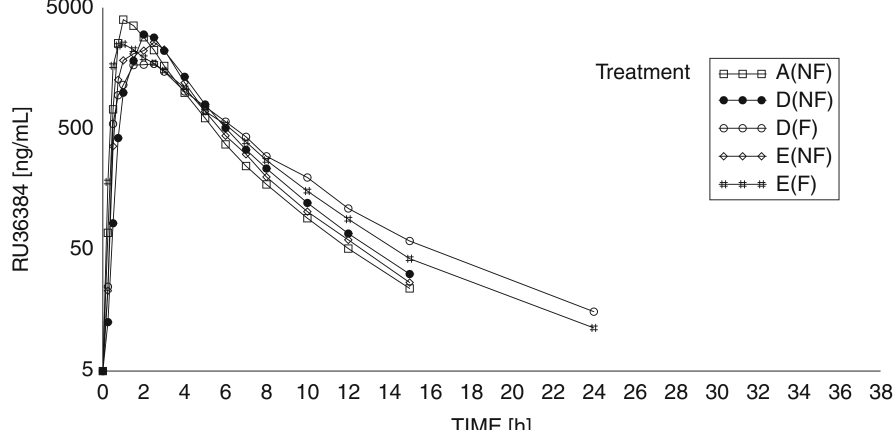

Fig. 45.14 XYZ123 concentration in plasma versus time following treatments A(NF), D(NF), D(F), E(NF), and E(F) Group II. Median plot—log-linear scale

Figures 45.13 and 45.14 show the plots of the median concentration-time profiles of XYZ123 following administration of the several treatments synoptically for the two groups in lin-lin-scaling.

45.17.1.10 Pharmacokinetic Measures and Parameters

The model independent pharmacokinetic characteristics for XYZ123 following single-dose administration of the different treatments were calculated using noncompartmental procedures. The following table gives the arithmetic means, standard deviations, and coefficients of variation as well as the medians and ranges of the primary pharmacokinetic measure $AUC_{0-\infty}$ and of the secondary measures $C_{12\ h}$, C_{max}, and MRT (Table 45.30).

The next table gives further arithmetic mean PK measures and parameters of XYZ123 following oral single-dose administration of XYZ123 (Table 45.31).

45.17.1.11 Statistical/Analytical Issues

The extrapolated part AUC_{ext} of the total areas $AUC_{0-\infty}$ following the four different treatments for XYZ123 did not exceed 4 % in mean and 9 % in maximum.

The primary parameter $AUC_{0-\infty}$ was subjected to an analysis of variance (ANOVA) including sequence, subject nested within sequence (subject (sequence)), period, and treatment (nonfasting/fasting) effects. The sequence effect was tested using the subject (sequence) mean square from the ANOVA as an error term. All other main effects were tested against the residual error (error mean square) from the ANOVA. The ANOVA was performed on ln-transformed data. For ratios, 90 % confidence intervals were constructed. The point estimates and confidence limits were calculated as antilogs and were expressed as percentages. The ANOVA was performed separately for subjects in group I and subjects in group II.

Table 45.30 Arithmetic means and standard deviations (SD) of the primary pharmacokinetic measure $AUC_{0-\infty}$, and of the secondary measures $C_{12\ h}$, C_{max}, and MRT following single-dose administration of the different treatments

Treatment		$AUC_{0-\infty}$ (ng*h/mL)	$C_{12\ h}$ (ng/mL)	C_{max} (ng/mL)	MRT (h)
Group I					
A(NF)	Arithmetic mean	11,076.98	47.66	4,879.50	2.87
	SD	2,357.94	20.93	1,723.06	0.68
B(NF)	Arithmetic mean	7,126.00	149.81	1,343.34	6.65
	SD	2,220.73	61.62	650.08	1.31
B(F)	Arithmetic mean	5,396.57	167.41	660.95	8.27
	SD	1,469.50	95.17	205.40	1.99
C(NF)	Arithmetic mean	9,264.27	110.70	1,955.25	4.80
	SD	2,147.19	53.02	472.25	0.79
C(F)	Arithmetic mean	9,195.10	148.35	2,319.81	5.24
	SD	1,930.40	81.09	598.63	1.13
Group II					
A(NF)	Arithmetic mean	11,079.02	56.68	4,460.81	3.12
	SD	1,988.99	19.80	1,212.04	0.66
D(NF)	Arithmetic mean	10,194.24	68.02	3,226.19	3.90
	SD	1,681.87	18.34	794.93	0.64
D(F)	Arithmetic mean	9,020.77	113.47	1,858.81	5.10
	SD	1,963.15	44.71	355.81	1.36
E(NF)	Arithmetic mean	10,244.97	62.47	3,340.25	3.55
	SD	2,021.91	23.64	902.63	0.48
E(F)	Arithmetic mean	10,634.66	106.72	2,747.50	4.10
	SD	1,506.00	67.24	315.39	0.77

Point estimates and confidence intervals were primarily calculated for the ratio of each ER formulation and the IR reference formulation. Additionally, the ratios fasting/nonfasting for each ER formulation were computed.

No significant effect of either period or sequence was found for the primary parameter $AUC_{0-\infty}$ and for the secondary parameters C_{max} and $t_{1/2\lambda z}$. Treatment effect was highly significant for all three PK parameters, and subject effect was significant for $AUC_{0-\infty}$ and $t_{1/2\lambda z}$ but not for C_{max}.

In addition, the times for which plasma concentrations of XYZ123 were above certain values (200, 500, 800, and 1,000 ng/mL), within the 12-h dosing interval, were calculated for the various formulations and treatment modalities. These results were subjected to ANOVA to assess the statistical significance of the differences. The control treatment A was tested under nonfasting conditions only. In order to get the statistical significance of the differences for the various formulations, without interference of food effects, ANOVA was carried out again comparing treatment A with B, C, D, and E nonfasting. This analysis revealed highly significant treatment effect for both treatment groups I (LLL) and II (KKK) for the time above 200 ng/mL and the time above 500 ng/mL. However, for the time above 800 and 1,000 ng/mL, only group I (LLL) showed statistical significance. Further examination of the results revealed that in fact only treatment C (LLL, bilayer) had greater time values than treatment A (treatment B had lower values).

Table 45.31 Mean pharmacokinetic measures and parameters of XYZ123 following oral single-dose administration of XYZ123

Treatment	$AUC_{0-12\ h}$ (ng*h/L)	AUC_{ext} (%)	t_{max} (h)	$t_{1/2\lambda z}$ (h)	t_{lag} (h)
Treatment group I					
A(NF)	10,881.36	0.83	1.27	2.56	0.02
B(NF)	6,309.06	2.02	3.31	3.66	0.20
B(F)	4,182.51	3.16	2.72	4.86	0.11
C(NF)	8,743.51	0.96	2.34	3.01	0.06
C(F)	8,303.25	1.84	0.98	4.24	0.02
Treatment group II					
A(NF)	10,857.58	0.90	1.52	2.53	0.09
D(NF)	9,908.92	0.95	2.20	2.73	0.11
D(F)	8,282.20	1.44	2.06	4.11	0.08
E(NF)	9,991.45	0.90	2.09	2.76	0.09
E(F)	10,052.60	1.01	1.08	3.25	0.02

The additional pharmacokinetic characteristics, i.e., plateau times of XYZ123 (time above 200, 500, 800, and 1,000 ng/mL [h]) were calculated in the interval from administration (t = 0) to exactly 12 h thereafter from the plasma concentration-time data pairs. Points of intersection with a specific plateau concentration were obtained by linear interpolation.

45.17.1.12 Hypothetical in Vivo Dissolution

The individual hypothetical in vivo dissolutions for the four extended-release formulations administered

Table 45.32 Hypothetical dissolution data for XYZ123 obtained by deconvolution using treatment A(NF) as impulse function. Medians

Measures	B(NF)	B(F)	C(NF)	C(F)	D(NF)	D(F)	E(NF)	E(F)
Maximum amount absorbed (mg)	358.97	290.50	485.97	561.49	582.56	460.12	629.25	652.95
Maximum amount absorbed (% of dose)	63.22	51.16	85.58	98.88	102.59	81.03	110.82	114.99
Time to reach maximum amount (h)	15.00	24.00	15.00	15.00	9.00	15.00	2.50	15.00
Time to reach 50 % of maximum amount (h)	2.80	3.34	0.91	0.40	1.04	0.69	0.81	0.37
Time to reach 80 % of maximum amount (h)	5.27	6.95	2.95	1.64	1.79	2.54	1.44	0.48

under fasting and nonfasting conditions relating to XYZ123 were estimated by numerical deconvolution using the individual response to the immediate-release formulation given under nonfasting conditions as the weighting (impulse) function using a hidden function of a validated software.

Deconvolution is used to evaluate in vivo drug release and drug absorption from orally administered drug formulations (i.e., extended release) when data from a known drug input are available. The applied deconvolution method requires data from a formulation with zero order absorption as known input, for example, an oral solution (oral bolus input); the immediate-release formulation used as known input only provides an approximation to the required properties.

The medians and ranges of the hypothetical dissolution data for XYZ123 obtained by deconvolution are listed in the following Table 45.32.

Treatments C and E (the bilayer tablets that contain the IR component) had a steeper amount absorbed profile as compared to the parallel matrix tablets (treatments B and D. This effect was more pronounced under fasting conditions. Only with treatment E (KKK bilayer tablets), the hypothetical in vivo dissolution profiles surpassed the 100 % absorption, both under fasting and nonfasting conditions. For treatment C, this occurred only under fasting conditions, and for treatment D, only under nonfasting conditions.

The mismatch of surpassing 100 % absorption is probably due to method constraints in combination with the immediate-release data, as the deconvolution method requires data from a formulation with zero order absorption for the impulse function, for example, an oral solution (oral bolus input); the immediate-release formulation only provides an approximation to the required properties.

PURPOSE AND RATIONALE

Variability in exposure to a drug leads to variability in the clinical response across a patient patient population (Rowland et al. 1985). Estimating the variability of the PK (pharmacokinetics) across a patient population requires data obtained from a large study, typically including more than 100 patients. For ethical and practical reasons, pharmacokinetic properties of a drug are difficult to study in large numbers of patients using the traditional approach.

The PPK (population pharmacokinetic) population approach was suggested by Sheiner et al. (1977) for investigating the typical PK of a drug in a large target population using sparse and unbalanced data obtained without any additional cost during routine care of patients. The PPK approach aims to quantitate the effect of various physiologic factors on drug PK with the overall goal of explaining as much variability as possible.

Using the PPK approach in the development of a new drug has the advantage that the relevant pharmacokinetic parameters for a reasonably large population can be obtained from only a few blood samples per subject. The PPK approach is the method of choice in all situations when only sparse and unbalanced data sparse can be obtained. This situation exists when the PK needs to be studied in elderly, critically ill, and pediatric patients, but also very often in preclinical studies investigating the effects of the drug in animals.

Once such a mathematical model is available, the concentration time courses for various scenarios of administration can be predicted. The dosage can be adjusted to achieve a specific clinical goal like drug exposure within the therapeutic concentration window in the whole population or, if necessary, for special

subpopulations characterized by their individual physiology. Following the learning and confirming approach (Sheiner 1997), the predicted clinical success for these optimized dose regimens needs to be confirmed in the next clinical study.

The PPK approach estimates the joint distribution of population-specific pharmacokinetic model parameters for a given drug. Fixed effect parameters quantify the relationship, e.g., of clearance to individual physiology like function of liver, kidney, or heart. The volume of distribution is typically related to body size. Random effect parameters quantify the intersubject variability which remains after the fixed effects have been taken into account. Then, the observed concentrations will still be randomly distributed around the concentration time course predicted by the model for an individual subject. This last error term called residual variability needs to be estimated. As fixed and random effects are included, this method is called mixed effects modeling.

The essential features of a population pharmacokinetic study are summarized in a guideline (FDA 1999).

PROCEDURE

The NONMEM (nonlinear mixed effects modeling) software (Beal et al. 1992), mostly used in population pharmacokinetics, was developed at the University of California and is presently distributed by Globomax. For data management, postprocessing, and diagnostic plots, the software S-plus *(Mathsoft)* is frequently used.

Before starting model fitting, all available information obtained in previous studies should be assembled (prior knowledge). The analysis starts with an exploration of the data to generate hypotheses for the model: a statistical summary of demography, plots of the logarithm of the concentration versus time indicate the number of pharmacokinetic compartments involved. With the help of plots of individual time courses in a common coordinate system, subgroups in the population may be identified. Normalizing the curves to unit doses should indicate dose linearity or nonlinearity.

Prior knowledge and various hypotheses are condensed into models. NONMEM determines the parameter vector including fixed and random effects of each model using the maximum likelihood algorithm. NONMEM uses each model to predict the observed data set and selects the best PPK parameter vector minimizing the deviation between model prediction and observed data. Comparing model fits by the criteria discussed in the section "Evaluation" should decide which hypothesis is the most likely. As a general rule, the model should be as simple as possible, and the number of parameters should be at a minimum.

The situation after an IV bolus for a system described by a one compartment model with first order elimination can serve to illustrate the procedure. The observed concentration $c_{i,j}$ of an individual i at the time t_j can be modeled as

$$c_{i,j} = \left(\frac{\text{Dose}}{V_i}\right) e^{-k_i t_j} + \epsilon_{i,j}; \quad \epsilon_{i,j} \sim N(0, \sigma^2) \quad (46.1)$$

with $k_i = \frac{CL_i}{V_i}$, where CL_i and V_i are the individual clearance and the individual volume of subject i. $\epsilon_{i,j}$ is the residual error drawn from a normal distribution with zero mean and variance σ^2 (covariance matrix describing the within subject or residual variability), the intraindividual variability.

The pharmacokinetic parameters themselves are modeled like

$$CL_i = \theta_{CL}\, e^{\eta_{CL_i}}; \qquad \eta_{CL_i} \sim N(0, \omega^2), \quad (46.2)$$

where θ_{CL} is a population mean clearance and η_{CL_i} is again a random variable representing the deviation from the population mean of the clearance for the i-th subject. η_{CL_i} is normally distributed with zero mean and variance ω^2 (covariance matrix describing the between subject variability). The unexplained intersubject variability acts as random effect η_{CL_i} on the clearance.

It is important to emphasize that all pharmacokinetic, fixed effect, and random parameters, i.e., θ, ω^2, and σ^2, are fitted in one step as mean values with standard error by NONMEM. A covariance matrix of the random effects can be calculated. For a detailed description of the procedure, see Grasela and Sheiner (1991) and Sheiner and Grasela (1991).

In a subsequent step, the modeler tries to explain part of the unexplained interindividual variability. Fitted individual parameters (or the variable part expressed by η) are plotted against physiological parameters like weight or indicators of renal or metabolic functionality. Identified dependencies should

enter into the model. For example, clearance is very often modeled as depending on the covariate CL_{CR} (creatinine clearance):

$$CL_i = \theta_{CL} \left(\frac{CL_{CR_i}}{4L/h} \right)^{\theta_{CL_{CR}}} e^{\eta_{CL_i}}. \quad (46.3)$$

In this equation, CL_{CR_i} is the actual creatinine clearance of subject i. The fixed effect parameters are now θ_{CL} corresponding to the clearance of a person with a CL_{CR} of 4 l/h the and $\theta_{CL_{CR}}$ as an exponent describing the increase of CL_i with CL_{CR}.

The relevance of CL_{CR} for clearance is tested using the likelihood ratio test (Beal et al. 1992). The so-called full model 1 (alternative hypothesis) given in Eq. 46.3 is tested against the reduced model with $\theta_{CL_{CR}} = 0$ (null hypothesis) characterized by Eq. 46.2.

The more complex full model is accepted only if the objective function obtained with the full model is more favorable than the objective function obtained with the reduced model (see "Evaluation").

Concentration time courses can be simulated by the model and the demographic parameters for different dose regiments. The final administration of the drug has to be adjusted so that, e.g., 95% of the target population falls into the therapeutic window. If subpopulations differ too much, adjusted administration regiments have to be considered.

EVALUATION

The following criteria determine about the best model:

1. The OF (objective function: negative log of probability, $-2\ \ln(\text{Prob})$), calculated by NONMEM, is a measure for the deviation between the model prediction and the observed data. It enters into the likelihood ratio test as follows: if the OF of the full model minus the OF of the reduced model is smaller than -3.84, then the full model can be accepted at a significance level of $p < 0.05$ (Beal et al. 1992).
2. The observed concentrations plotted against the predicted concentrations had to be more randomly distributed around the line of unity.
3. The weighted residuals and the individual residuals plotted against the predicted concentrations had to show the most symmetric distribution around zero.

In order to validate the final model, the data set can be split randomly into two parts. The model is developed with one part, the index data set. With this model and the demographic data of the second part, the validation data set, observations for the validation data set can be predicted. The difference of predicted data and observations is a measure of the accuracy of the model. An alternative is the bootstrap method (Efron 1981).

MODIFICATION OF THE METHOD

Data from individuals drawn from a target population are not completely independent. Concentration time curves (longitudinal data) of a subject are considered to be driven by a functionality depending on individual parameter values. But what is the connection between the same parameters in different persons? Parts of it may be described by a functionality depending on demographic variables. In any case, unexplained intra- and interindividual random effects remain. Mixed effect modeling clearly distinguishes between these two sources of randomness.

Modifications of the method differ in the way they deal with these different levels of random effects, i.e., how they distribute or confound them. It should be noted that the different handling of random effects has also consequences for the fixed effects.

1. In a situation with many data from each individual drawn in an intersubject balanced manner, a two-stage method is very often used: each individual is fitted individually without considering the interindividual dependencies. In a second step, the parameters are resumed as population mean and standard deviation, often considered as interindividual variability. (STS (standard two-stage method), (Steimer et al. 1985)).
2. If only a few data per subject are available, they are sometimes pooled and considered as coming from one hyperanimal. If several observations are available at the same time, they are averaged, and means and standard deviations can be calculated. In a second step, the mean values are fitted to a pharmacokinetic model. (NAD (naive averaging data method) (Steimer et al. 1985)). A different naive technique is the NPD (naive pooled data) method proposed by Sheiner (Sheiner and Beal 1980). Again, all data are pooled but fitted in one step to a pharmacokinetic model. In both cases, intra- and interindividual random effects are confounded. An influence of covariates cannot be determined by this approach.

3. Mixed effect modeling deals with the situation in between. Inter- and intraindividual variabilities are separated and calculated within the same step. Interindividual random effects are calculated for those parameters for which this information can be drawn from the data set. In general, only one residual error is calculated. The method is very well suited for sparse and unbalanced data situations.

Population pharmacokinetics can be extended to pharmacodynamics and PK/PD modeling using a link model like an effect compartment (Sheiner et al. 1979). In huge clinical trials, only a limited number of patients can be included in a pharmacokinetic satellite study. The model is developed in this satellite. Knowing the demographic covariates of the patients in the whole study, concentration time curves and even effect time curves can be predicted.

Alternative software like NPEM uses nonparametric procedures for the statistical part of the models (Jelliffe et al. 1990).

CRITICAL ASSESSMENT OF THE METHOD

The NAD and NPD methods confound several sources of variability and very often give biased estimates of the mean values of the pharmacokinetic parameters (Steimer et al. 1985). But when the population is very homogeneous, the naive approaches already give reasonable results. The widespread STS method requires the estimation of a large number of parameters, reducing the degree of freedom and leading to over parametrization (large SEMs).

Mixed effect modeling is a very flexible one-step method. It can cope with many situations. It is the only method which can deal with sparse data and unbalanced data sparse situations. The method can start in preclinical phases with animal data. In phase I with a homogeneous population and many observations per individual, the structural model, dose linearity, and bioavailability are determined. In phase II and phase III, patients are investigated, and the demographic parameters should spread over a large range in order to determine the variability in the target population. The method is well suited to perform meta-analysis of several studies.

It should be emphasized that models are not the truth and that different models can describe the same data with the same accuracy. Whereas interpolation for doses or covariates is in general possible, extrapolations should be considered with care. Extrapolation with different models, if available, can give a feeling about the range for the observations to be expected.

Simulations should be used for the design of the next experiment (trial). The new observations should be compared to the prediction allowing improvement of the model in an iterative manner (Sheiner 1997).

EXAMPLE

Introduction

Levofloxacin is the l-isomer of the racemate ofloxacin, a quinolone antibacterial agent used worldwide to treat a wide range of infections. The PK profile of levofloxacin was first characterized in healthy volunteers. The following prior knowledge was obtained before the clinical study presented below. Levofloxacin is primarily excreted renally. Increasing doses of levofloxacin showed linear PK over the investigated dose range between 50 and 600 mg. The PPK of levofloxacin used in patients with respiratory tract infections was investigated by Tanigawara et al. (1995).

Objective

Can 500-mg levofloxacin given twice daily achieve the therapeutic goal of plasma levels above 2 mg/l, the MIC (minimum inhibitory concentration) in male and in female patients?

Materials and Methods

The PPK were analyzed in a subpopulation of 44 out of 314 patients with pneumonia being treated with levofloxacin. Patients received two daily doses of 500 mg for 10 to 15 days. Initially, the drug was given intravenously as an infusion for approximately 60 min. The switch from IV to oral treatment was suggested after a minimum of four IV doses. Three to five blood samples were taken from each patient, 199 blood samples in total.

The available concentration time data is typical for a clinical study: there are relatively few observations on each of a large number of patients, and samples are not taken at the same time points (sparse and unbalanced data). Neither the NAD method nor the STS method can be used. A one compartment model with absorption compartment and first order elimination was fitted to the data by mixed effect modeling with

NONMEM. Clearance and volume of distribution were described by

$$CL_i = \theta_{CL}\left(\frac{CL_{CR_i}}{4L/h}\right)e^{\eta_{CL_i}} \tag{46.4}$$

(Eq. 46.3 with $\theta_{CL_{CR}} = 1$)

$$V_i = \theta_V \left(\frac{WT_i}{70\ kg}\right)\ (1 + (2 - SEX_i)\theta_{SEX})\ e^{\eta V_i}. \tag{46.5}$$

The model uses CL_{CR}, WT (body weight [kg]), and SEX (1 = male and 2 = female) as covariates.

Alternatively, the volume model was simplified using LBM (lean body mass in kg) instead of WT and SEX. LBM is related to WT, HT (height in cm), and SEX in the following equation:

$$LBM\begin{pmatrix} male \\ female \end{pmatrix} = \begin{pmatrix} 1.1 \\ 1.07 \end{pmatrix} WT - \begin{pmatrix} 128 \\ 148 \end{pmatrix}\left(\frac{WT\ \ cm}{HT\ \ kg}\right)^2 kg. \tag{46.6}$$

The model for V (volume of distribution) given as

$$V_i = \theta_V\left(\frac{LBM_i}{50kg}\right)\ e^{\eta V_i} \tag{46.7}$$

needs one parameter, θ_{SEX}, less than the model given in Eq. 46.5. Now, the PPK model uses in total only two covariates, i.e., CLCR and LBM.

RESULTS

PK Differences Between Male and Female Patients?

The volume given in Eq. 46.5 as a full model (A) changes with $\theta_{SEX} = 0$ to a reduced model reduced model (B). To perform the likelihood ratio test, both models were fitted with NONMEM, and the OF of the full model (A) was 6.39 points lower than the OF obtained for the reduced model (B). This difference is highly significant, so the full model (A) is preferred when compared to a reduced model (B).

WT and SEX are combined in LBM. To simplify the model, we described the fixed effect on V only with LBM as a single measure of body size. Using Eq. 46.7 in model (C), we repeated the NONMEM fit and compared the OF obtained for model (C) with the previous two fits. Model (A) was still 3.1 points better than model (C). We preferred model (C) because it uses only body size while model (A) uses body size and sex as demographic covariates in the V model. Table 46.1 resumes the values of the PPK parameter vector including θ (vector of parameter, describing the fixed effect model), ω^2, and σ^2 calculated for model (C).

Table 46.1 PK parameters from mixed effect modeling using Eqs. 46.4 and 46.7. The absorption coefficient θ_{KA} was fixed to 1/h

	Parameter	Mean	SEM
Fixed effects θ	θ_{CL} [l/h]	5.3	0.3
	θ_V [l]	76	5
	θ_{KA} [1/h]	1	fix
Random effects ω^2	${\omega_{CL}}^2$	0.12	0.02
	${\omega_V}^2$	0.11	0.04
Residual error σ^2	σ^2	0.03	0.01

Concentration time curves for three individuals with different kidney functions CL_{CR} are shown in Fig. 46.1. The broken lines CL_{CR} represent the time-dependent CL_{CR} as a measure of the kidney function. For the subject shown in the center panel, the CL_{CR} decreases at 3.5 days causing a steep increase in the drug concentration. Dots are observations CONC (observed concentration), and full lines PRED (model predictions for the population with $\eta = 0$) correspond to the model predictions for a typical individual with a specific set of mean covariates CL_{CR}, WT, and SEX (fixed effects). The broken lines IPRE (model predictions for the individual subject with random η_i) are the individual predictions for the subject taking the random effects on volume and clearance into account.

Once the model is in place, simulations can be performed in order to find or to verify the optimal dose regimen.

In Fig. 46.2, mean C_{ss} (concentration at steady state), given in Eq. 46.8, as a function of CL_{CR} is shown.

$$C_{ss,i} = \frac{dose\ rate}{CL_i} \tag{46.8}$$

The circles correspond to the observations. The lines are calculated using the fit parameters and Eq. 46.2 for the 2.5%, 50%, and 97.5% quantiles. All

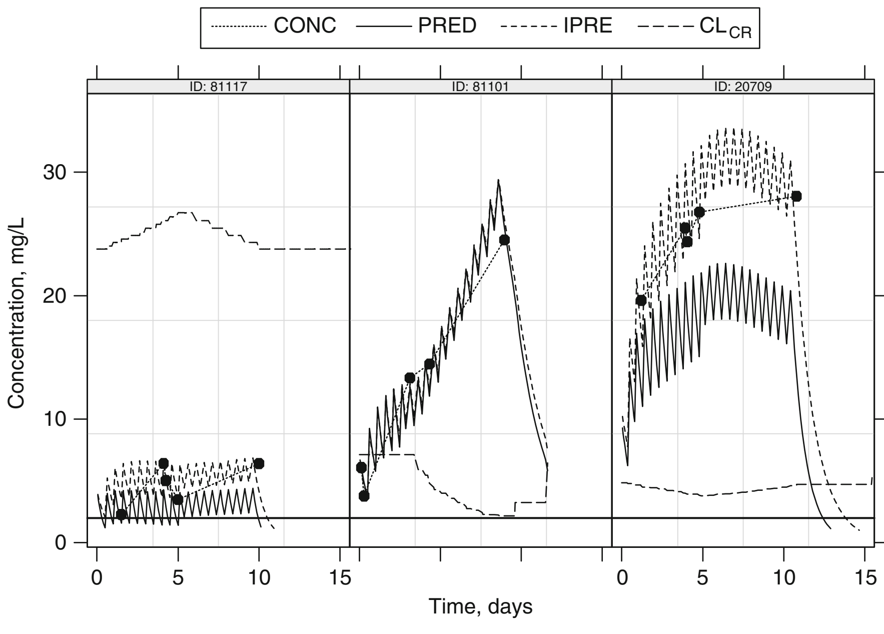

Fig. 46.1 Individual concentration time courses. *CONC* creatinine clearance; *PRED* model predictions for the population with $\eta = 0$; *IPRE* model predictions for the individual subject with random η_i; CL_{CR} creatinine clearance in l/h is calculated as left-hand scale *10/4

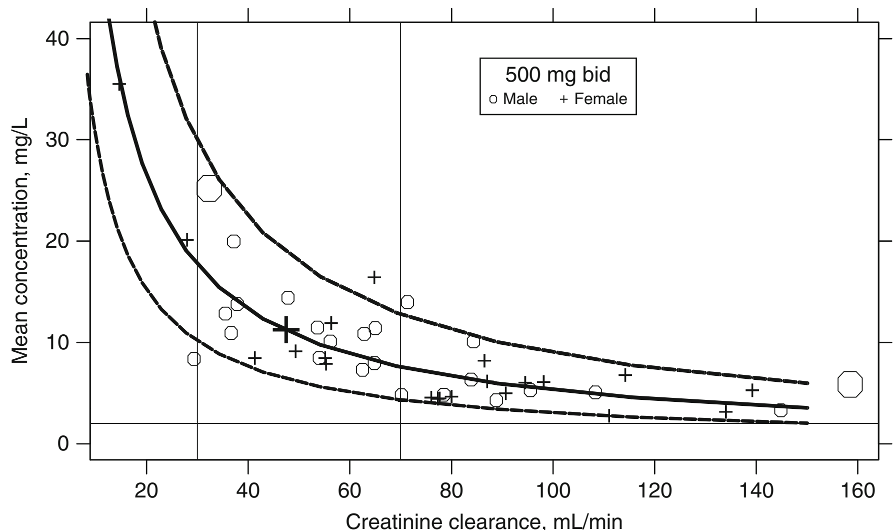

Fig. 46.2 Mean concentrations at steady state after twice daily 500-mg levofloxacin. The circles and crosses correspondent to the individual CL estimates in male and female patients, respectively. Three filled circles correspond to patients which PK is shown in Fig. 46.1. The lines are calculated using the fit parameters given in Table 46.1 and Eq. 46.2 for the 2.5, 50, and 97.5% quantiles. All except two individuals are within these limits. The vertical solid lines mark patients with creatinine clearances of 30 ml/min and 70 ml/min, curves stop at 150 ml/min

except two individuals are within these limits. As reveals from Fig. 46.2, the selected dose regimen of 500 mg twice daily achieves even in more than 95% of male and female patients with normal kidney function C_{ss} concentrations above the MIC of 2 mg/l.

Figure 46.3 shows the joint distribution of V and CL_{tot} (total clearance) for males and females as calculated by the model (C). Volume and clearance are distributed around mean values (center of the ellipse), and they are slightly correlated to

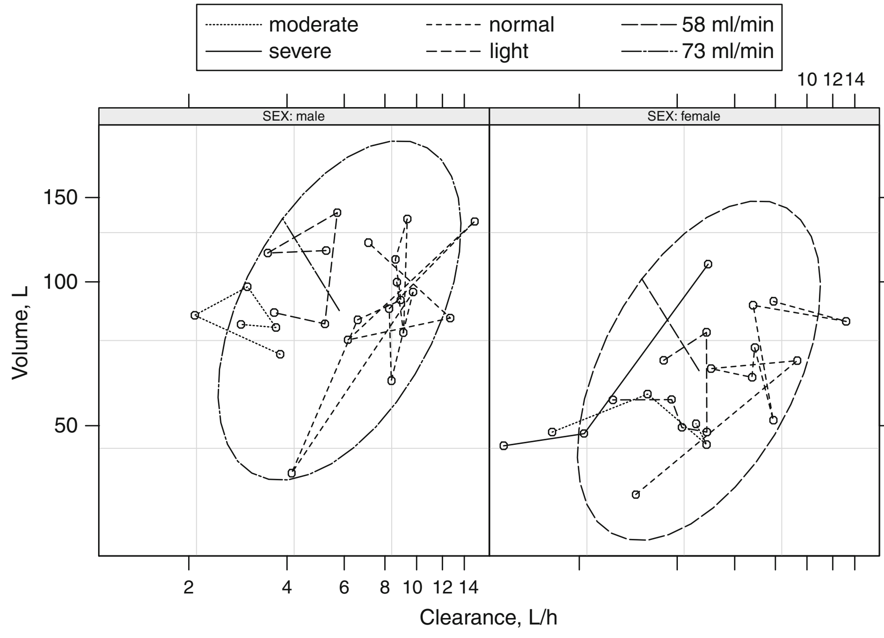

Fig. 46.3 Joint distribution of V and CL_{tot}. Ellipse joint 95% prediction interval in a subpopulation of male patients (CLCR = 72.53 ml/min and LBM = 57.63 kg) and in a subpopulation of female patients (58.32 ml/min and 43.12 kg). The individual V and CL_{tot} estimates calculated by NONMEM are grouped according to the degree of renal failure

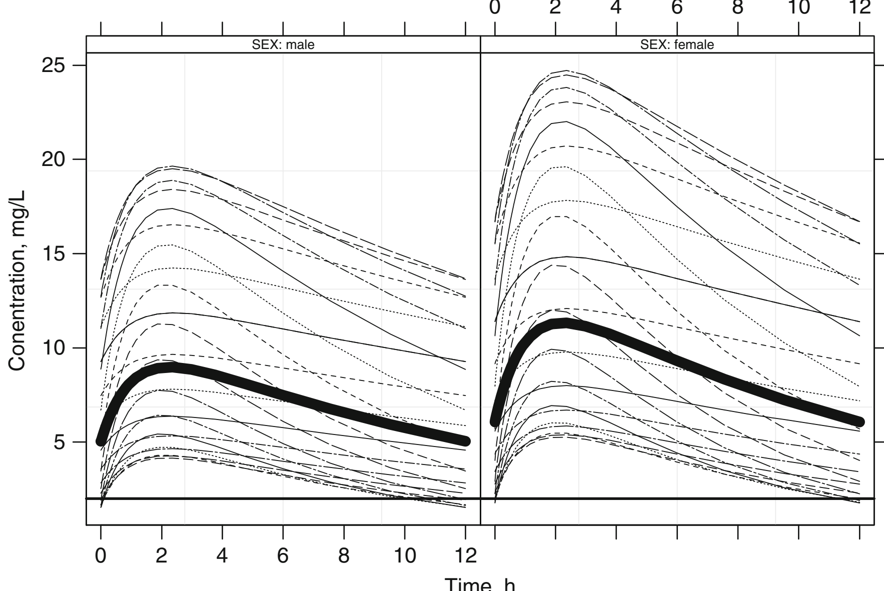

Fig. 46.4 Simulations of the concentration time course under steady state conditions as predicted by the model (C) for a 500-mg twice daily dose regimen. The broad line corresponds to the typical male (CLCR = 72.53 ml/min and LBM = 57.63 kg) and female (58.32 ml/min and 43.12 kg) patients. All other lines are calculated using only CL and V pairs of the 95% contour line of their joint probability of occurrence as shown in Fig. 46.3 as ellipses. The horizontal solid line marks the MIC of 2 mg/l

each other. The 95% contour line of their joint probability of occurrence is shown as ellipses for male and female.

Simulations of the concentration time course under steady state conditions as predicted by the model for a 500-mg twice daily dose regimen are shown in Fig. 46.4. The broad line corresponds to the typical male and female patients. All other lines are calculated using only CL and V pairs of the 95% contour line of their joint probability of occurrence as shown in Fig. 46.3 as ellipses. As reveals from Fig. 46.4, concentration time courses remain within an interval describing the concentrations expected in 95% of male or female patients.

DISCUSSION

The PPK approach uses all the data observed at all sampling times and from all subjects enrolled in the satellite study in a single step to extract the information necessary to optimize a dose regimen.

For the example of levofloxacin given twice daily 500 mg, 95% of male and female patients achieved the therapeutic goal and showed concentrations above 2 mg/l (MIC) for more than 10 hours of the 12-h dose interval. Due to their smaller volume of distribution, peak concentrations are higher, and half-lives are shorter in female patients. The different extents of accumulation as an effect of differences in half-lives become evident when comparing the through levels. The highest concentrations reached are still below the safety limits. Therefore, the same dose regimen for male and female patients was recommended.

PURPOSE AND RATIONALE

47.1 PKPD Modeling in Drug Development

A development project starts with someone identifying in a patient population an unmet medical need, which may offer a business opportunity. Even when successful treatments are available for the target disease, a medical need may exist when standard treatments fail or unacceptable adverse events (AE) occur after longtime treatment.

An unmet medical need was identified in the population of patients with rheumatoid arthritis (RA). RA belongs to the class of autoimmune diseases. Immunosuppressive drugs like methotrexate (MTX) were successfully introduced as RA standard therapy. However, after long-term treatment with MTX, severe AE like lack of efficacy or liver toxicity were observed.

In that situation, the patient could benefit from a new alternative treatment. As an alternative treatment, leflunomide (Lef) was developed and introduced as an immune-modulating drug into the market in 1998.

In the first part of this chapter, I will describe how medical knowledge about autoimmune diseases is transformed in a general PKPD model for immunosuppressive drugs (Bohl 2006).

In the second part, I will report about the use of the PKPD model during the development of Lef.

47.1.1 Model Described in Words

White blood cells play an important role in the immune defense of pathogens. In case of an infection, white

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_51,

© Springer-Verlag Berlin Heidelberg 2013

blood cells can grow very fast and can double their cell population within hours. Prior to cell division, the DNA content of the cell must be duplicated. A sufficient pool of nucleotides must be built. Pyrimidine is one important precursor for nucleotide formation.

In case of a normal infection, the body rapidly attacks and kills the invading infectious organism. In case of RA autoimmune disease, the immune attack cannot win. The attack is targeted against the body's own joint cartilage, which luckily cannot be destroyed completely. The surviving body's own antigen is continuously activating the immune system.

Immunosuppressive drugs like MTX reduce the immune activity, which otherwise would destroy the body's own joint cartilage. The mechanism of action is well known for MTX. MTX inhibits the pyrimidine neosynthesis. Lack of pyrimidine will reduce the neosynthesis of nucleotides. Lack of nucleotides is slowing down the growth rate of fast-dividing cells like the immune cells. Immune cells, like B- and T-lymphocytes, belong to the white blood cell population.

To build a PKPD model, we need to find first the right questions.

47.1.1.1 What Do We Know About the Disease States in RA?

The autoimmune response to the body's own joint cartilage leads to an increased growth rate of immunocompetent cells. The increased population of these cells attacks the cartilage even more efficiently, leading to accelerated destruction of joint cartilage. To reduce or even stop the autoimmune attack, our drug has to decrease the size of the attacking population of immunocompetent cells. The equilibrium size of the immune cell population during the chronic disease state has to descend to a lower equilibrium size during the drug treatment. The reduced clinical symptoms should increase the frequency of clinical success criteria like ACR20 in RA patients (Arnett et al. 1988). The PKPD model must include the dynamics of cell growth (PD model) and its interaction with the drug exposure (PK model). We assume that the increased size of the immune cell population is destroying the joint cartilage, which is causing severe RA symptoms. The goal of an immunosuppressive therapy is to reduce the size of the immunocompetent cell population and increase the probability of positive clinical outcome criteria.

After describing qualitatively the mechanism of the wanted drug action, we need to get more quantitative insight into the drug effects. We have to translate our words into mathematics. The result of our efforts will give us a PKPD model useful for optimizing immunosuppressive therapy in future clinical studies.

47.1.2 Mathematical Model

Let us start with the dynamics of cell growth. If resources are unlimited in the environment of a small biological cell population, its growth rate

$$\dot{x}(t) = k_f x(t) \tag{47.1}$$

is proportional to the actual size of the population $x(t)$. k_f is the growth rate constant per unit of time. Equation 47.1 describes an exponential growth of the population. The exponential growth will double the population size with a doubling time of $T_2 = log(2)/k_f$. A small number of cells grow independently from each other. Every cell can divide without limitation of resources.

However, with increasing size of the population, the resources in the environment will become more and more limited for the increasing population. The individual cells must share the same limited resources. If a group of cells occupy the resources, others have to wait for the renewal of resources, e.g., the neosynthesis of nucleotides.

Cells cannot divide unlimitedly anymore. The growth rate decreases. Before dividing, the cells must interact with each other. Verhulst introduced a negative quadratic interaction term in the exponential growth in Eq. 47.1. With increasing size, the growth rate is decreasing. The population is approaching an equilibrium state determined by the resources offered by the environment. Verhulst suggested the following equation:

$$\dot{x}(t) = k_f x(t) - k_d x^2(t) \tag{47.2}$$

with k_d as the fractional cell death per unit of time.

During the progress of RA, the immune cell population is growing due to the antigen stimulus. The population starts at an initial condition x_0 and approaches with time to its equilibrium population size K, which is given as

$$\dot{x}(t) = 0 \rightarrow \lim_{t \to \infty} x(t) = K = \frac{k_f}{k_d} \tag{47.3}$$

determined by the strength of the antigen stimulus.

Any maintenance treatment cares most on the equilibrium state conditions. In the light of a maintenance therapy, the equilibrium population size K is especially important to understand the Verhulst equation. Factoring out the expression $k_f x(t)$ and introducing the equilibrium population size K, we obtain a version of the Verhulst equation:

$$\dot{x}(t) = k_f x(t) \left\{ 1 - \frac{x(t)}{K} \right\} \tag{47.4}$$

which is the logistic differential equation (DG). The analytical solution of the Verhulst equation is given as:

$$x(t) = \frac{K}{1 + \left\{ \frac{K}{x_0} - 1 \right\} e^{-k_f t}}. \tag{47.5}$$

Both Eqs. 47.1 and 47.4 contain an exponential growth term $k_f x(t)$. While the doubling time T_D remains constant for exponential growth, the doubling time for the Verhulst equation prolongs more and more with growing population until an equilibrium state K of the population is reached. Growth and dying processes are now balanced out.

An equilibrium state will remain constant as far as the environmental condition remains unchanged. Changes of the environment will disturb the equilibrium. With increasing resources, the population will grow again until the additional resources are consumed. The goal of our immunosuppressive therapy is the opposite. We decrease the resources. After limiting cell division, the population starts to shrink until the smaller population can again balance the death rate loss.

The relation between $x(t)$ and K in Eq. 47.4 defines the sign of the growth rate. In case of a patient with autoimmune disease, we can differentiate three different states of the disease.

The disease state can

1. Progress, $x_0 < K \leftrightarrow \dot{x}(t) > 0$. Disease stimuli cause sigmoid growth with a positive cell turnover rate until the increased equilibrium size of the cell population K can respond with the requested immune activity.
2. Be stable, $x_0 = K \leftrightarrow \dot{x}(t) = 0$. The cell population remains constantly at the equilibrium size K with constantly increased immune activity. The cell turnover is balanced out.
3. Improve, $x_0 > \widetilde{K} \leftrightarrow \dot{x}(t) < 0$. After the start of an immunosuppressive treatment, a sudden lack of precursors slows down the cell growth rate. The now overcrowded cell population x_0 decreases with a negative turnover rate until the lower equilibrium size $\widetilde{K} < K$ with sufficient precursor production is reached.

47.1.3 Dynamics of Drug Effects on the Disease State

We assume that the probability of observing disease symptoms is directly related to the size of the immune cell population. Now we can start to think about the treatment effects in terms of the cell growth PKPD model described above. We assume the patients reached a stable equilibrium autoimmune disease state K before treatment starts. Unfortunately the size K of the immune cell population is increased by the autoimmune disease, causing severe damage of the joint cartilage and causing severe pain. The treatment idea is that decreasing the size of the immune cell population to a lower level $\widetilde{K}$ will attenuate the immune activity and immune attack of body's own tissue becomes less aggressive. The joint destruction slows down or stops. The body may even regenerate its damaged cartilage. Clinical symptoms in the patient should improve with time.

We start the treatment period from the baseline disease state K with severe symptoms before treatment. The drug will decrease the neosynthesis of required precursors for the cell division. The growth rate k_f will be reduced with increasing drug concentration $C(t)$. The drug effect on k_f is introduced by using the concentration-dependent inhibitor function $I(C(t))$ (Lambertus et al. 2005), which transfers the time dependency to $k_f^\star$ and to K^* as follows:

$$k_f^\star(t) = k_f \times I(C(t)) \tag{47.6}$$

$$K^\star(t) = \frac{k_f^\star(t)}{k_d} = K \times I(C(t)) \tag{47.7}$$

The link between PK and PD is described by the system of two linear DGs

$$PK \Rightarrow \dot{C}(t) = k_e C(t) + \frac{\dot{D}}{V}\sigma\left(t - T_{inf}\right) \qquad (47.8)$$

$$PD \Rightarrow \dot{x}(t) = k_f^{\star}(C(t))x(t)\left\{1 - \frac{x(t)}{K^{\star}(C(t))}\right\} \qquad (47.9)$$

using the ratio between the clearance CL and the volume of distribution V as pharmacokinetic elimination rate constant $k_e = \frac{CL}{V}$. The mean residence time (MRT) is calculated as the inverse of the elimination rate constant. We will use a constant infusion rate $\dot{D}$ as a step input function $\sigma(t–T_{inf})$ for the drug. During the infusion $\sigma(t \leq T_{inf}) = 1$ obtain the unity value, outside the zero value.

The solution of the Verhulst Eq. 47.5 holds only for a time-independent growth rate constant k_f. In case of a time-dependent change of $\widetilde{k_f}(t)$ as result of a time-dependent drug concentration, the solution of the system of two differential Eqs. 47.14 and 47.15 is much more complex than the solution given in Eq. 47.5. The dynamics of the growth rate inhibited by $\widetilde{k_f}(t)$ must be numerically calculated. However, if we reached a pharmacokinetic steady state with a constant steady state concentration C_{ss}, $\widetilde{k_f}(C_{ss})$ is a time-independent constant again dependent on the steady state concentration. The transition of the cell population from $x_0{=}K$ to $\widetilde{K}(C_{ss})$ is described by Eq. 47.5 using $\widetilde{k_f}(C_{ss})$ instead of k_f.

The extent of the enzyme inhibition depends on the ratio between the drug concentration and the drug potency IC_{50}. The sigmoid transition between no effect and full effect is well described using the logistic probability distribution. Enzyme inhibition may be limited to a maximum extent of I_{max}. The value range $0 < P_{logis} < 1$ of the logistic distribution describes an increasing inhibition with increasing drug concentration as follows:

$$I(C(t)) = 1 - I_{max} P_{logis}(C(t)) \qquad (47.10)$$

$$P_{logis} = \frac{e^{\eta}}{1 + e^{\eta}}, \quad \text{with} \quad \eta = logit(P) = S \times log\left(\frac{C(t)}{IC_{50}}\right) \qquad (47.11)$$

The reverse of slope S is the standard deviation of the logistic probability distribution P_{logis}.

The time dependency of the concentration-dependent inhibition of $\widetilde{k_f}(t)$ interconnects the PK and the PD of our PKPD system. Before introducing the inhibited growth rate constant into the PD system given in Eq. 47.4, we will make life easier by introducing dimensionless transformations of our variables. The dynamics of the DG system is easier overseen with the use of the following dimensionless variables:

$$\widetilde{t} = kt = \frac{t}{MRT}, \quad \widetilde{C} = \frac{C}{IC50}, \quad \widetilde{\dot{D}} = \frac{\dot{D}}{\dot{D}_{50}}, \quad \dot{D}_{50} = CL \times IC_{50} \qquad (47.12)$$

$$\widetilde{x} = \frac{x}{x(t=0)}, \quad \kappa = \frac{k_f}{k_e}, \quad \widetilde{K} = \frac{K^{\star}}{K} = I(\widetilde{C}) \qquad (47.13)$$

After transforming the system DGs 47.4 using dimensionless variables 47.12 and 47.13, we obtain the following equations:

$$\frac{d\widetilde{C}}{d\widetilde{t}} = -\widetilde{C} + \widetilde{\dot{D}} \qquad (47.14)$$

$$\frac{d\widetilde{x}}{d\widetilde{t}} = \kappa\widetilde{x}\left\{I(\widetilde{C}) - \widetilde{x}\right\} \qquad (47.15)$$

The new equilibrium disease state relative to the disease state before treatment is only dependent on $\widetilde{C}$, the ratio between drug concentration and drug potency. The dynamics of the transition depends on the ratio κ between the PD and the PK rate constants. Figure 47.3 illustrates the dynamics of the described PKPD model.

After the start of drug treatment, the dynamics of PK and PD progress simultaneously to their equilibrium states. To estimate the time needed until the onset of efficacy is obtained, we need to solve differential equation system given in Eqs. 47.14 and 47.15. Because the inhibition is changing with increasing concentration (PK 47.14), the turnover rate constant of the PD system 47.15 is time dependent as well. In such complex situation, using numerical methods is best applicable to solve the DG.

47.1.4 PD Dynamics When PK is at Steady State

Daily administration of the maintenance dose can often be approximated by a constant drug infusion rate $\dot{D}$. Without use of a loading dose, the steady state concentration $\widetilde{C}_{ss} \approx \dot{\widetilde{D}}$ is reached after approximately $\widetilde{t} = 3.7$ corresponding to 3.7 MRT (mean residence time, $MRT = k_e^{-1}$) time units. With a constant concentration, the inhibition function I will cause a constant decrease of k_f as well. With $k_f^\star$ no longer time dependent, we can again use the analytical solution of Verhulst Eq. 47.5. Using $\widetilde{x}(t)$ and the inhibited constants K^* and $k_f^\star$, Eq. 47.5 describes the change of the disease state relative to the disease state before treatment.

The PK time scale kt is no longer important because $\kappa \times t^* = k_f t$. We can return to the PD typical time $k_f t$. The patient is assumed in equilibrium disease state $\widetilde{x}_0 = 1$ before the treatment. The treatment period starts the transition from $\widetilde{K} = 1$ to the new equilibrium disease state $\widetilde{K} = I(\widetilde{C}_{ss}) < 1$.

We can establish the PK steady state from the start of treatment using an appropriate loading dose. If we are able to extract the drug after end of infusion almost immediately, the inhibition of the turnover rate constant would stop immediately. The undisturbed turnover rate constant k_f would determine the return to the pretreatment equilibrium state K. With $\widetilde{x}_0 = \widetilde{K}$, the transition back to the pretreatment disease state will again follow the Verhulst solution given in Eq. 47.5.

47.1.5 Equilibrium Disease State During PKPD Steady State

The PD system will follow the PK system in approaching its equilibrium state. The equilibrium disease state of the full PKPD system is only dependent on the inhibitor function I Eq. 47.10:

$$\lim_{t \to \infty} \widetilde{x}(t) = I(\widetilde{C}_{ss}) \tag{47.16}$$

In the following chapter, we will show the usefulness of the described PKPD model during the development of leflunomide for patients with rheumatoid arthritis (RA).

EVALUATION OF THE METHOD

47.2 PKPD of Leflunomide

Like methotrexate MTX, Lef (Rozman 2002) is used as immunosuppressive therapy in rheumatoid arthritis. Both are inhibiting the pyrimidine neosynthesis. The mechanism of action, although similar, revealed core enzymes, which are different between both drugs. Teriflunomide, the active metabolite of Lef, inhibits the dihydroorotate dehydrogenase DHODH enzyme in the metabolic pathway of pyrimidine neosynthesis.

47.2.1 Drug Potency for Enzyme Inhibition

To know the target enzyme is very important to estimate drug potency IC50, which determines the target concentration range of drug action. In preclinical experiments, the DHODH inhibition of various Lef concentrations was investigated. Experiments were performed using human DHODH enzyme and human cell cultures. Both Lef and its active metabolite teriflunomide are more than 99% bound to plasma proteins. Protein binding was found similar between healthy subjects and patients with RA. The potency IC50 was approximately 10 mg/L total concentration. The results for the slope $S \approx 5$ remained imprecise. The influence of S on the relationship between extent of inhibition and dose rate is shown in Fig. 47.1. The sigmoid relationship between the relative enzyme inhibition I and the dimensionless dose rate $\dot{D}^\star$ for S values between 1 and 6 is shown in the left panel. Inhibition up to 90 % would need for S values between $2 \le S \le 5$ a dimensionless dose rate $1.5 \le \dot{D}^\star \le 3$. For $S < 2$, the sigmoid curves are rather similar.

47.2.2 Probability of Success or Failure

We assume the change $I(\widetilde{C}_{ss})$ in the disease state $K \to K^*$ is proportional to the change of the probability of observing clinical symptoms like pain, number of swollen joints, and inflammation indicators. The change of clinical symptoms is summarized as a binary variable like ACR20 (Arnett et al. 1988), with P(Y = y) as the probability of observing

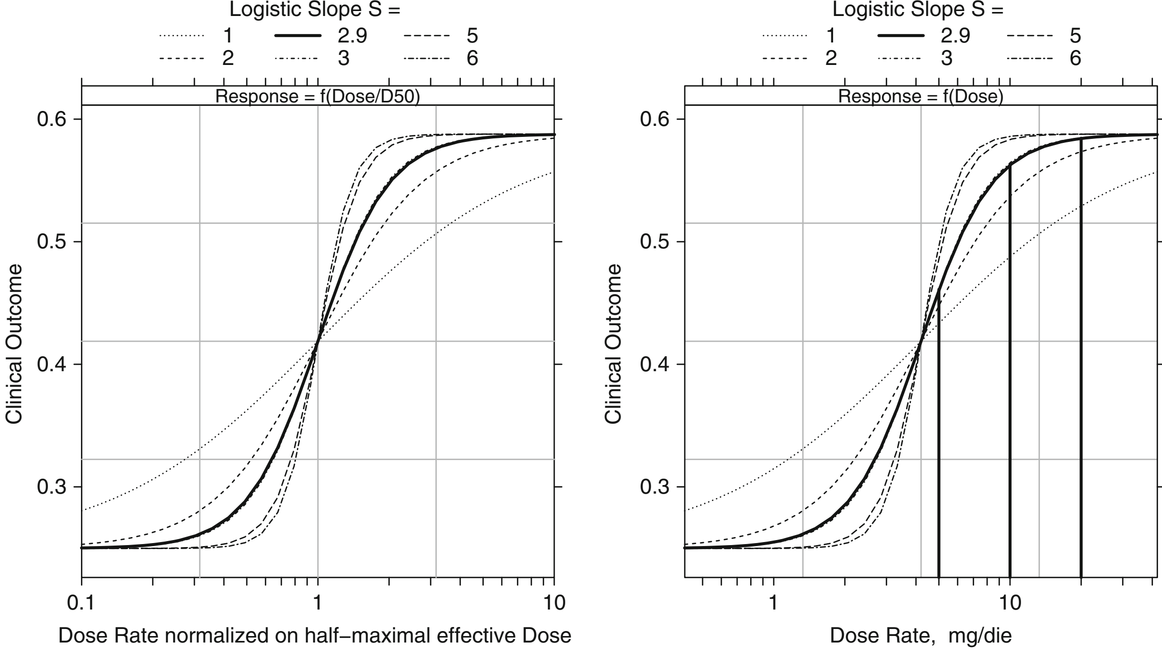

Fig. 47.1 Relationship between the D50-related dose rate D^* and drug response. The dose rate for a target response rate is influenced by the steepness of the logistic curve S = 1:6

a success (y = 1) or a failure (y = 0) as treatment effect. Clinical outcomes are compared to the pretreatment disease equilibrium states.

The success probability is given as the sum of the drug and placebo effects (see (Collett 2003), page 117). We used the following extended Aboth's formula:

$$P_i = P_0 + (P_{max} - P_0) \times P_{logis}\left(\tilde{\dot{D}}_i\right) \quad (47.17)$$

$$P(Y = y) = P_i^y \times (1 - P_i)^{1-y}; y = \{0, 1\} \quad (47.18)$$

P_{max} and P_0 are the maximum values for the probability of success observed in the treatment group and placebo group, respectively.

Appropriate dose regimen should at least reach the range of IC50 concentrations. The pooled phase I data were analyzed using the population approach. The dose rate achieving 50% of the maximum inhibition is given as:

$$\dot{D}_{50} = CL \times IC_{50} \quad (47.19)$$

Using the population mean estimate of the clearance CL = 0.6 L/day and the IC50 = 10 mg/L, we obtained a target dose rate of $\dot{D}_{50} \approx 6\,\text{mg/day}$ (Weber and Harnisch 1997a). Simulations of dose regimens of 5, 10, and 25 mg/day revealed reasonable exposure to cover active concentrations in the range of IC50 (see Fig. 47.1, right panel).

47.2.3 Clinical Outcome at PKPD Equilibrium

A clinical dose finding study was performed comparing the effect of 5-, 10-, and 25-mg daily Lef doses against placebo. Approximately 100 patients with severe RA were treated in each subgroup for 6 months (Balant and Aarons 1997; Mladenovic et al. 1995; Weber and Harnisch 1997b).

The treatment effect was estimated at monthly visits. The ACR20 criterion was chosen as primary clinical outcome variable. ACR20 summarizes 6 variables to a single binary response of success or failure. ACR20 was estimated at every visit. Only the last visit data was used to prove clinical efficacy of Lef (see Table 47.1).

The maximum success rate was $P_{max} = 0.58$. There was a remarkable placebo response of $P_0 = 0.25$. The

Table 47.1 Data used to calculate the relationship between dose/concentration and effect at steady state after 6 months of treatment

Dose mg/day	0	5	10	25
No. of patients treated	102	95	100	101
No. of successful outcome	25	32	56	59
Fraction of success %	24.5	33.7	56.0	58.4

difference (P_{max}-P_0) in the probability of success should be dependent on drug exposure.

The PK data obtained simultaneously was analyzed using the population approach. The clinical outcome data was analyzed by a logistic regression analysis (Groß 2010) using Eq. 47.17. The binary outcome data was used as dependent variable and the steady state concentration C_{ss} as predictor variable.

We assumed PK steady state for all patients after 6-month treatment. We estimated the individual steady state concentration $C_{ss,i} = \dot{D}_i / CL_i$ using the Bayesian estimates calculated from the observed individual concentration data and the population PK results. The following mean parameter estimates and the coefficient of variation CV diagonal of the covariance matrix:

$$\theta_{PK} = \{CL = 0.06/\text{day},\ \ V = 10\,L,\ \ k_a \approx 1\,h\} \tag{47.20}$$

$$CV_{PK} = \{CL = 0.6,\ V = 0.2,\ k_a = 0\} \tag{47.21}$$

$$\theta_{PD} = \{P0 = .25,\ P_{max} = 0.58,\ IC_{50} = 10\,mg/L,\ S = 5\} \tag{47.22}$$

$$CV_{PD} = \{P0 = 0,\ P_{max} = 0,\ IC_{50} = 0.2,\ S = 0\} \tag{47.23}$$

were estimated.

The relationship between the probability of success and failure, respectively, and the steady state concentration $C_{ss,i}$ is shown in Fig. 47.2. Summarizing the complete data, the full relationship is shown in the right panel. The data obtained for each treatment group is shown separately in the left panel. Although the success fraction obtained in the 10- and 25-mg dose group was not significantly different, the PKPD analysis revealed a relevant fraction of patients missing the full potential of the drug after 10-mg maintenance dose. The 25-mg dose group got the full benefit of leflunomide. However, an increased frequency of increased liver enzymes was observed. On the basis of this PKPD analysis, we decided to investigate 20 mg daily in the large clinical phase III trial (Horn and Oed 2003; Poor and Strand 2004).

47.2.4 Onset of Efficacy

The cell population model given in the differential equation system for the PK Eq. 47.14 and the PD Eq. 47.15 part and the estimated population PKPD parameters given in Eqs. 47.20, 47.21, 47.22, and 47.23 were used to simulate various dose regimens from 1 to 40 mg/day with and without loading doses. The PK and PD time courses for typical patients are shown in Fig. 47.3. The upper panels show the courses without the lower panels with loading doses.

Comparing the maintenance dose results with and without loading doses revealed an earlier onset of efficacy for lower-dose regimens. We accepted the time needed to reduce the relative disease state by ≈50 % as onset of efficacy. The results of simulations are given in Tables 47.2 and 47.3 without loading dose and with loading dose, respectively. For 40- and 20-mg daily onset of efficacy needed independently of a loading dose given or not given approximately 1.9 MRT units. However, for lower-maintenance dose regimens, a loading dose reduced the time to onset of efficacy slightly. Administering 10 mg daily, an additional loading dose shortens the time interval from 2.86 to 2.4 MRT units.

Increasing the maintenance dose from 10 to 20 mg daily alone reduced the time to onset of efficacy from 2.9 to 1.9 MRT units. The MRT of Lef was ≈25 days. Onset of 80% of efficacy using a maintenance dose of 10 and 20 mg daily is expected after 7 and 10 weeks, respectively. A single MRT unit of 25 days is clinically relevant for RA patients suffering severe pain. Because the coefficient of variation was 60% for the between-subject variability of the clearance, the MRT, as ratio between volume of distribution and clearance, is highly variable too. In extreme cases, the MRT was longer than 2 months. In such patient, starting the Lef treatment with 10 mg daily instead of the recommended 20-mg maintenance dose would delay the onset of efficacy for 2 months.

The effects of various loading doses alone were shown in Figure 47.4. A fast and extended disturbance

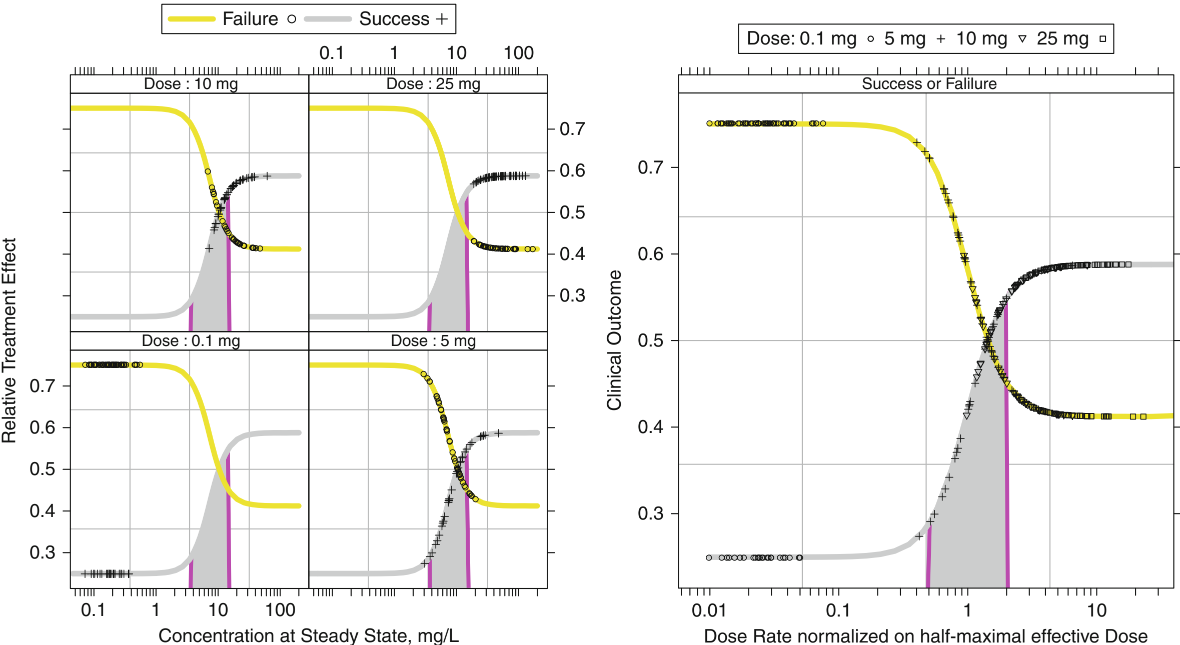

Fig. 47.2 Relationship between clinical outcome and drug exposure after 6 months of treatment. *Left panel*: complete data split per treatment group. Target steady state concentration ranges between 4 and 14 mg/L linked to 30 and 55% success, respectively. *Right panel*: complete data. Target standardized dose $\frac{\dot{D}}{CL \times IC_{50}}$ ranges between 0.5 and 2. To show the placebo data, a very low ineffective dose was used. Success data is following the increasing and failure data following the decreasing sigmoid curves

of the equilibrium disease state is followed by a slow return to the baseline. Drug concentration was almost diminished during the return to baseline. The return to baseline is determined predominantly by the dynamics of the PD system alone.

Our PKPD analysis estimated a turnover time for our PD system of approximately 17 days (Danhof and Steimer 1998; Weber and Harnisch 1998). The PK turnover time or MRT was approximately 25 days. We decided to investigate a dose rate of 20 mg daily in phase III. To obtain the onset of efficacy as early as possible, we started treatment with a loading dose. For a typical patient, an onset of efficacy after 6–8 weeks and an almost maximum probability of success (55%) were observed (Poor and Strand 2004).

47.3 Summary

The typical PKPD approach is describing the relationship between an administered dose and the observed clinical effects. Ideas about new innovative treatments are first described qualitatively in words. The PKPD approach should use all ideas and scientific knowledge as elements of the PKPD model. Using mathematical models helps thinking more quantitatively. PKPD modeling is always a learning process.

Autoimmune diseases are chronic diseases because the body's own antigen cannot be destroyed completely. The antigen continuously stimulates the immune system. A chronic increased population of immune cells is causing hyperactivity against the body's own structures. In case of RA, the joint cartilage is damaged. Inflammation and pain are the typical clinical symptoms.

Knowing about the circumstances of the disease, we can translate our knowledge into mathematics. PKPD modeling is the use of mathematics in medicine. The increased population of immune cells is the basic problem of autoimmune diseases. The right answer was found with immunosuppressive drugs reducing the critical population moderately.

Preclinical PKPD experiments with Lef revealed an antiproliferative effect on cells. Immune cells are

fast-dividing cells which are sensitive to antiproliferative effects.

The growth rate of such population is well described using the Verhulst equation. The PD effect of Lef inhibits the formation of precursors required for cell division. The size of the immune cell population shrinks, and the autoimmune attack against the body's own tissues is attenuated.

In our PKPD model for Lef, we assume that the probability of observing a clinical success is a linear function of the extent of the decrease of the immune cell population. The disease improves and the clinical outcome criteria will change more frequently to success.

The available PKPD model with the mean population parameter and its variance were used to predict the dose regimen for the successfully finished phase III study. The PKPD results obtained from the phase III data were important for the labeling and the question and answer process during the submission. Lef is on the market since 1998.

Safety Toxicology

48 Safety Toxicology: Introduction

Dieter Mayer

In 2006, the first Edition of *Drug Discovery and Evaluation. Safety and Pharmacokinetic Assays* was published by Springer. As methodologies of safety assays developed rapidly it appeared necessary to work on a second edition. The work on the second edition was initiated by our friend and honorable teacher Prof. Dr. Gerhard Vogel, Frankfurt, who passed away last year. Therefore, I would like to devote this section to him respectfully.

Major additions to the methods available at the end of 2005 happened in the area of in vitro toxicology, such as assays in isolated cells (e.g., renal cells). Phospholipidosis, hepatic cholestasis, and mitochondrial dysfunction were considered as important endpoints and new assays were developed.

In the area of genotoxicity, no major changes were noted with one small exception: the in vivo Comet Assay, which is used increasingly. Relevant protocols were developed for a large variety of tissues which can be used in the Comet assay.

With regard to reproductive effects, methodologies were enriched by OECD guidelines for combined studies with reproductive and classical toxicity endpoints. However, these new guidelines are mainly adopted in the area of industrial toxicology (REACH). In summary, the reproductive toxicology methods seemed to be rather stable.

No major methodologies were added in the field of in silico methods. However, efforts were conducted in order to further evaluate the predictive value of in silico methods such as MulticCASE and DEREK.

49.1 General Considerations

The *International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use* (ICH) is a project that brings together the regulatory authorities of *Europe*, *Japan*, and the *United States* and experts from the *pharmaceutical industry* and academia in the three regions to discuss scientific and technical aspects of pharmaceutical product registration of small molecules and biotechnology-derived compounds.

The International Conferences on Harmonization continue their endeavor to harmonize the regulatory recommendations for the development of pharmaceutical compounds by meetings of experts from the three supporting regions twice per annum. No big conferences are being organized any longer, because they are considered to be too expensive. The global cooperation continues by limited numbers of experts and Topic Leaders who publicize the progress of their documents in the internet www.ich.org. New guidelines have come into existence and older ones are being updated and improved. This holds true for all disciplines like Quality, nonclinical Safety, and Efficacy. This chapter will refer to the existing guidelines and report about the newer developments relevant for nonclinical Safety. ICH has produced a comprehensive set of safety Guidelines to uncover potential risks like carcinogenicity, genotoxicity, and reprotoxicity. ICH created a breakthrough with functional nonclinical testing strategy for assessing the QT interval prolongation liability: the single most important cause of drug withdrawals in recent years. With multidisciplinary guidelines ICH implemented crosscutting topics which do not fit uniquely into one of the Quality, Safety, and Efficacy categories.

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_53, © Springer-Verlag Berlin Heidelberg 2013

These multidisciplinary guidances include, e.g., the ICH medical terminology (MedDRA), the Common Technical Document (CTD), and the development of Electronic Standards for the Transfer of Regulatory Information (ESTRI).

Toxicology and safety pharmacology studies support the detection of undesirable adverse effects of pharmaceutical or chemical compounds and identify hazards; they describe the type and degree of toxicity and asses the risks. They support the management of the risks in humans, when participating in clinical trials or later as patients after market authorization, and analyze the mechanisms behind the alterations; they extrapolate preclinical hazards to humans and finally help to communicate these risks to populations concerned with exposure of that particular substance.

Toxicology therefore contributes to the safe use of pharmaceutical compounds in humans and facilitates the acceptability of submitted documents by regulatory agencies and later as therapeutic principles by patients.

For the safety of pharmaceutical compounds, a great number of in vitro and/or in vivo experiments are being conducted today. Test strategies for toxicological investigations have been refined and the extrapolation of preclinical results to humans improved. The prevention of toxic events in man became the main purpose of preclinical experimentation.

Considerable differences were observed in the creation of guidance and legal conditions. Accordingly, in different regions differently designed studies were conducted, but the repetition of similar studies in different regions did not support the safety but only increased the number of animals being used.

Accordingly, public resistance and concerns among researchers increased the desire to harmonize test procedures and recommendation worldwide. With the creation of the International Conferences of Harmonization (ICH) in 1989 these initiatives were channeled into a global continuing process.

The ICH focuses on guidances for Quality, Preclinical Safety (= Toxicology), and Efficacy (clinical effective substances) of pharmaceutical compounds. This section illustrates all ICH Guidelines important for the safe use of drugs worldwide.

49.2 Background to the ICH Conference

The International Conferences was jointly supported and organized by the Commission of the European Communities (CEC), the US Food and Drug Administration (FDA), the Japanese Ministry of Health and Welfare (MHW), together with the pharmaceutical industry, as represented by the International Federation of Pharmaceutical Manufacturers Associations (IFPMA), the European Federation of Pharmaceutical Industry Associations (EFPIA), the US Pharmaceutical Manufacturers Association (PMA), and the Japanese Pharmaceutical Manufacturers Association (PMA).

Many important initiatives have been undertaken between regulatory authorities and industry associations, particularly on a bilateral basis, to promote harmonization of regulatory requirements between the three regions Japan, USA, and the European Community. ICH owes much to these initiatives of experts during international symposia.

The Main Objectives of the ICH:

1. To provide a forum for a constructive dialogue between regulatory authorities and the pharmaceutical industry on the real and perceived differences in the technical requirements for product registration in the CEC, USA, and Japan.
2. To identify areas where modifications in technical requirements or greater mutual acceptance of research and development procedures could lead to a more economical use of human, animal, and material resources, without compromising safety.
3. To make recommendations on practical ways to achieve greater harmonization in the interpretation and application of technical guidelines and requirements for registration.

49.3 Preparatory Activities for ICH Conferences

A Steering Committee was appointed with members from EU, FDA, MHW, EFPIA, JPMA, PMA, and IFPMA, with observers from WHO and from the regulatory authorities of Canada and Switzerland (for EFTA).

The Steering Committee set up three joint industry/regulatory Expert Working Groups to deal with the technical aspects of the three main subject

areas—Quality, Safety, and Efficacy, these were discussed in three parallel workshops during the conferences. Each of the Expert Working Groups has members, representing EU, FDA, MHW, EFPIA, PMA, and JPMA. With advice from these technical Working Groups, the Steering Committee was responsible for the selection and prioritization of the topics discussed at the Workshops at the ICH conferences.

The International Conference on Harmonization differs from many other harmonization initiatives in that it has a recognized status and is backed by a commitment on the part of both industry and regulators. Commitment to these objectives, set out in the Terms of Reference, was reaffirmed by the Steering Committee in a statement issued following the meeting held in Tokyo, October 1990.

49.4 Success of the ICHs

There is considerable success of the international discussions and constructive solutions documented in the guidelines. There are more than 36 guidelines focusing on issues concerning the quality of compounds. There are more than 10 guidelines dealing with safety issues to be solved during development or later for marketing authorization and there are more than 20 guidelines dealing with problems of efficacy during clinical trials or after marketing authorization. Implemented guidelines are summarized in the following (Tables 49.1–4).

49.5 Description of the ICH Guidelines on Preclinical Safety

49.5.1 Carcinogenicity

In the following a survey is given in regard to the guidelines on preclinical safety.

There are a number of endpoints which cannot be tested in humans, these are mainly: genotoxicity, teratogenicity, and cancerogenicity. Especially, the cancerogenic risk can usually not be tested in humans, it is ethically forbidden and such a risk for patients is unacceptable.

The testing for carcinogenic potential today employs short-, mid-, and long-term studies in rodents, which have a relatively high power of predictivity for the carcinogenic risk in humans.

49.5.1.1 General Regulatory Background

Treatment with compounds associated with carcinogenic potential is unacceptable for banal indications; for severe indications like life-threatening cancer diseases the treatment with carcinogenic compounds often does not increase the overall risk of the underlying disease, especially when end-stage patients with limited life expectancy are being treated.

Carcinogenicity studies are the longest (lifelong or of 2 year duration) and most expensive (approximately 1.5–4 million dollars or Euros) preclinical studies. They should therefore be well designed and conducted in such a way that they clearly indicate any risk involved. These conditions explain why a great number of international and regional guidelines exist and give best advice for the researchers.

49.5.1.2 Guideline on the Need for Carcinogenicity Studies of Pharmaceuticals (S1A)

This guideline was adopted in 1997 and implemented in all regions.

The objectives of carcinogenicity studies are:

- To identify a tumorigenic potential in animals
- To assess the relevance of these identified risks for humans. Any cause for concern derived from laboratory investigations, animal toxicology studies, and data in humans, may lead to a need for carcinogenicity studies

Carcinogenicity studies should be performed for any pharmaceutical whose expected clinical use is continuous for at least 6 months. Certain classes of compounds may not be used continuously over a minimum of 6 months but may be expected to be used repeatedly in an intermittent manner. For pharmaceuticals used frequently in an intermittent manner during the treatment of chronic or recurrent conditions, carcinogenicity studies are generally needed. Examples of such conditions include allergic rhinitis, depression, and anxiety.

Pharmaceuticals administered infrequently or for short duration of exposure (e.g., anesthetics and radiolabel imaging agents) do not need carcinogenicity studies unless there is cause for concern.

Carcinogenicity studies may be recommended if there is cause for concern, e.g., due to:

- Previous demonstration of carcinogenic potential in the product class that is considered relevant to humans.
- Structure-activity relationship suggesting carcinogenic risk.
- Evidence of preneoplastic lesions in repeated dose toxicity studies.
- Long-term tissue retention of parent compound or metabolite(s) resulting in local tissue reactions or other pathophysiological responses.
- Unequivocally genotoxic compounds need not to be subjected to long-term carcinogenicity studies. However, if such a drug is intended to be administered chronically to humans a chronic toxicity study (up to 1 year) may be necessary to detect early tumorigenic effects. In practice, this option has not been used since 1997. Main concern of industry is the lack of historical comparison data. The tumor evaluation was always based on 2 year data.
- In instances, where the life expectancy in the indicated population is short (i.e., less than 2–3 years) no long-term carcinogenicity studies may be required. For example, oncolytic agents intended for treatment of advanced systemic disease do not generally need carcinogenicity studies. It is assumed that the limited life

expectancy is too short for the new development of a neoplasia.

- In cases, where the therapeutic agent for cancer is generally successful and life is significantly prolonged, there may be requirements to provide knowledge about the tumorigenic risk.
- When such pharmaceuticals are intended for adjuvant therapy in tumor free patients or for prolonged

Table 49.5 S1B: Basic principle for testing the carcinogenic potential

One long-term rodent carcinogenicity study plus
One short- or medium-term study that
Supplements the long-term carcinogenicity study and
Provides additional information not readily available from the long-term assay

use in noncancer indications, carcinogenicity studies are usually needed.

- Pharmaceuticals showing poor systemic exposure from topical routes in humans may not need studies by the oral route to assess the carcinogenic potential to internal organs.
- Carcinogenicity studies are not generally needed for endogenous substances, when given essentially as replacement therapy (i.e., physiological levels), particularly, where there is previous clinical experience with similar products (e.g., animal insulins, pituitary hormones).

49.5.1.3 Testing for Carcinogenicity of Pharmaceuticals (S1B)

S1B informs about the testing strategies, this guideline was adopted and implemented in 1997.

Historically, the regulatory requirements for the assessment of the carcinogenic potential were based on the conduct of long-term carcinogenicity studies in two rodent species, usually the rat and the mouse. It was the mission of ICH to examine whether this practice could be reduced without compromising human safety. The discussion in the Expert Working Group soon revealed that the rule of testing in two species had to continue, the American consumer societies demanded continuation with the same standard of safety, based on two species testing.

As the new experimental approach to testing for carcinogenic potential, a basic scheme was set up to comprise one long-term rodent carcinogenicity study, plus one other study of the type that supplements the long-term carcinogenicity study and provides additional information that is not readily available from the long-term assay (Table 49.5).

The species selected should be appropriate, based on considerations on pharmacology, repeated-dose toxicology data, metabolism (see also Guidelines S1C and S3A), toxicokinetics (see also Guidelines S1C, S3A, and S3B), and route of administration (e.g., less common routes such as dermal and inhalation). In the absence of clear evidence favoring one species, it is recommended that the rat be selected for the long-term study.

Additional tests may either be short- or medium-term in vivo rodent test systems, usually using the mouse. These models of carcinogenesis may use transgenic or neonatal rodents. The guideline also includes models of initiation promotion in rodents; but these models are today considered to be useful models for hepatic carcinogenesis or adequate mechanistic studies, but not as assays appropriate as general screen for drug-induced carcinogenesis.

A long-term carcinogenicity study in a second rodent species (e.g., mice) is still considered acceptable. This strategy is often used, because of the long-time experience with this model for decades and the rich historical data base.

The guideline describes in the "Notes" important information about the new models. Note 1 informs about the SHE assay; Note 2 on conditions to limit testing with one species only: if the findings of a short- or long-term carcinogenicity study and of genotoxicity tests and other data indicate that a pharmaceutical clearly poses a carcinogenic hazard to humans, a second carcinogenicity study would not usually be useful; Note 3 provides details about the short- or midterm models. Table 49.6 is a representative list of some approaches that may meet these criteria.

Evidence of tumorigenic effects of the drug in rodent models should be evaluated in light of the tumor incidence and latency, the pharmacokinetics of the drug in the rodent models as compared to humans, and data from any ancillary or mechanistic studies that are informative with respect to the relevance of the observed effects to humans.

The results from any tests cited above should be considered as part of the overall "weight of evidence" taking into account the scientific status of the test systems.

These new models have been accepted by Regulatory Agencies like FDA, EMA, and Japan. Most frequently, TgHras2 and p53 knock out models are being used, both models are considered suitable for detecting genotoxic potential, TgHras2 in addition also nongenotoxic mechanisms. XPA model is susceptible to faults, e.g., UV light, and is not recommended by regulators any longer (Table 49.7).

Table 49.6 New Approaches for testing the carcinogenic potential

Approach	Including
Several transgenic mouse assays	σp53+ / − deficient model
	σ Tg.AC model
	σ TgHras2 model
	σ XPA deficient model, etc.
The neonatal rodent tumorigenicity model	

Table 49.7 Transgenic mouse models

Model	Including
Activated oncogenes	TgHras2 model (Japan)
	Tg.AC skin model (USA)
	Also gavage
Inactivated tumor suppressor gene	p53 knock out (=p53+ / −) model (USA)
Inactivated DNA repair gene	XPA− / − (NL)

Table 49.8 General design of long-term cancerogenicity studies

Aspect	Parameters
Species	Rats, mice, rarely hamster
Duration	24 month rats, 24 months mice
Route	As in clinical conditions, in feed, water, by gavage, inhalation
Dose levels	Mostly 3, mostly with a factor (e.g., 1:3:9)
Animal numbers	50/group/sex
Results available	Prior to NDA
Cost	1.0–1.5 million Euros

The FDA considerations for assay selection are:

- P53+/−: If clearly or equivocally genotoxic
- TgAC: For dermally applied products
- Neonatal: If clearly or equivocally genotoxic
- TgRasH2: For genotoxic or non-genotoxic products

The EU evaluation as discussed in the Safety Working Party EMEA reaches the following conclusions:

- p53 and Tg.RasH2 are equally sensitive to genotoxic compounds (some false positives and false negatives).
- TgRasH2 is more sensitive to peroxisome proliferators.
- p53 and TgRasH2 are acceptable in a regulatory context.

49.5.1.4 Dose Selection for Carcinogenicity Studies of Pharmaceuticals (S1C)

The S1C guideline was adopted and implemented in the different regions in 1997.

Traditionally, carcinogenicity studies for chemical agents have relied upon the maximally tolerated dose (MTD) as the standard method for high dose selection.

The MTD is generally chosen based on data derived from toxicity studies of 3 months' duration. Testing options for dose-range-finding studies are as follows:

- Usually:
  - 3 months for long-term studies
  - 1 month for neonatal or transgenic mice
- Range of different dose levels, often 5
- Focus on toxicity endpoints, determination of MTD
- Profiling of AUC
  - E.g., 1 and 4 months for rats
  - E.g., 1 and 4 weeks for alternatives (transgenic = wild type).

Table 49.8 illustrates the general design of long-term tumorigenicity assays.

Ideally, the doses selected for rodent bioassays for non-genotoxic pharmaceuticals should provide an exposure to the agent, adequate margin of safety, no significant chronic physiological dysfunction, and compatible with good survival.

The guideline calls for a flexible approach to dose selection.

The guideline proposes five different approaches:

1. Toxicity-based endpoints (MTD = Maximum Tolerated Dose or Minimum Toxic Dose)
2. Pharmacokinetic endpoints (25 times the human AUC)
3. Saturation of absorption
4. Pharmacodynamic endpoints
5. Maximum feasible dose

Ad 1) The ICH Expert Working Group on Safety has agreed to continue the use of the MTD as an acceptable toxicity-based endpoint for high dose selection for carcinogenicity studies.

The MTD is defined as the top dose or maximum tolerated dose that produces a minimum toxic effect

Table 49.9 History of genotoxicity guidelines (ICH/S2A and S2B) replaced by ICH S2(R)

ICH No.	Title	CPMP Doc. No.	Step
S2A	Genotoxicity: Guidance on Specific Aspects of Regulatory Genotoxicity Tests for Pharmaceuticals	CPMP/ICH/ 141/95	Step 5
S2B	Genotoxicity: A Standard Battery for Genotoxicity Testing of Pharmaceuticals	CPMP/ICH/ 174/95	Step 5
S2(R1)	Guidance on Genotoxicity Testing and Data Interpretation for Pharmaceuticals Intended for Human Use	Nov 2011	Step 5

over the course of the carcinogenicity study. Factors to consider are alterations in physiological function, which would alter the animal's normal lifespan or interfere with interpretation of the study. Such factors include: no more than 10% decrease in body weight gain relative to controls, target organ toxicity, or significant alterations in clinical pathological parameters.

Ad 2) A systemic exposure representing a 25 times multiple of the human AUC (at the maximum recommended daily dose) may be an appropriate endpoint for dose selection for carcinogenicity studies for non-genotoxic pharmaceuticals, as a pragmatic solution.

Ad 3) High dose selection based on saturation of absorption measured by systemic availability of drug-related substances is acceptable. The mid and low doses selected for the carcinogenicity study should take into account saturation of metabolic and elimination pathways.

Ad 4) Pharmacodynamic endpoints for high dose selection will be highly compound specific. The high dose selected should produce a pharmacodynamic response in dosed animals of such magnitude as would preclude further dose escalation. However, the dose should not produce disturbances of physiology or homeostasis. Examples include hypotension, inhibition of blood clotting, or insulin-like effects.

Ad 5) The maximum feasible dose by dietary administration was considered 5% of diet. By many scientists this amount of drug is considered to be too high. Therefore, a new and more reasonable solution was formulated in the Guideline ICH/S1C (R), which follows.

49.5.1.5 Addendum to Dose Selection for Carcinogenicity Studies of Pharmaceuticals (Integrated into S1C)

Addition of a limit dose and related notes of pharmaceuticals. This addendum S1C (R) was adopted in 1998. This Addendum is today integrated in to the Guideline S1C. In determining the high dose for carcinogenicity studies, it may not be necessary to exceed a dose of 1,500 mg/kg/day. This limit dose applies in cases and where the maximum recommended human dose does not exceed 500 mg/day.

49.5.1.6 Genotoxicity Guidelines

A permanent alteration of genes or chromosomes can cause heritable effects leading to malformations and dysfunctions or affecting the individual by inducing tumors. Initiation of tumors can begin with a mutation of a single DNA base of an oncogene or a tumor suppressor gene leading to changes of normal activity and control. Initiation of neoplasia may also occur when there is displacement or translocation of a section of a chromosome which contains an oncogene leading to loss of normal control in its new location after breakage of chromosomes. Table 49.9 lists the former guidelines S2A and B, which were replaced in November 2011 by the new ICH guidelines S2(R1).

Testing of new drugs for their genotoxic potential is an important contribution to the safety of humans. The appropriate approaches for assessing the genotoxic potential of pharmaceutical compounds are recommended today in the ICH guidelines: ICH/S2(R) "Guidance on Genotoxicity Testing and Data Interpretation for Pharmaceuticals Intended for Human Use."

Valid information on gene mutations, structure chromosome aberrations (clastogenicity), and numerical chromosome aberrations (aneugenicity) is required. No single test is capable of detecting all relevant genotoxic agents, therefore, a battery of in vitro and in vivo tests is considered appropriate.

According to ICH/S2(R) there is a need to measure point mutation, chromosome damage, and

Table 49.10 Toxicokinetics/Pharmacokinetics (ICH/S3A and S3B)

ICH No.	Title	CPMP Doc. No.	Step
S3A	Toxicokinetics: A Guidance for Assessing Systemic Exposure in Toxicology Studies	CPMP/ICH/ 384/95	Step 5
S3B	PharmacoKinetics: Guidance for Repeated Dose Tissue Distribution Studies	CPMP/ICH/ 385/95	Step 5
S4A	Duration of Chronic Toxicity Testing in Animals (Rodent and non Rodent Toxicity Testing)	CPMP/ICH/ 300/95	Step 5

chromosome number changes. It is recommended to include a metabolic activation system with in vitro tests, usually rat liver S9 and to use predictive computerized SAR programs, e.g., DEREK and MCASE before testing begins.

Today there are two battery options:

Option I:

1. A test for gene mutations in bacteria (Ames), combined with
2. An in vitro test with cytogenetic evaluation of chromosomal damage with mammalian cells (e.g., human peripheral lymphocytes or established cell lines like Chinese hamster ovary—CHO—of fibroblasts—V 79—or lung cells—CHL—cells) *or* an in vitro micronucleus test or an in vitro mouse lymphoma *tk* assay and
3. An in vivo test for chromosomal damage using rodent hematopoietic cells

Option II:

1. A test for gene mutations in bacteria (Ames), combined with
2. An in vivo test for chromosomal damage using rodent hematopoietic cells, preferably integrated into a repeat dose toxicity study and
3. A second in vivo test using a different endpoint and a different tissue, also integrated into a repeat dose toxicity study

Additional tests are needed for compounds which are positive in one or more in vitro tests but negative in the micronucleus test. Such tests could be an ex vivo Unscheduled DNA synthesis test in hepatocytes measuring repair of DNA or the measurement of DNA adducts by chemical/radiolabeling methods, e.g., 32P-postlabeling or transgenic models, e.g., Mutamouse or Big Blue and possibly Comet Assay which detect DNA strand breakage. The UDS test has been preferred formerly but because it is nearly always negative today it is less recommended by the FDA.

Modifications of the standard battery may be necessary for some classes, e.g., antibiotics which are toxic to bacteria or, e.g., for compounds like topoisomerase inhibitors which interfere with the mammalian cell replication system.

The ICH guidance complements the details of study designs outlined in the OECD guidelines. Additionally, they inform about the top concentrations for in vitro tests and the expected levels of cytotoxicity, and about repeat or confirmatory testing and the proof of target tissue exposure to the test article in the in vivo studies.

Support for the interpretation of positive test results and considerations on conditions leading to false positive data can be found.

Genotoxicity results are very important for go/no go decisions. Positive results do not necessarily indicate "no go." Consistent results over the battery of tests provides the greatest level of confidence in predicting hazard as potent genotoxic carcinogens tend to give positive results across a number of in vitro and in vivo assays.

49.5.1.7 Toxicokinetics/Pharmacokinetics (ICH/S3A and S3B)

Table 49.10 cites the toxicokinetic and pharmacokinetic guidelines.

ICH/S3A

The objectives of Toxicokinetics are primarily to describe the systemic exposure achieved in animals and its relationship to dose level and the time course of the toxicity study. And further, to relate exposure levels to toxicological findings, to assess the relevance of these findings to clinical safety and to support the design as the choice of species and treatment regimen in nonclinical studies.

If animals or humans are exposed to pharmaceutical compounds, they will either elicit a pharmacodynamic effect, e.g., show a suppression of blood pressure, or reveal in analytical blood samples exposure levels of the compound. This kinetic information of the parent compound and its metabolites is an important

contribution for the extrapolation of safety data from animal studies to humans. Species differ considerably in regard to their kinetic conditions as C_{max}, T_{max}, Area Under the Curve (AUC), $t_{1/2}$, and ADME (Absorption, Distribution, Metabolism and Excretion).

Therefore, it is important to know what a drug does with the body (what pharmacology and toxicology is induced?); it is also crucial to know what the body does with the drug.

The following toxicokinetic studies are usually distinguished: concomitant toxicokinetics, which are normally integrated in the toxicity studies and other supportive studies which mimic the conditions of the toxicity study.

The focus before IND is on T_{max}, C_{max}, and AUCs, while the complexity of pharmacokinetic characterization (like oral bioavailability, plasma half-life, volume of distribution, mean residence time, absorption, solubility, and concentration) is built up during clinical trials and on the basis of comparable human data. The compound can be bound to plasma proteins, cells, or tissues. Therefore, a distinction between "unbound drug" or "free fraction" is relevant. Distribution studies help to design preclinical studies. Demonstration of accumulation can, e.g., explain toxicity at the site of increased compound accumulation.

Kinetic data should be considered in repeat dose toxicity studies, in genotoxicity studies when there are negative results and exposure can be characterized in the indicator tissue, in teratogenicity studies and in cancerogenicity studies, where monitoring is appropriate but according to the guideline not beyond 6 months duration. Here the author recommends to take blood samples also after 12 and 24 months of treatment, since drug or age induced toxic damage, especially of liver and kidney, may influence the exposure levels of individual animals considerably.

ICH/S3B

Single dose studies provide usually sufficient information about tissue distribution but there may be cases where assessments after repeated dosing may provide better information. Such studies are necessary when:

1. Single dose distribution studies suggest that the half-life of the test compound and/or metabolites in organs or tissues significantly exceeds the half-life of the elimination phase in plasma or
2. Steady-state levels of a compound/metabolite in the circulation, determined in repeated dose pharmacokinetic or toxicokinetic studies, are markedly higher than those predicted from single dose kinetic studies or
3. When histopathological changes were observed that were not predicted from short-term toxicity studies.

This information is provided in the ICH Guideline S3B: "Pharmacokinetics: Guidance for repeated dose distribution studies (CPMP/ICH/395/95)." Other relevant kinetic questions are the investigations of the potential of compounds to penetrate the barriers of placenta, blood-brain, or excretion into milk.

Knowledge about metabolites and their activity is further an important criterion for the assessment of species-specific effects and differences, e.g., the search for the most human-like test model as the best predictor for human reactions, focuses on such differences. Metabolism can lead to pharmacologically active metabolites; such knowledge is desirable early in development. In vitro metabolism studies normally precede in vivo preclinical safety assessments.

For safety reasons, it is important to identify, and perhaps eliminate, drugs from further development if they are subject to polymorphic metabolism or extensive metabolism by key human enzymes. Knowledge about the cytochrome P450 (CYP450) superfamily of drug metabolizing enzymes is of particular interest. Such data today are needed before IND according to the revised guideline M3(R).

49.5.1.8 ICH Guideline S4A, Duration of Non-rodent Repeat Dose Studies

This is a guideline where harmonization was difficult to reach. There was clear agreement that rodent studies were only needed for a maximum duration of 6 months. When a 6 month study in rodents is needed, then continuous application of pharmaceutical compounds will take place. Under such conditions, a long-term carcinogenicity study will usually be performed. Long-term exposure and lifelong observation is therefore possible. For non-rodents, lifelong exposure is normally not required. The EU proposed recommending a common maximum duration of 6 month studies for rodents and non-rodents, but there were 16 cases where unexpected findings appeared after the treatment time of 6 months.

Facing these results, the Guideline S4A recommends the following: For non-rodents, 12 month studies are usually not necessary, in the EU 6 month studies are acceptable based on the Directive 75/318/EEC.

Table 49.11 History of reproductive studies (ICH/S5 A + B) and preclinical evaluation of biotechnology-derived products (ICH/S6)

ICH No.	Title	CPMP Doc. No.	Step
S5A	Reproductive Toxicology: Detection of Toxicity to Reproduction for Medicinal Products	CPMP/ICH/ 386/95	Step 5
S5B (M)	Reproductive Toxicology: Toxicity on Male Fertility (Modification)	CPMP/ICH/ 136/95	Step 5
S5(R2)	Detection of Toxicity to Reproduction for Medicinal Products and Toxicity to Male Fertility	CPMP/ICH/ 386/05	Step 5

Accordingly, as a compromise, the Expert Working Group agreed that 9 month studies are recommended in general. In the US Federal Register this guideline was published with an FDA Note on ICH/S4A as follows: 9 month studies are acceptable for most development plans; shorter ones like 6 month studies may be acceptable for some drugs, while longer durations, e.g., 12 months, may be more appropriate for others. This advice is characterized by the FDA as their current line of thinking. In practice, FDA agreed with the sponsors in 50% for 9 month studies and in 32% for 6 month studies, while 12 month studies were only requested for compounds with novel mechanisms, or when only sparse clinical data were available, as in indications like HIV. Aids patients should be provided early on with the new treatment and the lack of complex clinical data is compensated by longer non-rodent studies. Sponsors are advised by the FDA to get in contact with the Agency when the maximum duration needs to be determined for non-rodents.

49.5.1.9 ICH S5(R2) Detection of Toxicity to Reproduction for Medicinal Products and Toxicity to Male Fertility

The Parent Guideline dated from June 1993, the Addendum on Toxicity to Male Fertility dated November 9, 2000, this Addendum was incorporated in November 2005 into the core guideline without any changes.

The special toxicology discipline "Reproductive and Developmental Toxicity" focuses on undesirable adverse effects on male and female fertility, birth defects (developmental toxicity, malformations, teratogenicity), and nonphysiological changes that appear shortly before, during, and after birth, and during the weaning period (Table 49.11).

S5(R) illustrates the testing of all stages for the reproduction cycle: in detail from premating to conception (adult male and female reproductive functions, development and maturation of gametes, mating behavior, fertilization); from conception to implantation (adult female reproductive functions, preimplantation development, implantation). From implantation to closure of the hard palate (adult female reproductive functions, embryonic development, major organ formation). From closure of the hard palate to the end of pregnancy (adult female reproductive functions, fetal development and growth, organ development and growth); from birth to weaning (adult female reproductive functions, neonate adaptation to extrauterine life, preweaning development and growth) and finally from weaning to sexual maturity (postweaning development and growth, adaptation to independent life, attainment of full sexual function).

Accordingly the study types can be divided into the former three segments following the different time periods:

Segment I: The early embryonic development (fertilized egg or zygote, prior to implantation, and prior to formation of the three primary germ layers)

Segment II: The embryo-fetal development (embryo during major organ development, i.e., organogenesis, the fetus in the postembryonic period)

Segment III: The prenatal and postnatal development (neonate or postnatal offspring)

These segments can be tested separately or in a combined manner. All stages of development from conception to maturity and the detection of acute and delayed effects of exposure through one complete life cycle should be examined. The standard species are rodents, rats as the preferred rodent species for all study types and, the rabbit as the second non-rodent species for the embryo-toxicity studies. In some rare cases mice or monkeys are used too, if special conditions—usually kinetic data—justify such species. The route of administration should be similar to the intended human usage.

Part two of S5(R) deals with male fertility. Compounds inducing selective effects on male reproduction are rare; compound affecting spermatogenesis

almost invariably affect postmeiotic stages and weight of testis; mating with females is an insensitive means of detecting effects on spermatogenesis. Histopathology of the testis has been shown to be the most sensitive method for the detection of effects on spermatogenesis. Good pathological and histopathological examination (e.g., by employing Bouin's fixation, paraffin embedding, transverse section of 2–4 μm for testes, longitudinal section for epididymides, PAS, and hematoxylin staining) of the male reproductive organs provides a direct means of detection. Sperm analysis (sperm counts, sperm motility, sperm morphology) can be used as an optional method to confirm findings by other methods and to characterize effects further. Information on potential effects on spermatogenesis (and female reproductive organs) can be derived from repeated dose toxicity studies or reproductive toxicity studies.

For detection of effects not detectable by histopathology of male reproductive organs and sperm analysis, mating with females after a premating treatment of 4 weeks has been shown to be at least as efficient as mating after a longer duration of treatment. Since 2 week study was validated to be as effective as a 4 week study, 2 weeks treatment before mating is also acceptable.

In humans, malformations and changes in development are relatively rare (around 6%) and often caused by accidental genetic errors; some are caused by external factors, e.g., chemical drugs. If a compound is labeled as a developmental toxicant, then the occurrence of structural or functional abnormalities in offspring is significantly increased at a dose level which does not induce severe maternal toxicity. If malformations are developed, then exposure levels of the individual fetuses are important, but also at which time of the development exposure was high. The inclusion of kinetic data helps to support the evaluation.

49.5.1.10 ICH/S6(R) Preclinical Safety Evaluation of Biotechnology-Derived Pharmaceuticals (June 2011)

The ICH S6—Preclinical Safety Evaluation of Biotechnology-derived Products continues to be implemented and valid, but an Addendum was created which illustrates a number of important details helpful when biotechnology-derived products are being developed and where regulatory advice is needed.

S6 outlines the products for which this guidance is applicable, such as recombinant DNA proteins, vaccines, peptides, plasma derived products, endogenous proteins extracted from human tissues, or oligonucleotide drugs, etc., while heparin, vitamins, and cellular blood components, e.g., are not covered.

In general, for biotech products high flexibility for the developmental scheme is recommended and should be reconsidered on a case-by-case basis.

Usually, as in other toxicity studies, two animal species should be used, but when the biological activity is well understood or when in short-term toxicity studies the effects were similar in both species, then longer-term studies could be run only with one species.

When no relevant species can be identified, one should consider the use of homologous proteins or transgenic animals.

With regard to Safety Pharmacology, testing of the vital function such as cardiovascular, respiratory, and CNS functions is recommended, but S 6 also mentions renal function, which from today's perspective would not be necessary before first administration of a compound in humans if there is no specific concern.

Some information on absorption, disposition, and clearance in the animal models is desirable before clinical trials and systemic exposure of the compound should be monitored as well as the appearance of antibodies and their ability to neutralize the intended effect.

The immune response could also alter the pharmacokinetic or pharmacodynamic effects. Anaphylactic responses tested in the guinea pig, at any rate, are not predictive for humans and therefore not necessary. The same holds true for the standard testing batteries for immunotoxicity, these are not recommended.

Studies with a duration of between 2 weeks and 3 months are often sufficient and it is only with chronic use in humans that 6 month studies should be considered.

Flexibility may allow further reduction of the traditional testing program for the reproductive endpoints. Such studies may not be necessary if a new one, related to well-known compounds, shows similar effects.

The same holds true for genotoxicity. The standard studies are not appropriate, but testing on a case-by-case basis of impurities or promoter studies might be helpful. Long-term carcinogenicity studies are usually not appropriate, but when there is cause for concern, studies with a single rodent species are sufficient.

Cause for concern may have arisen in general toxicity studies, or else a stimulation of the growth of normal as well as malignant cells can be assumed.

The ICH guideline S6 (R1)—Preclinical safety evaluation of biotechnology-derived pharmaceuticals was recommended for implementation as Step 5 on December 2011. This Addendum is complementary to the parent first guideline. Where the addendum differs from the original guideline, the guidance in the addendum prevails. The purpose of the addendum is a clarification and update on following topics: species selection, study design, immunogenicity, reproductive, and developmental toxicity and an assessment of the carcinogenic potential.

As factors for Species Selection consider the comparisons of target sequence homology between species as starting point, further in vitro assays to make qualitative and quantitative cross-species comparisons of relative target binding affinities and receptor/ligand occupancy and kinetics and finally an assessments of functional in species-specific cell-based systems and/or in vivo pharmacology or toxicology studies. Other aspects are: the modulation of a known biologic response or of a pharmacodynamic (PD) marker as evidence for functional activity to support species relevance. The model should be capable of demonstrating potentially adverse consequences of target modulation; when the target is expressed at very low levels in typical healthy preclinical species (e.g., inflammatory cytokines or tumor antigens), binding affinity and activity in cell-based systems can be sufficient to guide species selection.

A new and important change is the value of tissue cross-reactivity in animal tissues, which is today considered being of limited value for species selection.

As described in ICH S6 Guideline, when no relevant species can be identified because the biopharmaceutical does not interact with the orthologous target in any species, use of homologous molecules or transgenic models can be considered.

The question if one or two species should be used when assessing bioproducts is being taken up: If there are two pharmacologically relevant species for the clinical candidate (one rodent and one non-rodent), then both species should be used for short-term (up to 1 month duration) general toxicology studies. If the toxicological findings from these studies are similar or the findings are understood from the mechanism of action of the product, then longer-term general toxicity studies in one species are usually considered sufficient.

The rodent species should be considered unless there is a scientific rationale for using non-rodents. Studies in two non-rodent species are not appropriate. The use of one species for all general toxicity studies is justified when the clinical candidate is pharmacologically active in only one species. Studies in a second species with a homologous product are not considered to add further value for risk assessment and are not recommended.

For chronic use products, repeat dose toxicity studies of 6 months duration in rodents or non-rodents are considered sufficient. Studies of longer duration have not generally provided useful information that changed the clinical course of development.

Immunogenicity assessments are conducted to assist in the interpretation of the study results and design of subsequent studies. Such analyses in nonclinical animal studies are not relevant in terms of predicting potential immunogenicity of human or humanized proteins in humans. Measurement of anti-drug antibodies (ADA) in nonclinical studies should be evaluated when there is: (1) evidence of altered PD activity; (2) unexpected changes in exposure in the absence of a PD marker; or (3) evidence of immune-mediated reactions (immune complex disease, vasculitis, anaphylaxis, etc.).

Reproductive toxicity studies should be conducted in accordance with the principles outlined in ICH S5(R2) Guideline; however, the specific study design and dosing schedule can be modified based on an understanding of species specificity, the nature of the product and mechanism of action, immunogenicity and/or pharmacokinetic behavior and embryo-fetal exposure. The evaluation of toxicity to reproduction should be conducted only in pharmacologically relevant species. When the clinical candidate is pharmacologically active in rodents and rabbits, both species should be used for embryo-fetal development (EFD) studies, unless embryo-fetal lethality or teratogenicity has been identified in one species.

Developmental toxicity studies should only be conducted in nonhuman primates (NHPs) when they are the only relevant species.

If there is a specific cause for concern for any damage of fertility based on pharmacological activity or previous findings, specialized assessments such as menstrual cyclicity, sperm count, sperm morphology/motility, and male or female reproductive hormone levels can be evaluated in a repeat dose toxicity study.

Table 49.12 Safety Pharmacology (ICH/S/A + B) and Immunotoxicology Studies (ICH/S8)

ICH No.	Title	CPMP Doc. No.	Step
S7A	Safety Pharmacology Studies for Human Pharmaceuticals	CPMP/ICH/539/00	Step 5
S7B	Non-Clinical Studies for Assessing Risk of Repolarisation—Associated Ventricular Tachyarrhythmia for Human Pharmaceuticals	CPMP/ICH/423/02	Step 5

The species-specific profile of embryo-fetal exposure during gestation should be considered in interpreting studies. The following information is important: High molecular weight proteins (>5,000 D) do not cross the placenta by simple diffusion. For monoclonal antibodies with molecular weight as high as 150,000 D, there exists a specific transport mechanism, the neonatal Fc receptor (FcRn) which determines fetal exposure and varies across species. In the NHP and human, IgG placental transfer is low in the period of organogenesis and begins to increase in early second trimester, reaching highest levels late in the third trimester (Pentsuk and van der Laan 2009). Therefore, standard embryo-fetal studies in NHPs, which are dosed from early pregnancy up to Gestation Day 50, might not be of value to assess direct embryo-fetal effects in the period of organogenesis, although effects on embryo-fetal development as an indirect result of maternal effects can be evaluated.

For the assessment of neoplastic potential a number of considerations should be regarded: The mechanism of action of some biopharmaceuticals might raise concern regarding potential for carcinogenicity. If the weight of evidence supports the concern regarding carcinogenic potential, rodent bioassays are not warranted. In this case potential hazard can be best addressed by product labeling and risk management practices. However, when the weight of evidence is unclear, the sponsor can propose additional studies that could mitigate the mechanism-based concern. For products where there is insufficient knowledge about specific product characteristics and mode of action in relation to carcinogenic potential, a more extensive assessment might be appropriate (e.g., understanding of target biology related to potential carcinogenic concern, inclusion of additional endpoints in toxicity studies). Rodent bioassays (or short-term carcinogenicity studies) with homologous products are generally of limited value to assess carcinogenic potential of the clinical candidate.

49.5.1.11 S7A Safety Pharmacology Studies for Human Pharmaceuticals

S7B Non-Clinical Studies for Assessing Risk of Repolarisation—Associated Ventricular Tachyarrhythmia for Human Pharmaceuticals

S7A was implemented in 2001 and the S7B reached step 4 in June 2005 and are implemented now worldwide (Table 49.12).

S7A informs in general about the requirements necessary for testing the vital functions usually in single dose studies in Safety Pharmacology.

S7A differentiates between three types of studies: core battery, follow-up, and supplemental studies. The core battery of tests in S7A consists of an investigation of the effects of a test substance on three vital functions: central nervous system; cardiovascular system; respiratory system, and on other systems when appropriate. The exclusion of a system or function should be justified.

Safety Pharmacology studies carried out as necessary are:

Follow-up studies for core battery (they provide a greater depth of understanding than, or additional knowledge to, that provided by the core battery [e.g., mechanistic studies]).

Supplemental studies evaluate effects of the test substance on systems not addressed by the core battery when there is cause for concern not addressed elsewhere (e.g., in toxicology).

S7A expresses very clearly when such studies should be available and what conditions should be considered in regard to good laboratory procedures (see Table 49.13).

Special focus is given to the cardiovascular system. For the core battery of the cardiovascular system according to S7A blood pressure, heart rate, and electrocardiogram should be assessed, but also in vivo, in vitro, and/or ex vivo evaluations, including methods for repolarization and conductance abnormalities should be considered.

This text was finalized at a time when the details of S7B were not yet outlined. During recent years there has been an increase of regulatory concern. The awareness that non-cardioactive drugs, used for sometimes

Table 49.13

Guideline	Timing
ICH/S7A	Before first administration to humans
	Core battery tests. Follow-up or supplemental studies when appropriate
	During clinical development. Additional studies as required to clarify observed or suspected undesirable effects in animals or humans
	Before approval. Effects on all organ systems, if not covered elsewhere (e.g., toxicology) or in clinical trials
GLP/S7A	Core battery tests should be conducted according to GLP
	Follow-up and supplemental studies should be conducted according to GLP as far as possible deviation should be justified and impact discussed
	Primary and secondary pharmacodynamic studies need not be conducted according to GLP

Fig. 49.1 Increased risk of ventricular tachyarrhythmia

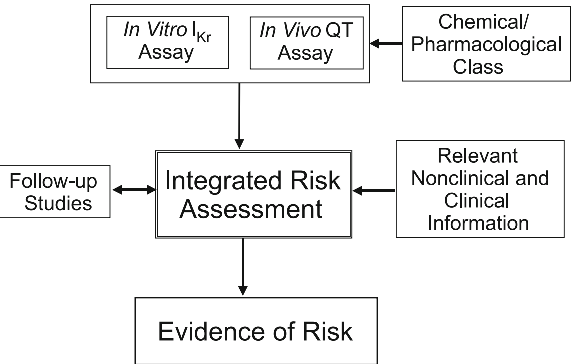

Fig. 49.2 Nonclinical testing strategy

nonlife-threatening diseases, can cause QT prolongation and serious dysrhythmias such as Torsades de Pointes (TdP) was intensified.

A greater number of compounds became known to be associated with QT prolongation and the potential to cause Torsades de Pointes.

Accordingly, the ICH Expert Working Group for S7B was created to work on this specific concern.

ICH S7B—Non-Clinical Studies for Assessing Risk of Repolarisation—Associated Ventricular Tachyarrhythmia for Human Pharmaceuticals

The background of S7B is summarized as follows:

The QT interval (time from the beginning of the QRS complex to the end of the T wave) of the electrocardiogram (ECG) is a measure of the duration of ventricular depolarization and repolarization.

QT interval prolongation can be congenital or acquired (e.g., pharmaceutical-induced)

When the QT interval is prolonged, there is an increased risk of ventricular tachyarrhythmia, including Torsade de Pointes (TdP), particularly when combined with other risk factors (e.g., hypokalemia, structural heart disease, bradycardia), see Fig. 49.1.

The basis for *Integrated Risk Assessment* is in vitro and in vivo assays, supported by any knowledge about the chemical/pharmaceutical class. This first risk assessment may later be modified when results from follow-up studies or relevant nonclinical or clinical information becomes available. The *Evidence of Risk* summarizes the preclinical evaluation of the proarrhythmic potential and should serve as the essential message for clinicians when treating volunteers or patients.

Parallel to the development of S7B a clinical guideline (ICH/E14) was drafted and reached step 4, also in 2005. During the discussion between these two expert groups, the question was raised again and again, if toxicologists could exclude any risk for QT prolongation for humans in their testing strategies. Of course they cannot, as clinicians cannot exclude any such risk for future patient generations based only on their clinical trial results. In addition, the Food and Drug Administration (FDA) is comparing preclinical data with clinical results and seems to have identified a few cases where QT prolongation was observed under clinical conditions while the preclinical tests were negative. This discrepancy is the basis for the diplomatic text in regard to the need for availability of S7B QT studies.

Timing of S7B Non-clinical Studies and Integrated Risk Assessment in Relation to Clinical Development/ Step 4, June 2005, Brussels:

Conduct of S7B non-clinical studies assessing the risk for delayed ventricular repolarization and QT interval prolongation prior to first administration in humans should be considered.

These results, as part of an integrated risk assessment, can support the planning and interpretation of subsequent clinical studies

The term “should be considered” allows flexibility either to do the studies before first time in humans or at a later stage of development. In practice, these S7B studies are most often available before IND, because one wants to cope with this issue in time and wants to provide best safety to volunteers and patients. S7B studies are most often requested by EMA or MHW in Japan.

In conclusion one can state:

S7B proposes a series of nonclinical tests which it is believed can predict the likelihood that a compound will prolong cardiac repolarization in vivo, in animals and in humans.

These data currently seem to have little impact on the clinical development proposals contained in the draft E14 guideline. A thorough analyses or more robust data from animals and humans is needed to arrive at a final testing strategy and at a valid assessment of this risk potential.

49.5.1.12 Immuntoxicology Studies (ICH/S8)

This guideline was implemented as step 5 in 2005 and replaces in Europe all the recommendations expressed in the EU Repeat Dose Toxicity guideline from 2002. In 2010, the Immuntoxicity part was deleted in this regional guidance.

S8 is restricted to unintended immunosuppression and immunoenhancement, excluding allergenicity or drug-specific autoimmunity. The guideline applies to new pharmaceuticals intended for use in humans, as well as to marketed drug products proposed for different indications or other variations on the current product label. The guideline does not apply to biotechnology-derived pharmaceutical products covered by ICH S6 and other biologicals.

Immunosuppression or enhancement can be associated with two distinct groups: (1) Drugs intended to modulate immune function for therapeutic purposes (e.g., to prevent organ transplant rejection) where adverse immunosuppression can be considered exaggerated pharmacodynamics. (2) Drugs not intended to affect immune function but cause immunotoxicity due, for instance, to necrosis or apoptosis of immune cells or interaction with cellular receptors shared by both target tissues and nontarget immune system cells.

Methods include standard toxicity studies (STS) and additional immunotoxicity studies conducted as appropriate. Whether additional immunotoxicity studies are appropriate should be determined by a weight of evidence review of cause(s) for concern.

Findings from standard toxicity studies (STS) pharmacological properties of the drug intended patient population structural similarities to known immunomodulators disposition of the drug clinical information.

Findings from standard toxicity studies (STS) pharmacological properties of the drug intended patient population structural similarities to known immunomodulators disposition of the drug clinical information.

The immunotoxicity evaluation follows a straightforward strategy which is detailed in Figs. 49.3 and 49.4 below.

Alterations in immune system organ weights and/or histology (e.g., changes in thymus, spleen, lymph nodes, and/or bone marrow), changes in serum globulins that occur without a plausible explanation, such as effects on the liver, can be an indication for immunogenic potential. Also increased incidences of infections and increased occurrence of tumors may be viewed as a sign of immunosuppression in the absence of other plausible causes such as genotoxicity.

The assessment of immunotoxicity should include the following:

- Statistical and biological significance of the changes
- Severity of the effects dose/exposure relationship
- Safety factor above the expected clinical dose
- Treatment duration
- Number of species and endpoints affected
- Changes that may occur secondarily to other factors (e.g., stress)
- Possible cellular targets and/or mechanism of action
- Doses which produce these changes in relation to doses which produce other toxicities and reversibility of effect(s)

Additional immunotoxicity testing should be considered:

- If the pharmacological properties of a test compound indicate it has the potential to affect immune function (e.g., anti-inflammatory drugs). If the majority of the patient population for whom the drug is intended is immunocompromised by a disease state or concurrent therapy.

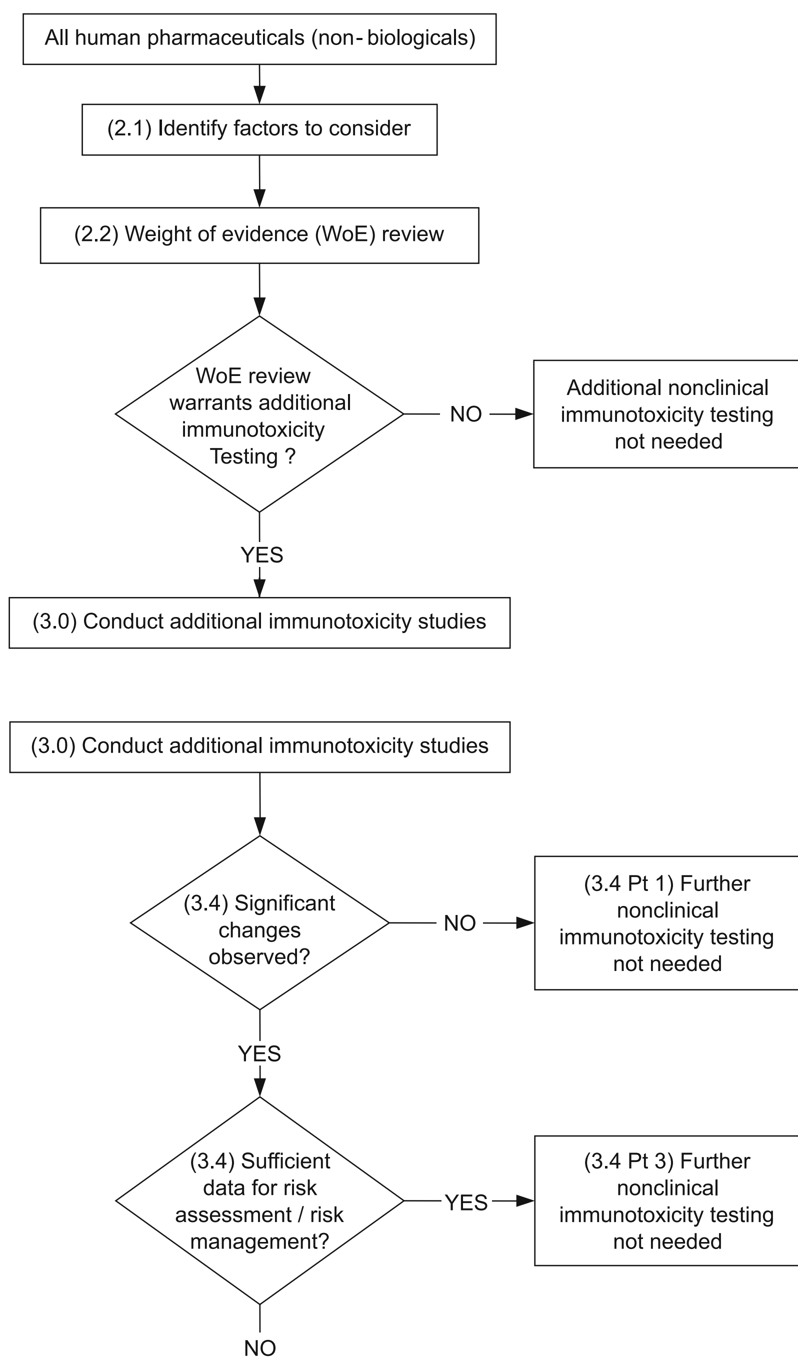

Fig. 49.3 ICH S8: Flow diagram for Recommended Immunotoxicity Evaluation

Fig. 49.4 ICH S8

- If a compound is structurally similar to compounds with known immunosuppressive properties.
- If the compound and/or its metabolites are retained at high concentrations in cells of the immune system.
- If clinical findings suggestive of immunotoxicity in patients exposed to the drug occur.

If the weight-of-evidence review indicates that additional immunotoxicity studies are needed, there

are a number of assays which can be used. It is recommended that an immune function study be conducted, such as a T-cell dependent antibody response (TDAR). If specific cell types are affected in STS not involving cells participating in a TDAR, assays that measure function of that specific cell type might be conducted. Immunophenotyping of leukocyte populations, a nonfunctional assay, may be conducted to identify the specific cell populations affected and may provide useful clinical biomarkers.

Generally accepted is the conduct of studies with 28 consecutive daily doses in rodents. Adaptations of immunotoxicity assays have been described using non-rodent species. The species, strain, dose, duration, and route of administration used in immune function assays should be consistent, where possible, with the nonclinical toxicology study in which an adverse immune effect was observed.

Usually both sexes should be used in these studies, excluding nonhuman primates. The high dose should be above the no observed adverse effect level (NOAEL) but below a level inducing changes secondary to stress. Multiple dose levels are recommended in order to determine dose-response relationships and the dose at which no immunotoxicity is observed.

Additional studies may show that no risk of immunotoxicity can be detected and no further testing is needed.

Additional studies may demonstrate a risk of immunotoxicity, but there are no sufficient data for a reasonable risk-benefit decision. In this case further testing may be of benefit to provide sufficient information for the risk-benefit decision. If the overall risk-benefit analysis suggests that the risk of immunotoxicity is considered acceptable and/or can be addressed in a risk management plan (see ICH E2E), then no further testing in animals might be called for.

If the weight-of-evidence review indicates the need for additional immunotoxicity studies, these should be completed before exposure of a large population of patients, usually Phase III. If the target patient population is immunocompromised, immunotoxicity testing can be initiated at an earlier time point in the development of the drug.

The different methods which are recommended for the evaluation of immuntoxic effects are summarized in Table 49.14.

Table 49.14 Standard toxicity studies

Area	Subject
Hematology	Total leukocyte counts and absolute differential leukocyte counts
Clinical Chemistry	Globulin levels and A/G ratios
Gross pathology	Lymphoid organs/tissues
Organ weights	thymus, spleen (optional: lymph nodes)
Histology	thymus, spleen, draining lymph node, and at least one additional lymph node, bone marrow, Peyer's patch[a], NALT[b], BALT[b]

[a]oral administration only
[b]inhalation administration only

Methods to evaluate immunotoxicity:
Additional immunotoxicity studies

- T-cell Dependent Antibody Response (TDAR)
- Immunophenotyping (lymphocyte subsets)
- Natural Killer Cell Activity Assays
- Host Resistance Studies
- Macrophage/Neutrophil Function
- Assays to Measure Cell-Mediated Immunity

This new ICH guideline replaces all guidances from EU, USA, and Japan. It represents a very pragmatic approach and uses studies, e.g., standard toxicity studies, which are conducted anyhow (see Table 49.15). There is great confidence in the prediction of these assays for any potential of new compounds to induce immune suppression or immune stimulation. This guideline helps to reduce the number of animals and requires additional studies only in special cases for concern.

49.5.1.13 ICH S9 Nonclinical Evaluation for Anticancer Pharmaceuticals

This guideline was implemented as step 5 in October 2009.

The guidance provides recommendations for nonclinical evaluations to support the development of anticancer pharmaceuticals in clinical trials for the treatment of patients with advanced disease and limited therapeutic options. The aim is to facilitate and accelerate the development of anticancer pharmaceuticals and to protect patients from unnecessary adverse effects, while avoiding unnecessary use of animals, in accordance with the 3R principles (reduce/refine/replace), and other resources.

Table 49.15 Recommended duration of repeated-dose toxicity studies to support the conduct of clinical trials

Maximum duration of clinical trial	Recommended minimum duration of repeated-dose toxicity studies to support clinical trials	
	Rodents	Non-rodents
Up to 2 weeks	2 weeks	2 weeks
Between 2 weeks and 6 months	Same as clinical trial	Same as clinical trial
Less than 6 months	6 months	9 months

For anticancer pharmaceuticals, clinical studies often involve cancer patients whose disease condition is progressive and fatal. Therefore, the dose selection may be different and often close to or at the adverse effect dose levels. For these reasons, the type, timing, and flexibility called for in the design of nonclinical studies of anticancer pharmaceuticals can differ from those elements in nonclinical studies for other pharmaceuticals.

The guideline applies to both small molecule and biotechnology-derived pharmaceuticals (biopharmaceuticals), regardless of the route of administration. It describes the minimal requirements to initiate clinical trials in patients with advanced cancer whose disease is refractory or resistant to available therapy, or where current therapy is not considered to be providing benefit. The nonclinical data to support Phase I and the clinical Phase I data would normally be sufficient for moving to Phase II and into second or first line therapy in patients with advanced cancer.

Studies to support clinical trials and marketing authorization:

1. *Pharmacology studies*: Prior to Phase I studies, characterization of the mechanism(s) of action and schedule dependencies as well as antitumor activity of the pharmaceutical should have been made.
2. *Safety Pharmacology studies*: An assessment of the pharmaceutical's effect on vital organ functions (including cardiovascular, respiratory, and central nervous systems) should be available before the initiation of clinical studies. Conducting stand-alone safety pharmacology studies to support studies in patients with advanced cancer is not called for.
3. *Pharmacokinetic information*: The evaluation of limited pharmacokinetic parameters (e.g., peak plasma/serum levels, area under the curve (AUC), and half-life) in the animal species used for nonclinical studies can facilitate dose selection, schedule, and escalation during Phase I studies. Further information on absorption, distribution, metabolism, and excretion of the pharmaceutical in animals should normally be generated in parallel with clinical development.
4. *General toxicity studies*: Phase I assessments can include dosing to a maximum tolerated dose (MTD) and dose limiting toxicity (DLT). Toxicology studies to determine a no observed adverse effect level (NOAEL) or no effect level (NOEL) are not considered essential to support clinical use of an anticancer pharmaceutical. For small molecules, the general toxicology testing usually includes rodents and non-rodents. In certain circumstances alternative approaches can be appropriate (e.g., for genotoxic drugs targeting rapidly dividing cells, a repeat-dose toxicity study in one rodent species might be considered sufficient, provided the rodent is a relevant species.
5. *Reproductive toxicity studies*: Embryo-fetal toxicity studies of anticancer pharmaceuticals should be available when the marketing application is submitted, but these studies are not considered essential to support clinical trials intended for the treatment of patients with advanced cancer. These studies are also not considered essential for the purpose of marketing applications for pharmaceuticals that are genotoxic and target rapidly dividing cells (e.g., crypt cells, bone marrow) in general toxicity studies or belong to a class that has been well characterized as causing developmental toxicity. For small molecules, embryo-fetal toxicology studies are typically conducted in two species as described by ICH S5(R2). For biopharmaceuticals, an assessment in one pharmacologically relevant species should usually be sufficient. A study of fertility and early embryonic development is not warranted to support clinical trials or for marketing of pharmaceuticals intended for the treatment of patients with advanced cancer. A pre- and postnatal toxicology study is generally not warranted to support clinical trials or for marketing of pharmaceuticals for the treatment of patients with advanced cancer.

6. *Genotoxicity*: Genotoxicity studies are not considered essential to support clinical trials for therapeutics intended to treat patients with advanced cancer. Genotoxicity studies should be performed to support marketing (see ICH S2).
7. *Carcinogenicity*: Carcinogenicity studies are not warranted to support marketing for therapeutics intended to treat patients with advanced cancer.
8. *Immunotoxicity*: For most anticancer pharmaceuticals, the design components of the general toxicology studies are considered sufficient to evaluate immunotoxic potential and support marketing. For immunomodulatory pharmaceuticals, additional endpoints (such as immunophenotyping by flow cytometry) might be included in the study design.
9. *Photosafety testing*: An initial assessment of phototoxic potential should be conducted prior to Phase I, based on photochemical properties of the drug and information on other members in the class. This recommendation may be modified by the new safety guideline S10 which is in progress within the ICH activities.
10. *Start Dose for First Administration in Humans*: For most systemically administered small molecules, interspecies scaling of the animal doses to an equivalent human dose is usually based on normalization to body surface area. For biopharmaceuticals with immune agonistic properties, selection of the start dose using a minimally anticipated biologic effect level (MABEL) should be considered. A common approach for many small molecules is to set a start dose at 1/10 the Severely Toxic Dose in 10% of the animals (STD 10) in rodents. If the non-rodent is the most appropriate species, then 1/6 the Highest Non-Severely Toxic Dose (HNSTD) is considered an appropriate starting dose. The HNSTD is defined as the highest dose level that does not produce evidence of lethality, life-threatening toxicities or irreversible findings.
11. *Duration and Schedule of Toxicology Studies to Support Initial Clinical Trials*: In Phase I clinical trials, treatment can continue according to the patient's response, and in this case, a new toxicology study is not called for to support continued treatment beyond the duration of the completed toxicology studies. Results from repeat dose studies of 3 months' duration following the intended clinical schedule should be provided prior to initiating Phase III studies. For most pharmaceuticals intended for the treatment of patients with advanced cancer, nonclinical studies of 3 months duration are considered sufficient to support marketing.
12. *Combination of Pharmaceuticals*: Pharmaceuticals planned for use in combination should be well-studied individually in toxicology evaluations. Data to support a rationale for the combination should be provided prior to starting the clinical study. In general, toxicology studies investigating the safety of combinations of pharmaceuticals intended to treat patients with advanced cancer are not warranted.
13. *Additional aspects*: Examples of Treatment Schedules for Anticancer Pharmaceuticals to Support Initial Clinical Trials are reported and recommendations for nonclinical studies to support trials in Pediatric Populations, conjugated and liposomal products, evaluation of drug metabolites and impurities are being illustrated.

49.5.1.14 ICH Multidisciplinary Guideline M3(R2) Guidance on Nonclinical Safety Studies for the Conduct of Human Clinical Trials and Marketing Authorization for Pharmaceuticals

The former Guideline M3 (Timing) was revised and complemented with a great number of new recommendations in June 2009. It continues to focus on the timing of nonclinical studies to support clinical trials and marketing and also on conditions which need to be considered when different patient populations like men or children or women of child bearing potential (WOCBP)are being included into clinical trials.

In more details, recommendations can be found for Timing of preclinical studies (IND, NDA), Duration of safety studies, Options for expediting development (exploratory trials, microdosing, etc.), Inclusion of patient populations, Case-by-case evaluations (e.g., phototoxicity) and development of combination drugs.

The guidelines expresses as goals that development of a pharmaceutical is a stepwise process, that evaluation of animal and human efficacy and safety is needed. Toxic effects should be characterized; there is a need for the identification of target organs, clarification of

dose dependence, relationship of toxicities to exposure, and assessment of potential reversibility.

M3 has contributed considerably to reduce differences between regions; to facilitate timely conduct of clinical trials; to avoid unnecessary use of animals and other resources and to promote early availability of new drugs. M3 (R) will continue to reduce further the differences of regulatory recommendations among regions like Europe, USA, Japan, and other areas of the world. The stress is on the concept, that such a guideline is not a legal requirement, but serves as supportive compendium of recommendations which are scientifically and ethically appropriate.

The core battery of *Safety Pharmacology* is recommended to be conducted prior to first administration in humans. Any follow-up or supplemental studies as appropriate. During clinical development, a clarification of observed or suspected adverse effects in animals or during clinical trials may be needed. Before NDA, an assessment of effects on all systems should be provided, either based on in vitro or animal or human data.

For *kinetics*, an information on exposure data (AUC) in animals prior human clinical trials is needed; while ADME data are needed at completion of Phase I (Human Pharmacology) studies.

The duration for *Repeat Dose Toxicity Studies* is related to the duration of clinical trials and their therapeutic indication. In principle, the duration of animal studies are equal to or exceed the duration of the human clinical trials. Thorough Japanese studies in 2000 compared the utility of routine 4 week toxicity studies with 2 week studies and concluded that in regard to the prediction of toxicities to the male reproductive organs, 2 weeks studies were as valid as 4 week studies. Therefore the former regional Japanese requirement to ask for a minimum duration of 4 week studies before starting trials in men was dropped for a global consensus that the minimum duration of nonclinical studies is 2 weeks in rodents and 2 weeks in non-rodents.

In general, there is a relationship of 1:1 ratio for studies in two mammalian species (one non-rodent) as long as clinical trials are running. The details can be found in Table 49.15.

For marketing the duration of repeat dose studies may be longer as illustrated in Table 49.16.

On the other hand, regional differences continue in regard to *Single dose animal studies* supporting single

Table 49.16 Recommended duration of repeated-dose toxicity studies to support marketing

Duration of indicated treatment	Rodent	Non-rodent
Up to 2 weeks	1 month	1 month
>2 weeks to 1 month	3 months	3 months
>1–3 months	6 months	6 months
>3 months	6 months[c]	9 months[c,d]

dose studies in humans: Historically, acute toxicity information has been obtained from single-dose toxicity studies in two mammalian species using both the clinical and a parenteral route of administration. However, such information can be obtained from appropriately conducted dose-escalation studies or short-duration dose-ranging studies that define an MTD in the general toxicity test species. On the other hand, information on the acute toxicity of pharmaceutical agents could be useful to predict the consequences of human overdose situations and should be available to support Phase III.

In the USA, single dose toxicity studies with extended examinations can support single-dose human trials since 1996. This concept encouraged the ICH to offer comparable options with the concept of *EXPLORATORY CLINICAL TRIALS*. This principle may be especially valuable for gaining early data for Go/No go decisions, when several candidates are being developed in parallel. Such streamlined early exploratory approaches can be conducted early in Phase I, may involve limited human exposure, have no therapeutic intent and are not intended to examine clinical tolerability. Table 49.17 reports about the different five options:

Genotoxicity in general: Results from two in vitro genotoxicity studies are recommended to be available prior to first administration to humans, while the standard battery should be completed prior to initiation of Phase II studies.

Carcinogenicity studies do not need to be completed in advance of the conduct of clinical trials unless there is cause for concern (ICH: S1A).

For pharmaceuticals to treat certain serious diseases, carcinogenicity testing, if needed, may be concluded post-approval.

Patient Population: The inclusion of different patient populations reveals regional differences, especially for women with child bearing potential. There is a high level of concern for unintentional exposure of an embryo/fetus.

Table 49.17 Five different exploratory clinical approaches

Single microdose of 100 μg: e.g., investigate target receptor binding or tissue distribution via PET study	*Repeat ≤5 administrations* of 100 μg (a total of 500 μg per subject). Useful for target receptor binding, but with less active PET ligands	*Single dose* studies at subtherapeutic doses or into the anticipated therapeutic range	*Dosing up to 14 days* into the therapeutic range but not intended to evaluate clinical MTD in two species with standard parameters	*Dosing up to 14 days* in rodents and a confirmatory study in non-rodent ($n = 3$) at the anticipated NOAEL exposure in rodent, with duration of a minimum of 3 days

The currently regional differences in the timing of reproduction toxicity studies to support the inclusion of women with childbearing potential are:

1. *Japan and EU*: Definitive nonclinical developmental toxicity studies should be completed before exposure of WOCBP
2. *US*: Assessment of embryo-fetal development can be deferred until before Phase III for WOCBP using precautions to prevent pregnancy in clinical trials.
3. *All ICH regions*: WOCBP can be included in repeated-dose Phase I and II trials before conduct of the female fertility study since an evaluation of the female reproductive organs is performed in the repeated-dose toxicity studies.
4. *All ICH regions*: Nonclinical studies that specifically address female fertility should be completed to support inclusion of WOCBP in large-scale or long-duration clinical trials (e.g., Phase III trials).
5. *In all ICH regions*: The pre-postnatal development study should be submitted for marketing approval.

The inclusion of *children* into clinical trials has gained tremendous interest. The following data are requested:

- Safety data from previous adult human exposure:
  - Most relevant information
  - Necessary before pediatric clinical trials
- Prior trials:
  - Appropriate repeated dose toxicity studies
  - All reproduction toxicity studies
  - Standard battery of genotoxicity tests
  - Juvenile animal studies should be considered
- Carcinogenicity testing:
  - Former: Prior to long-term exposure of children
  - Today: Unless there is a significant cause for concern (e.g., evidence of genotoxicity in multiple tests, or concern for pro-carcinogenic risk based on mechanistic considerations or findings from general toxicity studies), carcinogenicity studies are not recommended to support the conduct of pediatric clinical trials.

Abuse liability: Consider an evaluation of abuse liability for drugs with central nervous system activity by using PK/PD profile to identify the duration of action, similarity of chemical structure to known drugs of abuse, receptor binding profile, and behavioral/clinical signs from in vivo nonclinical studies. Three types of studies to evaluate the potential for abuse liability are often applied mostly as stand-alone tests: drug discrimination, self-administration of the compound, and an assessment of withdrawal.

Combination drug toxicity: M3R provides helpful details how to develop combination drugs of different maturity and data set. Provided complete nonclinical development programs are being conducted on the individual entities and a nonclinical combination toxicity study is warranted to support combination clinical trials, the duration of the combination study should be equivalent to that of the clinical trial, up to a maximum duration of 90 days. A 90-day combination toxicity study would also support marketing.

Summary of M3R

Marketing Approval

The nonclinical safety assessment for marketing approval of a pharmaceutical usually includes:

- Pharmacology studies
- General toxicity studies
- Toxicokinetic and nonclinical pharmacokinetic studies
- Reproduction toxicity studies
- Genotoxicity studies and possibly
- An assessment of carcinogenic potential

Other nonclinical studies conducted on case-by-case:

- Phototoxicity
- Immunotoxicity
- Juvenile animal toxicity
- Abuse liability

First in Man. Studies needed before first administration of a pharmaceutical compound:

Primary PD studies (in vivo and/or in vitro)

Safety pharmacology core battery studies (CV, CNS, respiration)

Kinetics: In vitro metabolic and plasma protein binding data for animals and humans and systemic exposure data from Tox species (AUC, cmax)

Repeat dose studies with minimum duration for 2 weeks in two species

No single dose studies or data on lethality needed

No reproductive studies

Other studies if concern, e.g., phototoxicity

49.5.1.15 Common Technical Document (ICH/M4)

M4 is another very important multidisciplinary guideline, which combines information for the three disciplines within the ICH Process: for Quality, Safety, and Efficacy. The following section focuses predominantly on the preclinical safety issues.

The total document is divided into *five modules*: Module 1 contains regional specific aspects, it provides for the European Union, e.g., the European Community specific data. This module therefore is not harmonized but region specific. Module 2 provides the Summaries for Quality, for Safety and Efficacy. The quality part uses as a headline "Quality Overall Summary," for safety and efficacy the terms "Non-Clinical or Clinical Overview." The different names signal that the quality part is a clear summary, while the nonclinical and clinical part should be critical evaluations. Module 3 provides chemical, pharmaceutical and biological information. Module 4 contains the nonclinical reports and Module 5 provides clinical study reports.

The Objectives of M4 are to assist authors in the preparation of nonclinical pharmacology, pharmacokinetics, and toxicology written summaries in an acceptable format. The CTD is not intended to indicate what studies are required, but provides an appropriate format for the nonclinical data. The Common Technical Document is nothing other than a placeholder for the different parts of a documentation for the market authorization process.

No guideline can cover all eventualities; common sense and a clear focus on needs of regulatory authority assessor are best guides to constructing an acceptable document. Therefore, modify the format if needed with the aim to provide best possible presentation and facilitate the understanding for the evaluation of the results.

Module 1 is regulated by regional requirements while the Modulus 2–4 are structured on an international basis. **Module 1** was agreed upon in the Europe in 2006 as follows:

Module 1 Table of Content

1.0	**Cover Letter**
1.1	**Comprehensive Table of Contents**
1.2	**Application Form**
1.3	**Product Information**
1.3.1	**SPC, Labelling and Package Leaflet**
1.3.2	**Mock-up**
1.3.3	**Specimen**
1.3.4	**Consultation with Target Patient Groups**
1.3.5	**Product Information already approved in the Member States**
1.3.6	**Braille**
1.4	**Information about the Experts**
1.4.1	**Quality**
1.4.2	**Non-Clinical**
1.4.3	**Clinical**
1.5	**Specific Requirements for Different Types of Applications**
1.5.1	**Information for Bibliographical Applications**
1.5.2	**Information for Generic, 'Hybrid' or Bio-similar Applications**
1.5.3	**(Extended) Data/Market Exclusivity**
1.5.4	**Exceptional Circumstances**
1.5.5	**Conditional Marketing Authorisation**
1.6	**Environmental Risk Assessment 1.6.1 Non-GMO 1.6.2 GMO**
1.7	**Information relating to Orphan Market Exclusivity**
1.7.1	**Similarity**
1.7.2	**Market Exclusivity**
1.8	**Information relating to Pharmacovigilance**
1.8.1	**Pharmacovigilance System**
1.8.2	**Risk-management System**
1.9	**Information relating to Clinical Trials**
1.10	**Information relating to Paediatric**
1.11	**Responses to Questions**
1.12	**Additional Data**

The CTD-Safety is organized as follows:

F. Nonclinical summary

1. *Pharmacology*
   a. Written summary
   b. Tabulated summary
2. *Pharmacokinetics*
   a. Written summary
   b. Tabulated summary

3. *Toxicology*
   a. Written summary
   b. Tabulated summary

This organization is kept up in all parts of the dossier; it is repeated for the overview, the summaries, and the reports.

The detailed organization for Pharmacology, Kinetics, and Toxicology are as follows:

1. Pharmacology Written Summary
   - Brief Summary
   - Primary Pharmacodynamics
   - Secondary Pharmacodynamics
   - Safety Pharmacology
   - Pharmacodynamic Drug Interactions
   - Discussion and Conclusions
   - Tables and Figures (either here, or included in text)
2. Pharmacokinetics Written Summary
   - Brief Summary
   - Methods of Analysis
   - Absorption
   - Distribution
   - Metabolism
   - Excretion
   - Pharmacokinetic Drug Interactions (Nonhuman)
   - Other Pharmacokinetic Studies
   - Discussion and Conclusions
3. Toxicology Written Summary
   - Brief Summary
   - Single-Dose Toxicity
   - Repeat-Dose Toxicity
   - Genotoxicity
   - Carcinogenicity
   - Reproduction Toxicity Local Tolerance
   - Other Toxicity Studies
   - Discussion and Conclusions

Examples of detailed advice for sections on discussion and conclusion of Pharmacokinetics: Information should be integrated across studies and across species, exposure in the test animals should be related to exposure in humans given the maximum intended doses.

Similar examples for toxicology: in vitro studies should precede in vivo studies. Where multiple studies of the same type need to be summarized within the Pharmacokinetics and Toxicology sections, studies should be ordered by species, by route, and then by duration (shortest duration first).

The species should be ordered as follows: 1. mouse; 2. rat; 3. hamster; 4. other rodent; 5. rabbit; 6. dog; 7. nonhuman primate; 8. other non-rodent mammal; 9. nonmammals (see also Table 49.18).

It is also recommended to limit the information in the summaries and overview. The overview should contain the essential and critical results on approximately 30 pages. The length of the Nonclinical Written Summaries should in general not exceed 100–150 pages.

The brief Summaries for Pharmacology should be written on 2–3 pages, for Pharmacokinetics the same length and for Toxicology approximately 6 pages.

Module 2 contains, in addition, 34 templates and 31 examples.

The examples have been taken from real dossiers and give good orientation on how to fill out the templates.

For illustration of the templates see Table 49.19 for Pharmacology, Table 49.20 as summary for Toxicology and Table 49.21 with details for a Repeat-Dose Toxicity Study.

Finally, the following list shows examples of recommendations for Module 4.

The appropriate location for individual-animal data is in the study report or as an appendix to the study report.

4.1 Table of Contents

A Table of Contents should be provided that lists all of the nonclinical study reports and gives the location of each study report in the Common Technical Document.

Study Reports

The study reports should be presented in the following order:

4.2 Pharmacology
- 4.2.1 Primary Pharmacodynamics
- 4.2.2 Secondary Pharmacodynamics
- 4.2.3 Safety Pharmacology
- 4.2.4 Pharmacodynamic Drug Interactions

4.3 Pharmacokinetics
- 4.3.1 Analytical Methods and Validation Reports (if separate reports are available)
- 4.3.2 Absorption
- 4.3.3 Distribution
- 4.3.4 Metabolism
- 4.3.5 Excretion
- 4.3.6 Pharmacokinetic Drug interactions (nonclinical)
- 4.3.7 Other Pharmacokinetic Studies

Table 49.18 Recommendations on how to summarize studies and tables

Studies	Recommendations
Repeat-Dose Toxicity (including supportive toxicokinetics evaluation)/CTD-S	Summarize in order by species, by route, and by duration
	Give brief details of the methodology
	Highlight important findings (e.g., nature and severity of target organ toxicity, dose (exposure)/response relationships, no observed adverse effect levels)
	Non-pivotal studies can be summarized in less detail (pivotal studies are the definitive GLP studies specified by ICH Guideline M3)
Carcinogenicity (including supportive toxicokinetics evaluations)/CTD-S	A brief rationale should explain why the studies were chosen
	The basis for high dose selection. Individual studies should be summarized in the following order:
	Long-term studies (in order by species; including range-finding studies that cannot appropriately be included under repeat-dose toxicity or pharmacokinetics)
	Short- or medium-term studies (including range-finding studies that cannot appropriately be included under repeat-dose toxicity or pharmacokinetics)
	Other studies
Other toxicity studies (if available)/CTD-S	If other studies have been performed, they should be summarized.
	When appropriate, the rationale for conducting the studies should be provided.
	Antigenicity
	Immunotoxicity
	Mechanistic studies (if not reported elsewhere)
	Dependence
	Studies on metabolites
	Studies on impurities
	Other studies

  - 4.4.3.1 In vitro
  - 4.4.3.2 In vivo (including supportive toxicokinetics evaluations)
- 4.4.4 Carcinogenicity (including supportive toxicokinetics evaluations)
  - 4.4.4.1 Long-term studies (in order by species; including range-finding studies that cannot appropriately be included under repeat-dose toxicity or pharmacokinetics)
  - 4.4.4.2 Short- or medium-term studies (including range-finding studies that cannot appropriately be included under repeat-dose toxicity or pharmacokinetics)
  - 4.4.4.3 Other studies
- 4.4.5 Reproductive and Developmental Toxicity (including range-finding studies and supportive toxicokinetics evaluations). (If modified study designs are used, the following subheadings should be modified accordingly.)
  - 4.4.5.1 Fertility and early embryonic development
  - 4.4.5.2 Embryo-fetal development
  - 4.4.5.3 Prenatal and postnatal development, including maternal function
  - 4.4.5.4 Studies in which the offspring (juvenile animals) are dosed and/or further evaluated.
- 4.4.6 Local Tolerance
- 4.4.7 Other Toxicity Studies (if available)
  - 4.4.7.1 Antigenicity
  - 4.4.7.2 Immunotoxicity
  - 4.4.7.3 Mechanistic studies (if not included elsewhere)
  - 4.4.7.4 Dependence
  - 4.4.7.5 Metabolites
  - 4.4.7.6 Impurities
  - 4.4.7.7 Other

4.5 Key Literature References

This CTD has been tested in practice for several years. Although not perfect for every case, it has proved its usefulness. Industry knows where to place specific information and data, and regulators know where to find them. This has facilitated the review process tremendously, only one dossier is necessary for international registration, a lot of resources can be diverted to more important issues.

But the CTD is a living document, its weakness is apparent. In order to improve its quality and practicability, suggestions and proposals for improvements are invited from the public. These modifications are being dealt with within the process of "Questions and Answers," the ICH experts publish their conclusions regularly.

49.5.1.16 Outlook and Future of ICH

ICH can look back to more than 20 years of achievements. As the most successful international harmonization initiative in the world, its achievements include: an understanding of innovation; a common regulatory platform based on more than 60 guidelines; guidance of guidelines based on science; facilitation of communication among regulators and industry; effective use of research and development (R&D) resources; greater mutual acceptance of R&D data realized.

In addition, the drafting process of guidelines has identified gaps in science, new studies analyzing problems have been conducted to validate the assays confirming safe use of drug in humans, like validity of 2 weeks studies to assess male fertility or the validity of transgenic mouse models for assessing the carcinogenic potential within the ILSI/HESI evaluation process.

ICH has stimulated a process of creating guidelines, e.g., within Europe, the drafting takes place among regulators but industry is always asked to comment and improve those recommendations. In the following some of the EMA/CHMP guidances are collected as examples of this dynamic process:

CHMP Guidance Documents in Preparation/ Released for Consultation:

1. Guideline on Environmental Risk Assessments for Pharmaceuticals
2. Guideline on the Limits for Genotoxic Impurities
3. Guideline on the Need for Pre-clinical Testing of Human pharmaceuticals in Juvenile Animals
4. Guideline on Drug-induced Hepatotoxicity
5. Guideline on the Non-Clinical Development of Fixed Combinations of Medicinal Products
6. Guideline on Risk Assessment of Medicinal Products on Human Reproductive and Development Toxicities: from Data to Labelling1. Guideline on Environmental Risk Assessments
7. Guideline on the Investigation of Dependence Potential of Medicinal Products
8. Guideline on the Assessment of Carcinogenic and Mutagenic Potential of Anti-HIV Medicinal Products
9. Guideline on the Non-Clinical Testing for Inadvertent Germ line Transmission of Gene Transfer Vectors
10. Guideline on Adjuvants in Vaccines
11. Points to Consider Document on Xenogenic Cell Therapy
12. Guideline on the Comparability of Biotechnology Products, Preclinical and Clinical Issues
13. Guideline on the Evaluation of Medicinal Products intended for Treatment of Chronic Hepatitis B.

But ICH will also continue to further draft guidelines on issues where discrepancies exist and where common solutions are desirable. There is a strong need for multidisciplinary guidances, here especially between Quality and nonclinical Safety. As examples the following themes in development should be mentioned: Residues of Metals (Q3D), Genotoxic Impurities (M7), and Phototoxicity (S10).

The enormous success of harmonization justifies the continuation. ICH stimulated the creation of new scientific approaches and data, there are new experiments for optimizing strategies, and there is support for new evaluations for better assessments, helping market authorization processes to be more effective.

ICH stimulated a considerable paradigm change, today there is an open dialogue and transparency among agencies and industries, there is increased consciousness for unnecessary hurdles, there is an optimized handling with limited resources at agencies and industry, there is an ongoing dynamic process via maintenance of guidelines with the implementation of the Questions and Answers options and there is recognition of advantages for drug development on an international basis.

A medical device is a product which is used for medical purposes in patients, in diagnosis, therapy, or surgery. In contrast to *pharmaceuticals* which achieve their principal effect by pharmacological, metabolic, or immunological mode of action, a *medical device* acts mechanical, physical, thermal, physicochemical, or chemical means.

Innovations in this sector contribute significantly to improve the efficacy of healthcare and patient's quality of life. Medical devices played a more and more important role in global healthcare in the past years. The global market of medical devices reached roughly 209 billion US Dollar in 2006 and is expected to grow with an average annual rate of 6–9% through 2010.[1]

For market access a risk management assessment approved by the relevant health authority is needed. A medical device is generally subject to pre- and postmarketing control regulated by the health authorities.

The ISO guideline 10993[2] is generally accepted by the health authorities and systematically describes the different steps in classification, risk assessment, and biological evaluation of medical devices.

The focus of the ISO guideline 10993 is the protection of patients by determination of biological reactivity of any leachable substances in a biological system and to demonstrate the hazard potential for the use of a medical device in humans. It was harmonized from numerous international and national guidelines

[2]DIN EN ISO 10993

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*, DOI 10.1007/978-3-642-25240-2_54, © Springer-Verlag Berlin Heidelberg 2013

and standards and serves as guide for biological evaluation of medical devices in a risk management process.

This extensive risk assessment has to be performed and the intended proper use, but also possible abuse of the device, has to be defined. The device has to be characterized physically and chemically. The biological hazard has to be assessed in an evaluation of the materials and parts used in the production process and of possibly extractable compounds from these materials. If possible, the chemical risk has to be assessed by toxicological data analysis with focus on dose response and mode of toxicity. In this evaluation the extraction rate of potential leachables and the resulting exposure for the patient is significant.

50.1 Nature and Duration of Body Contact

An essential part in the characterization of medical devices according to ISO guideline 10993 is the definition of nature and duration of body contact. (Medical devices that do not contact the patient's body directly or indirectly (so-called noncontact devices) are not included in the scope of ISO 10993.) In case the device may be placed in more than one category, the more rigorous testing requirements shall apply.

In a first step it has to be differentiated whether the device is a:

- Surface-Contacting Device with contact to:
  - Intact skin surfaces only (electrodes, external prostheses, fixation tapes, compression bandages)
  - Mucosal membranes (contact lenses, urinary catheters, intravaginal and intraintestinal devices, dental prostheses)
  - Compromised surfaces (dressings, healing devices, and occlusive patches for ulcers, burns, and granulation tissue)
- External Communicating Device with contact to:
  - The blood path at one point and serves as a interconnection for entry into the vascular system (solution administration sets, extension sets, transfer sets, and blood administration sets)
  - Tissue, bone, or pulp/dentin systems (laparoscopes, arthroscopes, draining systems, dental cements, dental filling materials, and skin staples)
  - Circulating blood (intravascular catheters, temporary pacemaker electrodes, oxygenators, extracorporal oxygenator tubing and accessories, dialyzers, dialysis tubing and accessories, hemoadsorbents, and immunoadsorbents)
- Implant Device with contact to:
  - Bone (orthopedic pins, plates, replacement joints, bone prostheses, bone cements, and intraosseous devices)
  - Tissue and tissue fluid (pacemakers, drug supply devices, neuromuscular sensors and stimulators, replacement tendons, breast implants, artificial larynxes, subperiostal implants, and ligation clips)
  - Blood (pacemaker electrodes, artificial arteriovenous fistulae, heart valves, vascular grafts, internal drug-delivery catheters, and ventricular assist devices)

Beside the contact definition the duration of contact has to be defined:

- Limited exposure: Single or multiple use or contact is likely to be up to 24 h.
- Prolonged exposure: Single, multiple, or long-term use or contact is likely to exceed 24 h but not 30 days.
- Permanent contact: Single, multiple, or long-term use or contact exceeds 30 days.

50.2 Materials of Manufacture

The characterization of the different materials used for manufacturing of the device, including intended additives, process contaminants, and residues, is the essential next step in the biologically risk assessment.[3] [4] If the chemical ingredients themselves, their combination and production were proven to be safe in former use, or in a literature research could be shown that materials have a known and acceptable toxicity profile, a further characterization might not be needed. A flow chart in ISO 10993-1 can guide through the decision tree.[5]

[3]ISO 10993–18:2005 Chemical characterization of materials

[4]ISO/TS 10993–19:2006 Physicochemical, morphological, and topographical characterization of materials

[5]ISO 10993–1:2009 Evaluation and testing in the risk management process, picture 1—Flow chart to aid in ensuring a systematic approach to biological evaluation of medical devices

50.3 Leachable Substances and Degradation Products

In consideration of the nature and duration of body contact and other components interacting with the final product (e.g., alcohol for disinfection purpose prior use) the potential occurrence of leachable substances that can be extracted from the medical device has to be evaluated. Where the potential for degradation exists, corresponding tests may determine the processes of absorption, distribution, biotransformation, and elimination of leachables and degradation products of medical devices, or their extracts.[6]

For leachables or degradation products with a sufficient toxicological data profile no further characterization is needed. Potential synergies between the different substances have to be taken into consideration.[7] In case of a potential risk remaining after toxicological data analysis, further biological testing in vitro and in vivo is required.

50.4 Extraction

The purpose of extraction of a medical device is to provide a suitable test sample to determine the biological reactivity of any leachable (and potentially toxic) substance in a biological system. Detailed description are given in ISO 10993-12.[8]

The extraction medium and conditions of extraction used should be appropriate to the nature and use of the final product, but should also cover all possible "worst case scenarios." Extraction conditions and application of the extract to test systems, therefore, should ideally reflect not only actual in-use conditions of the products but also exaggerated-use conditions, if possible.

The extraction is generally performed with polar and nonpolar extraction media, but can be adapted to apply to more rigorous extraction conditions. Examples of extraction media are:

- Polar medium: Water, physiological saline; culture media without serum
- Nonpolar medium: Freshly refined vegetable oil (e.g., cottonseed or sesame oil) of quality defined in various Pharmacopeia
- Additional media: Alcohol/water, alcohol/saline, polyethylene glycol 400 (diluted to a physiological osmotic pressure), dimethylsulfoxide, and culture media with serum

An extraction procedure using a volatile solvent such as acetone, methanol, etc., followed by evaporation of the solvent and application of the evaporation residue to the test system, shall be undertaken for polymeric materials for genotoxicity and delayed-type hypersensitivity testing.

Extractions are commonly performed with agitation. When extraction under static conditions is considered to be appropriate, the method should be justified, specified, and reported.

Liquid extracts shall, if possible, be used immediately after preparation to prevent adsorption to the extraction container or other changes in composition. If an extract needs to be stored longer than 24 h, then the stability of the extract under the conditions of storage should be verified.

The extract should not routinely be processed by filtration, centrifugation, or other methods to remove suspended particulates. However, if such processing is necessary, the rationale must be presented in regulatory documents.

Standard extraction temperatures and times (with permissible ranges) are as follows:

37°C ± 1°C for 72 ± 2 h (extraction at (37 ± 1)°C for (24 ± 2) h in tissue culture media might be acceptable for cytotoxicity testing. See ISO 10993-5)

50°C ± 2°C for 72 ± 2 h

70°C ± 2°C for 24 ± 2 h

121°C ± 2°C for 1 ± 0.2 h

The complex process of extraction is influenced by time, temperature, surface-area-to-volume ratio, and the extraction medium. The effects of higher temperatures or other conditions on extraction kinetics and the identity of the extractant(s) should be considered carefully.

It is preferable to test medical devices in their final product form whenever practical. If this is not possible, the second choice is to use representative portions of the device, or representative molded or extruded test

[6] ISO 10993–9:1999 Framework for identification and quantification of potential degradation products

[7] ISO 10993–17:2002 Establishment of allowable limits for leachable substances

[8] ISO 10993–12:2007 Sample preparation and reference materials

Table 50.1

Thickness (mm)	Extraction ratio (surface area or mass/volume) ±10%	Example
<0.5	6 cm^2/ml	Film, sheet, tubing wall
0.5–1.0	3 cm^2/ml	Tubing wall, slab, small molded items
>1.0	1.25 cm^2/ml	Elastomeric closures
>1.0	3 cm^2/ml	Larger molded items
Irregularly shaped solid devices	0.2 g/ml	Powder, pellets, foam, nonabsorbent molded items
Irregularly shaped porous devices (For testing absorbents and hydrocolloids, the "absorption capacity" of the material has to be determined, i.e., the amount of extractant absorbed per gram of the material is determined. In performing the material extraction, this absorbed volume is added to each 0.1 g or 1.0 cm^2 to the extraction mixture.) (low density materials)	0.1 g/ml	Membranes

specimens of the formulated material, that have been preconditioned by the same processing as the final product, shall be tested.

When test samples and reference materials need to be cut into pieces, the influence of previously unexposed surfaces, e.g., lumens or cut surfaces, shall be considered. Methods to cut medical devices into representative portions for testing should be as clean as possible to prevent contamination.

50.5 Standard Surface Areas and Extract Liquid Volumes

Test samples from sterilized devices and reference materials shall be handled aseptically if appropriate to the test procedure.

A blank control and positive and negative controls shall be used where appropriate.

50.6 Biological Tests (Biocompatibility)

Animal testing can only be justified if an in-depth review of available relevant information of the properties of the test material was performed and animal tests are essential to characterize the test material properly.

After classification of the device, data for possible biological effects should be available for an all-embracing risk analysis.

Detailed information about the planning and conduct of animal tests with focus on animal welfare requirements is given in ISO10993-2 (Table 50.2).[9]

The overall biological evaluation of the device should be performed and documented only by experienced experts in this field.

50.7 Cytotoxicity

The cytotoxicity testing is the first basic step of biocompatibility testing for all kinds of medical devices. With the use of cell culture techniques, these assays determine the lysis of cells (cell death), the inhibition of cell growth, and other effects on cells caused by the medical devices, or their extracts. Cytotoxicity tests are described in ISO 10993-5.[10]

50.8 Sensitization

These tests are essential for the risk assessment, because even single exposure or short contact of potential leachables can result in allergic or delayed-type hypersensitivity reactions. For the evaluation of the sensitizing capabilities of medical devices, or their extracts, the choice of the appropriate test model is a critical point.

[9] ISO 10993–2:2006 Animal welfare requirements

[10] ISO 10993–5:2009 Tests for in vitro cytotoxicity

Table 50.2 Initial evaluation: Tests for consideration[11]

Medical device categorization by			Biological effect							
Nature of body contact		Contact duration								
Category	Contact	A—Limited (<24 h) B—prolonged (24 h to 30 days) C—permanent (>30 days)	Cytotoxicity	Sensitization	Irritation or intracutaneous reactivity	Systemic toxicity (acute)	Subacute and subchronic toxicity	Genotoxicity	Implantation	Hemocompatibility

		C	x	x	x	x	x	x	x	x

The Guinea Pig Maximization Test (GPMT) of Magnusson and Kligman which uses adjuvant and the non-adjuvant occluded patch test of Buehler Test were given preference over other methods in the past and were usually accepted by health authorities.

Recently, mouse models have been developed that offer the advantages of short duration and minimal animal treatment. The local lymph node assay (LLNA) was established and internationally accepted but some health authorities still consider the tests for some chemicals as a first stage in the assessment of skin sensitization potential and expect confirmation of test results by GPMT or Buehler Test. Sensitization tests are described in ISO 10993-10.[12]

[11]ISO 10993–1:2009 Evaluation and testing in the risk management process, Table 1—Initial evaluation tests for consideration

[12]ISO 10993–10:2010 Tests for irritation and delayed-type hypersensitivity

50.9 Irritation

Tests with focus on the irritation potential of medical devices, or their extracts, using appropriate sites such as skin, eye, and mucous membrane in a suitable animal model. There are in vitro tests for skin irritation available for neat chemicals, but for medical devices these tests are still under validation.

Inflammatory changes in the skin as a parameter for the irritant potential of the material are primary endpoints of the tests. Irritation tests are described in ISO 10993-10, Annex B.[13]

50.10 Intracutaneous or Intradermal Reactivity

These tests are performed on rabbits and assess the localized reaction of tissue to medical device extracts. These tests have to be performed where determination of irritation by topical dermal or mucosal tests is insufficient (e.g., implants, or medical devices having access to the blood path). These tests may also be useful where extractables are hydrophobic. Formation of edema or erythema in the skin is the primary endpoint of the tests.

Intracutaneous reactivity tests are described in ISO 10993-10[12].

50.11 Systemic (Acute) Toxicity

These tests estimate the potential harmful effects of either single or multiple exposures to medical devices used in the intended clinical use, or their extracts in an animal model, during a period of less than 24 h. These tests are appropriate where a contact of the medical device allows potential absorption and systemic exposure of toxic leachables and degradation products.

Pyrogenicity tests might be included to detect material-mediated pyrogenic reactions of the body to medical devices, or their extracts. No single test can differentiate pyrogenic reactions that are material mediated from those due to endotoxin contamination. Systemic toxicity tests can be included in subacute and subchronic toxicity test protocols and implantation test protocols, if possible. Systemic toxicity tests are described in ISO 10993-11.[14]

50.12 Subacute, Subchronic, and Chronic Toxicity

These tests determine the effects of either single or multiple exposures or contact to medical devices, or their extracts for a period not less than 24 h but up to 28 days (subacute), not greater than 10% of the total life span of the test animal, e.g., up to 90 days in rats (subchronic), or during the majority of the life span of the test animal, e.g., up to 6 months in rats (chronic). So they are focused on the effects of a prolonged exposure, accumulation of chemicals leached from the medical device in the intended clinical use of the device.

Inclusion of immunotoxicity tests in these studies should be considered for devices where data from other sources is suggestive of immunotoxicological effects. Chronic toxicity test protocols may be expanded to include endpoints for subacute and subchronic toxicity test protocols and implantation test protocols.

Subchronic toxicity tests are described in ISO 10993-11[14].

50.13 Genotoxicity

These in vitro tests use mammalian or nonmammalian cell culture or other techniques to determine gene mutations, changes in chromosome structure and number, and other DNA or gene toxicities caused by medical devices, or their extracts. For the evaluation of the genotoxic capabilities of medical devices, or their extracts, the choice of the appropriate assay is essential. Due to the existing diversity of genotoxic endpoints it is in contrast to endpoints in general toxicology not (or only very limited) possible to combine different endpoints in one study. Therefore a well defined test strategy with different complementary studies is necessary to cover all endpoints. Genotoxicity tests are described in ISO 10993-3.[15]

[13] ISO 10993–10:2010, Annex B, Tests for irritation and delayed-type hypersensitivity

[14] ISO 10993–11:2006 Tests for systemic toxicity

[15] ISO 10993–3:2003 Tests for genotoxicity, carcinogenicity, and reproductive toxicity

50.14 Implantation

These tests assess the local pathological effects on living tissue, at both the gross level and microscopic level, of a sample of a material or final product that is surgically implanted or in a tissue appropriate to the intended application (e.g., special dental usage tests). These tests are equivalent to subchronic toxicity tests if test protocols are expanded and systemic effects are also investigated. Implantation tests are described in ISO 10993-6.[16]

50.15 Hemocompatibility

These tests evaluate the effects of blood-contacting medical devices or materials on blood or blood components. Specific hemocompatibility tests may also be designed to simulate the geometry, contact conditions, and flow dynamics of the device or material during clinical applications. Hemolysis tests determine the degree of red blood cell lysis and the release of hemoglobin caused by medical devices, or their extracts in vitro.

Hemocompatibility tests are described in ISO 10993-4.[17]

50.16 Carcinogenicity

These tests determine the tumorigenic potential of medical devices or their extracts from either single or multiple exposures or contacts during the majority of the life span of the test animal. These tests may be designed in order to examine both chronic toxicity and tumorigenicity in a single experimental study. Carcinogenicity tests should be conducted only if there are suggestive data from other sources and do not have to be performed if a reasonable biologic risk assessment can be provided, showing that carcinogenic effects of the medical device, or its extracts can be excluded. Carcinogenicity tests are described in ISO 10993-3[15].

50.17 Reproductive and Developmental Toxicity

These tests evaluate the potential effects of medical devices, or their extracts on reproductive function (fertility), embryonic development (teratogenicity), and prenatal and early postnatal development. Reproductive and developmental toxicity tests should only be conducted if there are suggestive data from other sources that the device has potential impact on the reproductive potential of the subject and do not have to be performed if a reasonable biologic risk assessment can be provided, showing that teratogenic effects of the medical device, or its extracts can be excluded. Reproductive and developmental toxicity tests are described in ISO 10993-3[15].

In drug development, it is very important to evaluate the potential toxicological risk of a drug candidate as early as possible to reduce costs and time in drug development process. In the traditional way the toxicological risk of a compound is investigated with the help of a battery of in vivo and in vitro methods. Since the late 1970s many different *in silico* methods for the prediction of toxicity have been developed. The term *in silico* stems from the computer component silicium; *in silico* methods, therefore, refer to methods or prediction using computational approaches. *In silico* methods have the advantage that they can make fast predictions for a large set of compounds in a high-throughput mode. Another advantage is that *in silico* methods make their prediction based on the structure of a compound even before it has been synthesized. *In silico* methods can, therefore, be used at a very early stage in the drug development process, for compounds planned to be synthesized, for which no or only little compound is available, or also for impurities or degradation products later in the drug development process, for which no synthesis is available. However, good predictivity of an *in silico* method is crucial if the method is to be introduced into the drug development process.

Two principle ways of performing *in silico* predictions of toxicity are the constructions of individual prediction models for a specific endpoint or the use of expert systems with already developed prediction models for several endpoints. Expert systems have been defined as "any formal systems" which make predictions about the toxicity of chemicals. All expert systems for the prediction of toxicity are built on experimental data and/or rules derived from such data (Dearden 2003). The expert systems can be further

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_55, © Springer-Verlag Berlin Heidelberg 2013

divided into subclasses based on the method of generating rules. Typical prediction methods are knowledge/rule-based, statistically fragment-based or quantitative structure-activity relationship (QSAR)-based systems.

In knowledge- or rule-based systems, experts/toxicologists create rules based on a list of structural features that have been related to a specified toxicity (Durham and Pearl 2001). These systems are based on structure-activity relationship (SAR), which means the qualitative relationship between a specific chemical structure and its biological/toxicological activity. In SAR, the occurrence of specific substructures in a molecule is correlated to be responsible and necessary for a biological/toxicological activity. An example of a typical knowledge- or rule-based expert system is DEREK, which will be described in this chapter later.

For statistically fragment-based systems a large training dataset of compounds with known toxicity is needed to derive structural features/fragments that are statistically highly correlated to the specified toxicity (Durham and Pearl 2001). Examples of statistically fragment-based expert system are MultiCASE and Leadscope, which will also be described in this chapter later.

QSAR methods are based on the quantitative relationship between a chemical structure and its biological/toxicological activity with the help of chemical descriptors that are generated from the molecular structure. The descriptors are statistically analyzed for the development of a model describing the specified activity, such as toxicity (Durham and Pearl 2001). Examples of QSAR methods will also be described later in this chapter; some local QSAR methods are also used by the expert systems MultiCASE and Leadscope as part of their predictions.

There are a number of commercial expert *in silico* systems available for the prediction of toxicity. Examples of knowledge/rule-based expert systems are DEREK (Leeds, UK), Hazard Expert (ComGenex, San Francisco, CA, USA), Oncologic (San Francisco, CA, USA), and COMPACT (University of Surrey, Guilford, UK). Examples of statistically fragment-based expert systems are MultiCASE (MultiCase, Beachwood, OH, USA), TOPKAT (Accelrys, San Diego, CA, USA), ADAPT (Jurs Research Group, Pennsylvania State University, Philadelphia, PA, USA), and common reactivity pattern (CORPEA, University A. Zlatarov, Bourgas, Bulgaria). Additionally, expert systems could be further classified according to their level of molecular structure assessment. Two-dimensional structure systems include DEREK and MultiCASE, whereas three-dimensional systems include COMPACT and COREPA. These systems are further described by Patlewicz et al. (2003). In the following chapters, the QSAR method and the three expert systems DEREK, MultiCASE, and Leadscope will be described in details.

Besides these commercial systems also some freely available expert systems and databases offered by different institutions could be used for the prediction of toxicity. Examples are summarized in Table 51.1 including their link on how to access them.

51.1 Quantitative Structure-Activity Relationship (QSAR)

PURPOSE AND RATIONALE

Quantitative Structure-Activity Relationship (QSAR) is a method that makes predictions by the quantitative description of molecular properties with the use of descriptors of the chemical structure (Dearden 2003). This means QSAR models describe the quantitative or calculated relationship between a chemical structure and their biological activity (e.g., toxicity) with the help of chemical descriptors that are generated from the molecular structure (Durham and Pearl 2001). This relationship is described in from of a mathematical equation (e.g., $\log 1/C = a\ \pi + b\ \sigma + \ldots + \text{const}$). QSAR models generally show better predictivity if all compounds of a dataset involved in the prediction are derived from a congeneric series of compounds, which means that they should all act by the same mechanism of action, since the physicochemical and structural descriptors used in the QSAR reflect the same mechanism of action. Sometimes it is difficult to determine the mechanism of action, so series of compounds involved in a QSAR model are often restricted to a given chemical class with the hope that this will ensure a single mechanism of action (Dearden 2003).

Most published QSAR models have been developed from congeneric series. But with the recent use of large, diverse chemical libraries, there is an increasing interest for QSAR models for a heterogeneous

[a]Available only as commercial systems in collaboration with DEREK, MCASE, Leadscope, etc.

collection of compounds, a non-congeneric series of compounds. It is often possible to develop QSAR models for non-congeneric series to be used as classification models, for example, for a classification into high, moderate, or low toxicity (Dearden 2003).

QSAR models exist for a wide range of biological and toxicological endpoints, for example, published QSAR models for toxicity cover over 30 different endpoints, from carcinogenicity, mutagenicity, skin sensitization, eye irritation, neurotoxicity to gastric irritancy, etc. Dearden (2003) and Barratt and Rodford (2001) review in their publications some of the recent QSAR models for various endpoints.

For the prediction of toxicity there are also QSAR-based expert systems commercially available, such as TOPKAT (TOxicity Prediction by Komputer Assisted Technology, Accelrys, San Diego, CA, USA). These systems already contain developed and predefined prediction models and cover up to 16 different toxicological endpoints including mutagenicity, carcinogenicity, developmental toxicity, skin sensitization, eye irritation and rat oral LD_{50}, etc. The QSAR models from TOPKAT are built on large, heterogeneous databases with carefully selected data and descriptors (Lemont and Lowell 1999).

PROCEDURE

QSAR modeling generally involves three steps: The first step is the collection of a training set of chemicals. The second step is the selection of descriptors that can properly relate chemical structure to biological/toxicological activity. At least the third step is the application of statistical methods, which correlate changes in structure with changes in biological/toxicological activity (Perkins et al. 2003).

The statistical methods of QSAR modeling are based on the correlation of changes in biological/toxicological activity ($\Delta\Phi$) resulting from certain chemical modifications (ΔC), either directly by structural parameters, called Free Wilson-type relationships, or

by the corresponding changes of molecular properties, called Hansch-type analyses (Kubinyi 2002):

$$\Delta\Phi = f\Delta C$$

The classical QSAR methodology started in 1964 with the publications of Hansch and Fujita (1964) and Free and Wilson (1964), and the statement of Hansch (1969) resulted from a proposal by Fujita. They proposed to combine several physicochemical parameters (π, σ), also called descriptors, in a quantitative model. This Hansch-type analysis is very flexible and describes many different kinds of biological activities, for example, in vitro data such as enzyme inhibition (Kubinyi 2002):

$$\text{Log } 1/C = a\pi + b\sigma + \ldots + \text{const}$$

(C is a molar dose that produces a certain biological response)

In an independent publication, Free and Wilson (1964) formulated their mathematical model. This model describes the biological activity in a logarithmic scale as the sum of the biological activity of the reference compound and the group contributions of all substituents that are attached to various positions of this molecule (Kubinyi 2002):

$$\text{Log } 1/C = \sum a_i + \mu$$

(a_i are the group contribution of the individual substituents X_i to the biological activity values and μ is the calculated biological activity of a reference compound, most often the unsubstituted analogue)

Free Wilson analysis is easy to apply. No physicochemical properties are needed to describe biological activity, just values of 1 or 0, to indicate the presence or absence of a certain position.

On the other hand, Free Wilson analysis is much more restricted than Hansch analysis, because of its many parameters and the corresponding decrease on the number of degrees of freedom of the statistical analysis (Kubinyi 2002).

In 1979, 3D QSARs were developed, which correlate spatially localized features across a chemical series with biological activity. The two primary types are 3D QSARs using lattice-based or surface-based descriptors. Among the lattice-based methods, Comparative Molecular Field Analysis (CoMFA) is the most used 3D QSAR method. In a CoMFA model, all molecules of a training set are aligned together regarding the similarities in their structure and then embedded in a 3D grid. 3D arrangements of molecular features are correlated to the biological activity (Perkins et al. 2003).

The molecular QSAR descriptors can be grouped into three categories: 2D descriptors (e.g., molecular connectivity), 3D descriptors (e.g., molecular surface area), and physicochemical properties (e.g., log P). They can also be categorized according to their nature as well as calculation method, such as constitutional, topological, geometrical, electrostatic, quantum chemical, and thermodynamic descriptors (Perkins et al. 2003). In the “Handbook of Molecular Descriptors” from Todeschini and Consonni (2000), an encyclopedic collection and description is available for all molecular descriptors from the beginning (about 2,000 of different definitions). A number of different commercial systems are available for the development of different kinds of QSAR models from a dataset. Examples are Cerius, Moe, Sybyl, TSAR, Golpe, Pipelinepilot (Scitegic), DRAGON, etc.

In the expert system, TOPKAT-predefined QSAR models are integrated in the system with the main use of topological, sub-structural, and electronic descriptors from the 2-D Kier and Hall type, which are developed from a large, heterogeneous databases with carefully selected data (Lemont and Lowell 1999). Thus, no self-development of QSAR models is necessary, and the structures can be immediately entered into the system and the prediction can be started for the different available toxicity endpoints. Continuous endpoints, such as LD_{50}, are modeled using multiple linear regression QSARs to generate different value predictions (e.g., different LD_{50} values). Other endpoints like carcinogenicity, where the endpoint is either positive or negative, are modeled using two-group linear discriminant regression functions (Greene 2002). The program also provides an estimate of confidence in the prediction that the user can examine the most similar compounds in the training set based upon their chemical descriptors. The program also provides an optimum prediction space (OPS) measurement that determines if the compound being investigated is well represented in the training set (Durham and Pearl 2001).

EVALUATION

To date a number of different QSAR models have been published, for the prediction of drug toxicity QSAR models cover over 30 different endpoints. It is not within the scope of this review to cover all of them here. Many authors have discussed and evaluated different QSAR models in the literature (Dearden 2003; Patlewicz et al. 2003; Tuppurainen 1999).

Good examples of QSAR models can be received for the prediction of mutagenicity with the Ames test (Ames et al. 1973). The Ames test is well suited to develop a robust QSAR because it is standardized, delivers a substantial amount of data within a short period of time, can be used for different chemical classes, covers a similar mechanism of toxicity for all compounds, etc. The mechanism of mutagenicity is the result of cell penetration, bioactivation, interaction, and modification of DNA together with various error-free and error-prone DNA repair processes. Many different types of mutagenic compounds follow this mechanism, which is reflected in the great diversity of chemical structures that have been associated with mutagenicity. Most QSAR studies of mutagenic activity have been based on Hansch-type regression models (Patlewicz et al. 2003). Tuppurainen (1999) reviewed some QSAR models for different congeneric series of mutagenic compounds like aromatic hydrocarbons, aromatic amines, nitrosamine, epoxides, etc. One example of these QSAR models is described from Debnath et al. (1992). He developed a QSAR model with a dataset containing the mutagenic activity of 67 aromatic and heterocyclic amines acting on the Ames stain TA100 after metabolic activation with S9-mix. In this model, the mutagenic activity (log TA100 in revertants/nmol) is linearly dependent on hydrophobicity (log P), the energy of the highest occupied molecular orbital (ε_{HOMO}), and the energy of the lowest unoccupied molecular orbital (ε_{LUMO}). The QSAR model representing the relationship between these parameters and activity is given in the following equation:

$$\log \mathrm{TA100} = 0.92(\pm 0.23) \log P + 1.17(\pm 0.83)\, \varepsilon_{HOMO} - 1.18(\pm 0.44)\, \varepsilon_{LUMO} + 7.35(\pm 6.90)$$

This relationship is interpreted in the way that the toxicological activity is dependent on log P, describing the ability of a compound to penetrate cell membranes to reach the target DNA, and on the molecular orbital energies (ε_{HOMO}, ε_{LUMO}), describing the ability of the metabolic activation to the electrophilic, reactive intermediate nitrenium-ion, which reacts with DNA resulting in a mutation and an increase in the revertants number in the Ames strain TA100.

The result of the internal evaluation of this QSAR model is shown in Fig. 51.1. In this figure, the calculated log TA100 values from the upper equation are plotted against the observed log TA100 values from the Ames tests for each of the 67 compounds. The line represents the regression, and results of the evaluation are expressed by the correlation coefficient $r = 0.887$ and the standard deviation from the regression $s = 0.708$. These data indicate the high potential of this QSAR model for the prediction of the mutagenic activity of aromatic and heterocyclic amines in the Ames strain TA100.

The expert system TOPKAT has been evaluated in several studies (Snyder et al. 2004; Dearden 2003; Patlewicz et al. 2003; Cariello et al. 2002; Durham and Pearl 2001; Richard 1998; Benfenati and Gini 1997; Enslein et al. 1994). In these evaluations, all statistical parameters, such as sensitivity, specificity, positive and negative predictivity, and the overall concordance range from 40% to 64% for the various endpoints.

CRITICAL ASSESSMENT OF THE METHOD

The development of a QSAR model with a good quality or predictivity depends on many factors. An important point is the quality of the dataset as bad data points will corrupt the model. In a qualitative good dataset, the number of chemicals should be sufficiently large to ensure statistical stability (at least 15–20 chemicals), the activity range should span two or more orders of magnitude and should be evenly distributed, the dose-response relationship should be smooth, and the chemicals should possess enough structural diversity. For robustness the right selection of descriptors is very important. The more is known about the biological mechanism, the better the descriptors can be selected to best encode the variation of activity with the structure. And finally, it is also very important to select the right QSAR method, which best describes the correlation between the structure and the biological/toxicological activity to give a QSAR model with a good prediction (Perkins et al. 2003).

Many different types of QSAR models and chemical descriptors for a wide range of endpoints are developed and published over the years. This makes QSAR

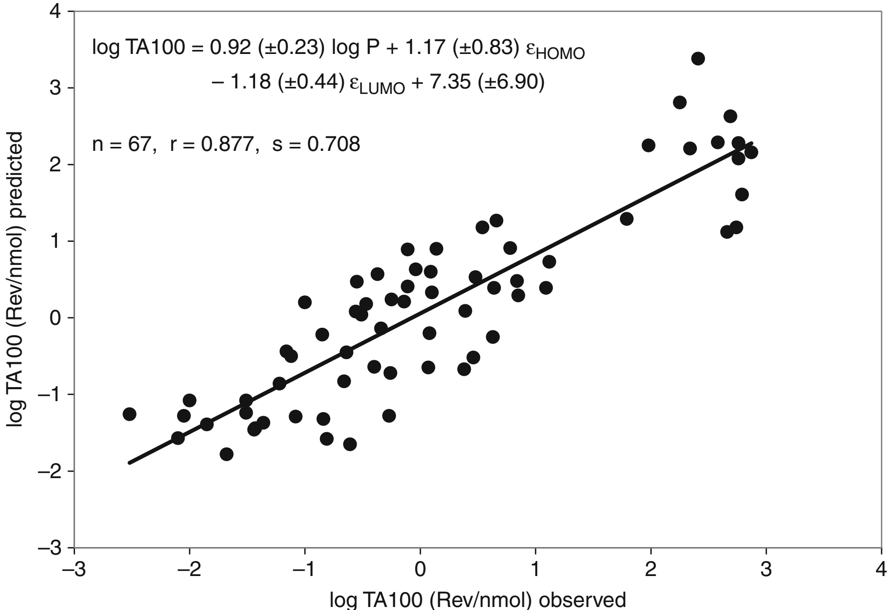

Fig. 51.1 QSAR model for the prediction of the mutagenic activity (in revertants/nmol) of aromatic and heterocyclic amines in the Ames strain TA100. The representing mathematical equation of the QSAR model is shown in the *top left corner*. In the graph, the calculated log TA100 values from QSAR model are plotted against the observed log TA100 values from the Ames tests for each of the 67 compounds of the dataset. The line represents the regression given by the equation. The model is further described in the paragraph evaluation. Abbreviations: *log TA100* mutagenic activity in revertants/nmol, *log P* hydrophobicity, ε_{HOMO} energy of the highest occupied molecular orbital, ε_{LUMO} the energy of the lowest unoccupied molecular orbital, *n* number of compounds from the dataset, *r* correlation coefficient, *s* standard deviation (Debnath et al. 1992)

a very flexible technique to be adapted for many different situations and a quite powerful technique that can provide a wealth of information. This has also a great potential for new QSAR models with every new experimental data.

One restriction of QSAR is that in most cases a good predictivity of a model is limited to a congeneric series or a specific class of compounds, which all act by the same mechanism of action. However, even for non-congeneric series it is often possible to develop classification of QSAR models, for example, for a classification of high, moderate, or low toxicity. So sometimes the QSAR models are not related to a specific mechanism. Therefore, it is not always possible to propose structural changes that will remove toxicity from the compound (Dearden 2003).

For the development of good QSAR models, experience with the method and time is needed, except when using the QSAR-based expert system TOPKAT, since QSAR models are already integrated in the system. TOPKAT has also the advantage that predictions are not limited to a single mechanism or class of chemicals, the program automatically supplies training sets of compounds for different endpoints. An important limitation of TOPKAT is that it is a closed system that does not allow users to expand the training set or to modify the method (Durham and Pearl 2001).

MODIFICATIONS OF THE METHOD

In the theory, it is possible to create new QSAR models with almost all datasets of compounds with known biological/toxicological activity. But practically it is a question of the quality and predictivity of a QSAR model to be applied in prediction of biological/toxicological activity. For this reason evaluation of each QSAR model is extremely important. The evaluation of a QSAR model can be performed either by internal validation (cross-validation) or external validation (use of a test-set). External validation is preferred but is not always possible, because of the small size of a dataset (Dearden 2003).

Unfortunately no modification of the training set or the prediction models is possible for the QSAR-based expert system TOPKAT.

51.2 DEREK for Windows (DfW)

PURPOSE AND RATIONALE

DEREK for Windows (DfW, *D*eductive *E*stimation of *R*isk from *E*xisting *K*nowledge) is a knowledge-based expert computer system for the prediction of toxicity. The prediction of toxicity is based on structure-activity relationship (SAR) analysis of a chemical structure. It provides a qualitative prediction. The knowledge is stored as rules in the computer system. When the software analyzes a compound, the rules identify features within the structure that have been shown to be responsible for toxicological activity when they have been present in other chemicals. DfW highlights these substructures and give structural alerts for this compound. These toxicological active substructures within the structures are called toxicophores in DfW (LHASA Limited homepage). Since substructures can exist in a variety of molecules, the rules are not chemical-specific, but rather serve as broad generalizations with regard to the chemical structure (e.g., alkylating agent, acid or halogen-containing molecule, Cariello et al. 2002).

The knowledge is based on researching literature data or internal company data with an emphasis on the understanding of mechanisms of toxicity and metabolism required for activation of a compound to

a toxicological intermediate (Patlewicz et al. 2003). It covers a wide variety of toxicological endpoints, which include genotoxicity, carcinogenicity, irritation, skin and respiratory sensitization, hepatotoxicity, hERG channel inhibition, reproductive/developmental toxicity, and other miscellaneous endpoints (LHASA Limited homepage). Its main strengths lie in the prediction of carcinogenicity, mutagenicity, and skin sensitization (Greene 2002).

The DfW software incorporates also a reasoning engine that uses log P (calculated by a ClogP plug-in) and molecular mass to predict the likelihood that a chemical will express its potential toxicity regarding a specific endpoint in the selected species. This feature is used in the evaluation of the skin permeability for the prediction of skin sensitization and photoallergenicity in humans (Patlewicz et al. 2003). This proprietary reasoning engine combines both numerical and non-numerical statements (like selected species, log P, endpoint, toxicophores, etc.) to reach a conclusion about a given event. It is based upon the mathematical framework of the logic of argumentation. The reasoning engine can be adapted to any toxicological endpoint within the DfW system (Greene 2002). The result of the reasoning is that the likelihood of a structure being toxic is then expressed in one of the following terms: Certain, Probable, Plausible, Equivocal, Doubted, Improbable, Impossible, Open, and Contradicted.

The rules are written and maintained by experts from LHASA Limited. LHASA Limited is a non-profit organization that facilitates collaborations between scientists from a wide range of educational, regulatory, and commercial institutions. The rules are regularly updated by LHASA Limited and new versions of the computer software are available every year. Regular collaborative user group meetings are organized with representatives from pharmaceutical, agrochemicals, and regulatory organizations. At these user group meetings, changes in computer software and knowledge base developments are presented and the users provide feedback about the improvements. User suggestions for improvements to knowledge base and software are discussed during the wish list session, and new rules and toxicological information derived from internal company data is presented from the users. This unique system encourages the sharing of toxicological information and knowledge for the benefit of all, without organizations compromising the confidentiality of their proprietary data (Patlewicz et al. 2003).

PROCEDURE

The new versions of DfW are compatible with Microsoft Windows. For the prediction of toxicity the chemical structure of a compound is input into the system with the use of ISIS/Draw (from MDL Information Systems) or by importing a mol-file or sd-file (Fig. 51.2a). After the system has the structure, pushing the “process” button starts the prediction. During processing, the system searches and identifies all known toxicophores in the structure from all the different toxicological endpoints within seconds. After completion of the analysis, the system opens a result window. The result window contains the imported structure, a list of toxicological endpoints that the system has made a prediction for, the number and name of the toxicophores found in the structure (the position of the toxicophores in the structure is highlighted in red), and the level of likelihood for each endpoint in each species (Fig. 51.2b). For each prediction in the result window additional information is available including a reasoning report, an alert description, supporting examples, and processing constraint details. For example by choosing the “Alert Description” button, additional information and a description of the alert including information about the SAR, references, endpoint, and comments are displayed in an extra window for a specific alert (Fig. 51.2c). From the “Alert Description” window users can choose the “Example” button; this opens a new window which displays toxicity data for a number of chemicals that are pertinent to the alert including information about the structure, name, CAS number, and toxic activity. References and comments can be displayed in an extra window (Fig. 51.2d). It is also possible to process a big list of many different structures in the mol-file or sd-file format with one button click by using the Auto DEREK function, making batch processing possible with DfW.

All the results described above can be exported from DfW to other applications by generating a “DEREK for Windows report” in either rich text (rtf), tab delimited text, or modified sd-file format (Fig. 51.3).

EVALUATION

Richardt and Benigni (2002) stated in their paper that there are two common approaches to assess the predictive performance of computer programs for the prediction of toxicity: beta-testing (also called internal

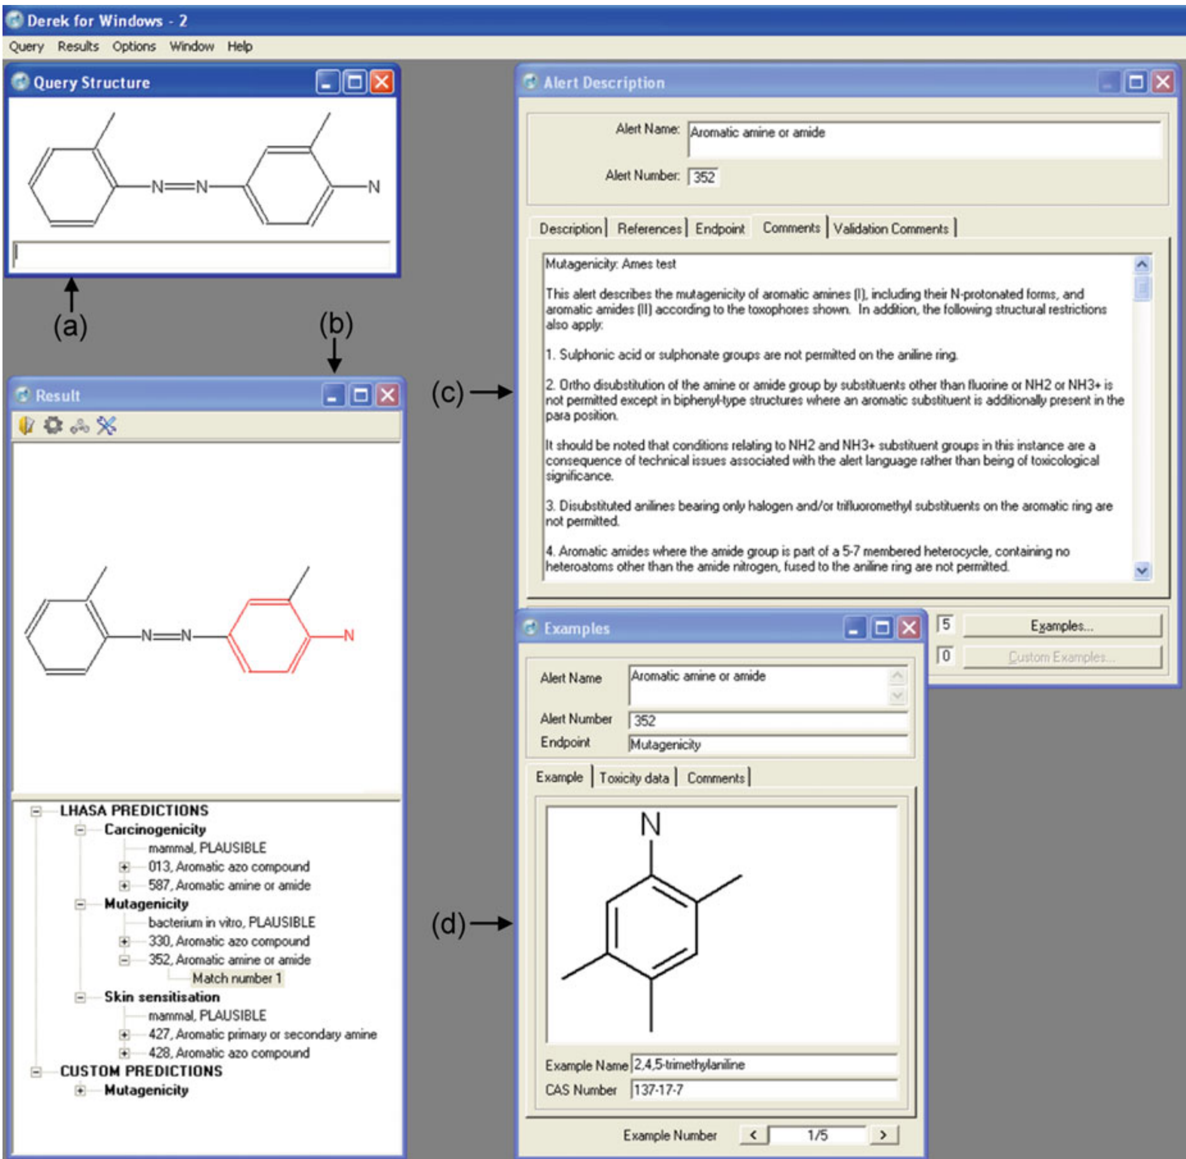

Fig. 51.2 Screen-print from the DEREK for Windows prediction (version 13.0) for the compound 2-methyl-4-[(2-methylphenyl)azo]benzenamine: (**a**) imported structure, (**b**) prediction results window, (**c**) alert description window, (**d**) example compounds window

validation or cross-validation) and prospective prediction (also called external validation). In beta-testing, the available dataset is divided into a training and test set. The model is built upon the training set and the performance is then measured for the test set. In prospective prediction, the model is applied to a novel group of chemical structures where there is often little consistency with training set used to generate the model. A good way to use the prospective evaluation method is for pharmaceutical companies to use their historical, unpublished toxicity data of internal compounds (unavailable to the model developers) to evaluate the prediction systems (Greene 2002).

The Ames test (Ames et al. 1973) is a well-established and fast assay for the prediction of mutagenicity of drug candidates in the pharmaceutical industry. The result of the Ames test is also necessary for approval of a drug. The consequence is that every

...groups in this instance are a consequence of technical issues associated

3. Disubstituted anilines bearing only halogen and/or trifluoromethyl substituents on the aromatic ring are not permitted.

4. Aromatic amides where the amide group is part of a 5-7 membered heterocycle, containing no heteroatoms other than the amide nitrogen, fused to the aniline ring are not permitted.

5. Disubstituted anilines bearing only one halogen or trifluoromethyl substituent and an alkyl carbon (with the exception of benzylic carbons in the para position) are not permitted.

6. Anilines are not permitted if they bear strong or moderate electron-withdrawing groups [F, CF3, CN, C=Q (except CO2H), OCN, SCN, OCF3 SCF3, SO2] without the presence of a suitable electron-donating group at another position.

7. Para-alkoxy anilines substituted only with alkyl groups in the ortho position are not permitted.

8. Ortho substitution of the amine or amide with hydroxyl, thiol or a cyclic secondary amine or amide is not permitted.

9. Para substitution of the amine or amide by a hydroxyl group is not permitted unless there are other heteroatoms on the aniline ring.

10. Anilines fused to an aliphatic carbocyclic ring system in the absence of a suitable electron-donating group are not permitted. Ring carbons that are not directly attached to the aniline ring may be replaced by any heteroatom.

11. Ortho substitution of the amine or amide with any ring system at either 0, 1 or 2 atoms distance from the ortho position is not permitted.

12. Anilines fused to an aliphatic ring system at the C2-C3 bond are not permitted if a chain of more than two non-hydrogen atoms is attached to the atom adjacent to the ortho position.

13. Anilines where the total number of non-hydrogen atoms is greater than 25 are discounted.

Many aromatic amines exhibit mutagenicity in the Ames test, notably in Salmonella typhimurium strains TA98 and TA100 in the presence, but not absence, of S9 mix [Debnath et al, Benigni et al 1998, Benigni et al 1994]. The mechanism of action is generally considered to involve N-hydroxylation, typically mediated by cytochrome P450 1A2, and subsequent O-esterification [Colvin et al]. The resulting esterified product may then give rise to a reactive nitrenium ion which is capable of binding to cellular nucleophiles such as DNA.

year a lot of unpublished propriety Ames results are produced in every company and are added to each company's historical toxicity database. In 2009, a prospective/external evaluation of DfW was performed at Sanofi-Aventis for the prediction of the endpoint mutagenicity. For this evaluation all proprietary compounds were used that were tested in the Ames assay at Sanofi-Aventis in the year 2008. From these 304 substances in total, 62 compounds (20%) were positive and 242 (80%) were negative in Ames test. For the prediction of these compounds the DEREK version 11.0 optimized with alerts from internal knowledge was used. The results of this evaluation are shown in Table 51.2.

The results of this evaluation are summarized with the statistical parameters such as sensitivity, the correctly predicted positive compounds; specificity, the correctly predicted negative compounds; and concordance, the correctly predicted positive and negative compounds. In this evaluation, 30 out of 62 Ames positive compounds were correctly predicted, which gives a sensitivity of 48% for the system. On the other hand 205 out of 242 Ames negative compounds were correctly predicted, which gives a specificity of 85% for the system. The overall concordance, correct positive and correct negative predictions, was 77%.

These results are in good agreement with those found by other authors (Hillebrecht et al. 2011; Matthews et al. 2008; Snyder et al. 2004; Cariello et al. 2002; Greene 2002; Durham and Pearl 2001; Greene et al. 1999; Benfenati and Gini 1997; Sanderson and Earnshaw 1991).

Table 51.2 DfW mutagenicity predictions (version 11.0 + alerts from internal knowledge) for Ames results of 304 Sanofi-Aventis proprietary structures

Ames results	DfW prediction: Mutagenicity alert	DfW prediction: No alert	Total	
Positive	30	32	62	Sensitivity[a] 30/62 = 48%
Negative	37	205	242	Specificity[b] 205/242 = 85%
Total	67	237	304	Concordance[c] (30 + 205)/304 = 77%

[a]Sensitivity is the percentage of correctly predicted positive compounds
[b]Specificity is the percentage of correctly predicted negative compounds
[c]Concordance is the percentage of correctly predicted positive and negative compounds

CRITICAL ASSESSMENT OF THE METHOD

Greene (2002) listed some strengths and limitations of DfW in his review article. One of the strengths highlighted in this review is that the rules from DfW are regularly updated by LHASA Limited and peer reviewed by the users. This unique system of collaboration between LHASA Limited and the users is also important for Patlewicz et al. (2003) specifically because it encourages the sharing of toxicological information and knowledge for the benefit of all without organizations compromising the confidentiality of their proprietary data. Another strength for Greene (2002) and Durham and Pearl (2001) is that DfW summarizes, on one screen or with one report, the full list of alerts, the highlighted toxicophores and the justification for its prediction including the alert description, published references, and example compounds credited for the generation of this alert. It is also very easy with DfW to add new company internal rules to the system together with an alert description, literature, and example compounds related to this alert. For Greene (2002) additional strengths are that with the batch-processing feature it is possible to make high-throughput predictions for a large number of compounds for both testing and validation. At least one of the most important strengths of DfW is that the rules are based on scientific knowledge of structure-toxicity relationships and mechanisms (Greene 2002).

For Greene (2002) one of the limitations of DfW is that only a few physicochemical parameters are used; he suggested that their use should be extended to include other 2D and 3D parameters and also their use in predicting other toxicological endpoints should be explored further. Another point is that the activating and detoxification effects of metabolism need to be explored in more detail. For Patlewicz et al. (2003) the primary limitations of DfW relate to the inadequate number of rules for a number of toxicity endpoints and chemical classes reflecting knowledge gaps of the developers and user groups. For Durham and Pearl (2001) the system is limited in that DfW only identifies activation fragments, so the negative prediction is solely based on the lack of positive toxicophores. Therefore, the program is extremely biased toward the prediction of positive compounds. Consequently, DEREK has a low percentage of false negative predictions. The program automatically screens for some simple rules

(e.g., identifying structural exceptions to a rule), but not for other complex rules (e.g., presence of toxicity related to the presence of two or more unconnected toxicophores), even though the program is capable of storing these kind of rules (Durham and Pearl 2001).

MODIFICATIONS OF THE METHOD

Besides the possibility of using the general knowledge base of DfW offered by LHASA Limited, it is also possible to create an internal knowledge base by adding alerts, reasoning rules, and supporting data examples and references in-house. For the creation of new rules a knowledge base editor is available that enables the users to define one or more "patterns" for a new alert. These patterns include the SAR for a new rule and the definition for alerting a fragment within a molecule. The original rules offered by LHASA Limited cannot be modified, but it is possible to duplicate the LHASA Limited rules and to modify these copies to create new rules.

To get a more specific prediction for a special study design it is possible to change the processing constraints in DfW. For example by choosing a species DfW will make a species-specific prediction. The different species that can be selected are human, primate, mammal, rodent, rat, mouse, guinea pig, hamster, and bacterium including *Salmonella typhimurium*. The other processing constraints that can be changed are as follows: consider tautomers or not, perform a DEREK prediction for a single alert, etc.

DfW predictions include information about the mechanism of activity, for example metabolic steps necessary for toxicity. For a more detailed analysis of the toxicity of a compound and its metabolites DfW can be used in combination with an *in silico* program for the prediction of metabolites. LHASA Limited offers such a program with the name METEOR. For the combination of these two systems, first the metabolites of a compound are predicted by METEOR. These metabolites are then sent to DfW for the prediction of toxicity of the compound and its predicted metabolites.

EXAMPLE

Figures 51.2 and 51.3 show the DEREK for Windows prediction (version 13.0) for the example compound 2-methyl-4-[(2-methylphenyl)azo]benzenamine (CAS-No.: 97-56-3). For this compound many positive mutagenicity and carcinogenicity results are reported in the literature (results from the CCRIS database search). In agreement with the literature, this compound was predicted by DEREK for Windows to be carcinogenic (carcinogenicity alerts 013: aromatic azo compound, 587: aromatic amine or amide) and mutagenic (mutagenicity alerts 330: aromatic azo compound, 352: aromatic amine or amide). Figure 51.2 shows the screen-print and Fig. 51.3 shows the report from the DfW prediction for this compound.

51.3 MultiCASE

PURPOSE AND RATIONALE

MultiCASE (*Multiple* Computer *A*utomated *S*tructure *E*valuating, MultiCase, Beachwood, OH, USA) is a statistically fragment-based expert computer system for the prediction of toxicity. It consists of a computer system to perform the prediction and different databases (modules). Each database contains a series of diverse non-congeneric chemical structures and their observed activity (quantitative or qualitative) for specific toxicological endpoints, including toxicological active and inactive compounds. Some authors also classify MultiCASE as a hybrid QSAR and artificial expert-structure-based program. The QSAR portion of the program is based upon 2-D chemical descriptors that utilize proprietary statistical analysis developed by Klopman (1984). The artificial expert-structure-based program is based upon the identification of atom fragments that are present in active and inactive molecules and that have a high probability of being relevant or responsible for the observed toxicological activity (Durham and Pearl 2001).

For the prediction of toxicity in a first step each molecule of a database is broken down from MultiCASE into all possible fragments from two to ten heavy (non-hydrogen) atoms including also overlapping fragments. These are then classified statistically as "biophores," fragments associated with toxicity, and "biophobes," fragments not associated with toxicity. In addition to utilizing molecular fragments, MultiCASE also identifies relevant two-dimensional distances between atoms within a chemical structure. MultiCASE then creates organized dictionaries of these biophores and biophobes and develops ad hoc local QSAR correlations that can be used to predict the activity of unknown molecules. The results of this first prediction step are saved, and identified biophores are visible for the users (MultiCASE homepage).

In the second step of the prediction a new molecule is entered into MultiCASE, and then the program evaluates this molecule against this organized dictionary and the appropriate QSARs it has created and makes a prediction of the toxicological activity of the molecule for the corresponding endpoint. To do this, MultiCASE identifies all relevant biophores and biophobes of the unknown molecule, combines these into an equation and calculates the toxicological activity expressed in CASE units with the help of the following equation (Dearden 2003):

$$\text{CASE units} = \text{constant} + \text{a(fragment 1)} + \text{b(fragment 2)} + \ldots$$

The scale of CASE units has linear range from 10 to 99 and normally chemicals with an assigned value of 10–19 are inactive, 20–29 have marginal activity, and 30–99 are moderately active, active, highly active, and extremely active. The system is also capable for identifying fragments that act as modifiers to the activity of each biophores class (Greene 2002).

MultiCASE covers different toxicological endpoints like genotoxicity, carcinogenicity, irritation, developmental toxicity/teratogenicity, adverse effects in humans for the endpoints hepatobiliary, renal/urinary tract and cardiac, and other miscellaneous endpoints. For each of these endpoints one or more databases (modules) containing active and inactive molecules are separately available, and most of the modules were constructed at the Food and Drug Administration (FDA) by the Informatics and Computational Safety Analysis Staff (ICSAS) group.

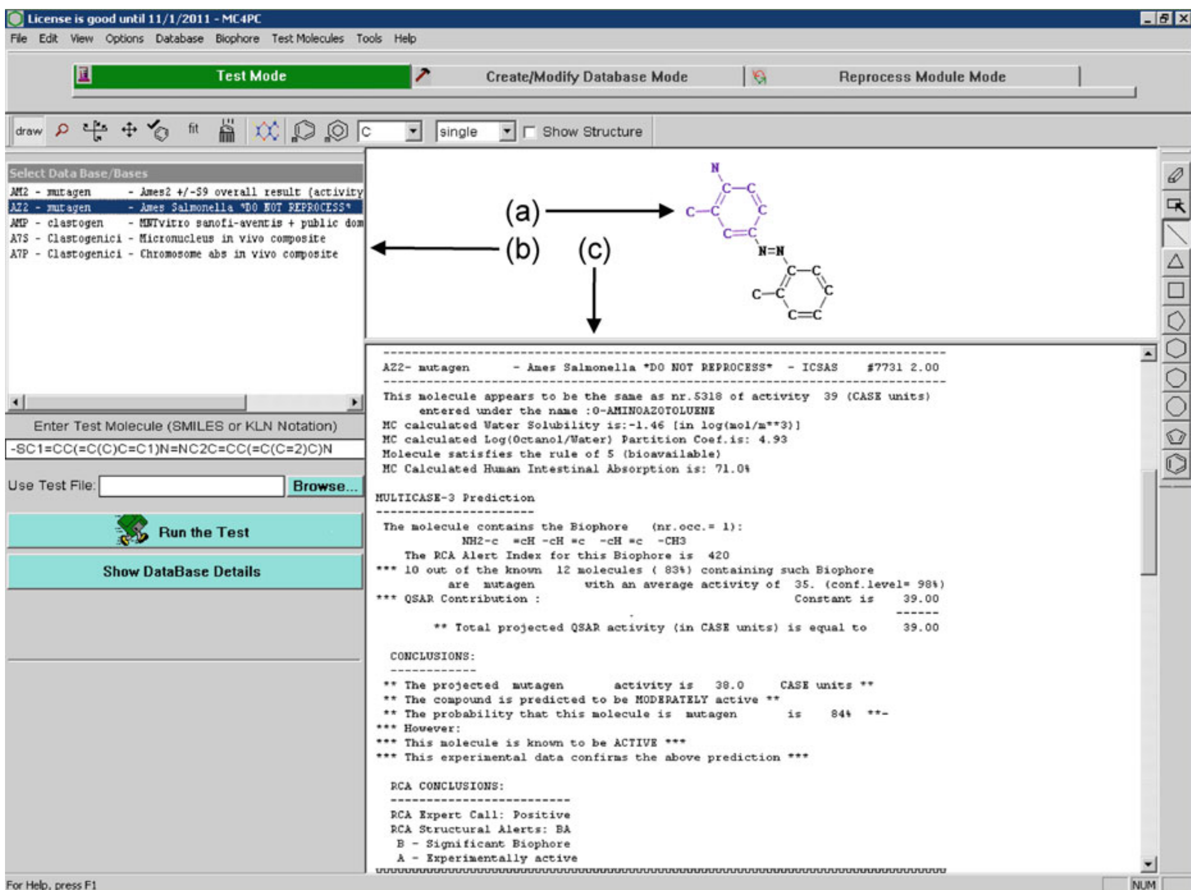

Fig. 51.4 Screen-print from the MultiCASE prediction (version 2.3) for the compound 2-methyl-4-[(2-methylphenyl)azo] benzenamine: (**a**) imported structure, (**b**) chosen modules for the prediction, (**c**) prediction results window

The number of compounds varies from 70 up to 6,000 per module (MultiCASE homepage).

There are also other systems available based on the MultiCASE technology. *C*omputer *A*utomated *S*tructure *E*valuating (CASE) was first developed before the MultiCASE system. It uses the same technology but differs in some ways. The major algorithmic difference in MultiCASE is the use of hierarchy in the selection of descriptors, leading to the concept of biophores and modulators. Another important difference is that only with MultiCASE new internal proprietary data can be used to create new databases.

PROCEDURE

The new versions of MultiCASE (MC4PC) run on Windows 9X/NT/2000 computers. For the prediction of toxicity, the structures of a compound can be easily entered into MultiCASE by using an internal graphical interface from the system (Fig. 51.4a). It is also possible to import structures in mol-file format or to run a set of compounds in an sd-file format. For MultiCASE prediction, one or more databases must be chosen, which should be used for the prediction (Fig. 51.4b). After starting the prediction, MultiCASE utilizes the set of statistically significant fragments and/or distance to find the biophore that has the highest probability of being responsible for the observed toxicological activity. The presence of biophores determines the likelihood of a compound to exhibit toxicity. The prediction then consists of the identification of the biophores responsible for toxicity and the probability (in percent) of a compound being toxicologically active. A compound is presumed to be inactive if it contains no biophore. Within each group of compounds containing a particular biophore, MultiCASE also performs a local QSAR in order to identify molecular

MultiCASE report

RCA Structural Alerts:
B - significant biophore
B? - possibly significant biophore
X - significant unknown fragment alert
X? - possibly significant unknown fragment alert
b - non-significant biophore
x - non-significant unknown fragment alert
D - significant deactivating fragment (biophobe)
d - non-significant deactivating fragment
A - experimentally active
M - marginal experimental activity
I - experimentally inactive
w - unknown fragment warning

Comments:
de - different environment
pos - 2D positional alert
qsar - a significant biophore +B is changed to -B because its total QSAR < 30
deg - highly degenerate fragment
bad alert - the fragment is a biophore for some of the databases and a biophobe for others
SSA - Structural Similar Alerts

features, which controls the degree of activity. These features, termed modulators, are selected from the pool of molecular fragments, 2-D distance descriptors, calculated electronic indices (molecular orbital energies, charge densities), and calculated transport parameters (octanol/water participation coefficient, water solubility). These local QSARs are utilized to predict the potency of chemicals containing specific biophore. At least for an overall prediction, the four individual predictions corresponding to the probability of activity and QSAR potencies are combined using Bayes' theorem. For that purpose the predictivity of each of the four SAR models are determined by analysis of the sensitivity and specificity of the model for chemicals not in the database (Rosenkranz et al. 1999).

During the MultiCASE prediction, the output of the prediction is displayed in a text window on the screen (Fig. 51.4c). This text will be automatically saved in several rtf- and xls-files (Fig. 51.5).

EVALUATION

Also for MultiCASE, in 2009 a prospective/external evaluation was performed at Sanofi-Aventis for the prediction of the endpoint mutagenicity. For this evaluation the identical proprietary compounds were used, which were also used for the DEREK evaluation: all proprietary compounds that were tested in the Ames assay (Ames 1973) at Sanofi-Aventis in the year 2008. Again, from these 304 substances in total, 62 compounds (20%) were positive and 242 (80%) were negative in Ames test. For the prediction of these compounds the MultiCASE version 2.0 together with the prediction module "Ames *Salmonella* (AZ2)" optimized with internal compounds was used. The results of this exercise are shown in Table 51.3.

The results of this evaluation are summarized with the help of the statistical parameters such as sensitivity, the correctly predicted positive compounds; specificity, the correctly predicted negative compounds; and concordance, the correctly predicted positive and negative compounds. In this evaluation, 34 out of 62 Ames positive compounds were predicted correctly, which results in a sensitivity of the system of 55%. On the other hand, 215 out of 242 Ames negative compounds were correctly predicted, which gives a specificity of the system of 89%. The overall concordance, correct positive and correct negative predictions, was 82%.

The sensitivity as well as the specificity of MultiCASE is minimally higher compared to the evaluation with DEREK but is overall very similar. In general, a combination of the DEREK and MultiCASE prediction is improving the sensitivity and the identification of the Ames positive compounds, since both systems use different prediction methods (the knowledge/rule-based approach from DEREK combined with the statistically fragment-based approach from MultiCASE).

These results of the MultiCASE evaluation are in good agreement with those found by other authors (Hillebrecht et al. 2011; Matthews et al. 2008; Snyder

Table 51.3 MultiCASE predictions (version 2.0) using the "Ames *Salmonella* (AZ2)" module, optimized with internal compounds, for Ames results of 304 Sanofi-Aventis proprietary structures

Ames results	MultiCASE prediction			
	Positive	Negative	Total	
Positive	34	28	62	Sensitivity[a] 34/62 = 55%
Negative	27	215	242	Specificity[b] 215/242 = 89%
Total	61	243	304	Concordance[c] (34 + 215)/304 = 82%

[a]Sensitivity is the percentage of correctly predicted positive compounds
[b]Specificity is the percentage of correctly predicted negative compounds
[c]Concordance is the percentage of correctly predicted positive and negative compounds

et al. 2004; Greene 2002; Durham and Pearl 2001; Rosenkranz et al. 1999; Cunningham et al. 1998; Benfenati and Gini 1997).

CRITICAL ASSESSMENT OF THE METHOD

In his review Greene (2002) pointed out some strengths and limitations of MultiCASE. One of the strengths of MultiCASE is that it is capable of generating predictive models without knowing the mechanisms of toxicity. The program also utilizes a number of physicochemical properties to modulate its predictions. Finally another strength is that due to the input of FDA data, MultiCASE has substantially increased the applicability to the prediction of rodent carcinogenicity for pharmaceutical type compounds. For Durham and Pearl (2001) some other strength of MultiCASE compared to a knowledge base system like DEREK is that it searches for both activating and deactivating fragments for the toxicity prediction. Another advantage is that it is very easy to add new proprietary data to the databases in order to increase the chemical space and to achieve a more specific prediction for the internal proprietary compounds.

The limitations for Greene (2002) are that the quality of the predictions made by the system is closely linked to the quality of the data used in the training set. The output from the program is also often ambiguous and can lead to misinterpretation of the predictions. Moreover the system often fails to distinguish between molecules containing several small chains within one complex fragment from other molecules containing the same fragments distributed separately.

MODIFICATIONS OF THE METHOD

To perform a prediction with MultiCASE different commercially available databases from the developer of the program can be used. They are updated regularly by adding new compounds to the databases. However, it is also possible to modify the commercial databases as well as to create new databases using internal company data. For this a dat-file first has to be created, containing all compounds for the new database together with their structure code and biological activity. By screening this dat-file with MultiCASE, statistical algorithms are used to create a model capable of predicting the biological activity of the new compounds. A chart-view is available to adjust the indicated properties. After that the dat-file can be stored and other fields for chemical properties calculated by the program, such as boiling point, molecular weight, water solubility, and Log P, are added. The next step is the creation of the new database. The database description must be entered after which MultiCASE starts to calculate the biophores and biophobes of the new database.

There is also a separate expert system for the combination with MultiCASE, which predicts the possible metabolites, formed of a compound. This system is known as META, which was developed to identify molecular sites susceptible to metabolic transformation. The metabolism dictionary associated with META is able to recognize 663 enzyme-catalyzed reaction rules, which have been categorized into 29 enzyme-reaction classes and 286 spontaneous reactions (Klopman and Rosenkranz 1994).

The US Food and Drug Administration (FDA) has adapted the MultiCASE technology and has developed a new system known as MultiCASE QSAR-ES (quantitative structure-activity relationships expert system). This system uses the MultiCASE program and new database modules that were developed under a Cooperative Research and Development Agreement (CRADA) between the US FDA and MultiCASE. It was designed to improve the prediction of the carcinogenic potential of pharmaceuticals. Matthews and Contrera (1998) performed a beta-test evaluation utilizing 126 compounds not included in the test database with 934 compounds. The results demonstrated an improvement in all statistical parameters for the prediction of carcinogenicity compared to the MultiCASE prediction with an overall concordance of 75% (Patlewicz et al. 2003).

EXAMPLE

Figures 51.4 and 51.5 show the MultiCASE prediction (version 2.3) for the example compound 2-methyl-4-[(2-methylphenyl)azo]benzenamine (CAS-No.: 97-56-3). For this compound many positive mutagenicity and carcinogenicity results are reported in the literature (results from the CCRIS database search). In agreement with the literature, this compound was predicted by MultiCASE to be mutagenic. Figure 51.4 shows the screen-print from the MultiCASE prediction for this compound and Fig. 51.5 shows an example of a MultiCASE report for a dataset of compounds.

51.4 Leadscope

PURPOSE AND RATIONALE

The Leadscope Model Applier (Leadscope Inc., Columbus, Ohio, USA) is an expert computer system using a fragment-based QSAR paradigm. Like MultiCASE, the system consists of a computer software to perform the prediction and different training databases (models) for the prediction of the respective toxicity endpoints. The fragments used for the prediction are predefined in a hierarchically organized dictionary that is closely related to common organic/medicinal chemistry blocks. For binary classification problems, such as the Ames test, the algorithm identifies toxicity-modulating fragments using a $\chi2$-test. Furthermore, the software is able to build superstructures from smaller fragments if they improve predictivity. Additionally eight global molecular properties are calculated (atom count, hydrogen bond acceptors, hydrogen bond donors, Lipinski score, LogP, molecular weight, polar surface area, and rotatable bonds). These global molecular properties together with the set of fragments are then used as a descriptor set in a partial least squares (PLS) logistic regression model of the activity class. Therefore, the predictions from this algorithm are continuous probabilities of class membership rather than binary outputs, given as the likelihood value between 0 (nontoxic) and 1 (toxic). All probabilities greater than 0.5 are considered as "active" predictions and probabilities smaller than 0.5 as "inactive" predictions. The higher the probability is, the greater chance there is of the test chemical being toxic in a particular endpoint. The program also assesses the applicability domain by measuring

the distance to training set molecules by using two parameters: (1) having at least one feature defined in the model; (2) having at least one chemical in a training neighborhood with at least 30% similarity. Compounds which are annotated as "out of domain" or "missing descriptors" are counted as "not predicted" (Hillebrecht et al. 2011).

Currently, Leadscope offers QSAR models for the prediction of eight different toxicity endpoints. All these QSARs were constructed at the Food and Drug Administration (FDA) by the Informatics and Computational Safety Analysis Staff (ICSAS) group. The training datasets were compiled by ICSAS and the models were built within the Leadscope Prediction Data Miner software using all default settings (Yang et al. 2008).

The QSAR models can be divided into two major groups of endpoints: human clinical endpoints and nonhuman toxicity endpoints. The first group includes three suites of models which predict the effects of compounds based upon human clinical data, including adverse cardiological effects, adverse hepatobiliary effects, and adverse urinary tract effects. The second group includes five different suites, predicting toxicities of compounds based upon results of in vivo animal toxicity and in vitro studies. They include carcinogenicity in rodents, genetic toxicity (i.e., mutagenicity, clastogenicity, and DNA damage), reproductive toxicity in male and female rodents, developmental toxicity (i.e., dysmorphogenesis, fetal development, and survival of the rodent fetus), and neurotoxicity in newborn rodents.

Each toxicity endpoint has many different QSAR models, for some sub-models are constructed to improve the predictive performance of the models. The predictive performance of global models depends highly on the ratio of active (toxic) to inactive (nontoxic) chemicals in a training set. A training set was divided into subsets to maintain optimal active-to-inactive (A/I) ratio to ensure high specificity. This A/I ratio ranges between 0.30 and 0.35 for most training sets. The rationale behind these QSAR models is that predicting true negatives must be maximized while false negatives must be minimized in product safety analysis within the regulatory agencies. In general, more than one sub-model is built for each model, and for best results, Leadscope runs each of the sub-models behind the scene and presents an overall result. The overall prediction results are based on averaging the probabilities (likelihood of being positive) from appropriate sub-models (Leadscope FDA Model Applier Documentation 2008).

PROCEDURE

For the predictions, structure can be imported into Leadscope as files or an entry for a single compound. It handles both MDL mol/SD files and SMILES. Then the individual QSAR models can be accessed via a prediction model wizard. The models are organized hierarchically in a tree view. When clicking the model name, a short description will appear in a "description" box. The wizard allows the review of both the overall average model as well as the sub-models. Then the next window from this wizard will display the cross-validated model results (performed for 10%) for chemicals in the training set. These validation results include concordance (overall accuracy), sensitivity, specificity, receiver-operator constant (ROC) for positives and negatives. After selecting the individual QSAR models, the predictions can be applied simultaneously for the imported structures. Running multiple models is possible and the results of the multiple models are displayed in the "Summary" tab of the prediction results table. The results are tabulated in a "Summary" table. This summary displays all the requested prediction results for each model as well as indicating whether any prediction calls from any of the models were positive. Prediction calls include positive, negative, not-in-domain, or missing descriptors. Also additional model parameters can be retrieved, including number of chemicals found to be within the neighborhood defined by 30% similarity, number of model features used to calculate the predictions, and the average domain distance of the test chemical to the training set structures (based on all chemical features). Once the prediction models are applied and the results are saved, some chemical inference and reasoning can be performed within the Model Applier from the review prediction results wizard. This wizard is also a convenient way to evaluate the external validation results. It displays the contingency table and allows exploration of true positives and negatives as well as false predictions via histograms or a scatter plot.

The last wizard page then correlates the Leadscope hierarchy features with the actual experimental data versus predicted data. The model applier provides ways to perform chemical inferences during the external validation process (Leadscope FDA Model Applier Documentation 2008).

EVALUATION

Also for Leadscope, in 2009 a prospective/external evaluation was performed at Sanofi-Aventis for the prediction of the endpoint mutagenicity. For this evaluation the identical proprietary compounds were used, which were also used for the DEREK and MultiCASE evaluations: all proprietary compounds that were tested in the Ames assay (Ames 1973) at Sanofi-Aventis in the year 2008. Again, from these 304 substances in total, 62 compounds (20%) were positive and 242 (80%) were negative in Ames test. For the prediction of these compounds the Leadscope version 1.3 together with the prediction model *Salmonella* optimized with internal compounds was used. The results of this exercise are shown in Table 51.4.

The results of this evaluation are summarized with the help of the statistical parameters, such as sensitivity, the correctly predicted positive compounds; specificity, the correctly predicted negative compounds; and concordance, the correctly predicted positive and negative compounds. In this evaluation, 36 out of 62 Ames positive compounds were predicted correctly, which results in a sensitivity of the system of 58%. On the other hand, 217 out of 242 Ames negative compounds were correctly predicted, which gives a specificity of the system of 90%. The overall concordance, correct positive and correct negative predictions, was 83%.

The sensitivity as well as the specificity of Leadscope is minimally higher compared to the evaluation with MultiCASE and DEREK but is overall very similar. In general, a combination of the DEREK and Leadscope (or MultiCASE) prediction is improving the sensitivity and the identification of the Ames positive compounds, since both systems use different prediction methods (the knowledge/rule-based approach from DEREK combined with the statistically fragment-based approach from Leadscope or MultiCASE).

Table 51.4 Leadscope predictions (version 1.3) using the *Salmonella* model, optimized with internal compounds, for Ames results of 304 Sanofi-Aventis proprietary structures

Ames results	MultiCase prediction			
	Positive	Negative	Total	
Positive	36	26	62	Sensitivity[a] 36/62 = 58%
Negative	25	217	242	Specificity[b] 217/242 = 90%
Total	61	243	304	Concordance[c] (36 + 217)/304 = 83%

[a]Sensitivity is the percentage of correctly predicted positive compounds
[b]Specificity is the percentage of correctly predicted negative compounds
[c]Concordance is the percentage of correctly predicted positive and negative compounds

These results of the Leadscope evaluation are in good agreement with those found by other authors (Hillebrecht et al. 2011; Valerio et al. 2010; Matthews et al. 2008).

CRITICAL ASSESSMENT OF THE METHOD

Possible strengths and limitations of the Leadscope Model Applier are described in the review article of Valerio et al. (2010). The strengths of this expert system include that it is easy to use and very intuitive with respect to navigating through the screens and the loading of molecules or sets of molecules for predictions. It also allows output to be easily interpreted and exported. Additionally, it shows also a wide variety of models which are available for prediction of different endpoints. The main strength of this expert system is that the chemoinformatics approach of the Leadscope structural feature analysis is unique among other computational methods, thus providing more insight into the chemical landscape. This includes that the predefined structural features are closely related to common organic/medicinal chemistry blocks and that the intuitive chemical interference of these is supported for open training sets.

The limitations for Valerio et al. (2010) include that the location of the array of different prediction models within the various suites is somewhat confusing and presents a rather daunting challenge as to which models should be selected for any given prediction. So are the genotoxicity and carcinogenicity models

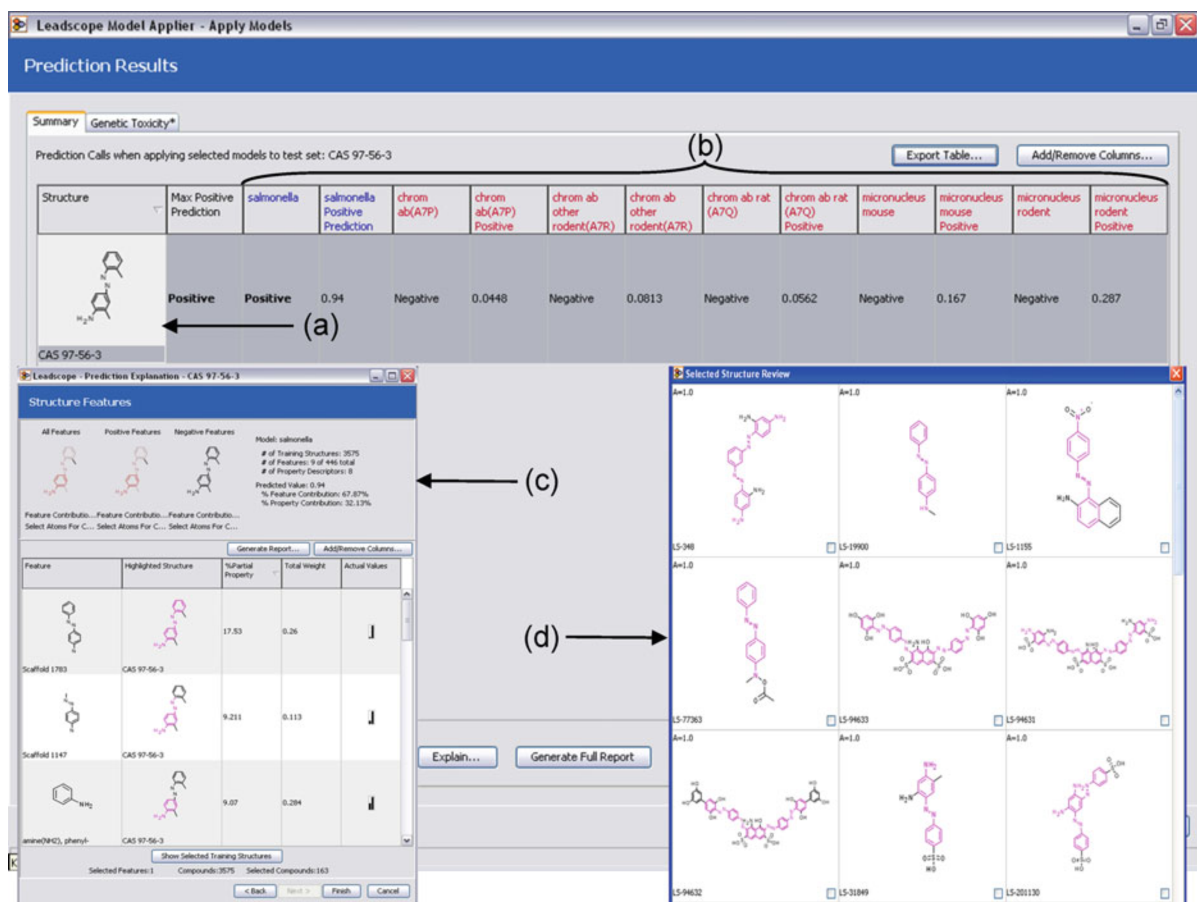

Fig. 51.6 Screen-print from the Leadscope prediction (version 1.3) for the compound 2-methyl-4-[(2-methylphenyl)azo] benzenamine: (**a**) imported structure, (**b**) chosen models for the prediction, (**c**) prediction results window, (**d**) Ames positive compounds from the training dataset on which the positive prediction is based

separated into two suites and therefore, different categories which could mislead users into inappropriate assumptions, organizing all of the toxicity models within their respective phenotype may be better. Also as with any new software package, there are a number of concerns regarding the development of the models (facets of construction and validation techniques used) and the software package, which should be addressed in the next version.

MODIFICATIONS OF THE METHOD

Like described for MultiCASE, also Leadscope offers the possibility to modify the commercially available databases as well as to create new databases using internal company data for the construction of new prediction models with the help of the application "Leadscope Enterprise." This system consists of a server application typically running on a high end computer and one or more client applications running on desktop PCs. All structures and associated data from the central corporate databases are stored on the server or in the personal database embedded in the client running on the PC. The structures and datasets imported are analyzed and then can be used for the construction of the new prediction models using the applications "QSAR analysis." Within these applications, the option "automatically build predictive models" can be chosen by using the default algorithms and parameters coming from the Leadscope system to construct a new prediction model. It is also possible to

Structure	Max Positive Prediction	salmonella	salmonella Positive Prediction Probability	chrom ab(A7P)	chrom ab(A7P) Positive Prediction Probability	chrom ab other rodent(A7R)	chrom ab other rodent (A7R) Positive Prediction Probability	chrom ab rat (A7Q)	chrom ab rat (A7Q) Positive Prediction Probability	micronucleus mouse	micronucleus mouse Positive Prediction Probability	micronucleus rodent
CAS 97-56-3	Positive	Positive	0.94	Negative	0.0448	Negative	0.0813	Negative	0.0562	Negative	0.167	Negative

Model: salmonella

Model: salmonella

# of Training Structures: 3575

EXAMPLE

Figures 51.6 and 51.7 show the Leadscope prediction (version 1.3) for the example compound 2-methyl-4-[(2-methylphenyl)azo]benzenamine (CAS-No.: 97-56-3). For this compound many positive mutagenicity and carcinogenicity results are reported in the literature (results from the CCRIS database search). In agreement with the literature, this compound was predicted by Leadscope to be mutagenic in the *Salmonella* Ames assay. Figure 51.6 shows the screen-print from the Leadscope prediction for this compound, and Fig. 51.7 shows the report from the Leadscope prediction.

52.1 Ingo Stammberger, Andreas Czich and Knut Braun

The task of the Genetic Toxicology is to use recognized test methods in order to identify the genotoxic or mutagenic potential of pharmaceuticals and chemicals. The genotoxic or mutagenic potential is what we call the potential health risk of a substance with respect to its ability to cause cell mutations. Substances with this potential are known as mutagens and genotoxicity studies, also called mutagenicity studies, help identify such substances.

Early warnings that a possible new drug product may have a genotoxic effect are of immense importance for drug development. If a potential new drug is proven to have a genotoxic potential, this generally leads to termination of development of that drug, thereby preventing human exposure to drugs with mutagenic effects (except cytostatic drugs).

In addition, in the last decade, the testing and identification of impurities was recognized as important step in the toxicological risk assessment of the drug substance. The identification of a genotoxic potential and the determination of acceptable limits for genotoxic impurities in active substances is a difficult issue and now a days addressed in several publications and Guidelines. The data set usually available for genotoxic impurities is quite variable and is the main factor that dictates the process used for the assessment of acceptable limits. A generally applicable approach was defined by implementing the Threshold of Toxicological Concern (TTC). A TTC value of 1.5 μg/day intake of a genotoxic impurity is considered to be associated with an acceptable risk (excess cancer risk of <1 in 100,000 over a lifetime) for most

Table 52.1 Overview of genotoxicity assays

Assay	Alternative name/ abbreviation	Genetic endpoint tested	Specific damage detected
Bacterial reverse mutation test	Ames test	Gene mutations	Base pair substitution, addition or deletion
L5178Y tk+/− mouse lymphoma test	MLA	Chromosome aberrations	Point mutations and structural alterations, based on mutations in the tk gene
Micronucleus test in vitro	–	Chromosome aberrations	Induction of micronuclei
Micronucleus test in vivo	–	Chromosome aberrations	Induction of micronuclei
Mammalian chromosome aberration test in vitro	–	Chromosome aberrations	Mainly structural alterations (chromosome or chromatid)
Mammalian chromosome aberration test in vivo	–	Chromosome aberrations	Mainly structural alterations (chromosome or chromatid) including polyploidies
Comet Assay in vivo	Comet in vivo	DNA strand breaks	DNA strand breaks
Unscheduled DNA synthesis test with mammalian liver cells in vitro	UDS in vitro	DNA repair	DNA repair synthesis
Unscheduled DNA synthesis test with mammalian liver cells in vivo	UDS in vivo	DNA repair	DNA repair synthesis

pharmaceuticals (Kroes et al. 2004). From this threshold value, a permitted level in the active substance can be calculated based on the expected daily dose and the duration of treatment (EMEA 2006). However, higher limits may be justified under certain conditions, e.g., based on the therapeutic area.

Numerous test methods are available in order to assess the genotoxic potential of drug substances. There are essentially three main categories of genotoxic damage that can be caused by a substance:

1. Gene mutations
2. Chromosome aberrations and genome mutations
3. DNA damage and DNA repair

For the assessment of potential genotoxic impurities, a combination of in silico analysis (see Chap. 41 "In-Silico ADME Modeling") and the detection of a direct DNA damaging potential of the compound is considered to be sufficient. For the detection of the direct DNA damaging potential, the bacterial reverse mutation test (Ames Test) is recommended by the Guidelines as stand-alone assay.

Gene mutations include base pair substitutions and frameshift mutations, where base pair substitutions arise from the substitution of one or several base pairs in the DNA, and frameshift mutations arise from an insertion or deletion involving a number of base pairs that is not a multiple of three and consequently disrupts the triplet reading frame, usually leading to the creation of a premature termination (stop) codon and resulting in a truncated protein product.

Chromosomal aberrations include both numerical and structural aberrations. Numerical aberrations are changes in the number of chromosomes of the normal number characteristic of the animals utilized (aneugenicity). Structural aberrations are classified into two types, chromosome or chromatid aberrations (clastogenicity). Chromosomal mutations and related events are the cause of many human genetic diseases and there is evidence that chromosomal mutations and related events are involved in cancer development.

DNA damage can happen in several ways. For example, energy production in cells can produce toxic molecules, such as the so-called free radicals. They can react with the bases in the DNA and modify them, thus preventing the genetic code from being used properly. Those DNA damages then need to be repaired. All cells have evolved a system of recognizing DNA errors, fixing them and in special cases repairing them. This DNA repair mechanism can be faulty, which in itself results in a genotoxic effect.

There are specific assays available to detect each of these types of genotoxic damage, and a battery of tests is often used to determine if a substance causes any or all of these three types of damage. An overview of which assays can be used to detect a given type of genotoxic effect is shown in Table 52.1.

These assays are generally performed by applying a test substance to well characterized cell systems (e.g., bacterial or mammalian cell cultures) and evaluating changes in the growth and characteristics of the cells. This may involve assessing the speed to form colonies and the size of the colonies as well as using markers to label chromosome structure or to monitor DNA synthesis.

Usually most bacteria and cell lines do not possess the full capability for metabolizing pro-mutagens and pro-cancerogens. To overcome this deficiency substances are tested in the presence of an exogenous metabolic activation system (S9-mix) as well as in its absence. Adding the S9-mix to the cell culture allows for metabolism of the test substance by enzymes not present in the bacterial cells. The S9-mix is a postmitochondrial supernatant fraction from liver supplemented with a NADP-generating system. It is generally made from rat liver induced with polychlorinated biphenyls, however, livers from hamsters, monkeys, or other species may be used depending on the anticipated metabolism of the substance being tested. An S9-mix has been successfully used in eukaryotic in vitro systems for the metabolic activation of various compounds.

In the last decade, a lot of effort was done to revise the ICH (International Congress on Harmonization) guidelines for genotoxicity testing of pharmaceuticals. Importantly, there are a number of changes to the previous testing strategy that reflects a desire to reduce the false positive rate in the in vitro test battery. For instance, the top dose was lowered for noncytotoxic drugs in the mammalian cell assays. In addition, one testing option eliminates the need to conduct the in vitro mammalian cell assays (and just conduct Ames and an in vivo assay with two endpoints included). New assays and endpoints were introduced (Micronucleus Assay in vitro for regulatory purposes, Comet Assay in vivo) and a few assays might be used as follow-up assays very soon (PigA Assay).

The test guidelines for new pharmaceuticals recommend that for follow-up testing to evaluate positive results in genotoxicity test in vitro, in vivo assays should be conducted in two tissues. In practice this is usually achieved by performing an erythrocyte chromosome-damage test in bone marrow and a genotoxicity assay in liver, because some genotoxic carcinogens are known to be positive in the liver but not in the bone marrow assays. In current regulatory guidance the rodent Comet assay is considered as a useful follow-up test in case of positive results in in vitro genotoxicity assays. The Comet Assay is recognized as a useful tool for the evaluation of genotoxicity in organs/cell types that cannot easily be evaluated with other standard tests, e.g., in skin and stomach.

In addition the implementation of Genetic Toxicology endpoints into repeat dose toxicity studies was evaluated and recommended by the scientific community, to reduce the numbers of animals within toxicological studies. Those endpoint were mainly the Micronucleus Assay and the Comet Assay.

52.2 Bacterial Reverse Mutation Test

PURPOSE/RATIONALE

The bacterial reverse mutation test (Ames Test) investigates the ability of chemicals and drugs to induce reverse (back) mutations in bacteria, which involves base pair substitutions additions and/or deletions (frameshift mutations) of one or a few DNA base pairs. The bacterial strains used in the test system have mutations in genes coding for enzymes required for the biosynthesis of the amino acids histidine (*Salmonella*

typhimurium) and tryptophan (*Escherichia coli*). If a test substance causes a mutation that restores function to the enzyme gene, then the bacteria will be able to grow and produce colonies. An extensive data base exists based on the use of this test, and it has been found that compounds producing a positive result in the bacterial reverse mutation test have a high potency to induce cancer in animal studies.

PROCEDURE

The commonly used strains for *S. typhimurium* are TA100 and TA1535 (base pair substitution), TA98 and TA1537 (frame shift mutations) and TA102 for cross-link mutations. The preferred strain of *E. coli* to detect base pair substitution mutations is WP2.

Bacteria of an overnight nutrient broth culture are mixed with the test compound or solvent (as a negative control), S9-mix or buffer, and molten top agar and poured into a petri dish containing a layer of minimal agar. After incubation for approximately 48 h at approx. 37°C in the dark, colonies (representing the number of revertants) are counted by hand or an automatic colony counter. The method can be modified by including a preincubation step or by using a higher amount of S9-mix in the test system. Preincubation would involve incubating the test compound, S9-mix or buffer, and bacteria for a short period before pouring this mixture onto plates of minimal agar. According to the current ICH S2R Guideline, one experiment is sufficient to determine the mutagenic potential. The assay can be conducted as plate or preincubation assay.

52.2.1 Rational for the Dose Selection

The highest dose level in each experiment should correspond:

- either to 5,000 μg/plate
- or to a dose level corresponding to the highest soluble concentration in the solvent
- or to a dose level producing a precipitation in the plates or to a dose level which induces bacteria toxicity, whatever the solubility

EVALUATION

To evaluate the result of a test compound, the number of revertant colonies has to be determined for each concentration used in the test system as well as for the negative (solvent or untreated) and positive control. Bacterial toxicity is expressed as a thinning of the bacterial lawn or in a reduction in the number of colonies compared to the negative control. Bacterial toxicity and precipitation should be taken into consideration when assessing the mutagenicity of a substance. The following criteria should be met to consider a bacterial reverse mutation test as valid.

- The number of revertant colonies on both negative (solvent or untreated) control plates should be in a historical control range described in literature or determined in the laboratory.
- The positive control should induce a significant increase in the number of revertant colonies.
- At least five dose levels for the test article are analyzable (i.e., number of revertant colonies can be determined), for each strain in each experimental condition.
- The highest dose level fulfills the rational for the highest dose level selection

A test compound is classified as inducing point mutations if it causes at least two of the following criteria:

- It produces at least a two- to threefold increase in the mean number of revertants per plate depending on the strain used of at least one of the tester strains over the mean number of revertants per plate of the appropriate vehicle control at complete bacterial background lawn
- It induces a dose-related increase in the mean number of revertants per plate of at least one of the tester strains over the mean number of revertants per plate of the appropriate vehicle control in at least two to three concentrations of the test compound at complete bacterial background lawn
- The increase number of revertant colonies is reproducible
- The number of revertant colonies exceeds the upper value of the range of the historical negative control data

Moreover, biological significance needs to be discussed, taking into consideration the criteria mentioned above.

If the test substance does not achieve either of the above criteria, it is not considered as showing evidence of mutagenic activity in this system.

CRITICAL ASSESSMENT OF THE METHOD

The advantages of the bacterial reverse mutation test are the ease with which it can be performed, the short amount of time required and the low cost. The test should be regarded as the first test in the GLP testing

strategy for the detection of a genotoxic potential of a test compound. The test is as well required as part of the nonclinical testing strategy before the start of Phase I in the clinical development.

MODIFICATIONS OF THE METHOD

52.2.2 Mini-Ames and Ames II

The bacterial reverse mutation test does not detect all compounds with the potential to induce point mutations. For some chemical series, modifications of the test system are necessary. For example, the potential for azo compounds to induce point mutations can only be detected by using an S9-mix prepared by hamster liver. To get an indication early in the development of a test compound for its potential to induce point mutations, modified test systems of the standard bacterial reverse mutation test are performed as a screening test. These are the so-called Mini-Ames test, performed on smaller agar dishes, or the Ames II™ test, performed with microtiter plates. The test design of the screening method should be as much as possible related to the standard method, e.g., same top dose, to reach highest comparability between both methods. Both screening tests have the same principle as the standard test, and use *S. typhimurium* strains. The advantages of both are that they need much less compound and have a higher throughput in the number of tests per week.

52.2.3 The Bacterial Reverse Mutation Test in the Light of Genotoxic Impurity (GTI) Testing

Genotoxic impurities need to be investigated as well for their potential to induce point mutations. Currently, the need for testing is triggered by in silico alerts. If a compound shows an in silico alert, testing in the Ames Assay is required. If the Ames Assay is positive, the compound is classified as a Genotoxic impurity (GTI) In this case the so-called staged TTC (Threshold of Toxicological Concern) will trigger the further handling of the GTI and no further testing is required as described in Müller et al. (2006) and McGovern and Jacobson-Kram (2006). A new ICH Guidance dealing with Genotoxic impurities is under evaluation (ICH M7).

52.3 L5178Y tk+/– Mouse Lymphoma Test (MLA)

PURPOSE/RATIONALE

The MLA is used for the detection of point mutations, structural aberrations, and aneugenicity. The principle

of the assay is that cells deficient in thymidine kinase (TK) due to the $tk^{+/-}$ or $tk^{-/-}$ mutation are resistant to the cytotoxic effects of the pyrimidine analogue trifluoro-thymidine (TFT). TK proficient cells are sensitive to TFT. This influences the cellular metabolism and leads finally to an inhibition of further cell division. Thus mutant cells are able to proliferate in the presence of TFT, whereas normal cells, which contain TK, are not. The major advantage of the assay is its ability to detect a broad range of mutagenic events represented by optimal detection of both large and small colonies.

The assay was described by Clive and coworkers (Clive et al. 1972) as a mutational assay system using the TK locus in mouse lymphoma cells. In the following years, he and his coworkers undertook a large-scale of investigation of the potential and optimal conduct of the assay. This included the use of the above-mentioned TFT to select tk mutants, a comparison of the hypoxanthine guanine phosphoribosyl transferase (hprt) and tk loci, an analysis of the best expression time for tk mutant selection and a description of distinct “large” and “small” colony tk mutants (Moore et al. 1985).

Originally, the assay was performed mainly in soft agar plates. In 1986, a protocol variation was successfully applied using cloning cells in liquid medium in 96-well microtiter plates instead of soft agar in Petri dishes (Cole et al. 1986). As a result, a better discrimination between small and large colonies was possible. Using a variety of chemicals, Doerr and Moore conducted an extensive evaluation of the correlation between gross chromosome aberration induction in mouse lymphoma cells and small colony tk mutant induction (Moore and Doerr 1990). From these studies it was clear that chemicals that induce small colony tk mutants also induce gross aberrations in the mouse lymphoma cells. Such mutants could result from alterations that: (a) affect expression of the tk and linked loci (chromosome 11 events); (b) affect the tk and other single essential loci in the genome, i.e., multiple point mutations; (c) affect the tk locus and have a chromosome event (other than chromosome 11) that results in slow growth.

In 1998, it was demonstrated that L5178Y cells contain two mutant p53 alleles (Clark et al. 1998). It is possible that the dysfunctional p53 protein in L5178Y cells may account for the sensitivity of these cells to mutagens and for the assay’s capability to detect the chromosomal rearrangements and mitotic recombination often seen in the later stages of cancer development.

A number of recommendations and comments were made on the conduct of the MLA (Sofuni et al. 1997), including heterogeneity and the use of single or duplicate cultures, cytotoxicity parameters, relative survival and relative total growth, strategies for dose range finding, and the statistical analysis of MLA data. From the International Working Group of Genotoxicity Testing a very detailed description of the protocol, the validity criteria and the evaluation was published in 2003, 2006, and 2007 (Moore et al. 2003, 2006, 2007). A detailed discussion on the selection of the top dose can be found in Moore et al., 2011.

PROCEDURE

The genotoxic potential of a compound in the MLA is generally evaluated with and without metabolic activation by S9 liver homogenate obtained from rats pretreated with Aroclor or Phenobarbital/ ßNaphtoflavone. The addition of the S9-mix allows for metabolism of the test compound by enzymes not present in mouse lymphoma cells. The cells were exposed to the compound for 3–4 h or 24 h without a metabolic activation system and for 3 h with metabolic activation. Cells were then grown for a 48-h phenotypic expression period (two cultures per concentration). The phenotypic expression period is the time required for the mutant (TK deficient) phenotype to be expressed, i.e., loss of preexisting TK and depletion of the preexisting TMP pool. Cells were then cloned and incubated for 10–13 days with the selection agent (TFT) while their cloning efficiencies were checked in nonselective medium.

The ICH4 committee concluded in 1995 that there is the capability of detecting point mutations and most substances that induce chromosome aberrations (including aneugens). Therefore the chromosome aberration assays and the Mouse Lymphoma assay are currently considered interchangeable, if the Protocol recommendations of the ICH S2 documents are fulfilled. That means: (a) in the case of a negative result following 3–4 h (treatment with and without S9), a continuous treatment of 24 h without activation was considered advisable; (b) a requirement for the use of the microwell cloning protocol rather than agar cloning to better discriminate small and large colonies; and (c) the use of an appropriate positive control inducing a higher proportion of small colonies. However, further validity criteria

were described in the OECD Guideline 476 and the ICH2b Guideline. One major point for the interpretation of the data is the fulfillment of the toxicity criteria (approximately 20%). In addition, in 2007, the Global evaluation Factor (GEF) was introduced, to judge if a compound is positive. This factor is based on the Induced Mutant Frequency (IMF), which is defined as the increase above the spontaneous background mutant frequency. For the microwell technique, the GEF has been defined to be equal to 126×10^{-6} (Moore et al. 2007). If the IMF exceeds the GEF, a compound is judged as positive.

EVALUATION

Small colony mutants have been shown to predominantly lack the TKb allele as a consequence of structural or numerical alterations or recombinational events whereas large colonies are the consequence of point mutations. Based on the recommendations of the ICH2b the following points should be considered in general for the interpretation of the results:

- Does the Induced Mutant Frequency (IMF) exceed the Global Evaluation Factor (GEF)? For microwell technique, the GEF has been defined to be equal to 126×10^{-6}.
- Is the increase in response over the negative or solvent control background regarded as a meaningful genotoxic effect for the cells?
- Is the response concentration-related?
- For weak/equivocal responses, is the effect reproducible?
- Is the positive result a consequence of an in vitro specific metabolic activation pathway/in vitro specific active metabolite?
- Can the effect be attributed to extreme culture conditions that do not occur in in vivo situations, e.g., extremes of pH; osmolality; heavy precipitates especially in cell suspensions?
- Is the effect only seen at extremely low survival levels/ high cytotoxicity?

In addition, the use of statistical methods is recommended for the evaluation of the MLA. Two methods should be used, one to evaluate the statistical difference between the different groups and, more importantly, the statistical significance of the dose-response curve. For the evaluation of the results the consideration of the biological relevance is the most important. A detailed discussion of parameters indicating a biological relevance is published in the ICH2B Guideline (1997) and in the recommendation of the International Working Group of Genotoxicity Testing (IWGT; Moore et al. 2003).

CRITICAL ASSESSMENT OF THE METHOD

It is apparent that the MLA has some advantages compared to other mutation assays including: (a) rapid growth in suspension culture to high cell density, which provided for the very large numbers of cells necessary for a statistically valid test and (b) the relatively short time (48 h) required for the expression of newly induced mutants.

However, the assay is only really capable of detecting large increases in mutation frequencies. This is because very small increases in mutation frequencies can often be seen at high cytotoxicity levels. At very low survival levels in mammalian cells, mechanisms other than direct genotoxicity per se can lead to "positive" results that are related to cytotoxicity and not genotoxicity (e.g., events associated with apoptosis, endonuclease release from lysosomes, etc.). It has long been recognized for all in vitro systems that mutations induced under these circumstances would not normally occur in vivo. Thus, these responses, while perhaps statistically significant by some methods, are not considered to be biologically relevant. A careful discussion of such responses is needed.

In addition, while the spectrum of mutations detected by the assay is very broad, it should be noted that not all such events are always detected with equal efficiency following treatment with particular test substances. Especially, for the detection of structural aberrations and aneugenicity the recommended conditions of the protocol should be kept in detail.

MODIFICATIONS OF THE METHOD

The test could be performed with different cell lines (e.g., TK6 cells) and different metabolic activation systems.

52.4 Micronucleus Test In Vitro

PURPOSE/RATIONALE

The purpose of the micronucleus test in vitro is to evaluate the potential of compounds to induce micronuclei (formation of small membrane-bound DNA fragments) in different cell lines or primary cultures, with and without metabolic activation by S9 liver homogenate.

The test system allows to discriminate between a clastogenic and aneugenic potential of a test compound by using an immunochemical labeling of the kinetochores or staining the DNA fragments with FISH (fluorescence in situ hybridization) technique.

PROCEDURE

The cells are treated with the test article in 96-well microplates for a short treatment period with metabolic activation (e.g., 3 h) and for a long treatment period without metabolic activation (e.g., 24 h) and harvested 24 h (recovery time) after the end of the treatment. Cells are then fixed and stained. The cytotoxicity of the test compound is evaluated by the relative cell growth, expressed as a percentage of the negative control. The highest evaluated concentration should produce approximately 50% cell survival or should be the first concentration where precipitation is observed. Duplicated cultures should be performed at each dose level. A very detailed description of the protocol, the validity criteria, and the evaluation was published by the IWGT in 2003 (Kirsch-Volders et al. 2003).

EVALUATION

Structural/numerical chromosome damage is evaluated by the increase in the number of micronucleated cells, scored out of 1,000 cells in three analyzable concentrations. The compound is considered positive if either:

- The increase of micronucleated cells is statistically significant compared to the negative (solvent or untreated) control, or
- The number of micronuclei is dose dependent and showed a biological relevance compared to the negative control.

The positive control must show a clear statistical significant effect compared to the negative control.

CRITICAL ASSESSMENT OF THE METHOD
The micronucleus test in vitro is easy and rapid to perform, inexpensive, and needs much less test compound compared to the mammalian chromosome aberration test. In addition no detailed training of the personnel for the light microscopical evaluation of the slides is necessary. In fact, the micronucleus test in vitro is currently the only in vitro test which allows the differentiation between a clastogenic or aneugenic effect, and is becoming ever more important in the genotoxic testing strategy. The finalization of the OECD Guideline for this assay and the implementation into the ICH S2R Guidance was key to use this assay for regulatory purposes. As the evaluation of micronuclei is much easier and less time consuming, this assay will replace the chromosome aberration assay in vitro in the future.

MODIFICATIONS OF THE METHOD
An alternative method for the evaluation of the induced micronuclei is measurement by Flow cytometry. This method allows the discrimination between micronuclei that contain one or several acentric chromosome fragments (clastogenic action) or one or several whole chromosomes (aneugenic action, interference with the mitotic spindle apparatus) or even a combination of both. To discriminate between the actions an additional staining of the micronuclei with, e.g., CREST antibodies is necessary.

52.5 Micronucleus Test In Vivo

PURPOSE/RATIONALE
The in vivo mammalian micronucleus test is used to assess the mutagenic hazard in consideration of factors like in vivo metabolism, pharmacokinetics, and DNA repair processes, although these may vary among species and among tissues. This assay is an important part of the gentox testing battery, applied for pharmaceuticals and chemicals.

During erythropoiesis, nuclei are expelled during the formation of polychromatic erythrocytes while micronuclei are retained in the cells. This fact is used for the detection of micronuclei. A significant increase in the number of micronucleated polychromatic erythrocytes is usually considered as indicative of structural and/or numerical chromosome damage caused by exposure to a clastogenic and/or aneugenic substance. The identification of the presence or absence of a kinetochore or centromeric DNA in the micronuclei is needed to discriminate a clastogenic effect from an aneugenic effect. The incidence of micronuclei in the polychromatic erythrocytes is scored 24 h after the end of treatment to take into account the time interval between the last mitosis and the formation of polychromatic erythrocytes (at least 8 h) and the lifespan of polychromatic erythrocytes, which is approximately 24 h.

PROCEDURE
The bone marrow of rodents (rats and mice) is routinely used in this test since polychromatic erythrocytes are produced in that tissue, it is a highly vascularized tissue and it contains a population of rapidly cycling cells that can be readily isolated and processed. The assay was developed by Schmid (1975) and modified by Salamone et al. (1980). Recent protocols and recommendations are published in the OECD Guideline 474 and Hayashi et al. 2000. The measurement of micronucleated immature (polychromatic) erythrocytes in peripheral blood is equally acceptable in any species in which the inability of the spleen to remove micronucleated erythrocytes has been demonstrated. The evaluation of micronuclei in peripheral blood is an easy method integrated the micronucleus assay into General toxicity studies (Rothfuss et al. 2011).

The route of administration of the test compound should ensure a relevant target exposure and in the case of pharmaceuticals it should consider the application route in humans. Each treated and control group must include at least five analyzable animals per sex. It is possible to use only one gender if it could be demonstrated that no substantial differences in metabolism, toxicity, and pharmacokinetics between genders was

observed. Test substances could be administered as a single treatment. Repeated treatment up to 28 days could is also possible. If a single treatment is used the sampling time should be between 24 and 48 h. If repeated treatment is used, the sampling time is 24 h after the last treatment.

Bone marrow cells are usually obtained from the femurs or tibias immediately following sacrifice. Usually, cells are removed from femurs or tibias in a suitable medium such as fetal serum, and are prepared and stained using established methods. DNA specific stains (e.g., acridine orange) are preferred instead of conventional stains like Giemsa.

The likelihood that the test substance or its metabolites reach the general circulation or the target tissue (e.g., systemic toxicity) should be demonstrated. Preferably, experimental evidence of systemic or target tissue exposure should be presented (e.g., blood level or bone marrow concentration analysis), especially in the case of a negative result with an agent that does not induce observable toxicity.

EVALUATION

The proportion of immature among total (immature + mature) erythrocytes as measure for target organ toxicity is determined for each animal by counting a total of at least 200 erythrocytes for bone marrow and 1,000 erythrocytes for peripheral blood. At least 2,000 immature erythrocytes per animal are scored for the incidence of micronucleated immature erythrocytes to determine the clastogenic/aneugenic potential of the test compound. The automatic analysis of micronucleated erythrocytes was developed by Romagna and Staniforth (1989).

For a discussion of the result of the micronucleus assay a comparison of the data from the treatment group versus concurrent negative control data and historical control data as well as a statistical analysis of the experimental data using trend analysis or pair-wise comparison (treatment group versus control) need to be considered. It is also recommended to check the variance between the animals and gender. However, for the final assessment, biological relevance of the results should be considered.

CRITICAL ASSESSMENT OF THE METHOD

There are compounds for which standard in vivo tests do not provide additional useful information. This is particularly true for compounds for which data from studies on toxicokinetics or pharmacokinetics indicate that they are not systemically absorbed and therefore are not available for the target tissues. Examples of such compounds are some radioimaging agents, aluminum-based antacids, and some dermally applied pharmaceuticals. In those cases other tests systems should be considered to be more relevant.

In addition, parameters like decreased body temperature may lead to an indirect induction of micronuclei that is not biologically relevant.

52.6 Mammalian Chromosome Aberration Test In Vitro

PURPOSE/RATIONALE

This in vitro cytogenetic test is a clastogenicity test system for the detection of chromosomal aberrations in cultured mammalian cells or primary cultures. Chromosomal aberrations may be either structural or numerical. However, because cytogenetic assays are usually designed to analyze cells at their first

posttreatment mitosis and numerical aberrations require at least one cell division to be visualized, this type of aberration is generally not observed in a routine cytogenetic assay. The best estimate of aberration frequency is the first cell division after the start of treatment. Structural aberrations are of two types: chromosome or chromatid aberrations.

Chromosome-type aberrations are induced when a compound acts in the G_1 phase of the cell cycle. Chromatid-type aberrations are induced when a chemical acts in the S or G_2 phase of the cell cycle.

- Chromosome-type aberrations are structural chromosome damages expressed as breakage, or breakage and reunion, of both chromatids at an identical site
- Chromatid-type aberrations are structural chromosome damages expressed as breakage of single chromatids or breakage and reunion between chromatids
- Numerical aberrations are changes in the number of chromosomes of the normal number characteristic of the animals utilized

The best estimate of aberration frequency is the first cell division after the start of treatment.

PROCEDURE

In this test, cultured cells are seeded onto slides and the cells, which have been treated with and without metabolic activation for a short-time period (e.g., 3 h). Where negative or equivocal results are obtained, an independent experiment is conducted in which cells are treated for long-time period (e.g., 20 h) in the absence of metabolic activation alone and then sampled and examined for chromosome analysis. In both experiments the cells are sampled 20 h after the start of treatment as are the concurrent solvent and positive control cultures. Colcemid is added to each culture 2 h before sampling in order to arrest cell division. Chromosome preparations are made, fixed, stained, and examined. However, if clearly positive results are obtained in the first experiment, those from the second assay are not examined. If equivocal or negative results are obtained in the first experiment, modifications to the testing procedure are included in order to clarify the result.

EVALUATION

The set of chromosomes is examined for completeness and the various chromosomal aberrations are assessed and classified. The metaphases are examined for the following aberrations: chromatid gap, chromosome gap, chromatid break, chromosome break, chromatid acentric fragment, chromosome acentric fragment, chromatid deletion, chromosome deletion, chromatid exchanges including intrachanges, chromosome exchanges including intrachanges, dicentrics, pulverization, and ring formation. Metaphases including five or more break events are scored as multiple aberrant. Furthermore the incidence of polyploid metaphases is determined for each cell culture. The quantity of cells is determined by counting the number of cells in, e.g., 10 fields of vision per slide as an indicator of toxicity. The survival of cells is expressed as a percentage. Additionally the mitotic index should be determined by counting the number of cells undergoing mitosis in a total of, e.g., 1,000 cells. The mitotic index is also expressed as a percentage. For each experiment the results from the dose groups is compared with those of the control group and the positive control at each sampling time.

The assay is considered *valid* if both of the following criteria are met:

- The solvent control data are within the laboratory's normal control range for the number of cells carrying structural chromosomal aberrations
- The positive controls induce increases in the number of cells carrying structural aberrations which are statistically significant and within the laboratory's normal range.

A test substance is classified as *non-clastogenic* if either of the following is met:

- The number of induced structural chromosome aberrations in all evaluated dose groups is in the range of our historical control data.
- No significant increase of the number of structural chromosome aberrations is observed.

A test substance is classified as *clastogenic* if both the following are met:

- The number of induced structural chromosome aberrations is not in the range of our historical control data.
- Either a concentration-related or a significant increase of the number of structural chromosome aberrations is observed.

When evaluating the findings, both biological and statistical significance should be considered together. If the criteria mentioned above for the test item are not clearly met, the classification with regard to the historical data and the biological relevance should be discussed and/or a confirmatory experiment should be performed.

CRITICAL ASSESSMENT OF THE METHOD

Care should be taken to avoid conditions (pH, high cytotoxicity, osmolality, etc) that would lead to positive results but which do not reflect intrinsic mutagenicity. Mammalian carcinogens are often positive in this test. Nevertheless, there is not a perfect correlation between this test and carcinogenicity, which depends on the chemical class. Some chemicals may test positive in this test because they appear to act through other mechanism than direct DNA damage, e.g., apoptosis.

MODIFICATIONS OF THE METHOD

The test could be performed with different cell lines (permanent and primary) and different metabolic activation systems.

52.7 Mammalian Chromosome Aberration Test In Vivo

PURPOSE/RATIONALE

Like the in vivo micronucleus assay, the in vivo mammalian chromosome aberration assay is especially relevant for assessing the mutagenic hazard while taking into consideration factors like in vivo metabolism, pharmacokinetics, and DNA repair processes, although these may vary among species and among tissues. In the gentox testing battery this assay is mainly used for further investigation of mutagenic effects detected by an in vitro test. In addition, the assay can be used for the detection of compounds that induce polyploidies. An increase in the number of polyploidy cells may indicate that a compound has the potential to induce numerical aberrations.

The induction of structural chromosome aberrations is classified in two types, chromosome or chromatid aberrations. The majority of induced aberrations are of the chromatid-type, but chromosome-type aberrations also occur. Chromosomal mutations and related events are the cause of many human genetic diseases and there is evidence that chromosomal mutations and related events are involved in cancer development.

In addition, the assay can be used for the detection of compounds that induce polyploidies. An increase in the number of polyploidy cells may indicate that a compound has the potential to induce numerical aberrations.

PROCEDURE

Rodents (rat, mice, Chinese hamster) are routinely used in this test. Although chromosome aberrations can be detected in various tissues, the most common methodologies are available for investigations of bone marrow (Preston et al. 1987), peripheral blood, and female and male germ cells (Russo 2000). Bone marrow is the normally used target tissue in this test, since it is a highly vascularized tissue, and it contains a population of rapidly cycling cells that can be readily isolated and processed (Tice et al. 1994). However, methodologies are available for investigations of other tissues and cells.

The route of administration of the test compound should ensure a relevant target exposure and in the case of pharmaceuticals it should consider the application route in humans. Each treated and control group must include at least five animals that can be analyzed per sex. It is possible to use only one gender if it can be demonstrated that no substantial differences in metabolism, toxicity, and pharmacokinetics between genders was observed. Test substances are preferably administered as a single treatment; however, repeated treatment up to 28 days could also be performed. If a single treatment is used two sample times (12–18 h and 36–44 h) should be used for bone marrow. If repeated treatment is used, the sampling time is 6–24 h after the last treatment. If species other than rodents or other tissues are used, the sampling time must be scientifically justified.

Prior to sacrifice (3–5 h), animals are treated with a metaphase-arresting agent (e.g., colchicine). Chromosome preparations are then made from the respective tissues and stained with an appropriate method. For a better discrimination of the chromosomes and to detect translocations, the FISH technology can be used (Natrajan and Boei 2004). Metaphase cells are microscopically analyzed for the occurrence of structural and numerical chromosome aberrations.

The likelihood that the test substance or its metabolites reach the general circulation or the target tissue (e.g., systemic toxicity) needs to be demonstrated. Preferably, experimental evidence of systemic or target tissue exposure should be presented (e.g., blood level or bone marrow concentration analysis), especially in the case of a negative result with an agent that does not induce observable toxicity.

EVALUATION

At least 100 metaphase plates per animal should be scored per animal based on the use of at least five animals per gender per treatment group. The minimal classes of aberrations to score and categorize would be chromosome type versus chromatid type. Within these two categories gaps, breaks, and rearrangements should be differentiated. To describe the toxicity in the target organ, the mitotic index is determined in at least 1,000 nucleated cells per animal. However, for the detection of polyploidies at least 22 metaphase cells should be scored. Due to differences in the mechanism of development, endoreduplicated cells should be scored separately.

For a discussion of the result of the chromosome aberration assay the following parameters need to be considered: (a) comparison of the data from the treatment group versus concurrent negative control data and historical control data (b) statistical analysis of the experimental data using trend analysis or pair-wise comparison (treatment group versus control). It is also recommended to check the variance between the animals and gender. However, for the final assessment, biological relevance of the results should be considered.

CRITICAL ASSESSMENT OF THE METHOD

There are compounds for which standard in vivo tests do not provide additional useful information. This is particularly true for compounds for which data from studies on toxicokinetics or pharmacokinetics indicate that they are not systemically absorbed and therefore are not available for the target tissues. Examples of such compounds are some radioimaging agents, aluminum-based antacids, and some dermally applied pharmaceuticals. In those cases other tests systems should be considered to be more relevant (p32 Postlabeling, Comet Assay in vivo).

52.8 Comet Assay In Vivo

PURPOSE/RATIONALE

The in vivo Comet assay (single-cell gel electrophoresis assay) is increasingly used in regulatory genotoxicity testing for the evaluation of DNA damage and repair in various tissues of mice and rats that cannot easily be evaluated with other standard tests. Protocols are established for liver, skin, stomach, gut, kidney, retina, and nasal tissues. The Assay is used as follow-up assay for in vitro positive results and is discussed as second endpoint for a combined in vivo protocol (micronuclei in bone marrow/Comet assay in liver) Rothfuss et al. 2010. The advantage of the model is that different target organs can be used to detect a genotoxic potential.

The test is in general conducted based on the method described by Singh et al. (1988) then modified by Hartmann et al. (2003), Tice et al. (2000) and the validation management team of the International Validation of the In Vivo rodent alkaline COMET assay. Protocols for conducting the in vivo Comet assay were developed by different expert panels, e.g., at the 2nd and 4th International Workshops on Genotoxicity Testing, Burlinson et al. (2007) and the 4th International Comet assay Workshop.

PROCEDURE

The Comet assay is used to visualize and measure DNA strand breaks in individual cells by microscopy. Animals are treated between 2 and 28 days. In general, the last compound administration is 3 h before the animals are anesthetized and euthanized. After necropsy of the specific organs, the cells are isolated by organ perfusion or mincing the cell tissues. It is in general recommended that at least three slides will be prepared per tissue and animal.

In the alkaline version, the isolated cells are embedded in an agarose gel on a microscope slide, immersed in a lysis solution to remove lipids and proteins. The slides will remain in the buffer for 20 min. Using the same buffer, electrophoresis will be conducted in general at a constant voltage of 0.7 V/cm. The current at the start of the electrophoresis will be adjusted to 300 mA, a weak electric field to attract broken negatively charged DNA toward the anode.

After electrophoresis, the DNA is stained using a fluorescent dye and viewed using a fluorescence microscope. When viewed under a microscope, the cell containing DNA strand breaks has the appearance of a comet, with a head (the nuclear region) and a tail containing DNA fragments or strands. Individual images are analyzed for quantifying DNA migration parameters such as the percentage of DNA that has migrated, named tail intensity. These measurements give an indication of the incidence of strand breaks present in the cell.

Coded slides must be scored in blind fashion. Slides will be stained with a DNA stain prior to scoring (SYBR-gold, propidium iodide, or any appropriate DNA stain).

EVALUATION

DNA effects will be assessed by the software system by measuring Comet tail migration, % tail intensity, and Olive tail moment. Tail migration is the distance from the perimeter of the Comet head to the last visible point in the tail; % tail intensity the percentage of DNA fragments present in the tail; and Olive tail moment is the product of the amount of DNA in the tail and the mean distance of migration in the tail. For each sample, 150 cells (three slides per sample with 50 cells per slide or two slides per sample with 75 cells per slide, if possible) will be scored for DNA damage.

Generally, all cells including heavily damaged cells are scored as long as the image analysis system can properly discern a head. Cells without discernable head and large diffuse tail which cannot be scored by the image analyzer (ghosts) are excluded from analysis. The frequency of such ghosts should be determined per sample, based on the visual scoring of 100 cells per sample.

As an example Liver Comet Assay data will be accepted if the following criteria are met: Negative control: Means of %DNA in tail are 1–8%.

Positive control: Ratio of means of %DNA in tail between groups of positive and vehicle control is twofold or higher.

Those values need to be verified for each organ, as there is high variability between organs.

CRITICAL ASSESSMENT OF THE METHOD

The assay is rapid and easy to conduct, but the laboratory needs experience in preparation of the cells. The quality of the assay is highly depending on that. The advantage of the assay is that the assay can be applied to any tissue and cell division not required for the detection of DNA damage. The analysis is conducted in individual cells; therefore low number of cells is sufficient. However, the assay is resource intensive and time consuming, in particular the scoring of comets takes time if not automated. Apoptosis/necrosis as indicators of tissue cytotoxicity needs to be controlled in the histopathology part of the study, and positive results in the presence of toxicity are difficult to interpret. At the moment there are no guidelines available. Different statistical methods are available but should be carefully applied for the interpretation of the results.

52.9 Unscheduled DNA Synthesis (UDS) Test with Mammalian Liver Cells In Vitro

PURPOSE/RATIONALE

The UDS test detects DNA repair synthesis after excision of damaged segments. DNA repair synthesis is demonstrated by autoradiographic measurement of tritium-labeled thymidine incorporation. Liver cells are routinely used for the UDS test because cells in S-phase are rare and easily distinguished from cells undergoing DNA repair and because hepatocytes exhibit a high metabolic activity that enables the detection of pro-mutagens.

PROCEDURE

Liver cells are isolated by a two-step perfusion procedure from anesthetized rats.

A medio-ventral incision is made from the pubic symphisis to the thorax. A catheter is inserted into the portal vein and the liver is perfused with collagenase solution. At the end of the perfusion, the liver is taken out, the liver capsule is removed, and the cells are mechanically dispersed by gentle shaking. After dispersion of the liver cells in medium, the vessels and remaining conjunctive tissue are removed and collagenase activity is neutralized. Cell viability is assessed by the percentage of refringent cells. Only cell suspensions with more than 70% viability should be retained.

Liver cells are then exposed in vitro to the test compound and incubated with tritium-labeled thymidine for about 18 h. At the end of the incubation, the cells are fixed on slides and prepared for autoradiography. For that the slides are first exposed to liquid photographic emulsion, air-dried and following a 7-day exposure in the dark, exposed to developing solution.

EVALUATION

Cells undergoing DNA repair are identified by the increase in the number of silver grains in the nuclei, i.e., the net nuclear grain count. Only normal-appearing nuclei are scored; occasional nuclei blackened by grains are excluded since these are nuclei undergoing replicative DNA synthesis. One hundred cells per concentration and control are analyzed. For each cell, the number of silver grains in the nucleus and the number of silver grains in three adjacent nucleus-equivalent areas on the cytoplasm are measured. For each cell, the following parameters are calculated:

- The nuclear grain count (N)
- The mean of the three cytoplasmic grain counts (C)
- The net nuclear grain count (NG), i.e., the difference between the nuclear grain count and the mean of the three cytoplasmic grain counts

A cell is considered undergoing DNA repair if the value of the net nuclear grain count is greater than five.

For each slide, the following parameters are calculated:

- The mean and standard deviation of nuclear and cytoplasmic grain counts, and of net nuclear grain count
- The percentage of cells undergoing DNA repair and mean value of net nuclear grain count for these cells.

The test article is considered positive in the UDS assay if the mean net nuclear grain count is greater than five and if the percentage of cells undergoing DNA repair is greater than 20%.

CRITICAL ASSESSMENT OF THE METHOD

The biological significance has to be taken into consideration for positive evaluation (i.e., cytotoxicity can artefactually lead to an increase in the value of net nuclear grain count). The positive control should induce a clear increase in the mean net nuclear grain count higher than the threshold value of five.

52.10 Unscheduled DNA Synthesis (UDS) Test with Mammalian Liver Cells In Vivo

The principles of this method are the same and the procedure similar as for the above described method "Unscheduled DNA Synthesis (UDS) Test with Mammalian Liver Cells in vitro." The differences between the in vivo and the in vitro method are related to the test compound exposure. In the in vivo assay, rats are first treated in vivo with the test compound and the liver cells are isolated 14 h after treatment. Then the liver cells are incubated for 4 h with a medium containing tritium-labeled thymidine, followed by 18 h in a medium containing non-labeled thymidine. The incorporation of tritium-labeled thymidine is measured by autoradiography. Cells undergoing repair are identified by the increase in the number of silver grains in the nuclei.

53.1 General Considerations

Developmental and reproductive toxicity is a special part of toxicology which comprises any effect of chemicals and active substances on mammalian reproduction (fertility, weaning) and development (embryonal and fetal development). The investigations and the interpretation of the results should be related to all other pharmacological and toxicological data available to determine the risk of the test compound to humans. To allow detection of immediate and latent effects of exposure, the observations should cover one complete life cycle from the mature adult through all stages of development from conception of one generation to conception of the following generation(s).

Animal use in preclinical studies. It is ethically mandatory to conduct preclinical safety studies in animals with new pharmaceutical products before their administration to humans, as laid down in the Declaration of Helsinki. Regulatory approval is required before the start of the first clinical trial and comprises the assessment of the intrinsic hazard of the compound as well as the assessment of the potential risk that such a hazard may pose to humans. Currently this process necessitates the use of animals.

53.2 New Pharmaceuticals: The ICH Guideline

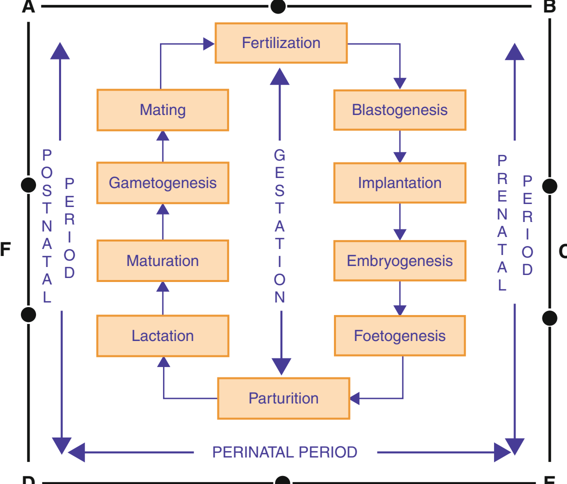
The first fundamental introduction in reproductive toxicology was given by Wilson and Warkany in 1965 (Wilson and Warkany 1965). The first test guideline was published by the FDA in 1966 (Food and Drug Administration 1966), followed by the Committee on Safety of Medicines (1974), MHW of Japan (Ministry of Health and Welfare (MHW) 1975) and many other countries and temporarily ending by the ICH Harmonized Tripartite Guideline “Detection of Toxicity to Reproduction for Medicinal Products” in June 1993, which was initiated by the IFTS (International Federation of Teratology Societies), pharmaceutical industry and the health authorities of EEC, Japan, and USA (Bass et al. 1991; ICH Harmonized Tripartite Guideline 1993).

The ICH tripartite guideline on detection of toxicity to reproduction for medical products comprises the fertility study (ICH 4.1.1), the pre- and postnatal toxicity study (ICH 4.1.2), and the embryo toxicity study (ICH 4.1.3). The former “three-segment classification” (original FDA: segment I: fertility; segment II: embryo toxicity; segment III: peri- and postnatal toxicity) was not transferred into the ICH guideline, but is still commonly used. The ICH guideline was designed to detect the four manifestations of developmental toxicity: death, growth retardation, malformation, and functional defects.

53.2.1 The Reproductive Cycle

The reproductive cycle of a mammalian individual consists of a sequence of various periods and interrelated events and is defined in the ICH guideline as follows:

A. Pre-mating to conception (adult male and female reproductive functions, development and maturation of gametes, mating behavior, fertilization)
B. Conception to implantation (adult female reproductive functions, pre-implantation development, cleavage, morula, blastula, implantation)
C. Implantation and organogenesis (adult female reproductive functions, embryonic development, major organ formation)
D. Fetal development (until the end of pregnancy adult female reproductive functions, fetal development and growth, organ development and growth)
E. Birth and pre-weaning development (adult female reproductive functions, parturition, lactation, neonate adaptation to extrauterine life, pre-weaning development, and growth)
F. Post-weaning development up to sexual maturity (growth, maturation, adaptation to independent life, attainment to full sexual function).



53.2.2 Testing Strategy

The testing strategy consists of various study designs according to the state of the art covering all stages of the reproductive cycle which can be used on a case by case basis.

In planning the studies, they must reflect human exposure to the medicinal product and should allow specific identification of stages at risk. Furthermore, the anticipated drug use especially in relation to reproduction, the physical nature of the test substance, and route of administration or exposure should be taken into account. Also any existing data on toxicity, pharmacodynamics, kinetics, mechanisms of reproductive toxicity in humans or known from previously conducted studies, and similarity to other class-related compounds in structure and activity should be taken into consideration.

The experimental strategy can be adapted on a case by case basis. However, according to the various events during the reproductive cycle, the following most probable option of study designs has been ascertained:

- Studies for effects on fertility and early embryonic development
- Studies for effects on pre- and postnatal development
- Studies for effects on embryo-fetal development

On principle, it is imperative to leave no gaps between the various stages, and thus to allow direct and indirect evaluation of all stages of the reproductive process. When an effect on reproduction is detected, further studies may be necessary to characterize the nature of the response on a case by case basis.

All these studies should be conducted according to the Principles of Good Laboratory Practice.

For basic drug discovery in the first stage of development of the test compound, the study program usually starts with testing for effects on embryo-fetal development including teratogenicity and maternal toxicity. The next step is to study the effects on fertility and early embryonic development. Testing for effects on pre- and postnatal development will be started at a later stage of preclinical and clinical development of the test compound.

53.2.3 Species Selection

Species selection for the different study types should be based on following considerations: Pharmacological activity in the species, together with comparative physiology to that in humans, similar toxicokinetic profile to that in humans, and proven susceptibility of the chosen species to teratogenic effects. The rat is the predominant rodent species, and the rabbit is the predominant non-rodent species, particularly since thalidomide was shown to be teratogenic in this animal species first. If the rabbit is not suitable as a second species in the embryo-fetal toxicity studies, alternative animal species should be considered on a case by case basis, e.g., mice, minipigs, or monkeys.

53.2.4 Number of Animals per Group

For all but the rarest events such as malformations, abortions, or total litter loss, the evaluation of between 16 and 20 litters for rodents and rabbits tends to provide consistency between studies. Below 16 litters per group for evaluation, the study results become inconsistent, whereas more than 20–24 litters per group do not greatly enhance the consistency and precision of the study data (ICH Harmonized Tripartite Guideline 1993). Therefore, and considering a certain non-pregnancy rate, generally 20–24 animals per sex are used per group.

53.2.5 Selection of Doses

In practice, the results from previous pharmacology and acute and repeated-dose toxicity studies of at least 1 month's duration are considered for dose selection. Additionally, preliminary or range-finding-studies are conducted using small amounts of test substance and low numbers of animals (three to ten per dose group) for justification of the doses to be tested in the main studies.

It makes sense to conduct preliminary or range-finding-studies to find out an adequate high dose for the definitive study, inducing maternal, embryo-fetal, or reproductive toxicity. Generally, at least three doses should be studied in the main studies. Ideally, the lowest dose should represent the one (or manifold) pharmacologically active—and presumably—daily therapeutic dose for humans, or that dose which is active in the test animal at which no toxic effects are expected in the parent animals and conceptuses. At the highest dose, signs of toxicity are expected to appear in

the parent animals and/or conceptuses. The geometric mean between the low and high dose is often used as intermediate dose.

The route and frequency of administration should be similar to those of the prospected human use considering the kinetic data. Kinetics should also be determined in the pregnant animal.

In each experiment, a simultaneous group of control animals is treated with the vehicle only in the same manner as the animals in the dose groups. If it is expected that the control preparation may cause effects, a group of same-treated or untreated animals should be added to the study.

The dose of 1,000 mg/kg/day can be used as an upper limit dose.

53.2.6 Data Presentation and Statistics

Good reporting includes tabulation of all individual data in a clear concise manner. Group summary tables should be presented in a biologically plausible manner. Presentation of individual fetal and pup data, especially structural changes, should clearly identify the litters containing the abnormal fetuses and pups, and also identify the individually affected fetuses and pups. All abnormalities should be attached to the individual offspring. As far as it is biologically acceptable, all the data and the occurrence of all abnormalities should be compared statistically with the simultaneous control group data. It should also be compared with the data of the previous relevant control groups (accumulated historical control data) on using scientifically well-defined methods. The litter should be used as the experimental unit, when statistical evaluation is performed.

53.2.7 Study for Effects on Fertility and Early Embryonic Development

This study covers ICH phases A and B of the reproductive cycle and is usually performed in rats. The aim of the study, often called "fertility study," is to assess adverse effects of the test compound on maturation of gametes, mating performance, fertilization, pre-implantation stages of the embryo, and implantation. Adverse effects can be detected on the estrus cycle, tubal transport, implantation, and development of the pre-implantation stages of the embryo. In males, functional effects on libido and epididymal sperm maturation may be detected which cannot be observed by histological examination of the male reproductive organs.

Young adult male and virgin female animals, preferably rats, are assigned to groups randomly by a computer-generated algorithm and are treated or exposed with the prepared test compound. Males and females are treated for at least 14 days prior to the cohabitation period covering the developmental stages of the germ cells relevant for copulation, and both through the mating period at a 1:1 mating ratio. After successful mating, the females are treated during the 1st week of assumed gestation. Treatment of the males continues until the end of the study. During the premating treatment period and cohabitation period, vaginal smears are taken from all females to determine the estrus cycle. If spermatozoa are found in the vaginal smear on the following morning, the females are considered to be on Day 0 of pregnancy, and separated from the assigned male. In cases of no spermatozoa, the vaginal smears and mating attempts can be continued with the same partner or another male of proven fertility from the same group. The fertility of those males which did not impregnate can be checked with untreated females not belonging to the study. The investigator decides which intensity the fertility of the animals should be tested by further mating attempts will lead to a most meaningful evaluation of this parameter. Pregnancy can be confirmed by the uterine status of the females at dissection.

Females which are found to be mated are killed at or after midpregnancy (usually Day 14), preferably on the same day of pregnancy to allow meaningful evaluation. After outwardly inspection the uterus is opened and examined for its contents. The live and dead conceptuses are counted. The embryo-fetal primordia undergoing resorption and the number of corpora lutea in the ovaries are also determined. The conceptuses in the amniotic sac after removal from the uterus can be placed in physiological saline and examined under a magnifying glass for gross anomalies if females are euthanized at a later stage of gestation (e.g., Day 17). The uterus of those females exhibiting no conceptuses can be stained in ammonium sulfide solution in order to identify those empty implantation sites which cannot be observed in the unstained uterus wall. Pregnant females without observed insemination

are either euthanized 14 days after end of cohabitation or sooner if the animal appears pregnant. In those females, the number of live and stillborn pups are likewise counted and the uterus contents and number of corpora lutea graviditates examined. Pre-implantation loss (number of corpora lutea—number of implantations) is calculated as absolute numbers and as percent per litter.

Parental toxicity, such as the animal's behavior, clinical signs, mortality and general physical condition, food consumption, and body weight are also examined during the study. Euthanasia of males should not occur before completion of the majority of uterine dissections. After euthanasia, the males and females are dissected and the internal organs examined macroscopically for pathological changes. Organs showing conspicuous macroscopic changes may be removed and preserved for possible histopathological examination. Ovaries (with oviduct), uterus, vagina, testes, and epididymides are collected for possible histopathological examination.

Optionally, spermatological examinations can be carried out. For this purpose, the males are euthanized, and samples of sperm from one cauda epididymis are collected for evaluation of percent motionless, locally and progressively motile sperm and the sperm concentration in the sperm sample. Motility can be assessed in samples of sperm obtained by incision of a tubule in the distal part of the cauda epididymis, insertion of a ball pipette, and transfer of the sample in HF-10 medium. Additionally, the number of sperm in a defined amount of liquid is determined by weighing a sample of liquid obtained after incision of a tubule in the distal part of the cauda epididymis, diluting with HF-10 medium, and counting the sperm content using a hemocytometer. To quantify spermatogenesis, testicular spermatid head count is determined by removing the tunica albuginea and homogenizing the testis. Homogenization-resistant spermatid nuclei can be counted after dilution using a hemocytometer. Alternatively to using a hemocytometer, spermatological parameters can be assessed by a computer assisted sperm analyzer (CASA).

53.2.8 Study for Effects on Embryo-Fetal Development

This study covers ICH phase C of the reproductive cycle and is usually performed in rats as rodent species and additionally in one non-rodent species, usually the rabbit. The aim of this study, often called "teratogenicity study," is to detect adverse effects of the test compound on the pregnant female and on the development of the embryo and fetus, from implantation of the blastocyst to closure of the hard palate. Adverse effects to be assessed are: enhanced toxicity to the pregnant organism in relation to the nonpregnant, death of the embryo or fetus, altered growth and structural changes in the conceptus.

Young adult females are used, mature for breeding and virgin. Rats in the estrus phase (observed by vaginal smears) are mated overnight with untreated sexually mature males at the ratio of one male to one female. The following morning, vaginal smears are examined for spermatozoa. Rabbits in the estrus phase—observed by slight external reddening and swelling of the vulva or provoked by hormonal induction of ovulation by injection of estrogen—are mated individually once or twice a day at an interval of approximately 5 h with an untreated male of proven fertility. Ovulation takes place approximately 10 h after copulation or hormonal injection. Copulation is confirmed by detection of spermatozoa in the vaginal smear after the mating attempt. Artificial insemination after hormonal induction is also possible. The day on which spermatozoa are detected is taken as Day 0 of pregnancy. Pregnancy is confirmed by the detection of implantation sites in the uterus or corpora lutea in the ovaries. The animals are assigned to groups simultaneously after spermatozoa detection. It is assumed that for rats and rabbits implantation occurs on Day 5–6 of pregnancy and closure of the palate on Day 16–19 of pregnancy. Other timing conventions of pregnancy are equally acceptable but must be defined. Therefore, the mated female rats are treated with or exposed to the prepared test compound from Day 6–17 and rabbits from Day 6–18/19 of pregnancy (depending on time of closure of the hard palate). The inseminated rats are killed and delivered by cesarean section and dissected on Day 20 or 21, and rabbits on Day 29 of pregnancy. Delivery by cesarean section is necessary to ensure examination of malformed fetuses which could otherwise be cannibalized by the mothers after delivery.

Maternal toxicity, such as altered behavior, clinical symptoms, mortality and general physical condition, food consumption, and body weight, is continuously examined during the study. All mated animals are autopsied and checked macroscopically for outward

appearance and outwardly visible organ changes, with emphasis on the uterus. The implantation sites in the uterus are counted macroscopically (rabbits) or after staining with ammonium sulfide (rats). The latter procedure, together with counting the number of corpora lutea in the ovaries, allows the detection of early embryonic deaths not visible in the unstained uterus.

The uterus is opened and the implantation sites and live and dead fetuses, dead embryo-fetal primordia undergoing resorption and the respective placentas, as well as the corpora lutea in the ovaries are counted and examined macroscopically. The fetuses are assessed for signs of life, sex, outward appearance and outwardly detectable anomalies, and their body weight and, optionally, crown-rump-length are measured. Then the rat and rabbit fetuses are euthanized.

In rats, approximately half of the fetuses from each litter are fixed in alcohol, dissected for macroscopic organ abnormalities (necropsy or micro-dissection), eviscerated, and the carcasses are then cleared in 1% caustic potash solution. The skeletons are stained in alizarin red S solution, then preserved in glycerol, and examined for anomalies with the aid of a stereomicroscope. The skeletal examination distinguishes between malformations (probably adversely affecting postnatal growth and development and probably irreversible), minor anomalies (variations, probably not adversely affecting postnatal growth and development and/or probably reversible), and ossification findings (usually reversible). Examination of both bones and cartilage can be performed by double staining with alizarin red (bones) and alcian blue (cartilage). The remaining rat fetuses of each litter can be fixed in Bouin's solution and examined in body cross sections for visceral anomalies according to the method of Wilson (1965). Alternatively, the fetuses may also be examined for organ abnormalities by using micro-dissection methods, e.g., according to Barrow and Taylor (1969). The examination of the internal organs also distinguishes between minor anomalies and malformations, with or without the aforementioned consequences. All rabbit fetuses are likewise examined for abnormalities of the internal organs (usually by fresh dissection with the aid of a stereomicroscope) and for skeletal abnormalities (with the aid of a magnifying glass) using the same procedures mentioned for the rat fetuses. Additionally, the skull cap is opened and the brain is removed and cross-sectioned according to the method of Wilson.

53.2.9 Study for Effects on Pre- and Postnatal Development Including Maternal Function

This study covers ICH phase C to F of the reproductive cycle and is usually performed in rats in case of development of small molecules. In case of development of biologicals (e.g., antibodies) the enhanced pre- and postnatal study design in monkeys (see below) is often used. The aim of this study is to detect adverse effects on the pregnant and lactating female, and on the development of the conceptus and the offspring following exposure of the female from implantation through weaning. Adverse effects to be assessed are: adverse toxicity relative to that of nonpregnant females, pre- and postnatal death of offspring, altered growth and development, functional deficits of offspring including behavior, maturation (puberty), and reproduction (F1-generation).

Young adult virgin females, preferably rats, are mated with untreated males of proven fertility. They are then assigned to groups randomly by a computer-generated algorithm. Then they are treated or exposed with the prepared test compound from implantation, through pregnancy and parturition, up to the end of the 3-week lactation period. Before implementation of the ICH Test Guideline, treatment or exposure of the animals started with closure of the hard palate of the fetuses on Day 17 of pregnancy. The females are allowed to deliver spontaneously and to rear their offspring up to weaning.

As in the other studies, maternal toxicity, such as animal's behavior, clinical signs, mortality and general physical condition, food consumption, and body weight, are examined during the study. Duration of pregnancy, birth process, and body weight gain until weaning are recorded. The number of live and dead pups, their sex, body weight at birth, and abnormalities are also obtained. During the lactation period, the behavior and body weight gain of the pups, and the number of surviving pups up to weaning, are evaluated. After weaning, the females are killed and dissected for macroscopic changes of the internal organs. The uterus is removed and stained in ammonium sulfide solution in order to count the number of all implantations and for detection of supernumerary implantation sites.

In order to find out adverse effects on postnatal development of the offspring, a great battery of physical landmarks, reflex and behavioral tests, was

established. Generally, the onset of the following physical landmarks can be tested (examples): pinna detachment, fur development, incisor eruption, eye opening, righting reflex, and pupil reflex to light. These parameters are studied in the lactation period. Sexual maturation of the offspring is assessed by the time of preputial separation and vaginal patency. Behavior is tested after weaning by activity, open field (often studied during lactation), photophobotaxis, maze test, social interactive test, electric current avoidance, passive avoidance, FOB including grip strength and/or landing food spread. Further studies are fore- or hind limb hanging, or rotarod. Learning behavior, such as trainability, memory, and re-trainability, as well as motor activity, coordination, and sense of balance, can be checked in a water-maze-test. It has to be decided which test should be used in a routine test battery and which should be used in special cases of test substances. How many pups from each litter and dose group should be examined to provide a meaningful evaluation must also be fixed. Sixteen to 20 litters per groups should be available for evaluation.

After behavioral testing, fertility of offspring is assessed using the procedures described under "Effects on Fertility and Early Embryonic Development" above. Alternatively, females may be necropsied with their pups on Day 4 postpartum.

53.2.10 Alternative Study Designs

One study design: This study design covers ICH stages A to F. Consequently it is a very large study and difficult to handle. An embryo-fetal toxicity study in a second species is needed.

Two-Segment design: These study protocols combine the design of a fertility study and of a pre- and postnatal toxicity study. The study design has the same limitations as the one study design.

Combined fertility and embryo toxicity study design: The treatment of females in the fertility study is prolonged until closure of the hard palate. This design is relatively easy to handle from a logistical point of view and considered as the most advantageous alternative design.

Combination of segments is not advisable if toxicokinetic parameters change over time (e.g., enzyme induction or accumulation). Study designs may furthermore be adapted in special cases, in which subgroups of pregnant animals are dosed in different "windows" of embryo-fetal development, e.g., gestation days 6–9, 10–13, 14–17. This design enables higher (adequate) maternal exposure, higher exposure ratios of animal/human, and a higher chance to detect teratogenic effects. This protocol is confined to special questions and not routinely used.

53.2.11 The "Enhanced Pre- and Postnatal Study" Design

In case of biopharmaceuticals (e.g., monoclonal antibodies) the Cynomolgus monkey is often preferred for preclinical safety testing since the pharmacological activity of the antibody is only present in this species. This enhanced pre- and postnatal study design combines the classical embryo-fetal toxicity study and the pre-postnatal toxicity study into one single study. A comprehensive review of this study design is given by Stewart (2009).

Pregnancy rate is low in Cynomolgus monkeys and is detected by ultrasound at gestation day 18–20. Dosing starts after detection of pregnancy, and therefore implantation and early embryogenesis are not covered in this species. However, since exposure of the fetus to monoclonal antibodies during organogenesis is limited, there is lesser concern of teratogenicity during this period compared to small molecules. Exposure to antibodies increases after organogenesis, and would therefore not be adequately addressed by a classical embryo-fetal toxicity study design (treatment from gestation day 20–50). In the enhanced pre- and postnatal toxicity study design, pregnant female Cynomolgus monkeys are treated from detection of pregnancy ($\sim$ Day 20 post coitum) until birth. Fetal growth is determined by ultrasound on gestation days 50, 90, and 130. Since monkeys do not eat stillborn offspring, their evaluation is possible in absence of a cesarean section. Exposure to the antibody is measured in mother and offspring at birth. Live offspring is weaned after birth. The length of the postnatal phase is variable and depends on the endpoints of concern. If offspring viability and growth is the primary endpoint, then the postnatal phase may be limited to 1–2 months (highest mortality occurs within the first week after birth). The postnatal phase is extended in case functional tests are needed like phenotyping and function of the immune system (e.g., lymphocyte

subpopulations, T-cell dependent antibody response, natural killer cell activity), behavior, learning, and memory. Further endpoints in offspring comprise ophthalmologic examinations, antibody exposure (may be prolonged), skeletal examinations (X-Ray), hematology, clinical chemistry, urinalysis, necropsy, organ weights, and histopathology.

The group size in this study design should be 20–24 animals to take into account abortions, stillbirths, and early postnatal deaths.

53.2.12 Timing of Studies

The requirement of non-clinical reproductive toxicology studies before enrolment of men or women in clinical trials is regulated in by ICH guideline M3(R2) (ICH International Conference on Harmonisation 2009).

Men can be included in Phase I and II trials without reproduction toxicity studies since evaluation of male reproductive organs is performed in repeated-dose toxicity studies. A male fertility study should be completed before initiation of large-scale or long duration clinical trials (e.g., Phase III trials).

Women not of childbearing potential can be included in clinical trials devoid of reproduction toxicity studies since evaluation of female reproductive organs is performed in repeated-dose toxicity studies.

For women of childbearing potential there is a concern for embryonic exposure. Therefore the risk of unintentional exposure has to be minimized (e.g., conduction of reproduction toxicity studies, precautions to prevent pregnancy, pregnancy testing (β-subunit of HCG), use of highly effective methods of birth control, study entry after confirmed menstrual period only). Women of childbearing potential can be enrolled in early Phase I clinical trials without reproductive toxicology studies under the following considerations: The disease is predominant in women; effective precautions to prevent pregnancy are used; duration of treatment is short (e.g., 2 weeks); the mechanism of action is known; the amount of embryo-fetal exposure can be estimated and is negligible. For inclusion of women of childbearing potential in limited phase II studies (up to 150 patients, up to 3 months duration) at least "extended preliminary reproduction toxicity data" are required, i.e., data of embryo-fetal toxicity studies in two species, consisting of at least six animals per group, with full external and visceral examination of the fetuses. In the USA definitive embryo-fetal studies are needed for Phase III whereas they are needed generally in EU and Japan except the cases mentioned above. Female fertility studies are required before long duration or large-scale clinical trials (e.g., Phase III) are initiated. Pre-postnatal toxicity data are needed for submission.

If pregnant women are planned to be included in clinical trials, all female reproductive toxicity studies are needed. In addition, evaluation of safety data (previous human exposure) is required.

53.3 OECD Guidelines

Besides the study designs described above for reproductive toxicity testing especially developed to examine medicinal products, a battery of further reproductive and developmental toxicity test guidelines was published by the OECD. The first OECD reproductive toxicity test guideline, especially developed for testing chemicals and agricultural products, was adopted in 1981.

Usually, three dose levels and a concurrent control group are used in these studies. The highest dose level should be chosen with the aim to induce some developmental and/or maternal/paternal toxicity (clinical signs or a decrease in body weight development) but not death or severe suffering. The dose of 1,000 mg/kg/day is generally accepted as an upper limit dose level. However, human exposure may indicate the need for higher dose levels.

53.3.1 OECD Guideline 414: Prenatal Developmental Toxicity Study

This guideline is similar to the ICH design for effects on embryo-fetal development. As a difference the administration period is at least from implantation through the last day before cesarean section. When appropriate, administration of the test compound through the entire gestation period is encouraged. As in the ICH guideline, the most relevant species should be used. The preferred rodent species is the rat, the preferred non-rodent species is the rabbit. The number of animals should result in approximately 20 pregnant animals, groups with less than 16 implantation sites

may be inappropriate. The high dose level should produce maternal toxicity (e.g., reduction of body weight gain), but mortality should not exceed 10%. In non-rodents, the heads of one half of each litter should be evaluated for soft tissue alterations (eyes, brain, tongue, and nasal passages) (OECD Guidelines for Testing of Chemicals 2001).

53.3.2 OECD Guideline 415: One-Generation Reproduction Toxicity Study

This study is usually conducted with rats or mice. Males are dosed for at least one spermatogenic cycle (70 days in rats, 56 days in mice). Females are treated for at least two complete estrous cycles (14 days) in order to detect adverse effects on estrous cyclicity. Treatment continues to both sexes during cohabitation, and thereafter to females during pregnancy and nursing of F1 animals. Females are allowed to litter normally. At least 20 females per group are needed at or near parturition. Litter size standardization to four males and four females on Day 4 postpartum is optional. Observations and measurements include clinical signs, body weight, food consumption, duration of gestation, number and sex of pups, still births, live births, and gross anomalies. Additionally, macroscopic examinations are performed at necropsy, and reproductive organs of P animals are preserved for possible microscopic examination. Microscopic examination is mandatory if these organs have not been examined in repeat-dose toxicity studies.

This Guideline is rather old. It was adopted in 1983 (OECD Guidelines for Testing of Chemicals 1983) and is usually replaced by OECD416 or the extended One-Generation Reproduction Toxicity Study (see below).

53.3.3 OECD Guideline 416: Two-Generation Reproduction Toxicity Study

In that study design, the exposure of the experimental animals to the chemical is continuously extended over two complete generations (P- and F1-generation), including weaning of the F2-generation (OECD Guidelines for Testing of Chemicals 2001). Assessment of sperm parameters (homogenization-resistant sperm heads in the testis, sperm reserves in epididymis (cauda), and sperm motility and morphology) are endpoints for P and F1 animals. The two-generation toxicity reproduction toxicity design is the only one that exposes the F1 animals from conception onward and would cover effects on fertility during this early period. Due to the high animal number used, discussions are being carried on to replace the OECD 416 with the extended one-generation reproductive toxicity test.

53.3.4 OECD Guideline 443: Extended One-Generation Reproductive Toxicity Study

This study design has been discussed as a replacement for the Two-Generation Toxicity Study design, as it requires considerably less animals. Pre-cohabitation treatment is 2 weeks in males and females. Dosing is continued during the mating period and until weaning. Dosing of F1 starts at weaning and continues until necropsy. After weaning, F1 animals are assigned to three cohorts, reproductive toxicity, neurotoxicity and clinical endpoints, and immunotoxicity; necessity of the latter two is dependent on available information as well as regulatory purposes. A second mating of P animals might be triggered in case of equivocal effects during the study and should be done preferably with untreated females (OECD Guidelines for Testing of Chemicals 2011).

Endpoints are similar to the pre- and postnatal toxicity study. In addition, developmental immunotoxicity is assessed by IgG and IgM antibody response to Keyhole Limpet Hemocyanin or sheep red blood cells. If antibody response is not or only marginally affected, cellular immune response and delayed type hypersensitivity response, cell mediated cytotoxicity, or natural killer cell assay are determined in the remaining animals. If antibody response is affected, the remaining animals are immunized with sheep red blood cells, and phenotypic analysis of splenocytes is carried out to identify affected cells. Assessment of reproductive toxicity (triggered) is done in case of equivocal effects on reproduction in P animals. The F1 animals of cohort I can be maintained until Day 90 and then cohabitation similar to P animals, but termination of F2 animals is on PND4.

Sperm parameters comprise testes and epididymis weight in all P and F1 males, histological examination

of one testis and epididymis, absolute and relative amount of different germ cell stages, and epididymal sperm count, motility, and morphology.

Organ weights are determined in P and F1 animals, and full histopathology is carried out in 10 randomly chosen rats per sex of the control and high dose group of the P generation and reproductive toxicity F1 cohort, respectively (low and mid dose animals are examined in case of compound-related effects). In F1 animals of the neurotoxicity cohort, CNS is fixated by instillation, and separate sections are immunostained for glial fibrillary acidic protein and a synaptic marker. Furthermore, quantitative morphometric evaluations are recommended to be carried out. Neurohistopathology should be consistent with OECD 426 (see below).

53.3.5 OECD Guideline 421: Reproduction/Developmental Toxicity Screening Test

In this test, which uses 10 animals per sex and dose group (usually rats), males are treated at least for 4 weeks and females 2 weeks before cohabitation. Then the animals are mated 1:1. Treatment continues during cohabitation and in females during pregnancy until 4 days postpartum. Observations and measurements include clinical signs, body weights, food consumption, and gestation length, number of live and dead pups, sex distribution, and pup weights at birth and postnatal Day 4. Further examinations comprise number of corpora lutea and implantation sites, weights of testes and epididymides, macroscopic examinations at necropsy, and histopathological examinations of ovaries, testes, and epididymides with special emphasis on stages of spermatogenesis and histopathology of interstitial testicular structure (OECD Guidelines for Testing of Chemicals 1995).

53.3.6 OECD Guideline 422: Combined Repeated-Dose Toxicity Study with the Reproduction/Developmental Toxicity Screening Test

This test system combines the repeated-dose toxicity study (OECD Guideline for Testing of Chemicals 2008) and the reproduction/developmental toxicity screening test described above. The design includes detailed clinical observations (outside the cage in a standard arena) and neurological examinations (sensory reactivity to auditory, visual, and proprioceptive stimuli, grip strength, assessment of motor activity) (OECD Guidelines for Testing of Chemicals 1996).

53.3.7 OECD Guideline 426: Developmental Neurotoxicity Study

This study has to be carried out in case of hints for neurotoxicity (e.g., based on results of other studies). Groups of 20 rats are dosed from implantation through lactation, with adjustment of litter size on postnatal Day 4. During the pre-weaning phase, subsets of pups are assessed regarding behavioral ontogeny, brain weight, neuropathology, and optionally brain morphometry. Likewise, subsets of pups are assigned to behavioral/functional tests, motor activity, sexual maturation, auditory startle response (as described in more detail above in the pre- and postnatal toxicity study), brain weight, neuropathology, and optionally brain morphometry during the post-weaning phase (OECD Guidelines for Testing of Chemicals 2007).

53.4 Alternative Test Systems

There are many alternative in vivo mammalian, nonmammalian, and in vitro test assays. However, at present no alternative test can totally replace the existing reproductive toxicity tests using live mammalian animals. The major drawback of these test systems is that the maternal component and its interaction with the conceptus is missing. However, these alternative methods can be used for screening of drug candidates for potential embryo toxicity. Commonly used alternative test systems are the frog embryo teratogenesis assay *Xenopus* (FETAX), the Zebra fish assay, the whole embryo culture test (WEC), and the mouse embryonic stem cell test (EST).

The FETAX test uses mid blastula stages of *Xenopus*, which are incubated with the test compound at different concentrations for 96 h. In the Zebra fish assay, embryos are exposed to the test substance 6–120 h after fertilization. In both assays, prediction of teratogenicity is based on the ratio of the concentration causing a distinct percentage of lethality and the

concentration causing a distinct percentage of larvae with malformations (Bantle et al. 1989; Fort and Paul 2002).

In the WEC test, rat embryos are removed from the mother at Day 10 of gestation, cultured, and exposed for up to 48 h to the test compound (Piersma et al. 2004). This period covers development of major organ systems, including closure of the neural tube, heart, limb buds, eyes, and ears. Endpoints are growth (head length, crown-rump length) and malformations.

The mouse EST uses cells derived from inner layer blastula cells, which develop to embryoid bodies. Originally the test used the development of contracting differentiated myocardial cells in relationship to cytotoxicity in 3T3 cells as an endpoint. Today, EST cells can also be developed into CNS, blood, bone, and cartilage cells to assess potential effects in these tissues. A further improvement of this test is the use of nonhuman primate EST cells instead of mouse EST cells, since the former are more similar to human EST cells (Davis et al. 2010). Recently, implementation of transcriptomics has been shown to improve the predictivity of this test system (Van Dartel et al. 2011).

In recent years, considerable progress has been made in developing in vitro test systems. In vitro assays are ideal tools for rapid screening with high reproducibility and increased sensitivity, and they are relatively inexpensive, especially compared with in vivo studies. In pharmaceutical industry, there has been a dramatic increase in interest in in vitro toxicology and in the search for in vitro methods for predicting toxicological effects. The industry needs early, rapid, and robust preclinical lead optimization technology screening assays, which allow a lead series of compounds to be ranked for desirable or undesirable characteristics.

A better lead candidate selection for preclinical drug development should reduce the high rate of attrition and the involved increasing costs. Outside the industry the prominent driving forces for the development and application of in vitro toxicity systems was (and still is) the societal criticism of using animals in toxicological studies as well as the growing demands for greater safety. Broad spectrums of in vitro systems, with individual techniques associated with particular classes of compounds, have already been tested in validation studies and their usefulness has been proved for the assessment of organ toxicities. The non-animal screening tests are now performed prior or in parallel to regulatory in vivo studies either to exclude potentially severe effects in vivo or to provide mechanistic data (Bugelski et al. 2000; Peters 2005; Dorato and Buckley 2007). Importantly, the screening assays should be predictive, sufficiently rapid, and cost-effective. This chapter describes the most in vitro approaches in molecular toxicology applied to drug development that fulfill all these criteria and that are based upon essential cellular, molecular, and biochemical processes. The central idea is that

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_60, © Springer-Verlag Berlin Heidelberg 2013

the investigation of toxic reactions should be expanded to multiple parameters, different cellular models and different end points combined with a detailed concentration-response relationship, to achieve a complex system closed to in vivo conditions. These in vitro data are then regarded as basic toxicological information that are used together with other data (in silico, target activity) for the final evaluation, hazard and risk identification (Atterwill and Steele 1987). Starting with in silico, the available knowledge and computer models/methods can be utilized to identify likely toxicity with significant scores. In the next tier, cell-based assays are conducted to unravel effects of the test compounds on cultured and primary cells. Using animal and human cell types may allow better estimates of risk for human situation. Finally, exploratory in vitro studies (probably supplemented by in vivo studies) are conducted to generate mechanistic data that can be used to decipher the processes associated with the observed target-organ toxicity. There have been many diverse sets of assays described in the literature that cover almost all targets of side effects including models for rare toxicities (e.g., thyroid gland). However, the in vitro methods described here focus mainly on hepatotoxicity, cardiotoxicity, and nephrotoxicity that build the most organ toxicities caused by side effects of therapeutics. The concerned action in each organ model is a multisystem approach with sequential examination in different cells and species applying multiple physiological end points (Gross and Kramer 2007; McKim et al. 2005).

54.1 General Insights into Cellular Systems

Since the development of cell culture techniques and the evolution of the culture media, almost all cell types can effectively be cultured. Cells from most mammals as well as lower vertebrates and insects are routinely cultivated and grown in vitro for short or long lasting periods. The cultivation period depends mostly on whether the cells are immortalized (transformed) or normal cells isolated from corresponding organs (primary cells). While the latter cells can be cultured just for a few days or weeks, transformed cells can be maintained in culture for many months or even years. Primary cells can be isolated using intact organs of experimental animals as well as humans. Immortalized cells are either isolated from malignant organs and are sequentially adapted to culture conditions, or are normal cells that are transformed in culture by virus infections. This origin and molecular programming of the cells determines the requirements for successful cultivation in vitro. The cells grow either without cell contact floating in the culture medium (suspension culture) or need cell contact and attachment to a suitable substrate and grow on that substrate (inert surface such as plastic). The design of culture dishes is fundamental for the culture of many primary cells and cell lines. While, for example, primary cultures of hepatocytes require collagen-coated dishes, fibroblasts can attach and grow in untreated culture dishes. In order to achieve a tissue-like cell architecture and function, three-dimensional matrices are developed that represent more complex in vitro tools. The matrix in this approach serves as a skeleton and directs a three-dimensional cell assembly. Differentiated cells in this culture method maintain their phenotype and functional characteristics. The matrix-assisted culture technique was fundamental for the development of some in vitro models, for example, the cholestasis model that is described below.

Unwanted contamination with microorganisms like bacteria is a permanent and serious issue in handling cells in culture. Therefore, it is of paramount importance to complying with laboratory hygiene to protect cultures from contamination with microorganisms. Supplementation of media with antibiotics prevents bacterial contaminations. However, the cross-reaction of antibiotica with test compounds should be appraised. Temperature and humidity are other important factors that need adaptation to culture needs (Waymouth et al. 1981; Walum et al. 1990).

54.1.1 Available In Vitro Models to Investigate Hepatotoxicity

Hepatotoxicity is one of the most important drug side effects. Therefore, in vitro hepatotoxicity assays are applied early in drug development to screen development compounds for their potential to induce hepatotoxicity. Generally, three different hepatic in vitro models are used to examine the toxic effects on the hepatic system: (a) The most frequently used model is the cell culture model of primary hepatocytes that can be isolated either from conventional laboratory

animals (rat, mouse, dog, rabbit) or human liver specimens. (b) Permanent hepatic cell cultures of animal (H4IIE) or human origin (HepG2) represent the second approach. (c) As an alternative to the cell-based approaches, precision-cut liver slices are applied to the studies of liver toxicity (Groneberg et al. 2002). Intact hepatocytes represent a complex biological system with high capacity for drug metabolism (Seddon et al. 1989; Bayliss et al. 1994). Working with permanent cell lines is easy, time-saving, compatible to high-screening modes, and they are accessible to genetic manipulations (Alley et al. 1988). Preparation and working with liver slices is quick and easy to handle. The more relevant usefulness of liver slices is that they are accessible to classical toxicological techniques and can be investigated as tissue-like in accord with histopathological examinations of the native organ (Ekins et al. 1996; de Kanter et al. 2002). In addition, they exhibit high conservation of drug-metabolizing enzyme activities (Sohlenius-Sternbeck et al. 2000). Nevertheless, each of these models has advantages and limitations. Therefore, depending on the toxicological aspects under investigation, one or all of these models can be applied (Guillouzo 1998).

54.1.1.1 Isolation and Culture of Primary Hepatocytes

For the isolation of primary hepatocytes, a rat is anesthetized with Hostaket/Rompun® (i.p.). The abdomen is washed with 70% ethanol and a ventral midline incision is made from the xiphisternum to the pupic bone. The hepatic portal vein and vena cava are exposed and a loose ligature is placed around the vena cava inferior under the departure of the left kidney. Next, the vena cava superior is clamped near by the diaphragm and the vena cava inferior is catheterized, and the ligature is tightened. The catheter is now attached to the perfusion tubing containing Gibco BRL Liver Perfusion Medium (Gibco, No. 17701-038) and at the same time the portal vein is cut. The liver perfusion starts with 100 mL Perfusion Medium at a flow rate of 20 mL/min. Following the first perfusion and to digest the liver, the liver is perfused with Gibco BRL Liver Digest Medium (Gibco, No.17703-034) until the liver is considered to be sufficiently digested. The liver is then excised and transferred into a sterile glass dish containing Digest Medium. The fully digested liver is gently teased with a sterile fork to free the cells from the connective tissue. In the next step the mashed liver is filtered through two layers of sterile gaze and washed up with cold Gibco BRL Hepatocyte Wash Medium. To harvest the primary hepatocytes the cell suspension is kept on ice for approximately 10 min to allow sedimentation of hepatocytes. After the sedimentation of the cells, the supernatant is discarded and the pellet is washed three times. After the last washing, the pellet is recovered in cold Attachment Medium (See Table 54.1). Yield and viability is immediately determined, and cell preparations with the viability of ≥80% are then seeded in culture plates coated with Collagen I in Attachment Medium. Cultures are incubated now for 4 h to allow them to attach to the substrate. Next, the Attachment Medium is removed and the cells are incubated for a further 20 h in Culture Medium (see Table 54.1). The overnight cultures are then used for in vitro experiments (Berry and Friend 1969; Seglen 1976; Quistorff et al. 1989; Le- Cluyse et al. 1996a, b; Mudra and Parkinson 2001). The graph in Fig. 54.5 represents the application of primary hepatocytes in cytotoxicity experiments. The application of primary hepatocytes is not restricted and a broad range of end points can be analyzed with primary hepatocytes (Eckl and Bresgen 2003).

For the isolation of primary hepatocytes from other mammals (rabbit, dog, monkey, and human) the liver is excised and the whole (rabbit) or a piece of liver (dog, monkey, human) is perfused ex vivo (Jamieson et al. 1988; Coulet et al. 1998). All other steps are according to the described method with some adjustments depending on the size of the liver or liver pieces. In this way, isolated primary hepatocytes in monolayer culture keep their metabolism for several days, but lose their tissue-like physiology over time. Therefore, it is important to start experiments immediately after

cell adaptation to in vitro cell culture conditions. Matrix-supported culture models may be considered when primary hepatocytes cultures are intended for longer experimental duration or if formation of hepatocytes-specific structures is desired (see formation of canaliculi in the cholestasis model bellow). Non-static cultures in bioreactors with continuous fluidic flow would also provide an alternative (Zeilinger et al. 2002; Allen et al. 2005; Novic et al. 2009; Kidambi et al. 2009).

Preparation and Culture of Liver Slices

Precision-cut liver slices are prepared from the liver obtained from a rat of 6–7 weeks of age. After sacrifice (Refer to hepatocytes isolation protocol), the liver is removed and the liver lobes are separated and stored in Washing Medium (Krebs-Henseleit-Bicarbonat buffer, containing HEPES buffer and gentamicin) on ice until the preparation of slices. Slices of dog, monkey, rabbit, and human liver can be prepared accordingly from samples of ca. 1 cm thickness. From the liver lobes cores of ca. 8 mm diameter are prepared using a motor-driven coring toll. The cores are stored in Washing Medium until preparation of slices. Slices of ca 250–100 μm thickness are prepared in medium at 2–8°C using a krumdieck tissue slicer (Krumdieck AR&D). Slices are washed in Washing Medium and stored in the same medium on ice until start of the culture or cryopreservation. To culture liver slices, three slices are transferred to a 20 mL glass Erlenmeyer flask containing 5 mL Culture Medium (Williams Medium E supplemented with glutamine [292 μg/mL], gentamicin [50 μg/mL], and insulin [0.1 μM]) and pre-incubated for approximately 1 h at 37°C in a shaking water bath. After pre-incubation, the medium is replaced with 5 mL fresh supplemented medium containing the test compound. Stock solution of test compounds are prepared in DMSO or other solvents and added to the culture in a broad range of concentrations. The cultures are kept under a carbogen atmosphere with 95% O_2 and 5% CO_2. The exposure period depends on the experimental design, but is normally 24 and 48 h. If cytotoxicity is measured, a positive reference compound, for example, 0.5% Triton, is tested in parallel. Cytotoxicity is measured either through the LDH leakage or MTT conversion. Liver slices can also be subject to histopathological examination. After the incubation time, slices are cut in half. One half is used for the determination of MTT conversion. The other half is fixed in 4% buffered formalin. Next, slices are horizontally embedded in paraffin and 8 μm sections are cut using a microtome. Sections are stained with H&E and evaluated microscopically. The so prepared slices are as nearest to in vivo situation a valuable tool in mechanistic studies, for example, apoptosis, cross-species comparisons, and metabolism (Bach et al. 1996; Hashemi et al. 1999; Glöckner et al. 2002; Jewell and Miller 1999).

54.1.1.2 Culture of Human Cell Line HepG2

HepG2 is a human hepatic carcinoma cell line and commercially available (HB-8065, ATTC, Manassas, VA).

HepG2 cells are cultured in high-glucose Dulbecco's modified Eagle's medium ([DMEM, Invitrogen, No. 11995-065] containing 25 mM glucose and 1 mM sodium pyruvate and supplemented with 5 mM *N*-2-hydroxyethylpiperazine-N′-2-ethanesulfonic acid [HEPES], 10% heat inactivated FBS, and penicillin-streptomycin [pen-strep; 500 μg/mL final concentration]) and kept in 5% CO_2 at 37°C. Cells are maintained on collagen-coated flasks and seeded onto 96-well plates for individual experiments. Culture of cells in collagen-coated dishes ensures a better cell growth and proliferation. To allow them to adhere HepG2 cells are incubated for 24 h at 37°C with 5% CO_2 prior to treatment. For culture of cells, different plate formats are available. The choice of white or transparent well plates depends on choice of biochemical assays. For cytotoxicity assays, LDH or NRU (see Sect. 54.1.4.1 Cytotoxicity Assays) clear well plates (e.g., Greiner No. 655098) are required, and for CellTiterGloTM assay, white well plates (e.g., Greiner No. 655183) are recommended.

54.1.1.3 Culture of Rat Cell Line H4IIE

H4IIE is a rat hepato carcinoma cell line and commercially available (CRL-1548, ATTC, Manassas, VA).

H4IIE cells are cultured in MEM Eagle medium ([Sigma No. M 5650] supplemented with 10% [5% in treatment medium] heat inactivated FCS, 2% glutamin, and 1% pyruvic acid sodium). Cells are expanded in 175 cm^2 culture flasks and subcultured in micro-well plates thereafter. To subculture H4IIE, cells are detached from the substrate by enzymatic digestion. Prior to enzyme treatment, media are removed, flasks are rinsed two times with 10 mL prewarmed phosphate buffered saline deprived

of Ca^{2+}/Mg^{2+} (PBS Sigma No. 20012-019). In the next step, 5 mL Accutase is added and the culture is incubated at 37°C for ca. 10 min. The reaction is terminated with addition of culture medium (about 25 mL) and continuous resuspension with a pipette. Cell number is determined and 1×10^4 cells per well are seeded into a 96-well plate and incubated for 24 h at 37°C with 5% CO_2 prior to treatment.

54.1.2 Available In Vitro Models to Investigate Cardiac Toxicity

The most common in vitro models for assessment of cardiac toxicity are cardiac cell lines or primary cardiomyocytes isolated from laboratory animals. The prominent cardiac cell lines in toxicity studies are H9c2 from rat embryonic ventricular myocardium and the human cell line AC16. H9c2 cells exhibit many cardiac muscle characteristics like electrophysiological activity, automatic receptors, and ion channels (Wang et al. 1999). Freshly isolated cardiomyocytes stand out due to having in vivo physiological properties like receptor and enzymatic activities. Embryonic stem cells represent an alternative source for cardiomyocytes. However, the physiological characteristics of these cells are not well defined yet.

54.1.2.1 Isolation of Primary Cardiomyocytes from Neonatal or Adult Rats

Primary cardiomyocytes can either be isolated from neonates or adult rats. For the isolation of neonatal rat cardiomyocytes, cardiac ventricles from 1- to 2-day-old rat neonates are excised, washed with PBS buffer to remove blood, and gently minced. The minced ventricles are then digested with collagenase H in Ca- and Mg-free HBSS medium. Dissociated cells are then filtered through 200-μm mesh and collected by centrifugation. The isolated cells are cultured in DMEM medium supplemented with fetal bovine serum. After a 24 h culture and adherence of cells, Cytosine 1-β-D-arabinofuranoside at a concentration of 10 μM is added to retard the growth of fibroblasts (Boerma et al. 2002; Fu et al. 2005). The isolated cultures are incubated for several days, before starting experiments. Even though the isolation and culture of fetal cardiomyocytes provides some technical advantages, there are a few drawbacks that limit their utilization. Cardiomyocytes derived from newborn animals are different in their physiology and morphological characteristics compared to cardiomyocytes isolated from adult animals.

For the isolation of primary cardiomyocytes, the heart of a rat is excised and stored in PBS buffer lacking $MgCl_2$ and $CaCl_2$. Before mounting the heart on the Langendorff apparatus for perfusion, the aorta is exposed and a cannula is inserted. Washing Solution ([Pure Joklik HEPES medium, PAN BIOTECH, Germany] supplemented with 1% Penicillin/Streptomycin, 250 μM EDTA, 15 mM 2,3-butandione monoxide [BDM]) is perfused with a fluid pressure of not more than 80 mm HG until all the blood is washed out. Then the heart is perfused with Digest Solution ([Washing Solution] supplemented with 20 μM $CaCl_2$, 1% BSA, 5 mg liberase™ [Roche] in 50 mL Washing Solution) for ca. 40 min. The digested heart is then transferred into a sterile glass dish containing Powell-Gradient Solution I (40 μM $CaCl_2$ in 120 mM NaCl, 5.4 mM KCl, 1.2 mM $MgSO_4$, 1.2 mM NaH_2PO_4, 20 mM $NaHCO_3$, 5.6 mM Glucose, 15 mM BDM, 5 mM Taurine, 5% BSA) and gently teased with a sterile scalpel. In the next step, the mashed heart is filtered through a sterile cell sieve and washed up with Powell-Gradient Solution I. To harvest the primary cardiomyocytes the cell suspension is centrifuged at 400 U/min for 3 min. The supernatant is discarded and the cell pellet is suspended in Powell-Gradient Solution II (200 μM $CaCl_2$ in Powell-Gradient Solution I). In the next step, cells are washed up with Powell-Gradient Solution III (400 μM $CaCl_2$ in 120 mM NaCl, 5.4 mM KCl, 1.2 mM $MgSO_4$, 1.2 mM NaH_2PO_4, 20 mM $NaHCO_3$, 5.6 mM Glucose, 15 mM BDM, 5% BSA) and finally the pellet is resuspended in Incubation Medium I. After the yield and viability of cells are determined, cell are seeded in culture plates coated with Laminin in Incubation Medium I and incubated for 1 h at 37°C to allow them to attach to the substrate. Next, the Medium is changed and the incubation is continued for next 1 h. At the end the culture medium is removed, and the cells are incubated in Incubation Medium II (Medium 199 [PAN BIOTECH] supplemented with 1 mM $CaCL_2$, 1% Pen/Strep). The cells isolated with this protocol can be cultured at 37°C at 5% CO_2 and used for the planned experiments within 4–8 days (Mitcheson et al. 1998; Thum and Borlak 2000, 2001; Zhou et al. 2000; Louch et al. 2011). This protocol can also be applied to other experimental models like mouse and rabbit. Considering this very complex and time-consuming procedure, these isolated

Table 54.2 Major classes of therapeutic agents that induce nephrotoxicity

Acute tubular necrosis	Interstitial nephritis	Medullary necrosis	Papillary necrosis	Glomerular damage

primary cardiomyocytes can mainly be used for investigative and mechanistic studies. For screening purposes, cell lines may be more beneficial.

54.1.2.2 Culture of Myocyte Cell Line H9c2

H9c2 is a rat cell line that was derived from the ventricular part of a 13th-day rat heart embryo and is commercially available (CRL-1446, ATTC, Manassas, VA).

H9c2 cells have been extensively used in cytotoxicity studies also because of their cardiac properties, for example, electrophysiological activity, ion channels, and autonomic receptors (Shi et al. 2009; Pereira et al. 2011). H9c2 cells express CYP1A1, 1B1, CYP2B1, 2B2, 2E1, and 2 J3 (Zordoky and El-Kadi 2007).

H9c2 cells are cultured in DMEM medium at 37°C at 5% CO_2. For planned experiments, they are seeded into 96-well micro well plates at 3×10^4 cells per well and incubated overnight. On the following day they can be exposed to test compounds.

54.1.3 Available In Vitro Models to Investigate Renal Toxicity

Kidney is a highly differentiated organ that possesses many specialized regions harboring very specialized cell types (Table 54.2). Nephrotoxicity following drug therapy is a common phenomenon that is mostly limited to a well-defined region of this organ. Hence, for the investigation of region-specific toxicities, culture of concerned regions is mandatory. Because of their role in secretion and reabsorption processes and their metabolic capacity, proximal tubular cells are the primary target of many nephrotoxic agents. In proximal nephron, metabolizing enzymes are expressed and higher concentration of GSH and GSH-dependent enzymes are present. The proximal tubular cells have the potential to accumulate high concentration of chemicals by active transport (by a factor of 100–1,000).

Protocols are developed to isolate and culture primary cells from different parts of the kidney, but

due to their importance most attempts relied on development of protocols to culture proximal tubules (Boogaard et al. 1989; Boom et al. 1992; Valente et al. 2011).

54.1.3.1 Isolation of Primary Tubular Cells from an Adult Rat Kidney

For the isolation of primary tubular cells a male or female rat is anesthetized with Hostaket/Rompun® (i.p.). The abdomen is washed with 70% ethanol and a ventral midline incision is made from the xiphisternum to the pupic bone. The aorta below and above the renal arteries are freed. After closing the celiac and mesenteric arteries, aorta is cannulated, renal veins are cut, and perfusion started immediately with 150 mL carbogen saturated calcium-free Hank's buffer (137 mM NaCl, 5 mM KCl, 0.8 mM $MgSO_4$, 0.33 mM Na_2HPO_4, 0.44 mM KH_2PO_4, 26 mM $NaHCO_3$, 25 mM HEPES, 0.5 mM EGTA) with a flow of 8 mL per minute at 37°C. After a second perfusion with 25 mL Hank's buffer without EGTA, the kidney is digested with collagenase (0.12% w/v) in Hank's medium containing 4 mM $CaCl_2$ for 20 min in recirculating system. Subsequently, the digested kidney is perfused with 10 mL Hank's medium containing 2.5% (w/v) BSA to wash out collagenase. Immediately after perfusions, the capsule is removed and the cortex is dispersed in cold Hank's buffer with 2.5% (w/v) BSA and 1.8 mM $CaCl_2$ (HB-BSA). The mashed kidney is then filtered through two layers of nylon gauze (first 135 μm and then 60 μm). The filtrate is centrifuged (80 × g, 4°C, 3 min) and washed with HB-BSA. The cell pellet is resuspended in Culture medium ([DMEM/F12] supplemented with 5% FCS, 1% penicillin/streptomycin, 5 mg/mL insulin, 0.5 μg/mL hydrocortisone, 10 μg/mL transferrin, 0.01 μg/mL hEGF, 0.5 μg/mL epinephrine, and 6.5 ng/mL triiodothyronine) and the cells are seeded into Collagen I-coated culture plates. The regular morphology check and marker analysis (e.g., NHE3) ascertain the identity of isolated proximal tubular cells. This protocol can principally be used to isolate tubular cells from mouse, rabbit, and with some modifications for the isolation of human proximal tubular cells.

The primary tubular cells isolated with this protocol can be used both for screening and for investigative studies. However, for a wide range of chemical series suspected to exhibit kidney toxicity the first line of cytotoxicity assays may include kidney-driven cell lines such as LLC-PK1 to sort out cytotoxic compounds or rank them based on their inhibitory properties. This cell line and MDCK cell line that have been regularly used in toxicity studies and proved to be useful are given bellow and their cultures are described.

54.1.3.2 Culture of Porcine Kidney Cell Line LLC-PK1

LLC-PK1 is a porcine cell line from proximal nephron and commercially available (CL-101 ATTC, Manassas, VA).

These cells are incapable of gluconeogenesis with low or no expression of CYP3A and CYP2B isotypes. LLC-PK1 cells are cultured in DMEM medium with 10% heat inactivated FBS and 1% glutamine at 37°C and 5% CO_2. For planned experiments they are seeded into 96-well micro well plates at 3×10^4 cells per well and incubated overnight. On the following day they can be exposed to test compounds. This cell line has been shown to be a valuable test system for prediction of kidney-specific toxicities (Fig. 54.1).

54.1.3.3 Culture of Canine Kidney Cell Line MDCK

MDCK is a canine cell line from collecting duct and is the most representative of the distal tubule, commercially available (CCL-34, ATTC, Manassas, VA).

MDCK cells are cultured in DMEM medium (supplemented with 10% heat inactivated FBS, 1% glutamine, 1% natrium pyruvat, and 1% NEAA) at 37°C and 5% CO_2. For planned experiments, they are seeded into 96-well micro well plates at 3×10^4 cells per well and incubated overnight. On the following day they can be exposed to test compounds.

54.1.4 Available Cytotoxicity and Functional Assays

54.1.4.1 Cytotoxicity Assays

Cytotoxicity assays can be used as ranking tool and for an organ or non-organ-specific early hazard identification (Xu et al. 2004; McKim 2010). Ranking test compounds allow selecting candidates with least toxicity potential. Cytotoxicity data determined in in vitro experiments applying a multisystem and multi-endpoint approach can provide a good estimate of the plasma concentration where toxicity in vivo

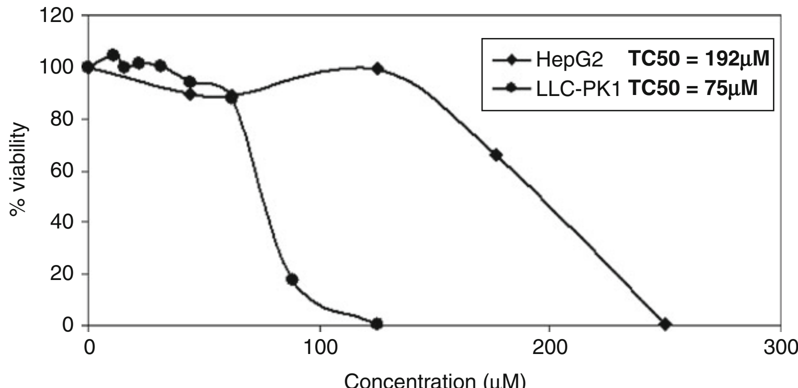

Fig. 54.1 Cytotoxicity of nephrotoxic 4-aminophenol hydrochloride on LLC-PK1 and HepG2 cells. The toxicity was measured by neutral red assay. The kidney LLC-PK1 cells exposed to 4-aminophenol hydrochloride display a specific response with much lower toxicity (TC50 = 75 μM) compared with human hepatoma HepG2 cell (TC50 = 192 μM)

Table 54.3 The cytotoxicity of therapeutic drugs tested on hepatocellular models compared to the no observed adverse effect level (NOEL) in plasma of patients

Compounds	TC50 (μM)	NOEL (μM)
Ketoconazol	18	30
Camptothecin	0.23	0.1
Acetaminophen	2,000	1,000
Chloramphenicol	1,000	300
Cyclosporin	6	1
Nitrofurantoin	45	4

(considering animal or human plasma data) would be expected (NIH publication 2001; Evans et al. 2001). Correlation of in vitro and in vivo data may provide a good rationale for using cytotoxicity assays as ranking tool and as a first step in hazard identification (Table 54.3). Combining primary hepatocytes from rat, dog, and man may allow the evaluation of cross-species differences and to estimate the relevance for human situation. The most sensitive evaluation timepoints for each assay (early response versus late response) should be determined prior to planned experiments. However, in many experimental settings, cultures are incubated for 6, 24, and 48 h as a single point or combined for kinetic determinations. To test the cytotoxicity or other potential effects of test compounds on the cell physiology several concentrations are tested, covering a concentration range of ≤1 μM to 1,000 μM. It is advisable to use six technical replicates per test concentration. The scheme in Fig. 54.2 represents a plate setup for such analysis.

To assess compounds for their cytotoxicity, basically any assay that can record cell perturbation could be used (Barile 1994; O'Hare and Atterwill 1995). However, a portfolio of physiological end points has been proved to be very useful (Ehrich and Sharova 2000). They have been tested thoroughly according to strict quality guidelines and regarding their performance, for example, reproducibility, sensitivity, organ expression and homogeneity, and of course ease of use. Some of physiological parameters that are used as markers of toxicity are described here (Fig. 54.3).

54.1.4.2 ATP Content, Measure of Energy Status

The catabolic pathways for the breakdown of glucose to produce energy in the form of ATP (adenosine triphosphate) and the replication process of DNA are very similar in all organisms. Consequently, ATP has been proved as a marker for cell viability because it is present in all metabolically active cells. The ATP concentration declines rapidly when cells undergo necrosis or apoptosis. The total intracellular ATP is assessed through an assay that is based on the generation of a luminiscent signal proportional to the amount of ATP present in the supernatant after cell lysis. The glow-type luminiscent signal is produced by a luciferase reaction and is detected in a device equipped with a luminescent signal detector (CellTiterGlo™ Luminescent Cell Viability Assay, Promega No. G7571).

In this assay, treated cells are lysed, which results in ATP release from cells. ATP present in the supernatant after cell lysis is then measured by a luminescent reaction. The quantified ATP is proportional to the viable

Fig. 54.2 Recommended plate setup for cytotoxicity assay in 96-well plates. Blank indicates wells containing culture medium without cells, N indicates negative control reference compound, P indicates positive reference compound, C represents different concentration of test compounds. According to this assay design 8 concentration of test compound in six technical replicates can be tested

cell numbers. In Fig. 54.4 the response of some therapeutic drugs in rat primary hepatocytes was assessed measuring the ATP content.

54.1.4.3 LDH Release, Measure of Membrane Integrity

Cell membranes protect cells from environmental insults. Therefore, their integrity is fundamental for the cell survival. Toxins can impair membrane function and integrity leading to leakage of intercellular components to the surrounding medium. Measuring leakage of components from the cytoplasm into the surrounding culture medium has been widely accepted as a valid method to estimate the number of nonviable cells. The enzyme lactate dehydrogenase (LDH-L) is expressed ubiquitously and is present in many tissues particularly in heart, liver, muscle, and kidney. This makes LDH a valuable marker for health status of cells (Fig. 54.5).

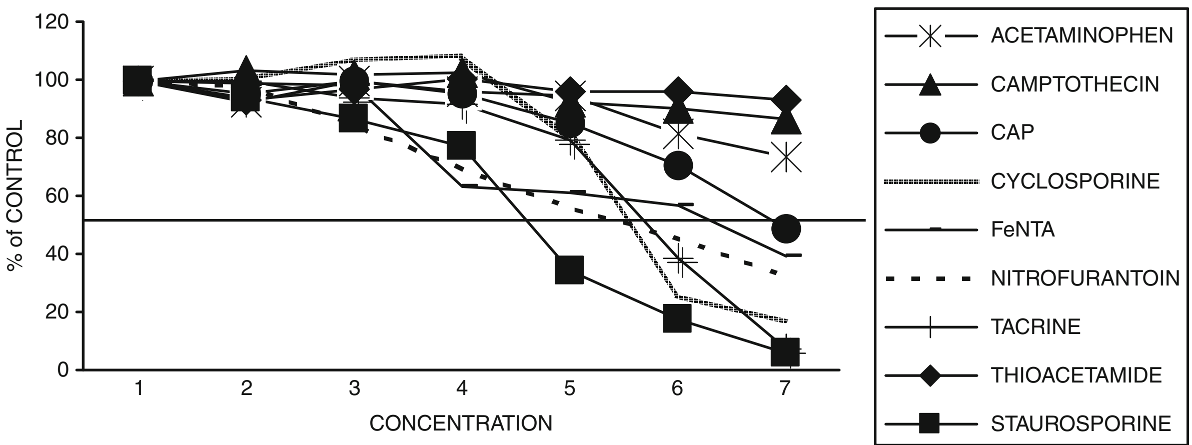

Fig. 54.4 The dose-response curve of therapeutics in rat primary hepatocytes. Rat primary hepatocytes were treated for 24 h at different concentrations and their response assessed measuring the ATP content. The toxicity potential varies among the tested compounds

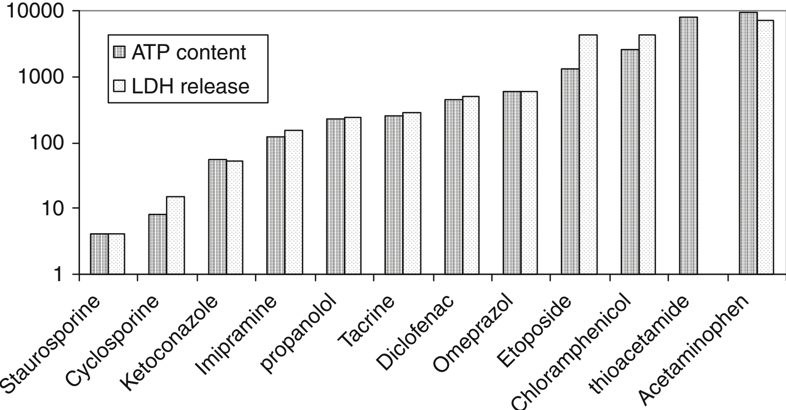

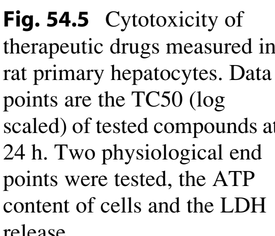

Fig. 54.5 Cytotoxicity of therapeutic drugs measured in rat primary hepatocytes. Data points are the TC50 (log scaled) of tested compounds at 24 h. Two physiological end points were tested, the ATP content of cells and the LDH release

Many colorimetric assays have been developed for the quantification of cell death and cell lysis based on the measurement of LDH activity (e.g., Roche No. 1 644 793). Principally, damaged cells leak LDH from cytosol into the culture medium, in which LDH activity ca be determined in an enzyme activity test: In the first step, NAD^+ is added to an aliquot of supernatant that is reduced to $NADH/H^+$ by the LDH-catalyzed conversion of lactate to pyruvate. In the second step, the catalyst (diaphorase) transfers H/H^+ from $NADH/H^+$ to the tetrazolium salt (yellow), which is reduced to red formazan. The amount of red color formed in the assay is proportional to the number of lysed cells. This assay, as a kit or the single components, can be purchased by many vendors.

54.1.4.4 Protein Content, Measure of Cell Viability

To maintain function and physiology, cells synthesize proteins according to their program and their differentiation status. Proteins are integral part of a cell and their content can be used as a measure of cell viability. Dead or impaired cells cannot maintain their protein stores leading to the reduction of total protein of a defined cell population. Protein assays are mainly detergent-compatible formulations based on bicinchoninic acid (BCA) for the colorimetric detection and quantification of total proteins. The BCA assay (Pierce) measure cell number based on the content of total protein. This assay combines the well-known reduction of Cu^{2+} to Cu^{1+} by protein in an

alkaline medium (biuret reaction) with the highly sensitive and selective colorimetric detection of the cuprous cation (Cu^{1+}) using the reagent BCA. The Pierce BCS assay is compatible with most ionic and nonionic detergents. To conduct the assay, 10–25 μl of cell lysate from the ATP assay is transferred into an separate well plate, 200 μl per well of the Working Reagent is added and incubated at 37°C for 30 min. The purple colored reaction product of this assay is formed by the chelation of two molecules of BCA with one cuprous ion. The absorbance is measured at or near 562 nm on a plate reader.

The ATP, LDH, and BCA assays can be combined and performed in one single experiment (Figs. 54.3). Availability of data from three different physiological end points strengthens data accuracy and judgment of cytotoxicity potential of compounds under investigation.

Lysosomal Neutral Red Content (NRU), Measure of Lysosomal Integrity and Function

A measure of cell viability is the assessment of lysosomal function. In the Neutral Red Assay, the ability of intact lysosomes to store the dye neutral red is used to assess cytotoxicity. To measure neutral red retention, treated cells are incubated with a neutral red solution for 3 h (e.g., Merck No. 1.01376.0025). After incubation, the cells are washed twice and lysed subsequently. After complete lysis of the cells, the content of neutral red is determined in each well by measuring the absorption at 540 nm. Cells demonstrating less dye retention indicate lysosomal and cell damage due to treatment. The NRU assay can be adapted to high-through formats and may be used as substitute for LDH assay (Babich and Borenfreund 1992).

54.1.4.5 Detecting Reactive Oxygen Species (ROS) Indicative of Oxidative Stress

Excessive ROS production under pathological conditions results in oxidation of cellular macromolecules altering their functions. Therefore, methods are developed to detect oxidatively stressed cells. In this protocol, excessive intracellular levels of ROS are measured with the fluorescent dye marker 5-(and-6)-carboxy-2′,7′-dichlorodihydrofluorescein diacetate (carboxy-H2DCFDA, Molecular Probes, Invitrogen), which is a fluorogenic indicator for reactive oxygen species in living cells. DCFDA is nonfluorescent until the acetate groups are removed by intracellular esterases to nonfluorescent DCFH. In the presence of ROS, DCFH is oxidized to fluorescent dichlorofluorescein (DCF) with excitation/emission maxima of 495/529 nm.

H9c2 cells (or other cell types) are seeded into black 96-well plates containing DMEM medium at a density of 3×10^4 cells per well and incubated overnight. The overnight cultures are then stained with 20 μM H2DCFDA for 10 min in HBSS (Gibco, No.14025-092) before exposure to test compounds. Test compound dilutions are added and incubated for 0.5 h to several hours. It is wise to test several concentrations of the compound at μM range. At the end of the incubation time cells are washed two times with HBSS and reconstituted in the same buffer. The florescence signal is detected by fluorescence excitation/emission maxima of 495/529 nm in a plate reader. Quantified parameter levels are normalized to respective control conditions and mean fluorescent intensities are visualized. The graph in Fig. 54.6 demonstrates a significant increase in fluorescence intensity of DCFDA in H9c2 cells treated with the reference compound doxorubicin at two different treatment times.

54.1.5 Functional Assays

54.1.5.1 Drug-Induced Phospholipidosis

Phospholipidosis is a storage disorder induced by cationic amphiphilic drugs (CAD) and is characterized by accumulation of phospholipids and drug in acidic lysosomes. This accumulation results in unique histological effects in cells of impaired organs observed as electron-dense membranous lamellar inclusions or whorls in electron micrographs. More than 50 marketed therapeutic drugs are reported to induce phospholipidosis (Table 54.4) in a variety of organs mostly lung, liver, and macrophages. The conventional method for assessing phospholipidosis involves animal studies and histological evaluation of lamellar bodies, the hallmark feature of phospholipidosis by electron microscopy. The toxicological significance of phospholipidosis is not understood in every detail. But development of phospholipidosis is a serious issue and can result in delay or discontinuation of development compounds. Therefore, phospholipidosis assays are developed that are applied early in drug development to monitor the potential of CAD drug candidates to induce phospholipidosis. A tiered

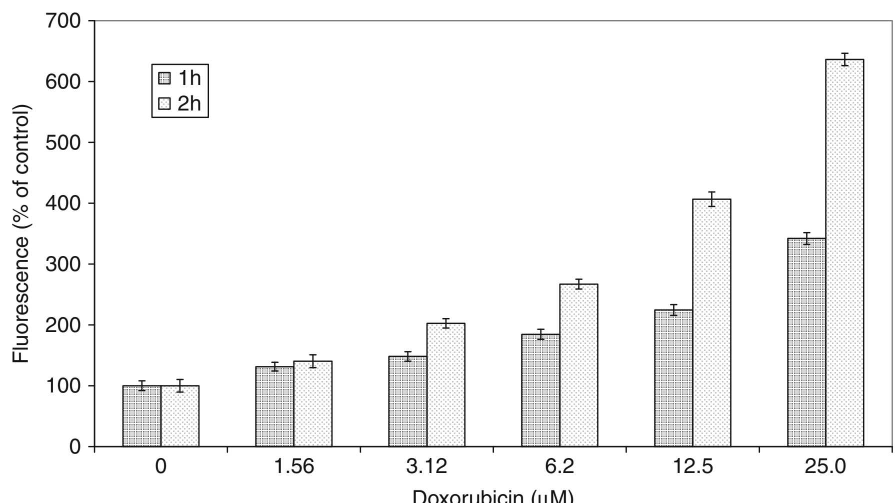

Fig. 54.6 ROS formation in H9c2 myocytes in response to doxorubicin treatment. Treatment of H9c2 cells with doxorubicin results in a significant increase in fluorescence intensity of DCFDA at both 1 h and 2 h indicating ROS production

Table 54.4 Phospholipidosis potential of reference compounds and the correlation of results from in silico, in vitro, and in vivo models

	Induction of phospholipidosis

Doxorubicin	–	–	–

approach, combining in silico, in vitro, and in vivo approaches has been very successful in prediction of phospholipidosis. In general, in vitro phospholipidosis assays are carried out after in silico methods predict phospholipidosis liabilities. A positive outcome from in vitro experiments would trigger the third line experiments consisting of animal studies that provides ultimate data for a "Go or No Go" decision (Reasor and Kacew 2001; Monteith et al. 2006; Nioi et al. 2008; Nanoyama and Fukuda 2008).

For detection of drug-induced phospholipidosis several in vitro models have been described using different cell types and detection modes. But despite the diversity in assay design, all these in vitro phospholipidosis assays use mainly fluorescent dyes, for example, Nile red, or fluorescent phospholipid analogues, for example, 1-acyl-2-[12-[(7-nitro-2,1,3-benzoxadiazol-4-yl)amino]dodecanoyl]-sn-glycero-3-phosphocholine phosphatidyl choline (NBD-PC) to flag lysosomal phospholipid accumulation. The method described here uses human hepatoma cell line HepG2 in combination with a fluorescent-labeled phospholipid analogue provided by LipidTOX™ phospholipidosis Kit (Invitrogen). This method is qualified for routine screening with an acceptable degree of reproducibility and easiness (Tomizawa et al. 2006; Nioi et al. 2007; Bhandari et al. 2008; Miyamoto et al. 2009).

54.1.5.2 Assay Design

HepG2 cells are seeded into collagen I-coated black 96-well micro plates at 3×10^4 cells per well for 24 h and 1×10^4 cells per well for 48 h in DMEM medium. The test compounds are dissolved in DMSO or other solvents (the solvent concentration should not exceed 0.5%) and added to culture medium with 1x LipidTox™ Red phospholipidosis detection reagents (Invitrogen). Based on cytotoxicity data, a broad range of nontoxic concentrations should be selected and tested. Six technical replicates are recommended per test concentration to fix the bias.

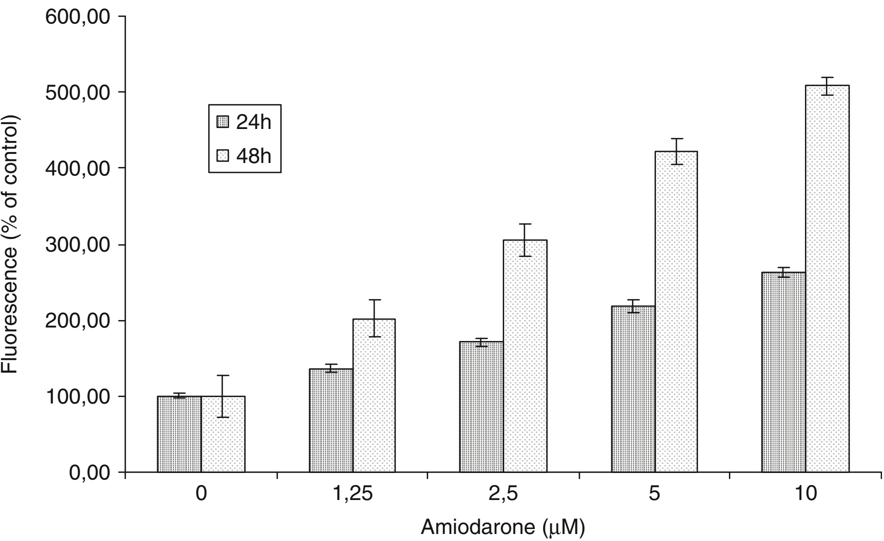

Fig. 54.7 Induction of phospholipidosis in HepG2 cells in response to amiodarone exposure and after different incubation periods. The selected concentration range was devoid of cytotoxicity

Table 54.5 Compounds that are known to induce cholestasis in vivo with their correlation to in vitro cholestasis model. Salisylic acid at concentrations up to 1 mM has no effects on Bsep transporter

	Induction of cholestasis	
Reference compounds	In vitro	In vivo
Cyclosporin A	+	+
β-estradiol-17β-D-glucoronide	+	+
Troglitazon	+	+
Erythromycin estolate	+	+
Salisylic acid	–	–

Cells are exposed to the test compound concentrations for either 24 or 48 h. After incubation, the cells are fixed with 4% formaldehyde for 30 min. Following fixation, cells are washed with HBSS (transparent, with $CaCl_2$ and $MgCl_2$) and measured in HBSS by fluorescence excitation/emission maxima 595/615 nm in a plate reader. Results can be expressed as the percent of phospholipid accumulation. Quantified parameter levels should be normalized to respective control conditions. Amiodarone in a concentration range of 1–10 μM and acetaminophen in a concentration range of 10–100 μM can be used as positive and negative reference compounds, respectively. The graph in Fig. 54.7 represents the potential of amiodarone to induce phospholipidosis. To assess the cytotoxicity aliquots of treated culture medium can be assayed for LDH release, or cytotoxicity assays with multiple end points can be conducted in parallel.

54.1.6 Drug-Induced Cholestasis

Cholestasis is one of the most manifestations of drug-induced liver injury. The drugs responsible for cholestasis (Table 54.5) are excreted by hepatocytes into bile where they interact with bile transporters and impair their function. Several forms of cholestatic liver injury can be produced by therapeutic drugs. The inhibition of bile acid efflux transporters Bsep (bile salt efflux pump) and Mrp2 (multidrug resistance–associated protein 2) seems to be an important mechanism in producing cholestatic liver injury. Inhibition of Bsep and Mrp2 may lead to reduced bile salt secretion and hence their retention within hepatocytes, which can lead to worse liver injury. The diagnosis of drug-induced cholestasis is poor, and therefore in vitro assays may help to sort out early in development the toxic agents (Pauli-Magnus et al. 2010; Padda et al. 2011; Yashikado et al. 2011). Furthermore, using hepatocytes form different species may allow cross-species comparison and at the end the relevance of findings for clinics.

The described model here is based on the sandwich cultured primary hepatocytes that allow the formation

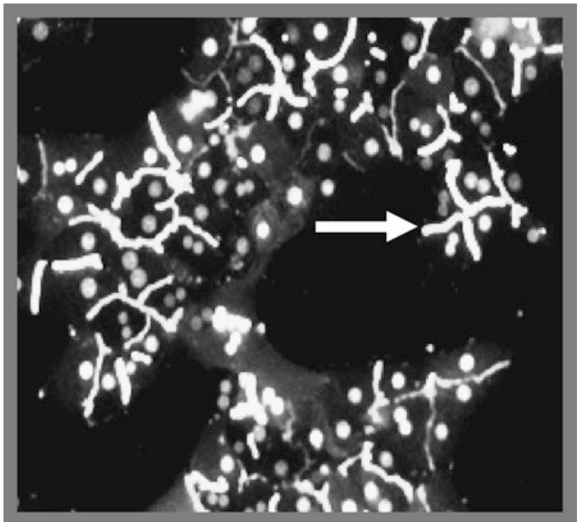

Fig. 54.8 Formation of canaliculi domains by rat hepatocytes in sandwich culture. The *arrow* indicates canaliculi domains

of canaliculi. Once the canaliculi are formed, cells are exposed to fluorescent-labeled bile salt analogue cholyl-lysyl-fluorescein (CLF; Solivas, Switzerland) that mimics cholylglycine and is therefore, a substrate for bile salt transporter Bsep. The intensity of accumulated CLF in canaliculi can then be detected in a spectralphotometer at 490 nm (Mills et al. 1991; Hopwood et al. 2006; Wolf et al. 2008; Min Dong, personal communication).

54.1.6.1 Assay Design

For this cholestasis model, freshly isolated hepatocytes in sandwich culture are used. Applying the protocol described above enables isolation of required primary cells for this protocol. Isolates from different animal models as well as human donors can be used. The monolayer cultures of hepatocytes do not form intact canaliculi. Therefore, a matrigel-based sandwich culture is used that allows the development of canaliculi domains (Fig. 54.8) capable of bile salt efflux. Cell preparations with the viability of $\geq$80% are seeded out on Collagen I coated 6-well plates in Attachment Medium with a density of 1×10^5 cells per cm^2. After hepatocytes are incubated (37°C, 5% CO_2) 1.5 h for attachment, subsequently the cells are washed with ice cold PBS to remove nonattached cells. Matrigel is diluted 1:20 v/v% in cultivation medium (ice cold) and 2.5 mL of diluted solution is put with a precooled pipette on top of the cells (6-well: 2,5 mL of 250 μg/mL). Culture plates are put back to incubator and the medium is changed every 24 h. After 2–4 days canaliculi domains are structured (examine canaliculi formation by light microscopy). When canaliculi are formed, the culture medium is discarded and cells are washed two times with 37°C HBSS. Cells are then incubated in prewarmed HBSS for 10 min at 37°C. After this short incubation, HBSS is removed and treatment medium is added (5 μM CLF and Hoechst in HBSS, plus reference or test compound at different concentrations). Treated cultures are incubated for 25 min at 37°C. At the end of the treatment period, aliquots of supernatant are sampled for LDH cytotoxicity assay. In the next step, wells are rinsed four times with HBSS to remove any remaining medium or substrate and HBSS is added. At the end, the fluorescent intensity is measured using FITC channel and signals are quantified. After the measurement, cells may be lysed and ATP, LDH, and protein assays conducted.

54.1.7 Methods to Detect Mitochondrial Dysfunction

Mitochondrial dysfunction is increasingly implicated in the etiology of drug-induced toxicities. Mitochondria are the energy powerhouses of cells and produce approximately more than 90% of the cell’s energy in the form of ATP (adenosine triphosphate). Mitochondrial injury can occur through several mechanisms including disturbance of mitochondrial membrane potential, induction of mitochondrial membrane transition pore, and inhibition of respiratory chain complexes leading to uncoupling of electron transport and inhibition of ATP production. Due to these serious implications, the investigation of drug-induced mitochondrial dysfunction is receiving increasing attention (Dykens and Will 2007). Therefore, in pharmaceutical companies, a comprehensive set of assays have been developed that help recognize mitotoxic compounds early (Hynes et al. 2009). These assays also provide information on mechanisms of mitochondrial impairments late in more advanced projects. In this part, a set of developed methods that are thought to detect mitochondrial toxicities are described.

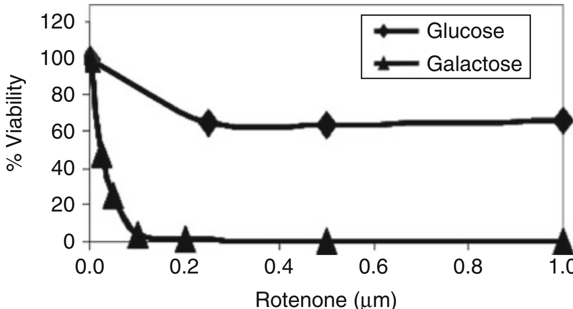

Fig. 54.9 Susceptibility of HepG2 cells grown on high glucose (25 mM) versus cells grown on galactose (10 mM). HepG2 cells grown in galactose medium increase their respiration rate to maintain their ATP level. Therefore, cells oxidizing galactose are more susceptible to mitochondrial poisoning. This is indicated in this graph in the different response of galactose-adapted cells to rotenone ($TC50gal = < 0.025$ μM) compared to glucose-adapted cells ($TC50glu = 16.9$ μM)

54.1.7.1 Galactose-Adapted HepG2 Model to Assess Mitochondrial Toxicants in Screening Mode

Many immortalized cells lines are metabolically adapted for rapid growth under hypoxic and acidic conditions, and they derive almost all of their energy from glycolysis rather than via mitochondrial oxidative phosphorylation (a circumstance known as the crabtree effect; Rodrguez-Enrquez et al. 2001). Such adapted cells are resistant to xenobiotics that impair mitochondrial function. Thus, the immortalized cell lines cannot be appropriately used in screening assays of mitochondrial toxicity. To increase detection of drug-induced mitochondrial effects in a preclinical cell-based assay, HepG2 cells are forced to rely on mitochondrial oxidative phosphorylation rather than glycolysis by substituting galactose for glucose in the growth media. Oxygen consumption doubles in galactose-grown HepG2 cells and their susceptibility to canonical mitochondrial toxicants correspondingly increases (Marroquin et al. 2007). As such, these cells are better qualified for assessments of drug-induced mitochondrial dysfunction and can be used in a high-throughput mode for a first-line screening of compound to reveal mitochondrial dysfunction.

In order to adapt HepG2 cells to the galactose supplemented culture medium, the cells are first cultured in high-glucose DMEM medium (for constituents see above). In the next step, the high glucose medium is gradually replaced first by low-glucose medium ([DMEM, Invitrogen No. 11966-025] supplemented with 5.5 mM glucose, 5 mM HEPES, 10% FBS, 1 mM sodium pyruvate, and pen-strep as above) and then by galactose medium ([DMEM free of glucose, Invitrogen N0.11966-025] supplemented with 10 mM galactose, 2 mM glutamine [6 mM], 5 mM HEPES, 10% FBS, 1 mM sodium pyruvate, and pen-strep as above). The adaptation period to each of the media needs to be assessed based on cell morphology and appearance.

The HepG2 cells adapted in this way can be combined either with cytotoxicity assays described above to unravel the primary cause of cytotoxicity, or they can be subjected to the oxygen consumption assay in combination with MitoXpress probe (Luxcel Biosciences) that is detailed bellow. The graph in Fig. 54.9 shows the response of galactose-adapted HepG2 cells compared to glucose-adapted cells measured in ATP cytotoxicity assay.

54.1.7.2 Real-Time Image-Based Detection of Mitochondrial Membrane Potential in Living Cells

The major function of mitochondria is concerned with ATP synthesis. The ATP production relies on the translocation of electrons across the inner mitochondrial membrane that is directed by respiratory chain complexes. The capacity of mitochondria to produce ATP can be assessed directly through measure of the rate of ATP formation and its efficiency (See ATP assay above) or indirectly by measure of the mitochondrial membrane potential.

For the measurement of mitochondrial membrane potential in living cells, the fluorescence-based specific mitochondrial dye marker tetramethyl rhodamine (TMRM, excitation/emission 550/575 nm) can be utilized combined with a confocal real-time single-cell imaging system (Nieminen et al. 1995; Scaduto and Grotyohann 1999; Heiskanen et al. 1999; Gogvadze et al. 2004). In the process, rat primary hepatocytes (also other cell types) are seeded into 96-well culture plates at 25×10^3 cells per well. The cells are allowed to grow and equilibrate for 24 h prior to being exposed to the test compounds. On the following day, test material is prepared and applied to the cells across a wide concentration range. It is recommended to include negative and positive controls. The equilibrated cells are allowed to incubate with the test compound for a defined period of time (30 min to 4 h) at 37°C. At the end of the treatment period cells are washed

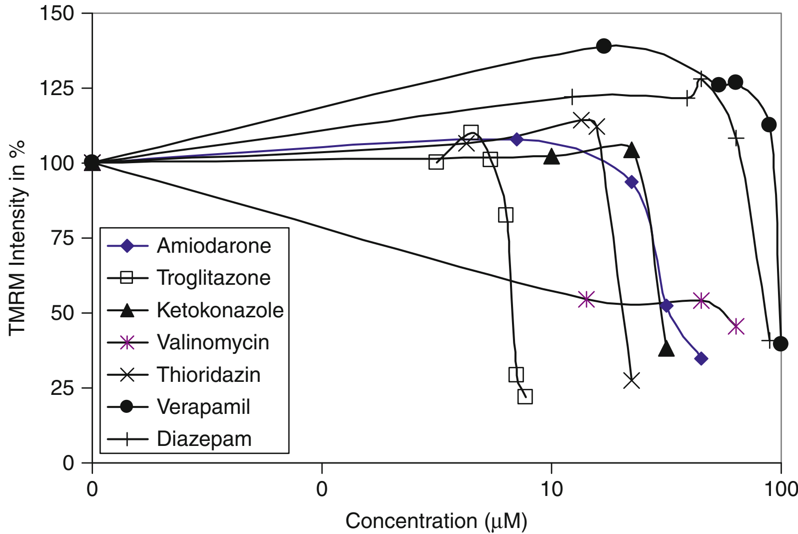

Fig. 54.10 Inhibitory effects of mitotoxic compounds amiodarone, troglitazone, ketoconazole, valinomycin, thioridazine, verapamil, and diazepam on mitochondrial membrane potential measured in rat primary hepatocytes with TMRM on an imaging system. Test compound concentrations are expressed in log scale

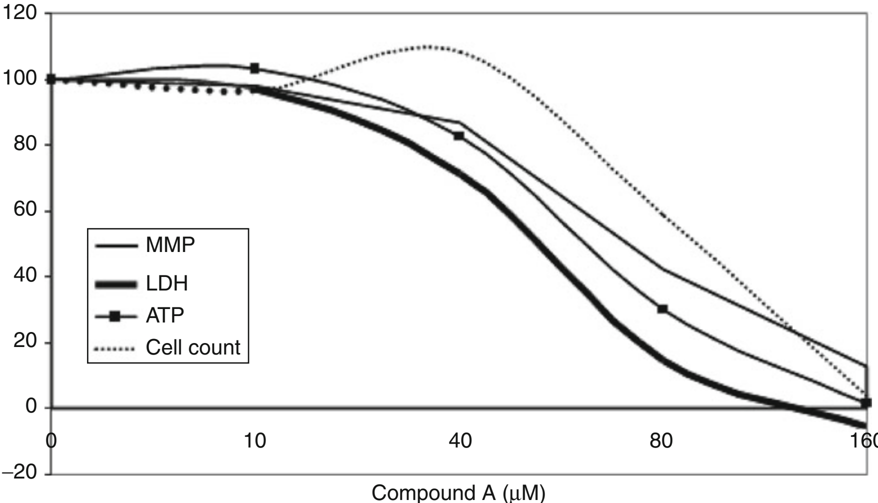

Fig. 54.11 Effects of a test compound (Compound A) on mitochondrial membrane potential (MMP) of primary rat hepatocytes exposed for 4 h. The mitochondrial membrane potential was assessed using the dye marker TMRM. The dose-dependent reduction of membrane potential is paralleled by reduction in ATP content in cells

with warmed HBSS and cultured in incubation buffer ([HBSS] supplemented with 5% heat inactivated FBS, 1% HEPES, 1% Probenecid [P36400, Invitrogen]) containing TMRM (0.5 μM) at 37°C for 15 min. Following the staining, the cells are washed and subjected to analysis either in kinetic mode or as end-point measurements. The change in mitochondrial membrane potential is assessed by quenching of the fluorescent. Signal intensities are recorded according to the manufacturer's instructions for the instrument used. Using confocal, real-time, and single-cell kinetic imaging system allows high-resolution imaging, fast and reliable quantification of effects in cells. This method can be used for quantification of mitochondrial effects in primary hepatocytes from rat, human, rabbit, and dog, as well as cell lines HepG2 and H9c2. Figure 54.10 shows the inhibitory effect of a couple of reference therapeutics that was measured on rat primary hepatocytes.

By combining this assay with membrane leakage marker LDH, cell count, and ATP content assay that are conducted in parallel to MMP analysis it is possible to evaluate the achieved data and more important get more insight into the physiological sequence of events that primarily harm the subcellular targets (Fig. 54.11). As is indicated in the diagram, LDH release occurs prior to the reduction of MMP. Furthermore, reduction in MMP is observed at concentrations where cell count

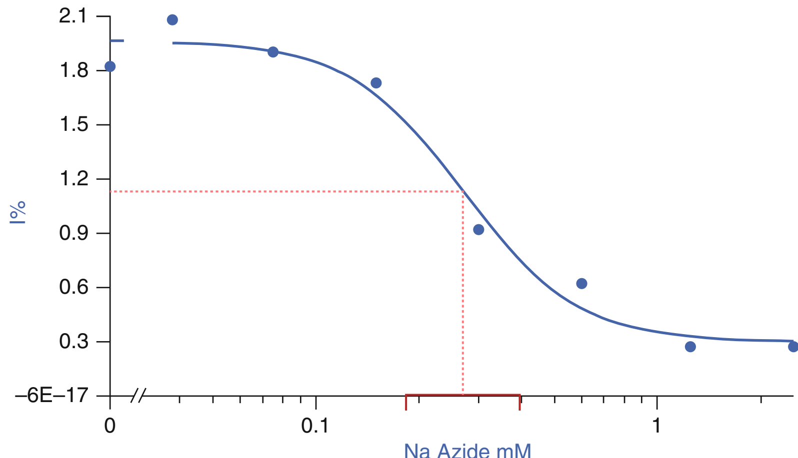

Fig. 54.12 Inhibitory effect of Na Azide on Complex IV activity. To achieve a complete dose-response curve 50 μg rat liver mitochondria were exposed to Na Azide at concentrations ranging from 0.01 to 15 mM resulting in the IC50 = 0.25 mM

goes down. These observations together indicate that reduction in MMP and ATP content may not be the primarily event that harm the cells.

54.1.7.3 Inhibition of Respiratory Chain Complexes

(Methods: Immunocapture-based respiratory chain activity assays)

The oxidative phosphorylation process in mitochondria that ends up with ATP synthesis is carried out by the respiratory chain complexes. The free energy released by oxidation of carbon hydrates is used to build NADH (nicotineamide adenine dinucleotide) and FADH2 (flavin adenine dinucleotides), which in turn, donate electrons to Complex I and II, respectively. The translocated electrons are then passed to complex III and complex IV, and the energy that is released during the electron transport is used to build a chemiosmotic gradient across the inner mitochondrial membrane. This gradient is used by complex V for ATP synthesis.

Because of the complexity of the respiratory chain complexes, they are often the target of drugs. A set of immunocapture-based assays have been developed to identify enzyme complexes, whose inhibition is directly responsible for any observed toxicity. In three assays (for complexes I, IV, and V), a 96-well plate coated with a monoclonal antibody raised against one of the complexes is used to immunocapture a functionally active complex from small amounts of isolated mitochondria. Mitochondria are isolated either from animal tissues (e.g., rat liver or heart), or from cell cultures. Meanwhile, a global and specialized line of industry has been established that offers besides ready-to-go mitochondrial assays also high quality purified mitochondria from different sources (e.g., MitoExpress). To ensure the specificity of these complex activity assays, their respective classical inhibitors rotenone (complex I), KCN (complex IV), and oligomycin (complex V) are used as positive controls. All three activity assays allow for rapid screening of drugs and provides a low cost method of identifying mitochondrial toxicity in vitro. In Fig. 54.12, the inhibitory effect of Na Azide on complex IV was evaluated using the complex I assay.

54.1.7.4 Assays to Monitor Mitochondrial Oxygen Consumption

The uncoupling of oxidative phosphorylation modulates the rate of oxygen consumption. Oxygen consumption is also affected by the inhibition of either citric acid cycle or the β–oxidation of fatty acids. Molecular oxygen is a key substrate of all aerobic organisms and the terminal acceptor of the electron transport chain. Therefore, analyzing mitochondrial oxygen consumption is one of the most informative ways of assessing mitochondrial dysfunction. The electron transport chain (ETC), ATPase, and adenine-nucleotide translocator (ANT) inhibitors decrease ADP-activated respiration while uncouplers induce an increase in basal respiration (Hynes et al. 2009; Will et al. 2006).

The two most applied methods for measuring oxygen consumption are the polarography using the

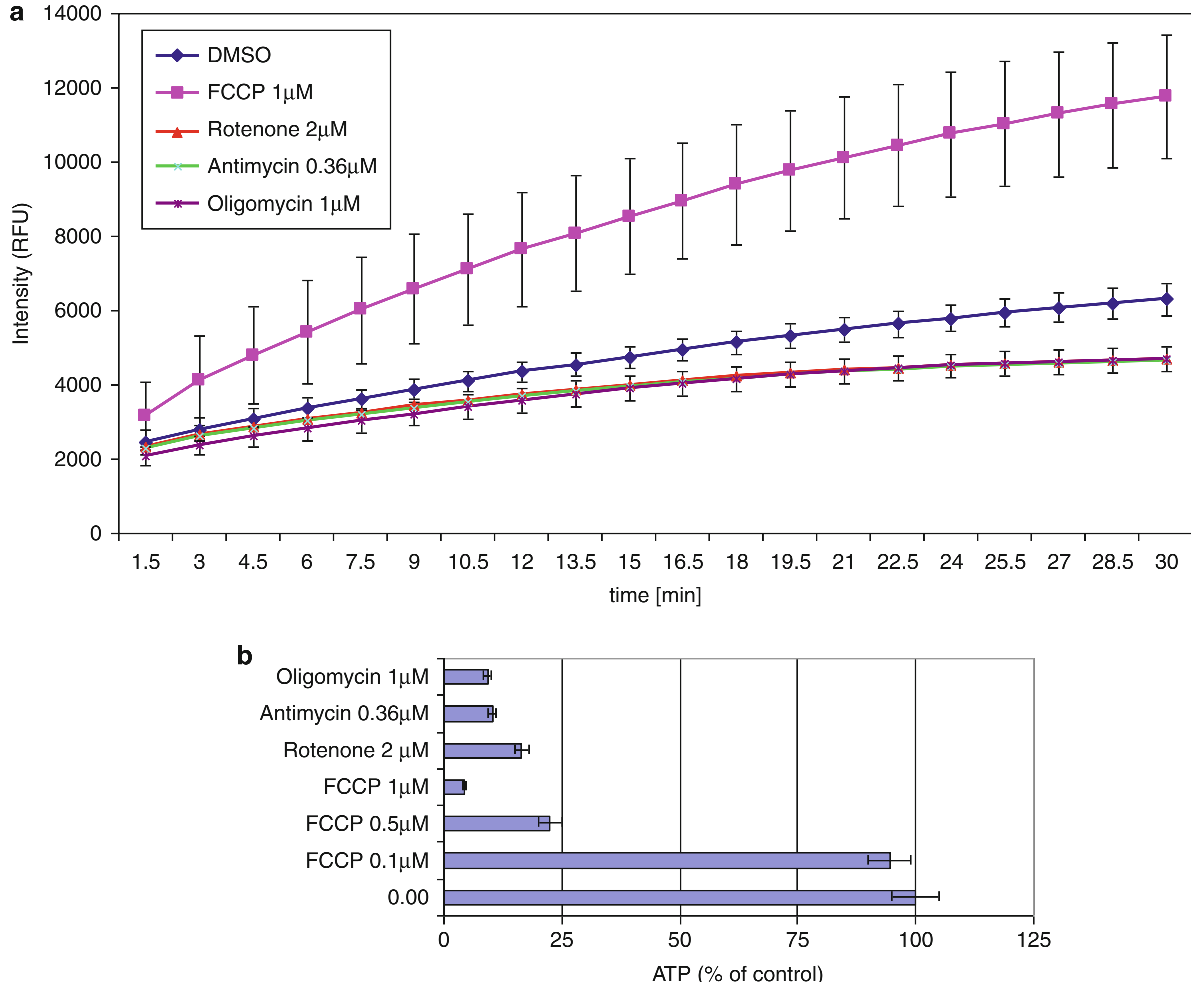

Fig. 54.13 (**a**) The effect of a panel of classical electron-transport chain inhibitors on O_2 consumption of primary rat hepatocytes using MitoXpress probe (Luxcel Biosciences), and (**b**) total ATP concentration at same indicated concentrations. Figure 54.3a illustrates treatment-related mitochondrial dysfunction with classical electron-transport inhibitors rotenone (inhibits complex I; nicotinamide adenine dinucleotide hydrogen (NADH)-ubiquinone oxidoreductase), antimycin (inhibits complex III; cytochrome c reductase), oligomycin (inhibits F1/F0 ATPase), and the uncoupler FCCP. DMSO was analyzed as control producing the base line respiration rate. While the inhibition causes a reduction in oxygen consumption (above the DMSO baseline), uncoupling increases the oxygen consumption rate (bellow the DMSO baseline). Analysis of ATP concentrations immediately posttreatment indicated dose-dependent drop in ATP production. The 0.00 bar in graph (**b**) indicates the ATP level in solvent-treated control cells

OROBOROS Oxygraph for high-resolution respirometry and the phosphorescent oxygen probe MitoXpress (Luxcel Biosciences) a 96-well-based assay.

The OROBOROS Oxygraph is used in cases where high resolution counts and the high throughput is not required, for example, measurement of oxygen consumption in living and permeabilized cells, small amounts of tissue that requires high-resolution respirometry to obtain accurate results even at high sample dilution. In contrast, the MitoXpress assay is used as a sensitive high-throughput detection assay in combination with either isolated mitochondria or cultured living cells (Luxcel Bioscience). Whereas in polarography an oxygen-sensitive electrode detects the modulation of oxygen, measurement of oxygen by MitoXpress is based on the ability of molecular oxygen to quench the excited state of the probe. As the mitochondria respire, oxygen is depleted, which is seen as an increase in probe

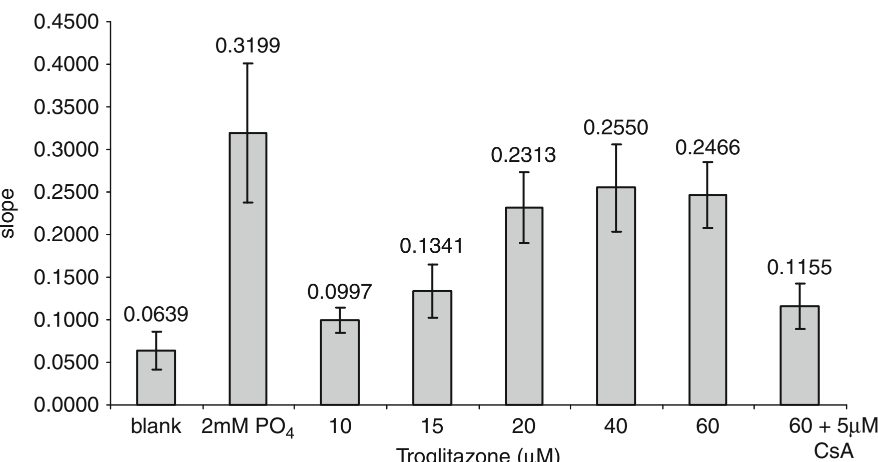

Fig. 54.14 Dose-dependent swelling of rat mitochondria. Treatment of mitochondria with troglitazone induce transition pore opening that in turn induce mitochondrial swelling. PO_4 was used as positive reference compound with maximum effect at 2 mM. Mitochondrial swelling can be inversed through incubation with cyclosporine A (CsA)

phosphorescence signal (Fig. 54.13). The protocol described here uses whole cells, but this assay can also be used with isolated mitochondria from different sources. To perform the assay, primary rat hepatocytes (or other cell types) are seeded in 96-well plates at 3×10^4 per well and incubated overnight. Next day, MitoXpress probe is reconstituted in 1 mL respiration buffer and diluted to 10.5 mL with the same buffer. Test compound dilution series are prepared in the appropriate solvent and added to the culture medium. All reagents and instruments are warmed to 30°C. The culture medium is removed and replaced by 150 µl fresh medium with or without test compound supplements. The reconstituted MitoXpress probe (10 µl) is added to each well and 100 µl of prewarmed heavy mineral oil (MP Biomedical cat. no. 150138) is quickly added to each well. At the end, the plate is inserted into the fluorescent reader preset at 1.5-min intervals over 30–60 min (Hynes et al. 2006, 2009). The recommended instrument settings for Tecan Genios reader are Gain: 65, Lag time: 100 µs, Integration: 300 µs, cycles: 20 (every 1.5 min), Filter: Exc. 370 nm, and Em.: 635 nm. Figure 54.13a is a representative of data output from oxygen consumption analysis assayed on primary rat hepatocytes.

54.1.7.5 Estimation of Mitochondrial Swelling (Opening of the Mitochondrial Permeability Transition Pore)

Mitochondrial permeability transition pore (MPTP) is a megachannel formed by the outer and inner mitochondrial membrane, composed of a number of protein complexes.

Binding of compounds to these protein complexes can lead to the opening of the channel promoting influx of solutants into the mitochondrial matrix. Consequently, mitochondria swell and lose their ability to produce ATP (Blattner et al. 2001) Therefore, swelling is one of the most reliable manifestations of mitochondrial permeability transition that can be utilized to assess the affinity of compounds to bind the mitochondrial megachannel and induce its opening (Taya et al. 2005).

Here is a 96-well-based nephelometric technique described that fits for monitoring mitochondrial swelling in screening or investigative mode. In this assay, mitochondrial swelling can be monitored continuously as changes in OD540 (Zhao et al. 2004; Taya et al. 2005). To start the assay, isolated mitochondria (0.1 mg) are added to 0.2 mL of incubation buffer (210 mM mannitol, 70 mM sucrose, 5 mM HEPES, 7.5 mM succinate, plus 3 µM Rotenone) in a 96-well plate with flat bottom. In the next step KH_2PO_4 (2 mM final, as positive reference control) or concentrations of test compounds are added and the absorption at 540 nm is measured. These data are used as null point. At the end, $CaCl_2$ from a stock solution (the final concentration is 20 µM) is added and mixed immediately. The plate is inserted into a plate reader (e.g., Tecan genius pro) preset to 37°C and changes at OD540 are measured for 30 min with 2 min intervals (shake between measures). Swelling is measured by decrease in absorbance at 540 nm. Swelling assay can

be performed on isolated mitochondria from rat heart or liver, or mitochondrial from any other resources. The quality of mitochondrial preparation is critical to this assay. Therefore, mitochondrial isolation should be in the hand of skilled labor staff that operates with special attention and according to expert protocols. Alternatively, Mitochondria can be purchased by vendors, for example, MitoScience and Mitenyi Biotec. Figure 54.14 shows the dose-dependent swelling of rat mitochondria in response to treatment with troglitazone affecting mitochondrial permeability transition pore.

54.1.7.6 Isolation of Mitochondria from Rat Liver

The mitochondrial fraction is prepared according to Schneider and Hogeboom (1950) with some modifications. The protocol is a general method for the isolation of pure mitochondria from rat liver tissue. But it is possible to scale the protocol and use heart or brain tissue. Also tissues collected from other mammalian species such as rabbits and mice can be subject to isolation taking this protocol. The mitochondria collected in this way can be utilized for all studies of mitochondrial functions.

The liver is removed from an anesthetized rat according to the protocol described above. The liver tissue is transferred immediately in ice-cold MSH buffer (5 mM HEPES, 70 mM sucrose, 210 mM mannitol, 1 mM EDTA, pH 7.35 at 4°C). The liver tissue is freed from fat and connective tissue, and minced with scissors. The minced tissue is washed with MSH buffer several times until the wash solution is free of blood and clear. Now, per gram of liver 8 mL homogenization buffer ([MSH] supplemented with aprotinin [65 µg/mL], PMSF [1 mM], and Leupeptin [1 µM]) is added and the tissue is homogenized in a glass homogenizer with a teflon pestle using six up-and-down strokes at 500 rpm. The homogenate is divided and centrifuged at 4°C for 10 min at approximately 800 × g. The supernatant is collected and immediately centrifuged at 10,000 × g for 10 min. After centrifugation, the supernatant is carefully decanted and the pellet resuspended in 80 mL of chilled mitochondrial isolation buffer (homogenization buffer without EDTA). The mitochondrial suspension is centrifuged at 3,000 × g for 5 min. The supernatant containing the mitochondria is transferred into a new tube that is centrifuged at 10,000 × g for 10 min. The supernatant is discarded and the mitochondrial pellet resuspended in mitochondrial isolation buffer. At the end, this mitochondrial suspension is centrifuged once again at 9,000 × g for 10 min and the mitochondria pellet recovered in 1 mL of mitochondrial isolation buffer. The protein concentration of the isolate is measured and the yield calculated. The isolation generally results in 20–50 mg mitochondria depending on the tissue used. These mitochondria can be used directly for planned studies or stored at −80°C for later applications.

55.1 Introduction

Traditionally, toxicologists define the risk of a new compound to human safety using animal models supported by histopathological and biochemical approaches. However, despite decades of experience, the limitations remain:

- The extrapolation dilemma is still challenging.
- The relevance of animal data to real life continues to be a controversial issue.
- Long-term exposure in humans remains unclear.

Therefore, there is a need for the development of novel test systems that can complement or yet replace the conventional experimental approach in toxicology and thus improve the pharmaceutical drug development process and at the end the quality of new drugs.

The genomics revolution of the recent years led to development of many new and innovative technologies that can change this paradigm and address uncertainty issues in the current toxicological practice and safety assessment. The foundations of the new era build the "OMICS" triads: toxicogenomics, toxicoproteomics, and metabonomics through the identification of novel key genes, marker proteins and metabolites, or gene, protein, and metabolite profiles. These new disciplines combine toxicology with global gene, protein, and metabolite alterations in response to toxic substances and put this knowledge into a toxicological context for a better risk calculation. Global analysis of genes, proteins, and metabolites in cell or tissues has been achieved using a set of different technology platforms such as DNA and protein microarrays (chips), two-dimensional gel electrophoresis (2DGE) combined with mass spectrometer, and liquid chromatography in connection to spectral analysis. The potential of "OMICS" platforms for a better prediction, biomarker identification, and mechanistic explanations of toxicity has been demonstrated in a panel of pilot and comparative studies. Whereas the "OMICS" technologies proved superior alternative to traditional toxicological approaches for biomarker identification or mechanistic investigation, the predictive potential remains difficult and unsatisfactory. "OMICS" data are very complex in volume and content and demand the support of other sciences, for example, bioinformatics, biostatistics, and regulatory, to collect and decipher the whole information. Further variations such as strain and genetic variations, dose, and duration are challenging and demand validation. In recent years, much effort has been made to standardize study designs, experimental procedures, and data processing. Nonetheless, the replacement of conventional in vivo animal studies by "OMICS" platforms is still dreams of the future. A big step forward is the regulatory acceptance that is beginning and would be considered case-by-case. The continued development and refinement of the new methods will alleviate further regulatory appreciation.

In this chapter, Ph. Hewitt and M. Kroger describe toxicogenomics and show examples of its application in toxicological investigations. M. Kabiri deals with toxicoproteomics and outlines the established and alternative methods of global protein analysis, and provides an example of utilization. A. Amberg gives an introduction into metabonomics and presents some details of this technology.

55.2 Toxicogenomics

In toxicology, a full range of genomics technologies are now being used in efforts to uncover the cellular and biochemical mechanisms at work in response to xenobiotic/toxin exposures. The development of these new technologies represents a great opportunity to elucidate toxicological responses to pharmaceuticals, and other chemicals, at a very early stage in drug development. Toxicogenomics (or "transcriptomics") is becoming a well-accepted technology to complement traditional toxicology methods. Since molecular changes occur prior to pathological outcomes, detection of disease and organ toxicity should be possible at earlier time-points during a pathological process. In addition, these technologies are highly sensitive, so that long-term toxic effects can potentially be detected at lower doses. This has the potential to greatly impact toxicology, and to help in the risk assessment of new drug entities. Toxicogenomics represents a desire to step outside the boundaries of traditional toxicology. It is based on the measurement of thousands of genes simultaneously and has shown potential to revolutionize toxicity testing. It has been successfully used as a tool to elucidate mechanisms of toxicity as well as having the potential to predict toxicities much earlier during drug development (Schena et al. 1995; Hamadeh et al. 2002; Ganter et al. 2008).

The advanced knowledge of gene and protein expression patterns, together with modern classification algorithms, has also demonstrated practical benefits for predicting pathological events and toxic end points (Waring et al. 2001; Steiner et al. 2004). Unfortunately, these early promises are only being realized after a period of relatively expensive and deliberate test validation and generation of large reference databases, which are still essential for the future of mechanism elucidation. Without adequate study design, appropriate use of controls, and multidisciplinary development of standardized methods, acceptance has been slow.

Applications can be divided into two broad and partly overlapping classes: investigative studies and predictive toxicology. Investigative studies may help to identify new molecular targets for toxicants or provide novel and deeper insights into mechanisms of action (Man et al. 2002; Ruepp et al. 2002; Fella et al. 2005; Hewitt et al. 2005). The belief that different groups or classes of compounds will induce specific molecules or expression patterns provides the basis for predictive toxicology. Such single markers or gene/protein patterns can have a high degree of predictive power (Elcombe et al. 2002; Li et al. 2002; Petricoin et al. 2002; Ellinger-Ziegelbauer et al. 2004; Boehme et al. 2011; Hrach et al. 2011). Currently, researchers try to set up databases with expression profiles derived from known toxins. These can in the future be used to screen novel compounds in the drug discovery and preclinical evaluation processes.

The full power of toxicogenomics has yet to be realized, and there are numerous platforms available on the market. Both global expression systems (whereby all genes in a given organism are examined simultaneously) and smaller applications (hypothesis-based selection of a small number of specific genes or verification of detected genes of interest observed in microarray analysis) are widely used for many different purposes. Most people involved agree that standardization of microarray experiment procedures and of genomic signatures are keys to the broad acceptance and use of these data. Most journals now only accept papers that have used the MIAME (minimum information about a microarray experiment) guidelines. In traditional toxicology, histopathological evaluation is the gold standard to understand toxicity. Therefore, organs are fixed in paraffin and embedded in paraffin to produce tissue sections for microscopic evaluation. A huge number of formalin-fixed and paraffin-embedded (FFPE) tissues are stored in the archives of toxicology departments, providing a valuable source of molecular biological information. The enormous disadvantage is the low quality of the RNA extracted from such tissue. Thus, special technologies are needed for genomic analyses. In the meanwhile, many companies provide such platforms, either based on microarrays, qPCR, or branched DNA (bDNA) technologies. However, tissue blocks are still not commonly used for molecular profiling in the field of toxicogenomics.

This chapter will be separated into different subjects based on different levels of expression profiling: global expression arrays and multiplexed expression profiling as well as future technologies – namely next generation sequencing. All of these technologies should complement a toxicogenomics study, and their use will be dependent upon the questions being asked.

55.2.1 Total RNA Isolation

PURPOSE AND RATIONALE

For the investigation of expression changes due to xenobiotic/toxin exposure, total RNA must be extracted, whether from body fluids, tissues (including FFPE tissues), or cells. Bolton and McCarthy first published a method for RNA isolation in 1962 (Bolton and McCarthy 1962). Since then many extraction protocols have been developed and adapted to different sample types. All protocols follow the main objective to recover high yield, high quality RNA with as little contamination by DNA and protein as possible. Sample preparation has to be performed prior to any toxicogenomics technology used in investigative studies, and predictive toxicology. For all these approaches, high-quality total RNA (or mRNA) has to be extracted first.

PROCEDURE

Prior to total RNA extraction, sample lysis procedures have to be performed. Lysis conditions are very important for the success of the RNA extraction and depend strongly upon the sample used. Due to great diversity, the biological sample can be pulverized, homogenized, or otherwise disrupted to yield a mixture that contains cells, subcellular components, and other biological debris in an aqueous buffer or suspension. Here is described the protocol for the Trizol® method of RNA extraction.

Trizol® is a mono-phasic solution of phenol and guanidine isothiocyanate, maintains the integrity of the RNA, and is an improvement on the original single-step RNA isolation method described by Chomczynski and Sacchi (1987). After addition of chloroform, vigorous shaking for several minutes, and centrifugation, the RNA exclusively remains in the aqueous phase generated. RNA is recovered by precipitation with isopropyl alcohol, after incubation, and centrifugation at 12,000 *g*. The isolated RNA is then washed with 75% ethanol, and centrifuged at a lower speed. This method facilitates isolation of a variety of RNA species, both of small and large molecular size.

The resulting cleaned RNA pellet should be briefly dried (air-dry, but not to complete dryness) before redissolving in either RNase-free water, or an appropriate buffer. To remove any remaining DNA, a DNase digestion after RNA recovery is highly recommended.

EVALUATION

After sample preparation, total RNA yield can be measured by optical density. Several methods are available. Typically OD at both 260 and 280 nm gives an indication of RNA purity and quantity; thus, the ratio of OD 260/280 should be close to 2. The integrity of RNA can be checked by gel electrophoresis. A convenient platform is the Agilent 2100 Bioanalyzer which is based on capillary gel electrophoresis (Liu et al. 2003). Strong 28 S and 18 S bands or peaks should be visible to indicate high quality RNA. This will most likely not be the case for RNA extracted from FFPE tissues. An additional parameter reflecting RNA quality is the RNA integrity (RIN) introduced by Schroeder et al. (2006). The integrity is lower with many short RNA fragments, with 18 S and 28 S peaks often not being present.

CRITICAL ASSESSMENT

Since differential expression analysis means to compare the quantities of RNA species in two samples, every step during sample preparation has to be highly reproducible. In order to maximize reproducibility, complete total RNA extraction in a one step procedure is recommended. Care must always be taken when

working with RNA, to avoid contamination with RNases, which may result in RNA degradation.

MODIFICATIONS OF THE METHOD

RNA extraction using the relatively toxic Trizol® can also be substituted by numerous other technologies available. Many vendors provide ready-to-use extraction kits including column-based extraction methods. Some kits already include the DNase digestion step, either on column or in solution.

When extracting RNA from FFPE tissues an additional proteinase K digestion step is required to release RNA (Jiang et al. 1995). Due to the "extreme" cross-linking of RNA to proteins initiated by formalin, RNA cannot easily be extracted using common methods. The quality of such FFPE RNA is dependent on several parameters, including warm ischemia time, duration of fixation, embedding process, and blockage.

55.2.2 Global Expression Profiling

The determination of gene expression changes due to toxic insult has become the area of intense research. These changes can be monitored by comparing the level of mRNA for each gene of interest in control and treated tissues/cells/fluids, etc. More recently, it has often been shown that global expression profiling can give hints to molecular changes that lead to overt toxicity (Ellinger-Ziegelbauer et al. 2011).

Global gene expression profiling can be exploited to clarify mechanism of toxicity but also to identify marker genes for the prediction of certain toxicities (Boehme et al. 2009; Boehme et al. 2011; Hrach et al. 2011). These biomarker "fingerprints" can be utilized in later studies without running further genome-wide analyses (Fig. 55.1).

55.2.2.1 Affymetrix GeneChip

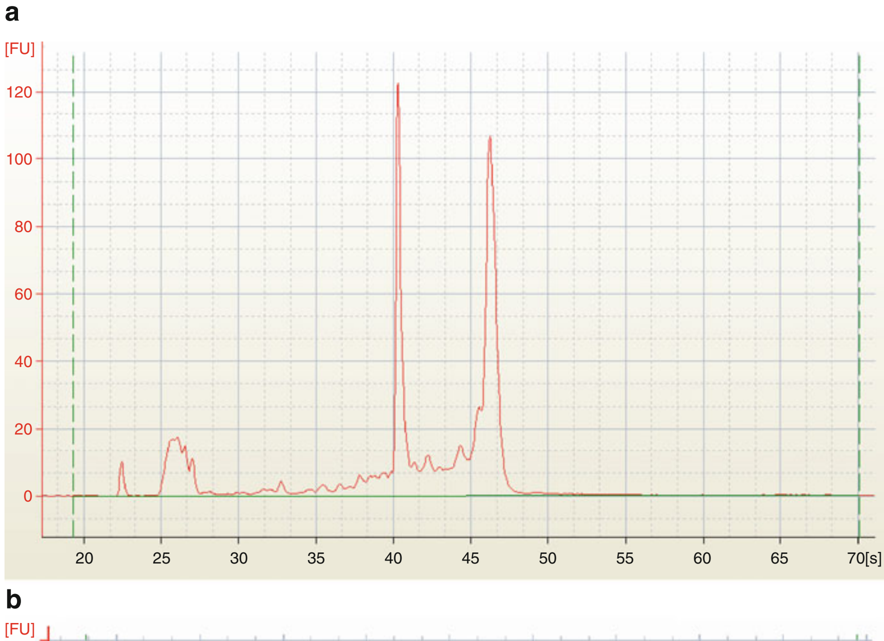
PURPOSE AND RATIONALE

There are multiple platforms available that allow one to look at the gene expression of all known genes in a given organism. The aim of this chapter is not to cover all of them, but to give an overview of one such method, the Affymetrix GeneChip®. Affymetrix can be considered to be one of the market leaders in such classical microarray technologies. Correspondingly, it is a highly reproducible, robust system and is based on single-color analysis (Shi et al. 2006). Each transcript is represented by eleven 25-mer probe pairs, with both match and mismatch probes (whereby the central nucleotide is changed). By comparing whole genome expression changes, we have an objective and hypothesis-free method to gain better understanding of the relationship between toxicity and gene expression. Currently, there are several genome-wide arrays commercially available from Affymetrix, covering more than 30 different organisms.

PROCEDURE

The following paragraph describes the sample processing using the GeneChip® 3′ IVT Express Kit generating cRNA and hybridization onto GeneChip 3′ expression arrays. In a reverse transcription reaction, cDNA is synthesized from total RNA or mRNA using reverse transcriptase and a T7 Oligo (dT) primer. Double-stranded cDNA is subsequently synthesized in a reaction mix containing DNA polymerase and RNase H. The cDNA is then used as a template for in vitro transcription using biotinylated nucleotides to produce biotin-labeled amplified cRNA (User Manual, Affymetrix).

The purified material is then assessed for yield, purity, and integrity by spectrophotometric and Agilent Bioanalyzer analyses. Fragmented (35–200 bases) in vitro transcripts (cRNAs) are generated and purified before hybridizing overnight together with



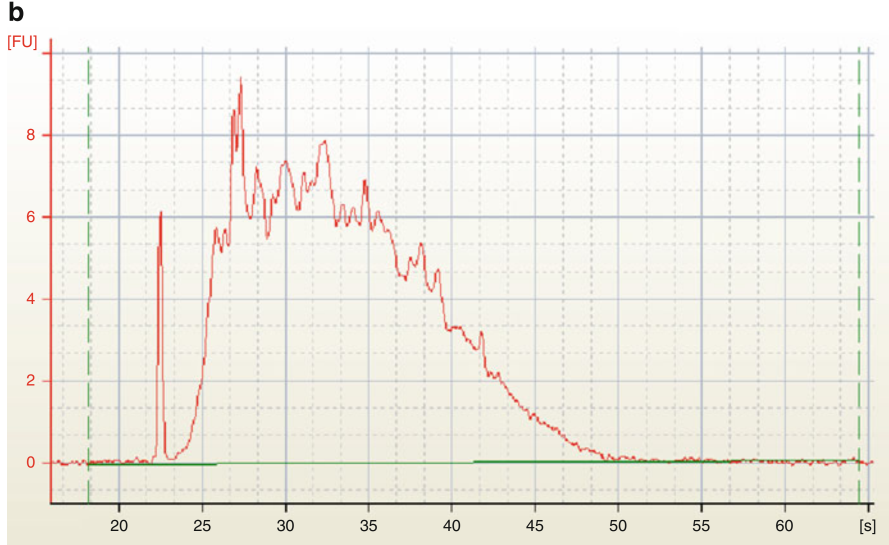


Fig. 55.1 Typical Bioanalyser spectra. Showing two distinct peaks for 18 S and 28 S RNA in high quality samples (**a**) and a trace of degraded RNA derived from FFPE tissues (**b**)

controls onto the Affymetrix GeneChip® (e.g., the Rat Expression 2.0 array contains approximately 31,000 rat-specific probe sets). The hybridized samples are stained with streptavidin-R-phycoerythrin (SAPE) and the signal is amplified using a biotinylated antibody, followed by a final staining. Washing, staining, and amplification are carried out using the manufacturer's fluidics station. The arrays are scanned using the manufacturer's fluorescent scanner (Fig. 55.2a).

EVALUATION

Normalization and scaling of the expression data across arrays can be performed based on a set of maintenance genes included on most Affymetrix arrays The raw data is firstly quality checked and transformed into expression values whereas different algorithms can be used, for example, MAS5.0 from Affymetrix or RMA. These algorithms include background correction, normalization, and summarization of the data. To identify differentially regulated genes, for example, in comparison to a control group, a threshold value of twofold is commonly applied. To aid data interpretation, it is essential that statistical analysis, false discovery rate, t-test or n-way Anova are also included. Expressionist® Refiner and Expressionist® Analyst from Genedata or GeneSpring GX

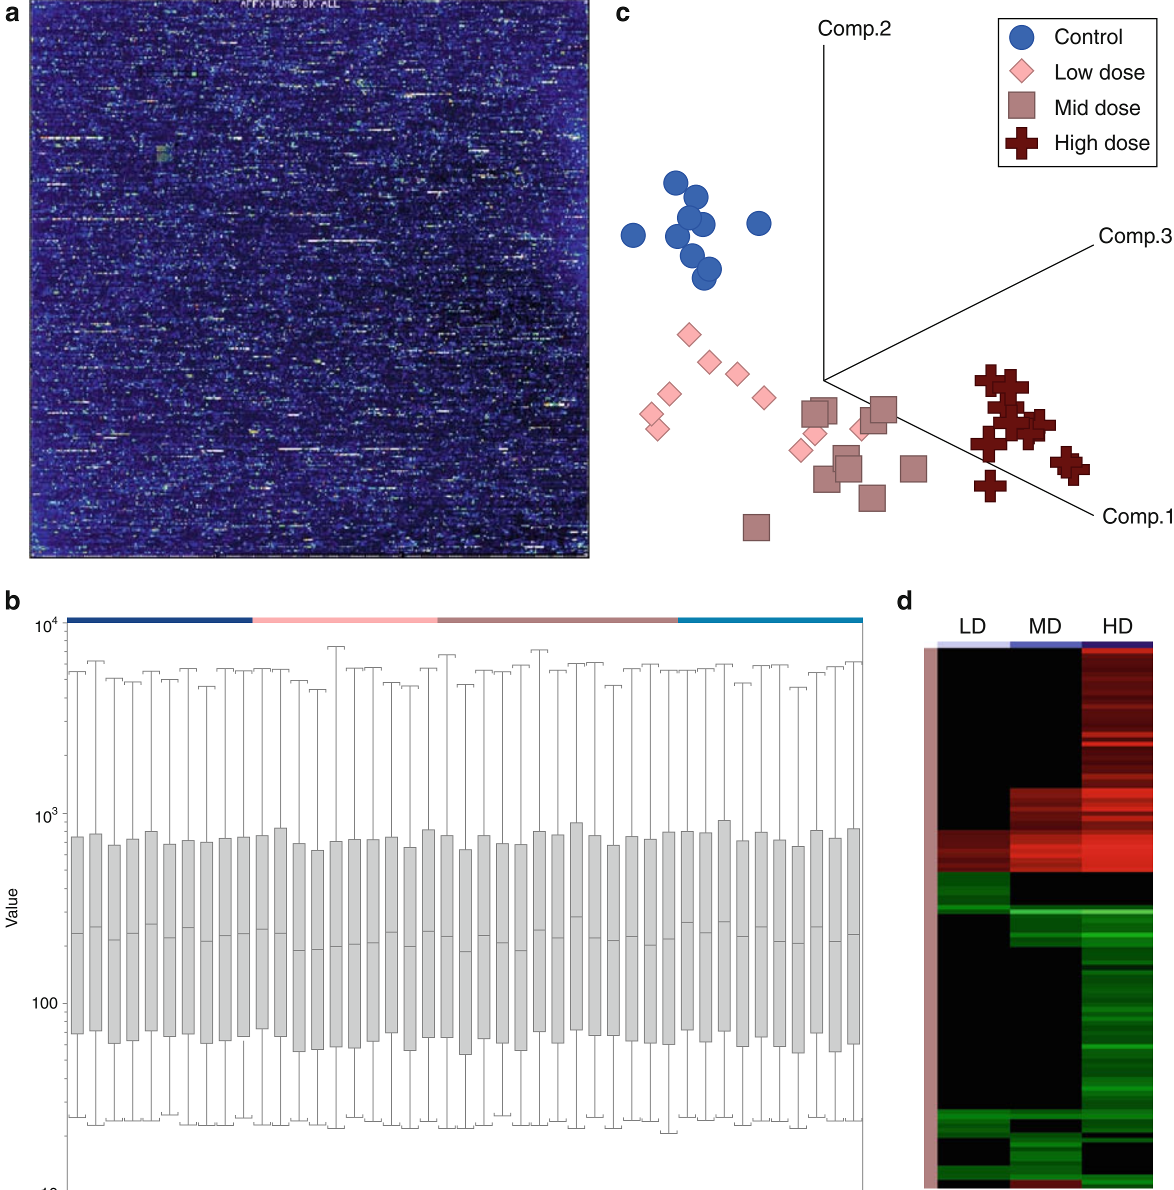

Fig. 55.2 Whole genome gene expression data of a toxicogenomic study. Computer image of a single Affymetrix GeneChip after sample hybridization (**a**). Presentation of gene expression data from rats treated with a low dose, mid dose, or high dose, respectively, of a potential drug in comparison to control animals analyzed with Expressionist® Analyst from Genedata. Non-normalized expression values of individual samples presented in separate Box Plots (**b**). Principal Component Analysis (PCA) after data normalization, showing differences between samples in their overall gene expression (**c**). The so-called heat map displays upregulated (*red*) and downregulated (*green*) genes in comparison to control animals (**d**)

from Agilent are possible software tools where such specific analysis can be performed. Dose-responses or time-effects can be evaluated by special statistical methods. An example of gene expression data from a toxicogenomic study is given in Fig. 55.2b–d.

CRITICAL ASSESSMENT

Affymetrix, as a tool, is well accepted in the scientific community and is highly reproducible (mean false change rate of triplicates $\leq 0.18\%$ and the percentage of concordant detection call is $\geq 91\%$) and sensitive

(down to 1.5 pm mRNA); therefore, chip-to-chip variation is kept to a minimum (Technical Note, Affymetrix). The major advantage of this method is that you can simultaneously monitor the expression changes of tens of thousands of individual genes. Mechanisms of toxicological response can be teased out of the data and gene expression patterns (signatures) may lead to a more predictive approach to early toxicological assessment. However, the data is cumbersome and the amount of data generated is enormous, and therefore, appropriate software tools and large databases are essential. Interpretation of such large datasets is difficult and care must be taken not to over-interpret such data. For all array technologies, a second method is recommended to confirm a small number of the gene expression changes, for example, real-time PCR (see Sect. 55.2.3).

MODIFICATIONS OF THE METHOD

The actual protocol for running Affymetrix arrays is well standardized—as recommended by the manufacturer. However, it is clear that this method is only a tool, and many researchers have reported different uses for this technology (and not only in toxicology).

There are also obviously many other companies offering similar global expression arrays. These include Agilent, Illumina, Roche NimbleGen, Applied Microarrays, to name just a few. All are based on oligonucleotides attached to an array surface where the target sequences will be captured. The most popular systems are synthesized oligonucleotides spotted onto the array (customized or standard arrays). This is in contrast to the Affymetrix array described above, where the manufacture is based on a combined chemical and photolithographic method of oligonucleotide synthesis directly on the array (Pease et al. 1994). In addition to Affymetrix, spotted cDNA arrays have been widely used for mechanistic toxicity testing (e.g., Kultima et al. 2004). Due to the availability of new genomic technologies (next-generation sequencing), the conventional microarray analysis has already lost importance, at least in other fields of research. So this new technology might also enter toxicogenomic evaluations in the near future (see Sect. 55.2.4.2).

Expression analysis using FFPE tissues is not commonly applied in toxicology but a lot is known about their use in other fields of research. Tissue blocks have been assessed for molecular toxicology processes and can successfully be used (Schmitt et al. 2009; von Landenberg et al. 2011). Due to the nature of RNA extracted from FFPE tissues, special technologies are required for successful sample processing. For example, Genisphere and NuGEN Technologies provide sample processing kits to perform expression profiling on Affymetrix and Illumina whole genome arrays. Furthermore, the DASL™ assay from Illumina was specifically designed for analyzing degraded RNA and is no available for whole genome expression analysis of FFPE tissues (Fan et al. 2004).

EXAMPLES

Many researchers have used genome-wide expression profiling to elucidate toxic mechanisms and/or to find marker gene(s) for specific toxicity end points. Ellinger-Ziegelbauer et al. (2004) have used Affymetrix technology to characterize genotoxic carcinogens in rat liver. Ezendam et al. (2004) have used toxicogenomics for the elucidation of the mechanism of toxicity after sub-chromic hexachlorobenzene exposure in rats. Hewitt et al. (2005) have reported the use of the Affymetrix technology to elucidate the teratogenic mechanism of two drugs (retinoic acid and a novel pharmaceutical agent). In a larger in vivo study, it was demonstrated how toxicogenomic evaluations together with toxicoproteomics and metabonomics can contribute to the detection of liver toxicity, biliary injury, or hepatocellular hypertrophy, as well as kidney toxicity (Boitier et al. 2011; Ellinger-Ziegelbauer et al. 2011; Matheis et al. 2011). Yuan and coworkers successfully used toxicogenomic approaches to identify the reprotoxicity potential of specific phthalates in rat testicles (Yuan et al. 2010). Microarrays have even been applied in the fields of environmental biology and ecotoxicology (Hook 2010; Martyniuk et al. 2011). In addition, many in vitro studies have been reported, for example, in hepatocytes to evaluate liver toxicity or HepG2 cells for mutagenicity studies (Jessen et al. 2003; Kostrubsky et al. 2003; Harris et al. 2004; Boehme et al. 2011; Hrach et al. 2011).

55.2.3 Multiplexed Gene Expression Analysis

PURPOSE AND RATIONALE

The quantitative analysis of gene expression changes is important if we are to trust data generated by larger gene arrays. The real-time PCR technique (e.g., TaqMan® from Applied Biosystems) allows fast and very sensitive detection of even rare RNA molecules and is routinely used for analyzing a small set of distinct preselected genes. It can also be applied for the validation of array data. This high specificity is due to a complementarity between the primer set, the internal probe, and the target. It is widely believed to be the most sensitive and specific method with a wide dynamic range for mRNA quantification. The TaqMan® assay was used as gold standard in the MAQC project (Shi et al. 2006). Very small amounts of RNA are required, ensuring economic use of

precious samples, as well as the possibility of using micro-dissected tissue.

PROCEDURE

For the TaqMan® assay, purified RNA is first subjected to reverse transcription using random primers. The subsequent PCR reaction includes individual primers (both forward and reverse), a sequence-specific probe, and the polymerase. Ready-to-use primer/probe mixes can be purchased from the supplier or custom primer/probe mixes can be designed on their website (Primer Express® software). The software produces sequences that comply with requirements regarding the melting point, G/C content, length, and configuration. Furthermore, the amplicon should not exceed 150 bp. The characteristic TaqMan® probes are labeled with the fluorescent dye FAM (6-carboxy-fluorescein) and a nonfluorescent quencher together with a minor groove binder (MGB) at the 5′- and 3′-end, respectively. The MGB stabilizes the probe binding and enables higher melting temperatures. Probe and primers are provided in one mix and the TaqMan® Universal Master Mix comprises all remaining components necessary for a real-time PCR. The TaqMan® reaction exploits the 5′-nuclease activity of the Taq polymerase releasing the reporter dye from the 5′-end of the annealed TaqMan® probe during amplification. Reporter dye fluorescence is no longer transferred (Forester energy transfer) and suppressed by the quencher, resulting in an increasing fluorescent signal. The reaction is performed on the real-time PCR systems from Applied Biosystems (e.g., 7,500 Real-Time PCR System) and the accumulating reporter dye fluorescence is detected in real time. For amplification, the reaction starts with 2 min at 50°C and 10 min at 95°C followed by up to 40 cycles with 15 s at 95°C for denaturation and 1 min at 60°C for annealing/extension for each amplification cycle (Protocol, Applied Biosystems). Each sample is analyzed for the target gene of interest and at least one endogenous control (e.g., 18 S ribosomal RNA (rRNA)) for normalization. It is important to correctly choose an endogenous control which is consistently expressed in all samples independent of tissue source and treatment. A no template reaction can be run as the negative control. If a standard curve is required, different dilutions of a sample with known quantities are analyzed for each target, including the endogenous control. All samples and controls are run in triplicates (Fig. 55.3).

EVALUATION

In the resulting amplification curve, the baseline and the threshold within the exponential phase are set to determine the threshold cycle (C_T) (Protocol, Applied Biosystems). Two methods are usually used for the evaluation of real-time PCR data, namely, the standard curve method or the comparative C_T method. The standard curve method relies on the use of dilutions of cDNA reverse transcribed from a reference RNA, which will result in only a relative quantification. Other more specific standards can be used, for example, in vitro transcribed RNA, which gives an absolute quantitation; however, this method is very labor intensive and not commonly used (Martell et al. 1999). The standard curve is included in each PCR run, and therefore provides a correction control for the PCR efficiency, making inter-assay comparisons easier. The comparative C_T method uses algorithms to calculate relative expression levels, compared to a calibrator (e.g., a control sample). A detailed description of the mathematics is given by Livak and Schmittgen (2001). After calculation, the normalized expression of the target gene in the unknown sample relative to the normalized expression of the control (calibrator) sample is produced. It is important when using this method that the PCR efficiency of the target gene and the housekeeping gene is equal, then more samples can be run in one PCR run (i.e., no wells lost to the standard curve).

The housekeeping gene is one that is universally expressed, and does not change under the conditions of the assay employed. 18 S rRNA, β-actin, glyceraldehydes-3-phosphate dehydrogenase (GAPDH), cyclophilin, mitochondrial ATP synthase 6, hypoxanthine guanine phosphoribosyl transferase 1 (HPRT), and succinate dehydrogenase complex subunit A (SDHA) have, for example, been reported (Zhong and Simons 1999; Gerard et al. 2000; Cicos et al. 2007). Assays are evaluated only when negative controls do not show any amplification products.

Statistical analyses (e.g., t-test) are performed and significant differences between treated samples compared to vehicle control are determined.

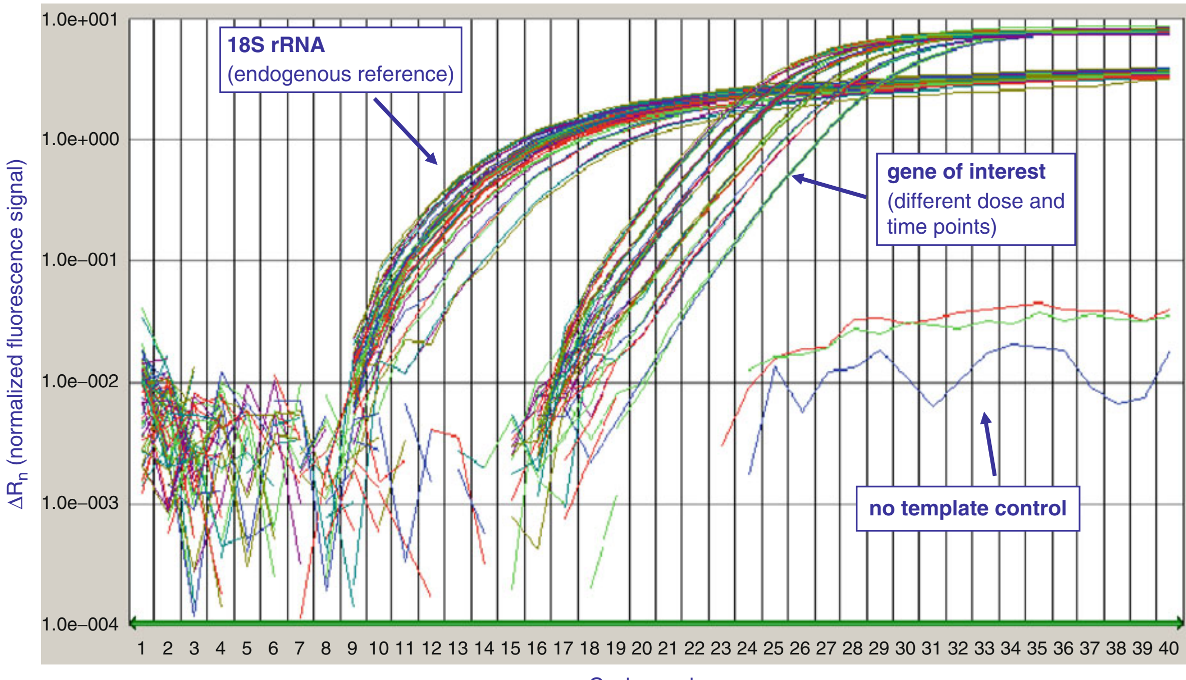

Fig. 55.3 Representative real-time PCR (TaqMan®) trace. Showing the housekeeping gene, 18 S, and the test gene of interest. Increased fluorescence intensity indicates increasing levels of cDNA and more cycles needed indicate smaller amount of starting material (RNA)

CRITICAL ASSESSMENT

Real-time PCR can be considered to be a highly sensitive, specific, and reproducible technology for quantitation of gene expression. Reliability is very high and the data generated is of the highest quality. This method would be the method of choice, when expression of a limited number of genes is required. The obvious drawback is that the number of gene expressions possible is limited. Therefore, higher-throughput gene arrays for the study of larger numbers of genes are needed.

Care must be taken when choosing housekeeping genes for normalization, as there are many citations reporting the gene expression regulation of all of these commonly used housekeepers.

Table 55.1 A selection of currently available real-time PCR systems

Company	PCR cycler
Life Technologies	7300, 7500 (Fast), 7900HT, OpenArray®, StepOne(Plus)™, ViiA™ 7 (Dx) Real-Time PCR Systems
Roche	LightCycler® 2.0, 480, 1536, Nano
Illumina	Eco® Real-Time PCR System
Eppendorf	Mastercycler® ep realplex
BioRad	MiniOpticon, MyiQ2, CFX96 Touch, CFX384 Touch
Qiagen	Rotor-Gene® Q
Cepheid	SmartCycler, GeneXpert
Agilent Technologies	Mx3000P/Mx3005P qPCR System

MODIFICATIONS OF THE METHOD

More recently intercalating double-stranded DNA-binding dyes (e.g., SYBR Green),have been introduced (Giulietti 2001) which removed the need for an expensive, specific probe to be designed. Other sophisticated tools have been developed to work in conjunction with the TaqMan® method, for example, molecular beacons, scorpions, and hybridization probes. These techniques also rely on the FRET (Fluorescence Resonance Energy Transfer) principle but the emergence of the fluorescent signal does not require the nuclease activity of the Taq polymerase. Some of the different real-time PCR providers currently available on the market are given in Table 55.1. Applied Biosystems

have introduced “microfluidics cards” or low-density gene expression arrays. These cards follow the main TaqMan® principles, but are based on a 384-well plate design. Therefore, multiple samples and genes can be monitored, quantitatively, at the same time. Maley et al. (2004) have reported the use of a multiplexed TaqMan® model for high-throughput screening applications. Instead of the nonfluorescent quencher at the 3′-end of the TaqMan® probe, a fluorescent quencher (TAMRA) is linked, especially when designing custom gene expression assays.

Other multiplexing solutions are available on the market, for example, the QuantiFast® Multiplex PCR Kit from Qiagen, which enables the analysis of up to four targets in a single tube. A flexible multiplexing PCR solution is provided by Life Technologies/ Applied Biosystems. The OpenArray® technology contains several individual PCR assays on a conventional microscope slide format with 48 subarrays. The subarrays enable analysis in a mid-density manner for higher throughput applications (up to 48 samples or 224 individual assays). PCR reactions can either be TaqMan or SYBR® Green based that can be used for gene expression but also for genotyping, GWAS, and miRNA analysis.

A PCR-free system is provided by Affymetrix/ Panomics. The QuantiGene® assay, based on the branched DNA technology, applies signal amplification rather than DNA amplification. Various sample types, for example, cells, tissues, FFPE tissues, blood, can be run in this assay without the need to extract pure RNA. Either a single gene or several genes can be multiplexed in one assay. After capturing the target sequence on the plate surface or on beads for single and multiplexed assays, respectively, the signal is ~400-fold increased by the use of pre-amplifiers and amplifiers which build a branch-like structure. The bead type (target) and the signal intensity are detected using the Luminex® instrument (Dunbar 2006).

EXAMPLE

There are numerous publications where real-time PCR analysis has been used to follow the changes in expression of specific toxic relevant genes. Fox et al. (2010)

identified potential biomarkers for the identification of acetaminophen toxicity in HepG2 cells and primary rat hepatocytes by qPCR analysis. RT-qPCR analysis was applied to validate a gene marker set observed by microarray analysis describing the molecular changes in rat liver after AhR ligands exposure (Ovando et al. 2011). Testicular toxicity of emodin, a herbal medicine, was observed and analyzed by qPCR (Oshida et al. 2011). The neurotoxic effect of lead during early development was assessed by real-time PCR using zebra fish embryos (Zhang et al. 2011). Giulietti (2001) have used real-time PCR techniques to evaluate cytokine profiles in both mouse and human cells and tissues. Heregulin (a member of the neuregulin family) and its binding receptors (ErbB-2, ErbB-3, and ErbB-4) are induced by gentamicin treatment, and are therefore postulated to play an important role in hair cell regeneration following ototoxic shock (Zheng et al. 1999). Campbell et al. (2004) showed, using TaqMan®, the importance of matrix metalloproteinases in kainic acid–induced excitotoxicity in the rat brain.

55.2.4 Recent Innovations and Future Technologies

55.2.4.1 Small Noncoding RNAs in Toxicogenomics

PURPOSE AND RATIONALE

The evaluation of epigenetic factors, for example, DNA methylation, histone modifications, as well as the impact of micro RNAs (miRNAs) on mRNA regulation, has become very important in many fields of research. In the following chapter, the impact of small RNAs, with a focus on miRNA, in toxicogenomics is described. Assessing such factors has already been well established in cancer research (Munker and Calin 2011) and the importance also for toxicology has been recognized. Polymerase II promoters are often involved in the induction of toxicological effects and miRNAs are mainly transcribed by this important enzyme; thus, it has been stated that miRNAs play a crucial role in the development of certain toxicities (Taylor and Gant 2008). miRNA expression has been confirmed to be affected by extracellular signals, cellular stress, and xenobiotics (Lema and Cunningham 2010). Therefore, miRNA expression profiles could support the identification, classification, or prediction of adverse effects and serve as safety-specific biomarkers. Identifying effected miRNAs by a certain toxicant, and the posttranscriptional modification of the miRNA's target gene can be estimated which would be a crucial contribution to the clarification of a toxicity mechanism. It is also of great interest whether changes in miRNA expression affect an individual's susceptibility to xenobiotics.

miRNAs are small endogenous noncoding RNA molecules (~22 nt) with regulatory functions. The major effect of these molecules is binding to the 3′UTR region of particular mRNAs and posttranscriptionally inhibiting their translation into proteins. In the most recent release of the commonly used miRBase database (17; April 2011), 16,772 entries are recorded with 1,424 and 408 miRNA sequences for *Homo sapiens* and Rattus norvegicus, respectively (http://www.mirbase.org). In contrast to miRNAs, small interfering RNAs (siRNAs) are mainly exogenous molecules from viruses, transposons, or transgenes that achieve posttranscriptional silencing via mRNA degradation. These RNAs are used in the RNA interference (RNAi) technology to knock down genes of interest, used in gene function studies for analyzing the association of specific genes to a particular phenotype (Hannon 2002). Specifically, in toxicology, it can be studies whether the genes of interest correspond to certain toxicity.

PROCEDURE

miRNA expression can be analyzed with different technologies, including northern blotting, qPCR, microarrays, and next-generation sequencing. Since most technologies are described in other parts of this chapter, they will not be described in detail here.

Small RNAs are not extracted with common RNA extraction methods. Therefore, it has to be ensured that the extraction kit used does not lose the small RNA molecules. Products that provide small RNA enrichment (< 200 nt) in total RNA or separated small RNA extractions are available on the market. For example, the mirVana™ Kit from Ambion, Life Technologies, or the miRNeasy Mini Kit from Qiagen. Furthermore, phenol-based RNA extraction methods usually yield total RNA including small RNAs. The quality check for miRNAs can be performed using the Agilent Small RNA Assay on the 2100 Bioanalyzer.

For qPCR analysis, a special reverse transcription of miRNA is necessary. Regular oligo d(T) or random priming is not suitable due to the short nature of miRNA molecules which have no poly-A tail. Applied Biosystems describes a reverse transcription procedure where a specific stem-loop RT primer is annealed to the 3′ end of the mature miRNA (Protocol, Applied Biosystems). The primer is extended by reverse transcriptase producing a longer cDNA molecule containing the primer sequence and the first strand cDNA complementary to the mature miRNA sequence. The TaqMan® MicroRNA assay is based on the TaqMan® assay already described in Sect. 55.2.3. Here, a forward primer, as well as the TaqMan® probe, is designed specifically for the small RNA sequence, whereas the reverse primer is complementary to the RT primer sequence. Analysis of siRNA can also be performed by the same assay procedure using the TaqMan® siRNA Assay from Applied Biosystems.

EVALUATION

Quantitation of miRNA expression in the TaqMan® assay is performed based on the C_T values, similar to the evaluation described in Sect. 55.2.3. Comparable to transcriptomics data, statistically relevant differentially expressed miRNAs should be observed. Several miRNA databases are available online to obtain more information on the miRNAs of interest, for example, http://www.mirbase.org/, http://mirnamap.mbc.nctu.edu.tw/, or http://www.microRNA.org. It is often of great interest to additionally know the mRNA targets of the relevant miRNAs. Therefore, the MicroCosm Targets website is a valuable source of information (www.ebi.ac.uk/enright-srv/microcosm/).

CRITICAL ASSESSMENT

In molecular toxicology, it is often not sufficient to have information of the transcriptome. Proteins are the actual active molecules and mRNA expression alone does not mean that a protein is expressed. Due to the complexity of the proteome and the adjacent technologies, protein expression profiles are often not available. Having mRNA and the adjacent regulatory miRNA expression patterns would be a step toward protein translation which could help to postulate/predict the proteomic status of an organ/cell. An issue in interpretation of miRNA data is that many mRNAs are eligible to be targeted by one miRNA. Therefore, miRNA expression is suggested to be analyzed in conjunction with gene expression. This results in the need for additional experiments on different expression platforms. Due to the short length of miRNA primer, binding is often relatively instable and only one miRNA sequence-specific primer can be included. Others have also reported high false-positive and false-negative rates in miRNA microarray experiments (Choudhuri 2010).

MODIFICATIONS OF THE METHOD

Other qPCR technologies require a polyadenylation reaction before the reverse transcription with a universal primer. This cDNA consists of a miRNA complementary sequence at the 3′ end and a universal 5′ end. The qPCR is subsequently run with a miRNA-specific and a universal primer. The NCode™ SYBR® Green miRNA qRT-PCR Kit (Invitrogen) or miScript PCR System (Qiagen) are examples applying this polyadenylation reaction. Other providers use locked nucleic acid (LNA™) oligonucleotides as primers. LNA™ are chemically modified nucleic acids providing more stable binding to miRNA and therefore enabling higher melting temperatures (Exiqon).

EXAMPLES

Several Phase I enzymes and transporters, including Cyp2E1 and MDR1, were found to be posttranscriptionally regulated by miRNAs (Nakajima and Yokoi 2011; Klaassen et al. 2011). miRNAs also regulate many transcription factors involved in xenobiotic toxicity. Thus, miRNA expression is involved in the translation of PPARα, P53, PXR, and NRF2, to name only a few. A miRNA targeting MRP1 (and MRP1 itself) was found to be a key factor in the establishment of resistance to the cytostatic Cisplatin (Pogribny et al. 2010). Lema and Cunningham reviewed how several toxicants effect miRNA expression and their targets leading to a distinct adverse effect, for example, hepatocyte proliferation induced by PPARα agonists, Tamoxifen-induced hepatocarcinogenesis or acetaminophen-induced hepatotoxicity (Lema and Cunningham 2010). Choudhuri reported that neurotoxicity, developmental toxicity, hepatotoxicity, and carcinogenesis are all affected by miRNA expression (Choudhuri 2010). Furthermore, Wang and coworkers have suggested several miRNA biomarkers for drug-induced liver injury (Wang et al. 2009).

55.2.4.2 Next-Generation Sequencing

PURPOSE AND RATIONALE

The emergence of next-generation sequencing (NGS) technologies has revolutionized the field of genomic research. Steadily decreasing cost for analysis of a genome has enabled their expansion. This is leading the displacement of traditional microarray technologies from the market. NGS platforms are able to perform massively parallel sequencing, have a higher dynamic range, and are more sensitive compared to microarrays. So far these technologies have not yet been extensively applied in the field of toxicology, but this is sure to change in future. NGS is a further development from the shotgun sequencing technology which was already an improvement of the Sanger sequencing. Numerous genomic analyses are possible, including DNA and transcriptome sequencing for genotyping and copy number variation, linkage analysis, gene regulation, and epigenetic evaluations (e.g., ChIP-Seq, methylation, small RNA discovery and analysis, histone modification) (Mardis 2007).

PROCEDURE

The most widely used NGS system is the Genome Analyzer from Illumina. It is easiest to handle with superior data quality and accuracy (Zhang et al. 2011). The Illumina NGS systems are based on the TruSeq™ technologies (Data Sheet, Illumina). For library preparation, DNA is fragmented, a blunt end generated, and an adenosine is added to the 3′end. In case of transcriptome analysis, mRNA is reverse transcribed using random primers to generate double-stranded cDNA. Adapter oliogos containing universal primer sites with a 5′ overhang are ligated to both ends and fragments are purified after size selection. The fragments are hybridized with their adapter onto a flow cell and bridges built for amplification. The generated cluster can now be sequenced by synthesis. Here all four bases with different labels are added simultaneously and the hybridized base is identified by fluorescence signal (Technology Spotlight, Illumina).

EVALUATION

After read-generation “base-calling” is performed. With this information, sequences can be aligned to a reference genome or assembly can be carried out for de novo sequences.

Proper alignment or assembly is critical and many open source bioinformatic tools are available online, for example, ELAND, MAQ, and BLAST. More information about these software tools are described in the review from Zhang and coworkers (Zhang et al. 2011). High professional information technology infrastructure is not available in every lab; thus, vendors of NGS technologies also provide so-called cloud computing end-user software for data processing (e.g., the CASAVA package from Illumina). Uniquely mapped reads are then used for further analyses. To observe differentially expressed genes, for example, all reads of a specific gene transcript are counted and compared between samples. Furthermore, normalization, transformation, and statistical analyses are carried out in a similar way to microarray data analysis.

CRITICAL ASSESSMENT

NGS technologies have the potential to be of great added value to genomic research. An enormous amount of data can be obtained in a relatively short period of time from limited samples. Additionally, these technologies have the potential to pave the way toward personalized medicine. In the case of toxicogenomics, by sequencing individual genomes, interindividual differences could be potentially

Table 55.2 A selection of currently available next-generation sequencing systems

Company	Template preparation	Sequence by	System	Read length	Max output
Illumina	Bridge amplification	Synthesis	HighSeq 2000	2x100b	600 Gb
			Genome Analyzer IIx	2x150b	95 Gb
			MySeq	2x150b	~1 Gb
Roche	Emulsion PCR	Pyro-sequencing	GS-FLX+	<1,000b	700 Mb
			GS Junior	400b	~35 Mb
Applied Biosystems	Emulsion PCR	Ligation	SOLiD 4	50b	100 Gb
			5,500xl Genetic Analyzer	75b	10–15 Gb
			5,500 Genetic Analyzer	75b	7–9 Gb

detected after exposure to a toxicant/new drug entity. However, many issues exist concerning the use of NGS. Especially the handling of the huge amount of data generated is extremely challenging, specifically concerning data transfer, storage, analysis, and interpretation (Metzker 2010). Due to the short read length, reads often cannot uniquely be aligned and therefore cannot be included in the analyses, repetitive sequences alignment is especially difficult. Improvement of software tools is thus essential to be able to properly adopt this technology. These technologies still need to be validated for data quality, reliability, reproducibility, and biological relevance. In 2008, a consortium has been founded coordinated by the FDA to deal with these challenges, namely, the MAQC-III project, called Sequencing Quality Control (SEQC) (www.fda.gov/MicroArrayQC).

Furthermore, sequencing is still relatively expensive—when compared to the costs of whole genome microarrays. This is an especially sensitive issue for toxicogenomics where usually large numbers of animals are need to be analyzed/sequenced; therefore, costs would be too high to use sequencing in routine studies. To reduce costs, it can be considered to sequence only preselected regions rather than analyzing the whole genome. As the technologies are continually and rapidly being improved, there is hope that in the near future they will become affordable soon.

MODIFICATIONS OF THE METHOD

Three major NGS technologies are currently available on the market. One is the technology from Illumina described above, with different sequencers available (HighSeq, HiScanSQ, Genome AnalyzerIIx and the MySeq) and the two others are from Roche and Applied Biosystems. The major differences of all technologies are in template preparation or in sequencing. Templates can be prepared by emulsion PCR or the amplification is performed on a solid phase. The 454 Sequencing Systems (Roche) are pyrosequencer and performs emulsion PCR for template preparation. Sequencing by ligation is required on the SOLiD platform (Applied Biosystems). Here the template is amplified on a solid phase. In addition, all platforms differ in the obtained number and length of reads (Table 55.2). All sequencing technologies are described and compared by Voelkerding et al. (2009) and Metzker (2010).

EXAMPLES

The first toxicogenomics study applying NGS was described by Su and coworker in 2011. They compared

the RNA-Seq data to data from an Affymetrix microarray analysis, which was based on a real-life toxicological study where rats were treated with aristolochic acid. Differentially expressed genes compared to control animal were assessed. NGS was observed to be more sensitive in identifying a great number of deregulated genes. Although they found only 40–50% common genes, gene expression patterns obtained from both technologies were similar, as was the biological outcome. For example, typical nephrotoxic and carcinogenicity GO processes were observed with both technologies (Su et al. 2011). NGS has been applied in several phases of drug discovery and development process, and has been extensively reviewed by Woolland et al. (2011). NGS can support target identification, but can also be used in drug resistance studies, biomarker discovery, and RNA-protein identification studies. For personalized medicine, the identification of interindividual variations is important for therapy which might improve drug efficacy and safety.

55.3 Application of Toxicoproteomics in Profiling Drug Effects

PURPOSE AND RATIONALE

Traditionally, toxicologists define the preliminary risk of a new compound to human safety using animal models supported by histopathological and biochemical approaches. However, despite decades of experience, the extrapolation dilemma and the relevance of animal data to real-life, long-term exposure in humans remained unclear. The genomics revolution of the recent years led to development of many new and innovative technologies that can change this paradigm and address uncertainty issues in the current toxicological practice and safety assessment through the identification of novel key genes, marker proteins, or protein profiles. Thus, these technologies provide a superior alternative to traditional rodent and canine bioassays to identify and accurately assess the safety of chemicals and drug candidates for human safety.

Toxicogenomics, the use of DNA microarray for comprehensive RNA expression analysis, has recently caused a great deal of interest (Pennie et al. 2000; Nuwaysir et al. 1999). This technology has been used to monitor changes in gene expression in response to drug treatment. However, analysis of the information produced by toxicogenomics has proven to be unsatisfactory (Anderson and Seilhamer 1997; Mann 1999; Srinivas et al. 2001). Fundamental studies have illustrated the usefulness and potential of the toxicoproteomics, the proteomic approach, to complement RNA microarray data. Proteomic technology helps identify corresponding changes in the level of protein, which is critical because the protein is the basic component of a cell. Additionally, toxicoproteomics helps resolve issues involving differential protein modifications. These are critical for the function of many proteins, in that they may lead to changes in the activity of gene products. Primarily, the manifestation of protein modifications is the reason for undesired, compound-related effects. Toxicoproteomics helps to determine such changes, and to gain insight into the mode of action of drugs (Kumagai et al. 2006; Gao et al. 2009). Furthermore, toxicoproteomics technologies can also be applied in identification, characterization, and evaluation of new prognostic and diagnostic biomarkers (Merrick 2006; Bjørnstad et al. 2006; Provan et al. 2006; Glückmann et al. 2007).

Toxicoproteomics studies, as they have been conducted so far, focused mainly on investigation of toxic effects of known toxicants and reference chemicals. These studies were of paramount importance to show the potential of proteomics technologies and their application in toxicological research. In recent publications, however, researchers report investigations with new chemical entities within pharmaceutical and chemical industry, and scientific institutions. These studies herald the next period of practicing toxicoproteomics with more focus on issue resolution or biomarker identification. To achieve this goal, the knowledge from proteomics approach needs to be combined with the information from classical disciplines such as toxicology and pathology.

PROCEDURE

55.3.1 Available Technology Platforms

The most common implementation of proteomic analysis involves protein separation 2-D gel electrophoresis (2DGE), quantification of proteins with analytical methods for their identification in mass

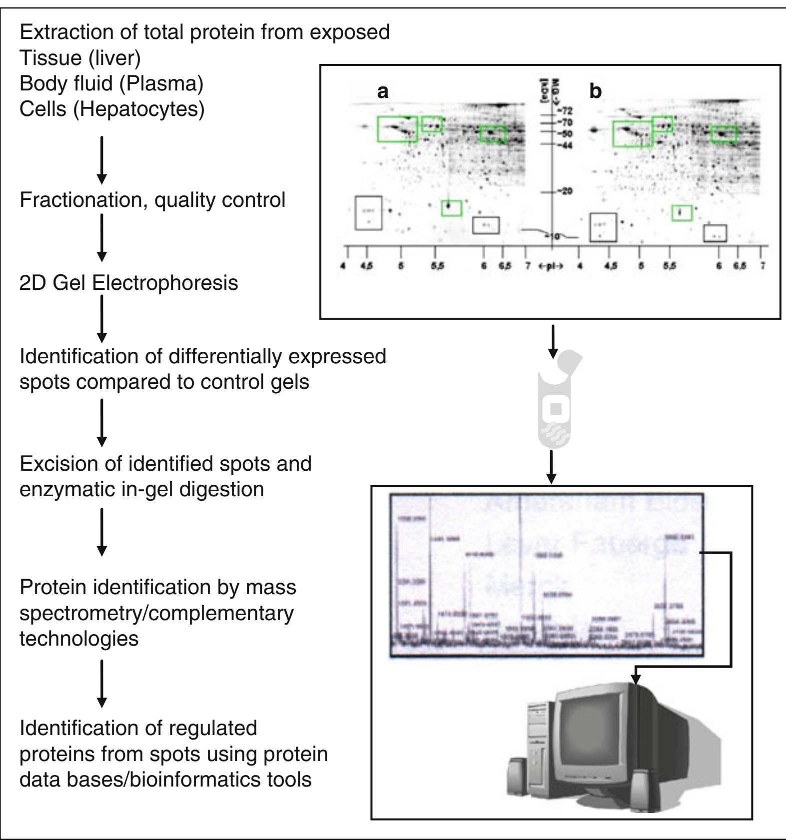

Fig. 55.4 A general flow chart of sequential steps for conducting standard proteomics studies

spectrometer (MS), and at the very least data integration and analysis using bioinformatic tools. Figure 55.4 represents the sequential steps for conducting standard proteomics studies.

55.3.1.1 Protein Extraction and Fractionation

The first step in the protein identification and characterization process by different proteomics technologies is the extraction of proteins from cell cultures, body fluids, or tissue samples. As total protein extracts harbor many abundant proteins such as immunoglobulins or albumin, the removal of abundant proteins could be considered for the purpose of increasing number of detectable and identifiable proteins (Merrick 2006).

The first step in the preparation of protein extracts is to mix samples (cell or tissue pieces) with a lysis buffer, for example, 20 mM Tris-HCL, pH 7.4, 1% CellLytic-M (Sigma). To avoid the enzymatic degradation of proteins by proteases, protease inhibitors are added. When organ samples are used for protein extraction, as soon as these constituents are added, tissue are homogenized using a Polytron type homogenizer. During the homogenization process, the tube is kept submersed in a water ice bath to maintain the sample at 4°C. After homogenization, samples are centrifuged to separate the solubilized proteins from cell debris and insoluble membrane components. The supernatant is aspirated and can be divided into aliquots. At the end, the total protein concentration can be determined using a BCA protein assay with BSA as the standard. Depending on the purpose and experimental design, a protein fractionation can be followed, or the protein extracts are analyzed without further processing. If the protein extracts are not used immediately, they can be frozen at < -70°C until tested.

55.3.1.2 2DGE

Initially, proteins in a sample are separated according to their isoelectric point in a pH gradient. Next, the proteins are separated according to size on a SDS-polyacrylamide gel. A dye marker such as coomassie blue, silver, or fluorescent dyes then detects the resolved proteins. In order to analyze differentially expressed protein spots in an experimental set of gels,

a computerized detection and matching system is required. Finally, MS identifies selected protein spots. The 2-D gel electrophoresis allows separation of around 3,000 proteins. Even though the 2DGE is an effective method for the separation and quantitation of proteins from different sources, it has some limitations. Working with 2DGE technique takes time and demands intensive skilled labor, and hence is not practical for high throughput. Other limitations like lack of reproducibility narrow the application of 2DGE. Liquid chromatography is an alternative and straightforward method with the advantage of direct connection to mass fingerprinting technologies (Link et al. 1999).

55.3.1.3 MS

Mass fingerprinting of excised and trypsin-digested gel spots is the method of choice to identify proteins. The masses of the tryptic fragments in a sample are accurately and quickly measured using a matrix assisted laser-desorption/ionization time-of-flight (MALDI-TOF) instrument. In this technique, purified or partially purified proteins are mixed with a crystal-forming matrix, placed on an inert metal target, and subjected to a pulsed laser beam to produce the phase ions that traverse a field-free flight tube. They are then separated according to their mass-dependent velocities. The mass peak list obtained is searched by means of in silico digest of sequence databases for comparison and identification of proteins.

EVALUATION

55.3.2 Performed Studies to Figure Out the Mechanism of Organ Toxicity by Proteome Analysis

The proteomic investigation has been applied to a series of compounds to examine the response of in vitro and in vivo models after exposure to toxicants. The main focus of these studies has been to understand the mechanism of their toxicity. In an attempt to develop a rodent liver proteomic toxicity database, Anderson and colleagues characterized the effect of a range of xenobiotics on protein expression in the liver (Anderson et al. 1996a). Using this database, it was possible to detect, classify, and characterize a broad range of hepatotoxins. Toxicoproteomics was the key tool used to gain new insights into the molecular mechanism involved in cyclosporine A (CsA) nephrotoxicity. The initial study reported by Steiner et al. (1996) investigated changes in the kidney protein pattern of CsA treated rats in order to determine the nephrotoxic mechanism of this drug. Using this proteomic approach, the investigators discovered an association between decreased calcium binding protein, calbindin-D 28 kDa, and CsA-mediated medullar nephrotoxicity (Aicher et al. 1998). Since these early studies, the potential of toxicoproteomics to identify protein changes associated with nephrotoxicity has

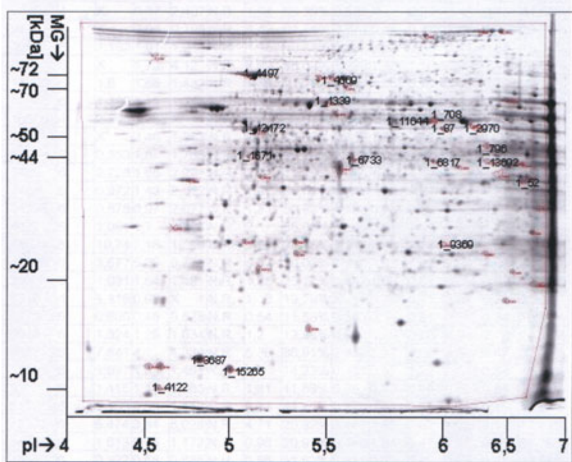

Fig. 55.5 Protein pattern of treated cells compared to control obtained after separation of 350 μg protein sample. Cells were exposed to 0.5 mM fenofibrate for 24 h. Spot IDs marks differentially regulated proteins

Table. 55.3 Identified proteins from rat primary hepatocytes involved in energy metabolism and electron transfer

Protein identification[a]	Molecular mass (kDa)[b]	pI[b]	Regulation
ATPase chain B, liver	51.35	4.95	Down
ATP synthase δ-chain	15.79	4.74	Down
NADH ubiquinone oxidoreductase	26.52	6	High
malate dehydrogenase	36.48	6.16	Down
NAD-specific isocitrate dehydrogenase	39.6	6.47	High
Enoyl-CoA hydratase	31.5	8.4	High
Aldehyde dehydrogenase	48.27	6.06	High
Guanidino acetate N-methyl transferase	26.4	5.7	High

[a]Peptide masses were identified in the positive ion reflector mode (MALDI-TOF) and protein identification was performed using the program MS-Fit
[b]Theoretical calculated pI and molecular masses

been shown in further investigative animal and clinical studies (Witzmann and Li 2004; Janech et al. 2007; Mischak et al. 2009; Klawitter et al. 2010). Data on H1 receptor antagonist, pyrilamine, and the non-genotoxic carcinogenic analogue, methapyrilene, showed differing proteomic profiles despite a similar chemical structure. Widespread changes in hepatic protein composition were observed for methapyrilene but not for pyrilamine (Cunningham et al. 1995). The proteomic approach further assisted numerous mechanistic investigations followed by explanation of regulatory changes implemented at the protein level. This included testing of pharmaceuticals for carcinogenic potential, hepatocellular hypertrophy, and peroxisome proliferation (Arce et al. 1998; Anderson et al. 1996b). The proteome profiling in these studies was partially used for lead prioritization, emphasizing the potential role for toxicoproteomics in lead candidate selection.

To investigate the significance of the 2-DE technology in determining changes in protein expression, Kabiri et al. (unpublished data) exposed rat primary hepatocytes to the peroxisome proliferator fenofibrate. Several important aspects of this study are discussed here. To investigate the proteome profile, we isolated and cultured primary hepatocytes in the presence of various concentrations of fenofibrate. To reduce the complexity, protein extracts were narrowed by prefractionation procedure and cytosolic fraction was collected for further analysis. After 2-DE separation, protein spots with an alteration in their abundance were excised and subjected to the MS. Figure 55.5 shows the 2-D pattern obtained after separation of 350 μg protein sample from treated cells as an example. When primary cells were treated with 0.5 mM fenofibrate over 24 h, a total of 30 protein spots were strongly affected. Some of these are summarized in Table 55.3. Many of the identified proteins are involved in cell proliferation, protein metabolism, and energy. In addition, proteins associated with defense reactions to cellular stress are expressed at high levels in response to fenofibrate exposure. These results are consistent with mRNA abundance as indicated in microarray experiments (data not shown). However, we detected expressed changes in protein, for which no changes at RNA level were measured. We have investigated the comparative effects of additional compounds on the rat primary hepatocytes and the results show the potential of toxicoproteomics to serve as a complementary technology to microarray-based approach.

CRITICAL ASSESSMENT OF THE METHOD

55.3.3 Alternative Proteomic Technologies and Options

Although 2DGE is unchallenged in its ability to resolve thousand of proteins, it has several limiting factors. Firstly, it is labor intensive, requires large quantities of proteins, and may not be suitable to serve as an effected diagnostic tool. Secondly, the application of 2DGE is limited because it fails to detect proteins at the extremes of separation either by size or by isoelectric point, and because it is insufficiently sensitive for low-abundant proteins (Moseley 2001). Therefore, additional innovative methods are needed to measure broad protein abundances and activity.

55.3.3.1 SELDI-TOF/Protein Biochips

SELDI-TOF is beginning to offer an alternative to 2DGE. Surface-enhanced laser-desorption/ionization (SELDI) is an affinity-based mass spectrometric method in which proteins of interest are selectively adsorbed to a chemically modified surface on a biochip (Weinbergera et al. 2002, Ciphergen Protein Chip® Arrays).

This system has already been used to identify markers of prostate cancer and changes in renal cell carcinoma. It also has been applied to the discovery of new toxicity markers (Grizzle et al. 2004; Jr et al. 1999; Paweletz et al. 2001; Vlahou et al. 2001). Taking advantage of the recent development in SELDI and the protein chip technology, it will be possible to simultaneously analyze protein profiles of body fluids such as serum and urine samples very rapidly. The SELDI mass spectrometry in conjunction with bioinformatics tools could greatly facilitate the discovery of new and improved toxicologic biomarkers (Collins et al. 2010).

Protein biochips (gel-based microarrays) represent a further development of proteomics technologies with the potential for screening of protein subsets. In this technology, proteins (mostly antibodies) are immobilized and trapped in gel-based matrices and thus are made accessible for target proteins. The combination with dye marker like fluorescence and chemiluminescence and detection of their signal intensities allows detection of protein modifications or deregulations. The gel-based protein chips can also be

combined with MALDI-TOF MS to achieve a specific analysis of protein subclasses (Rubina et al. 2003; Rubina et al. 2008).

55.3.3.2 ICAT

A recent and exciting development by Aebersold and colleagues is the isotope-codes affinity tag (ICAT) method, which can be used to label proteins before separation (Gygi et al. 1999). By using two different isotopes for labeling, it is possible to perform a binary comparison in a single step. After labeling, test and control samples are pooled and digested with proteases to produce peptide fragments. ICAT-labeled peptides are separated and analyzed by tandem MS. Due to the fact that the ICAT method is designed to combine labeling, separation, and the analysis of peptides into a single automated procedure, it is possible to scan several thousand peptide pairs a day.

55.3.4 Phosphoproteomics and Detection of Posttranslational Modifications

Proteomics is complicated by the fact that the absolute quantification does not always reflect the molecular function of proteins, because protein activities are highly regulated posttranslationally. Posttranslational modifications modulate the function of proteins and thus directly impact their capacity to participate in cellular regulatory events (Cravatt and Sorensen 2000). Due to posttranslational modifications, the numbers of proteins in human are estimated to be at least three times the amount of genes. Therefore, the elucidation of protein posttranslational modifications is the most important justification for biochemical and structural relationships. Hence, these modifications need to be evaluated.

However, establishing a proteomics platform initially requires implementation and combination of a series of systems to allow a flexible and reliable approach for analysis and identification of differences observed on 2-D gels. Proteomics in this sense is more interdisciplinary, combining aspects of biology, chemistry, toxicology and pharmacology, bioinformatic and information sciences. Use of bioinformatics is essential for analyzing the massive amount of data generated by proteomics.

The throughput of proteomics is currently much lower than that of RNA microarrays, largely due to the requirement of MS analysis, or similar technologies. However, the microarray-based approaches of protein detection may overcome this limitation.

While the combination of 2DGE with protein analytic techniques has been established for toxicoproteomics, the integration of bioinformatic and appropriate software is yet to be implemented.

For toxicoproteomics, the ideal proteomics platform would be one that is:

- Sensitive enough to detect high- and low-abundance proteins
- Easily implemented and performed quickly
- Able to detect modifications and alternative splice forms in addition to abundance
- Able to deliver sophisticated data for protein-protein networking

There are many obstacles to overcome in regard to current limitations of toxicoproteomic technologies. Thus, in the near future, proteomics will play an important role in the research toxicology.

MODIFICATIONS OF THE METHOD

55.3.5 Subcellular Proteomics

One-step characterization of a eukaryotic cell proteome is difficult if not impossible to achieve. There is a growing trend in eukaryotes proteomics toward characterization of subcellular and organellar structures. The reason for this shift from global proteomics to subcellular proteomics is the complexity of eukaryotic cells and subcellular organelles. Therefore, the proteomic analysis of subcellular organelles will be an important aspect of toxicoproteomics (Lee et al. 2010; Gatto et al. 2010).

55.4 Metabonomics

Metabonomics, or "metabolomics" or "metabolic profiling" as it is often mentioned in the literature, is closely related to the other "-omics" technologies toxicogenomics and toxicoproteomics, linking genotype to phenotype. This is also reflected by the most cited definition of metabonomics that was published in 1999 as "the quantitative measurement of the dynamic multiparametric response of living systems to pathophysiological stimuli or genetic modification" (Nicholson et al. 1999). Therefore, metabonomics means the investigation of endogenous metabolites in biofluids or tissues and the changes on this system caused by different factors such as drug treatment, environmental influences, nutrition, lifestyle, genetic effects, or diseases. Metabonomics has become increasingly popular in drug development, molecular medicine, and other biotechnology fields, since it profiles directly the phenotype and changes therefore in contrast to other "-omics" technologies (Dieterle et al. 2011). It is also often described as the analysis of the "metabolic profile" or "metabolome," which is defined as all small, nonprotein metabolites with molecular weight not more than 1,500–2,000 Da, estimated up to several thousand different molecules. Therefore, analytical technologies for metabonomics are faced with the challenge to analyze all these chemically diverse high and low molecular weight molecules in a wide variety of different concentrations simultaneously. There are various technologies capable to analyze these metabonomics samples, including nuclear magnetic resonance Spectroscopy (NMR) and mass spectrometry coupled with liquid chromatography (LC-MS) or gas chromatography (GC-MS), which will be described later in this chapter. Metabonomics investigations can be performed by the principal approaches of global or targeted metabonomics analysis. In global metabonomics analysis, all the changes on the metabolic profile, measured by the different analytical technologies, are analyzed by statistical methods followed by an identification of the changed analytical signal with the help of databases with known endogenous metabolites. In targeted metabonomics analysis, the changes of a predefined subset of known endogenous metabolites of interest are quantified in the analyzed samples for which no statistical analysis and good databases are needed which is often crucial in metabonomics analysis.

55.4.1 Nuclear Magnetic Resonance (NMR) Spectroscopy

PURPOSE AND RATIONALE

The principle of nuclear magnetic resonance (NMR) analysis is described in many publications (Ernst et al. 1990; Goldman 1991). For the acquisition of a NMR spectrum, a liquid sample is placed in a static magnetic field. After irradiation with high-frequency pulses (pulse-sequences), the response of the NMR sample is detected by an induced current. The highest field strength available today in NMR spectrometers is 21 T corresponding to 900 MHz ^{1}H (proton) frequency. Most applications in metabolic profiling are using 600 MHz (14.1 T) instruments.

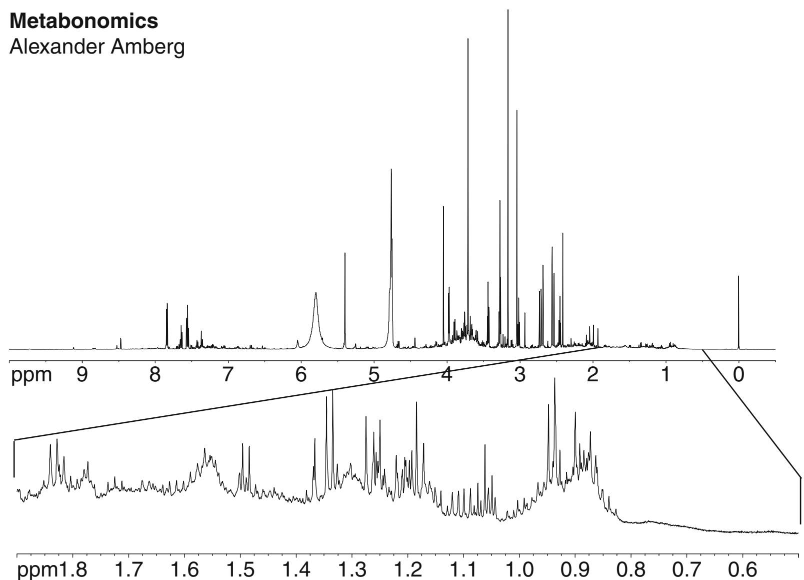

Fig. 55.6 Typical 600 MHz ^{1}H-NMR spectrum of rat urine after dilution with 10% D_2O buffer

The amplitude response of a NMR spectrometer is perfectly linear to the concentration of the sample, which allows easy quantification of compound concentrations for metabolic profiling in the μM to mM range. All steps involved in the acquisition and processing of NMR data, including preparation and exchange of samples, can be performed fully automated for hundreds of samples without the need for manual interaction (Dieterle et al. 2011).

PROCEDURE

With NMR it is possible to analyze all different kinds of liquid samples, including the noninvasively biofluids urine and blood (plasma or serum) but also many other biofluids like seminal fluid, amniotic fluids, cerebrospinal fluid, synovial fluid, etc. Organs, tissue, or cells can be analyzed after extraction of the endogenous metabolites using standard extraction methods (Lindon et al. 2006).

NMR analysis of biofluids needs no sophisticated sample preparation, details for the different biofluids are described by Lindon et al. 2000. In most cases, adding H_2O/D_2O (90:10) or buffer to account for pH variation or to reduce viscosity is sufficient as sample preparation before the NMR measurement (Keun et al. 2002). This means that one potential source of variance due to sample extraction procedures is absent (Dieterle et al. 2011).

The most used analytical technology in NMR metabonomics is ^{1}H proton spectroscopy of biofluids. For the analysis of these samples, water suppression techniques have to be applied, since endogenous metabolites can be present in low μM concentrations in an aqueous environment. Different water suppression techniques are available and described by Prince (1999). Additionally, blood serum/plasma samples or tissue extracts have high concentrations of macromolecules like proteins and lipoproteins, this means the NMR signals of these macromolecules have to be removed in the spectra by employing diffusion editing methods to avoid overlapping with NMR signals from the other endogenous metabolites (Dieterle et al. 2011).

After recording of the NMR raw data, the NMR signals (FID) are processed by application of the Fourier transformation (FT) followed by a phase correction and baseline correction to obtain the final NMR spectrum. A typical example of a 600 MHz ^{1}H spectrum of rat urine is shown in Fig. 55.6.

EVALUATION

The next step applied to the NMR spectra is the exclusion of spectral regions without interest in metabonomics. This includes the exclusion of the water region between 4.6 and 5.0 ppm, as this region does not contain any information due to the water suppression. In urine samples also, the urea is excluded because the amplitude of the strong urea signal is falsified due to proton exchange with water.

Small changes in the chemical shift of NMR signals can be caused by variations of the pH, salt

concentrations, overall dilution, etc. To reduce this effect for data analysis and interpretation, different mathematical methods can be applied. Normally the equidistant binning method is used for this, which is the integration of the signals in small spectral regions called "bins" or "buckets" of 0.04 ppm, for example (Dieterle et al. 2011).

To better identify the changes of a NMR signal in samples with varying concentration like urine, normalization methods of the quantified concentration have to be performed. Mostly, creatinine normalization is used for which each peak is divided by the creatinine signals at 3.05 and 4.05 ppm. The assumption behind this method is that the excretion of creatinine into urine is constant over time. Additionally, integral normalization is used very often for which each peak is divided by the total integral of all peaks. Alternatively also quotient normalization can be used for which each peak is divided by the corresponding peak of a reference spectrum (Dieterle et al. 2011).

The last and most important, but also often very time intensive step then is the assignment of the changed NMR signals of interest. This can be performed by reference spectra, many reference spectra are also available in different public and commercial databases (Dieterle et al. 2011).

CRITICAL ASSESSMENT OF THE METHOD

The inter-laboratory comparability of NMR data was tested for a set of samples shipped to different laboratories. Data were acquired with NMR spectrometers operated at different field strengths. Compared to any other analytical technology, NMR shows an impressive analytical reproducibility and repeatability reflecting itself in a coefficient of variation of 2% for a study invoking a large set of spectra (Goldman 1991). Thus, the observed variances in NMR spectra of a biological study are highly dominated by biological effects (Dieterle et al. 2011). This is also supported by other authors who see the main advantages of NMR metabonomics in the nonselectivity, lack of sample bias, and cross-laboratory/cross-platform reproducibility and in the good reference databases that are available for NMR. Some of the limitations are the lower sensitivity compared to mass spectrometry and the issue with the resolving of many different metabolites in the same region of a NMR spectrum (Keun et al. 2002; Robertson 2005; Lindon et al. 2006).

MODIFICATION OF THE METHOD

With the use of two-dimensional NMR techniques, more structural information can be extracted from the NMR spectrum, which can be used especially for the elucidation of an unknown structure of a newly found biomarker in a biological sample. But the use of 2D NMR in metabonomics is limited to small sample arrays as the measuring time is up to several hours per sample (Dieterle et al. 2011).

Intact tissue samples can directly be analyzed only by magic angle spinning (MAS) NMR without sample extraction. For this a small sample of intact tissue is placed into the spectrometer and is analyzed directly. But this technology requires specialized equipment and expertise for the conduction and is therefore used less often like the other technologies (Robertson 2005).

55.4.2 Liquid Chromatography: Mass Spectrometry (LC-MS)

PURPOSE AND RATIONALE

Other metabonomics technologies which are capable to analyze a complex mixture of molecules simultaneously include the separation of the different compounds by chromatographic methods, like liquid chromatography (LC) in combination with mass spectrometry (MS) used as detector. In LC analysis, liquid samples flow with a mobile phase at high pressure through a column that is packed with a stationary phase of different particles. In most metabonomics applications, a reversed-phase LC is used. The separation here is based on adsorption of the compounds on a nonpolar stationary phase followed by elution of the compounds as a result of the hydrophobic interaction with the mobile phase by using a gradient from a polar to nonpolar solvent. As a consequence compounds are eluted over time from the column based on their polarity with different retention times. These analyses are known as HPLC (high performance liquid chromatography) or UPLC (ultra performance liquid chromatography), which are using higher pressures that results in better separations. The opposite principle using a polar stationary phase and a gradient from a nonpolar to polar solvent is called normal phase LC. These approaches are known as HILIC (hydrophilic interaction liquid chromatography).

After LC separation, the compounds are analyzed and quantified by mass spectrometry (MS). For this the solvent that is coming from the column is vaporized, afterward the remaining compounds are ionized, and the charged molecules are accelerated and separated in electromagnetic fields according to their mass-to-charge (m/z) ratio. In most metabonomics investigations, electrospray ionization mass spectrometry (ESI-MS) is used as ionization method in negative mode (ESI−) or positive mode (ESI+).

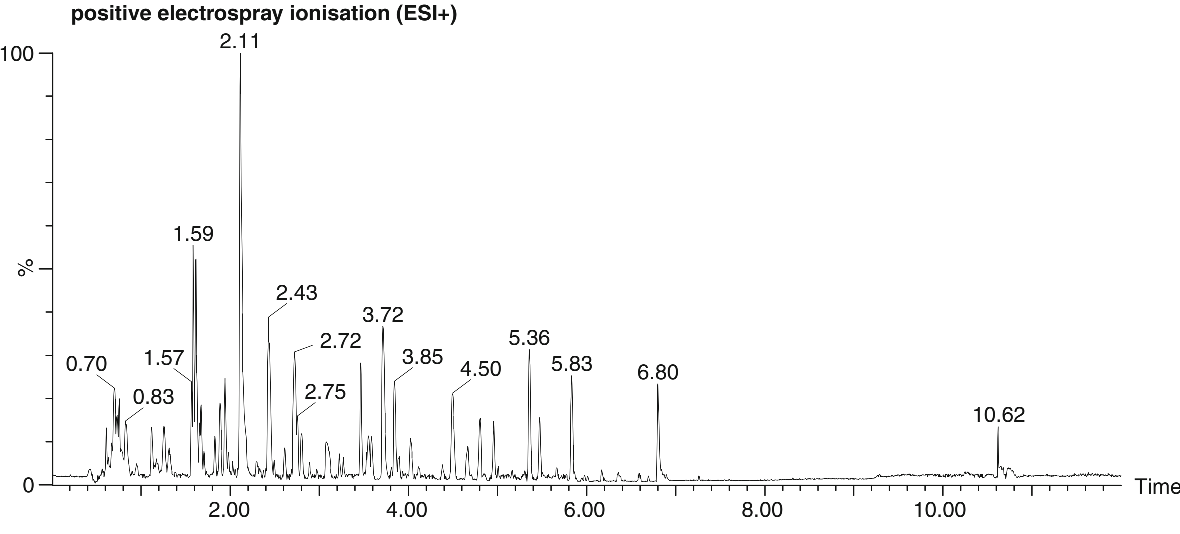
PROCEDURE

The samples which can be used for metabonomics LC-MS analysis are the same already described for NMR analysis. The analysis of the noninvasively biofluid urine can be challenging due to the high salt content, the complex composition, and the varying dilution. To overcome these problems, urine samples can be desalted before LC-MS analysis by solid phase extraction (Wagner et al. 2007) or column switching procedures (Waybright et al. 2006).

For the analysis of blood plasma or serum, it is of key importance to selectively remove proteins before analysis without affecting the low molecular weight metabolome. This is mandatory to reduce signal suppression of low-abundance compounds and to avoid protein precipitation under reversed-phase (RP) liquid chromatography conditions. Several procedures for deproteinization exist, such as extraction of low molecular weight compound by organic solvents, acids, or denaturation of proteins by heat (Want et al. 2006; Boernsen et al. 2005; Trygg et al. 2005). With regard to reproducibility, number of metabolic features detected, and robustness, extraction by methanol followed by evaporation and resuspension in the mobile LC phase proved to be the best method (Dieterle et al. 2011).

The most common method for metabonomics analysis is a reversed-phase LC (e.g., LC column packed with C_{18} particles) by using a water/acetonitrile (both with 0.1% formic acid) gradient as mobile phase (e.g., starting from 5% to 90% acetonitrile). As mass analyzers, mainly quadrupole- and time-of-flight (TOF)-based analyzers and hybrid forms of them are used (Dunn and Ellis 2005; Ackermann et al. 2006). Quadrupoles are robust, flexible, have a high linear dynamic range, but are limited in full-scan data acquisition due to long duty cycles. TOF instruments on the other hand have fast scanning capabilities, wide mass range, and high resolution. Quadrupole TOF (Q-TOF) hybrid instruments combine the stability and robustness of the quadrupole analyzer with TOF features and allow for MS-MS experiments (Dieterle et al. 2011).

Nontargeted metabolite profiling approaches require a sensitive full-scan mode and exact masses. Therefore, Q-TOF instruments or linear ion trap FT-MS instruments are advantageous. In contrast, for targeted analysis of selected metabolites, triple quadrupole instruments and Q TRAP instruments with their capability for multiple reaction monitoring are frequently used (Dieterle et al. 2011).



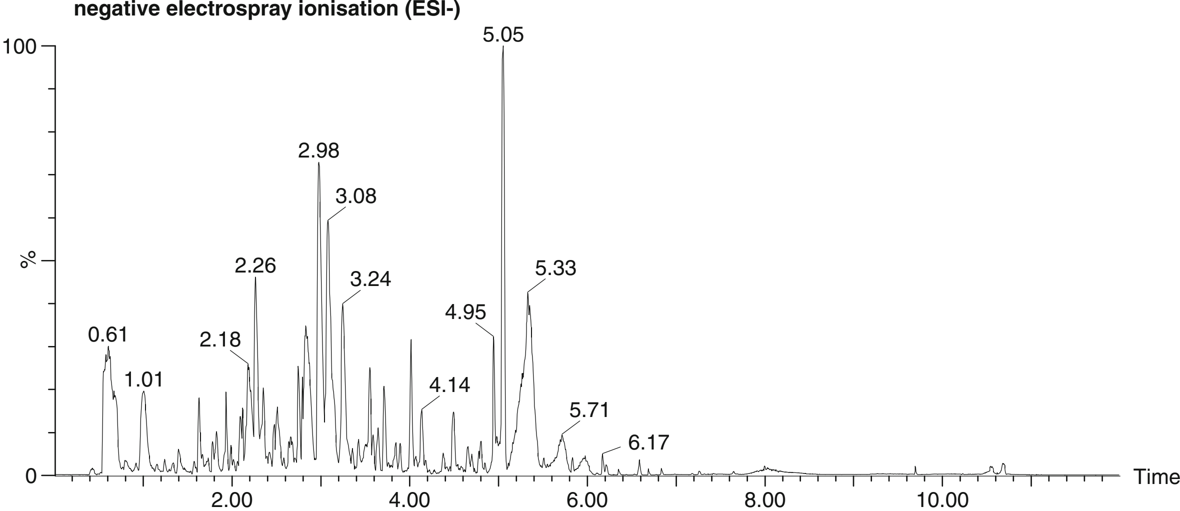


Fig. 55.7 Typical UPLC-TOF-MS chromatogram of rat urine with positive electrospray ionization (ESI+) and negative electrospray ionization (ESI−) after dilution of urine with water (1:3)

A typical example of an UPLC-TOF-MS chromatogram of rat urine is shown in Fig. 55.7.

EVALUATION

Full-scan LC-MS chromatograms contain many data (full mass spectra at the different retention times) from all the analyzed compounds in complex samples like urine, serum, or plasma. Therefore, an extraction of the relevant information (most expressed as m/z to retention time pairs) and de-noising from full-scan metabolic profiles is an important step in processing and statistical analysis of such LC-MS data. But a prerequisite for statistical analysis is to apply data alignment procedures and to reduce variance between samples that is not attributed to true differences. The major sources of such variances are nonlinear shifts in retention time, peak overlap, and m/z shifts. In general, three preprocessing strategies are used for LC-MS data sets. First, the spectra are aligned along the chromatographic and spectral axis. Then the dimensionality is reduced by binning or bucketing procedures. With the last step, significant peaks are automatically detected and quantified. Several commercial and open source routines for automatic

alignment, de-noising, deconvolution, and extraction of peak have been published and are reviewed by Katajamaa et al. (2007).

For samples with varying concentrations like urine, analogue normalization methods which are already described for NMR metabonomics analysis can be used.

Also in LC-MS metabonomics analysis, the last and most important step is the assignment of the changed LC-MS signals (m/z to retention time pairs) of interest with reference LC-MS spectra/chromatograms, which are also available in different public and commercial databases (Weckwerth and Morgenthal 2005; Dieterle et al. 2011).

CRITICAL ASSESSMENT OF THE METHOD

The main advantage of LC-MS metabonomics analysis is the better sensitivity with lower detection limits compared to NMR. This is very important in metabonomics analysis especially if novel biomarkers want to be identified. Other advantages are better resolutions by chromatographic separation of complex samples mainly for analysis of higher molecular compounds. As already described, some limitations of LC-MS metabonomics analysis are the potential for sample bias and the lower cross-laboratory/cross-platform reproducibility compared to NMR (Robertson 2005). But in summary, NMR and LC-MS approaches are highly complementary and use of both is often necessary for molecular characterization (Lindon et al. 2006).

MODIFICATION OF THE METHOD

HILIC (hydrophilic interaction liquid chromatography) as an alternative approach to reversed-phase LC was recently applied in metabonomics studies as a complementary tool to study polar metabolites (Idborg et al. 2005). However, until now, HILIC has not reached the level of reliability, stability, and reproducibility of HPLC or UPLC methods (Dieterle et al. 2011).

Also alternative mass spectrometer like ion traps, Fourier transform and Orbitrap instruments can be used in metabonomics analysis. Benefits of ion trap instruments are their capability to perform progressive fragmentation steps (MS^n), compact size, and fast full scanning but with low resolution. Linear ion traps quadrupole hybrid instruments (Q TRAP or QqLIT) combine the MS^n capabilities of ion trap instruments with the neutral loss and precursor ion scan capabilities of triple quadrupole instruments. Therefore, the shortcomings of both approaches are overcome.

55.4.3 Gas Chromatography: Mass Spectrometry (GC-MS)

PURPOSE AND RATIONALE

An alternative chromatographic method which can be applied for metabonomics analysis is the use of gas chromatography (GC) in combination with mass spectrometry (MS) as detector. In GC analysis, gaseous compounds from the samples are analyzed or compounds which are vaporized before analysis. The compounds to be analyzed flow with an inert carrier gas, such as helium or nitrogen, as mobile phase through a column. The stationary phase in the column is a microscopic layer of a liquid film of a polymer coated on the surface of the column, normally a nonpolar but sometimes also a more polar stationary phase. The separation of a complex mixture is based on the interaction of the compounds from the sample between the liquid stationary phase and the gaseous mobile phase by using a temperature gradient of the gas and column which is located in an oven. As a consequence compounds are eluted over time from the column with different retention times which is based primarily on their boiling point or vapor pressure but also on the interaction with the stationary phase.

After GC separation, the compounds are analyzed and quantified by mass spectrometry (MS). This is very similar to the previously described LC-MS analysis, including ionization of the compounds and acceleration and separation in vacuum of the charged molecules in electromagnetic fields according to their mass-to-charge (m/z) ratio. As the ionization method in GC-MS metabonomics investigations, typically electron ionization (EI) is used or chemical ionization (CI) as a softer alternative method with the help of a reagent gas like methane.

PROCEDURE

The samples which can be used for metabonomics GC-MS analysis are the same already described for NMR and LC-MS analysis. But since these are primarily very polar samples and the prerequisite for GC-MS is the analysis of volatile compounds, sample preparations methods have to be performed before analysis. This includes normally an extraction procedure that maximizes the number and amounts of the endogenous metabolites combined with a derivatization that converts polar compounds (e.g., sugars, amino acids, organic acids, etc.) into volatile compounds (Dieterle et al. 2011). Most extraction procedures are based on methods from Bligh and Dyer's (Bligh and Dyer 1959; Peña-Alvarez et al. 2004) with little variations and optimization combined with 2-stage derivatization methods (Gullberg et al. 2004; Schröder et al. 2003). In the first step, a methoxymation converts aldehyde and keto groups into oximes using hydroxylamines or alkoxyamines to reduce the number of tautomeric forms (due to the limited rotation along the C = N bond). The second step of silylation then derivatizes polar functional groups (e.g., −OH, −SH, −NH) into trimethylsilyl groups (TMS ethers, TMS sulfides, TMS amines) resulting in more volatile compounds (Dieterle et al. 2011).

After this sample preparation, GC analysis is normally performed with a nonpolar column (e.g., DB5-MS with 0.18 μm film column) by using a temperature gradient typically from 70°C to 320°C with an increase of 15°C/min and a flow of 1 ml/min of the carrier gas helium. The mass analyzers in GC-MS are analogous to the previously described LC-MS mass analyzers, this means mainly quadrupole- and time-of-flight (TOF)-based analyzers are used.

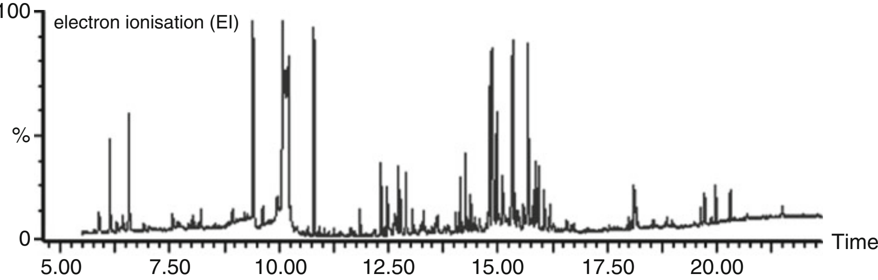
As ionization methods in GC-MS, an EI or CI can be used depending on the results that are favored. With EI ionization, the molecules break down into different fragments that give some structural information of the molecules. On the other hand, CI ionization is a less energetic process and often results in less fragmentations and the formation of the molecular ion species to access the mass of the molecules (Dieterle et al. 2011).

A typical example of a GC-TOF-MS chromatogram of rat urine is shown in Fig. 55.8.

EVALUATION

Full-scan GC-MS chromatograms have the same format and are in principle the same like LC-MS chromatograms, they differ only in the chromatographic method that was used. Therefore, the same processing, normalization, and assignment methods previously described for the evaluation of LC-MS chromatograms are valid and are used for GC-MS chromatograms.

For GC-MS, reference spectra/chromatograms are also available in different public and commercial databases (Dieterle et al. 2011).



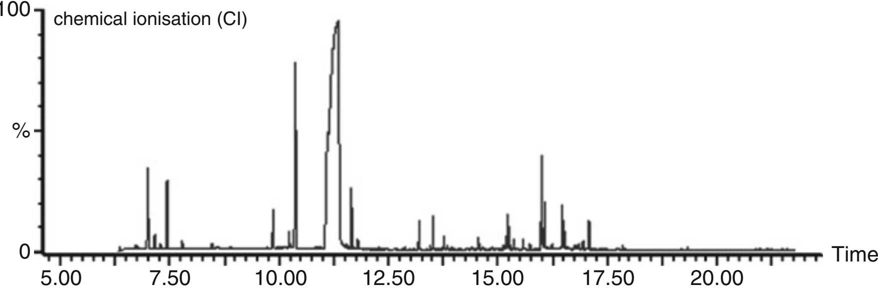


Fig. 55.8 Typical GC-TOF-MS chromatogram of rat urine with electron ionization (EI) and chemical ionization (CI) after extraction and silylation derivatization of the urine

CRITICAL ASSESSMENT OF THE METHOD
All advantages and limitations which were already described for the LC-MS analysis are also valid for metabonomics analysis with GC-MS compared to NMR. Further advantages are that GC-MS analyses show no problems with ion suppression of co-eluting compounds as observed in LC-MS analysis. Also, the assignment of the identity of peaks via a database of mass spectra is straightforward, due to the extensive and reproducible fragmentation patterns obtained in full-scan mode. Further limitations of GC-MS analyses exist for thermally labile compounds at the temperatures required for their separation or for compounds that are not volatile at all. Also since most endogenous metabolites in metabonomics analysis contain polar functional groups and are therefore less volatile, additional sample preparation steps of derivatization prior to GC-MS analysis are needed in most analysis to extend the application range of GC-based methods (Koek et al. 2011). But in summary, also GC-MS approaches are highly complementary to NMR and LC-MS approaches and the use of all the different technologies is often necessary for molecular characterization (Lindon et al. 2006).

MODIFICATION OF THE METHOD
Besides normal GC-MS also two-dimensional GC×GC-MS techniques can be used to increase the resolution of peaks in complex mixtures (Shellie et al. 2005; Van Mispelaar et al. 2003). Many different columns are available for GC analysis with different stationary phases, common GC columns are packed, for example, with different polysiloxane, polyethylene glycol polymers, resulting in columns with different polarities and other different characteristics.

Modifications in the mass analyzers which were already described for LC-MS analysis are also valid for metabonomics analysis with GC-MS (Weckwerth and Morgenthal 2005; Dieterle et al. 2011).
