In principle, all hormones can be determined from pituitary homogenates. Specific RIA methods are available from several suppliers (see “Internet Resources”), and hormone assays may also be performed using reagents of the National Pituitary Program, USA. For the reproductive system of rats, species-specific reagents and assays are available, as well as some cross-reacting RIA methods based on hormones of others species. Make sure that in the analytical department, there is some prior experience with rat hormone determination, to avoid problems of assays designed for other species. Contents of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are to be determined; prolactin (PRL) and growth hormone (GH) are optional depending on the known pharmacology profile of the test compound. These hormones may change due to target organ effects of the test compound, in particular due to estrogenic effects or to stimulation of estrogen secretion.

Testes, Prostate, and Epididymis

Determine testis weight and histology. There are several methods for obtained additional information about the mechanism of observed changes in androgen biosynthesis.

The tissue content of the testis can be analyzed by several methods for androgens, for example, high-performance liquid chromatography (HPLC), specific RIA or ELISA for testosterone and progesterone, and HLC analysis of testosterone precursors in the biosynthetic pathway (Sanderson 2006).

MODIFICATIONS OF THE METHOD

There are a number of interesting options to include investigation of biological samples of the male gonadal system from a targeted repeated-dose study. Receptors for FSH and LH in the testis may be determined for specific investigations targeted at Sertoli cell and Leydig cell function. The risk assessment

information provided by this determination is useful in mechanistic studies. Incubation of the testis ex vivo with human chorionic gonadotropin (hCG) is of considerable importance, and biosynthesis of androgens may be assessed by measurement of the incubation media.

The ventral prostate may be dissected in rats in order to obtain tissue for investigation of nuclear receptors (Gaston et al. 2002); similar investigation may be carried out with the epididymides (Robaire and Hamzeh 2011). The receptor for luteinizing hormone and chorionic gonadotropin (LHCG-R) has been studied extensively and may be measured in gonadal tissue (Christin-Maitre and Bouchard 1996; Hakola et al. 1997) in the context of evaluating biosimilar preparations of human recombinant luteinizing hormone and derivatives. Interestingly, non-peptide ligands of the LHCG-receptor have also been explored (Heitman et al. 2009).

Specific relevance for the assessment of changes observed in the pituitary glands of rats in long-term toxicology studies (Sandusky et al. 1988; Jameson et al. 1992; Brown et al. 1993) is attributed to measurement of pituitary hormone contents after repeated-dose treatment. Even though the formation of pituitary tumors in rat toxicology is of limited clinical relevance when epidemiology studies are compared (Tucker 1999; Gopinath 1999), questions for translational relevance may be investigated.

CRITICAL ASSESSMENT OF THE METHOD

The application of methods to the assessment of endocrine safety pharmacology depends on trends in research and development. Hypothalamic hormones, their agonists, and antagonists have been an active area of clinical development for considerable time, the LHRH antagonists had safety problems of histamine release, the desensitization of gonadotropin secretion by continuous infusion and controlled release required a number of mechanistic studies, and direct actions on the ovary and testis were explored to understand and differentiate mechanisms of action in oncology. Endocrine safety pharmacology of the new gonadotropin preparations is an ongoing task; there are biosimilar products and closely related derivatives to be characterized. In the field of new gonadal steroid derivatives, there are numerous new developments which may require mechanistic studies. The endocrine profile is a valuable step toward clinical studies because the extensively characterized interaction with nuclear receptors needs to be supplemented by evidence for the biological system effects (Riggs and Hartmann 2003). There are striking similarities in the methods for evaluation of environmental and industrial chemicals (EPA program) to characterize the toxic effects of endocrine disruptors (Whitehead and Rice 2006) and explore their level of risk at concentrations found in the environment (endocrine disruptors with hormonal activity).

14.3.1.2 Testis Incubation and Androgen Biosynthesis

PURPOSE AND RATIONALE

Androgen biosynthesis (secretory capacity for androgen precursors and testosterone) is assessed by incubation of the testis in vitro with hCG 250 mU for 3 h.

PROCEDURE

The testes of each rat were decapsulated and gently washed in tissue culture medium (TCM) 199 (Sigma biochemicals #M 2154) previously gassed with carbogen (95% O_2, 5% CO_2). Each decapsulated testis was transferred into a 20-ml glass vial containing TCM 199 at +35°C and preincubated for a minimum of 10 min in a temperature-controlled water bath (+35°C) with shaking at 80 cycles per minute. After 10 min, the incubation medium was removed and replaced with 6 ml of pregassed TCM 199 at +35°C containing 250 mU hCG (Sigma biochemicals CG5, 5,000 IU/vial). Throughout the incubations, each vial was continuously gassed via a plastic tube, with carbogen (3 L per min supplied to 8 vials). After 3 h, the incubation was terminated by removing the vials from the incubator, decanting the incubation medium into refrigerated test tubes, and transferring the testis tissue to separate vials. The incubation medium and testis tissue were stored frozen at −20°C for subsequent steroid hormone assays.

EVALUATION

The steroids in the incubation medium and in the tissue are determined (testosterone, progesterone, 17-OH-progesterone, delta-4-androstenedione). Steroids measured in medium and tissue may be testosterone (testo), progesterone (prog), 17alpha-OH-progesterone (17a-OH-prog), delta-4-androstenedione (4-A-dione),

and estradiol-17beta (E2). Testosterone and progesterone in unextracted media and ether extracts of testicular homogenates can be determined by radioimmunoassays (RIA). The steroids 17a-OH-progesterone, 4-alpha-androstene-dione, and E2 can be measured by specific 125-I-RIA methods using commercially available reagents and procedures suitable for steroid hormones without prior extraction ("Internet Resources").

Group means are calculated, and the significance of differences between groups is assessed by analysis of variance and appropriate tests of significance.

CRITICAL ASSESSMENT OF THE METHOD

Testis incubation is a valuable and flexible approach to risk assessment, which can be applied ex vivo, in repeated- dose studies for clarification of mechanisms of action, and as part of subacute toxicology studies. The immediate processing of the decapsulated testis is an advantage when compared with the assays based on an enzymatic dispersion of Leydig cells.

14.3.1.3 Testosterone Secretion In Vivo

The stimulation test can be performed as a single-dose test in rats during the treatment period, preferably 3–4 days before the end of the study, or as a single-dose test in separate groups of animals. Stimulation of testosterone in rats can be indirect via the release of luteinizing hormone by injection of LHRH (gonadorelin) or an LHRH agonist (e.g., buserelin at an equipotent dose). This stimulation test can be combined for the measurement of FSH, LH, and testosterone after a single dose of LHRH injected subcutaneously in conscious rats, or by infusion of LHRH for in rats during anesthesia. Another possibility is to stimulate testosterone secretion directly in conscious rats by the injection of hCG. These stimulation tests are similar to the procedures used in clinical pharmacology.

CRITICAL ASSESSMENT OF THE METHOD

The ex vivo assessment of steroidogenic capacity after repeated-dose treatment is much preferred when compared with the options of in vitro incubation of Sertoli cells to assess FSH-related effects (Wang 1988; Reichert and Dattatreyamurty 1989; Sairam and Krishnamurthy 2001; Heckert and Griswold 2002; Moffit et al. 2007; Hermann and Heckert 2007) or Leydig cells (Steinberger and Klinefelter 1993).

14.3.1.4 Female Reproductive System

For reproductive organ weight and histology, dissect out and determine weight of the ovaries and uterus, and take tissue samples of the mammary gland (optional). For any specific investigation of cell proliferation (biomarkers), satellite groups are added. This is especially important for investigation of the mammary gland.

Preparation of hypothalamic and pituitary tissue and storage for assay is identical with the procedures for male animals.

Ovaries

There are all many possibilities for a detailed investigation of ovarian function (Findlay 1994). The problem for safety pharmacology is the complexity of ovarian function and the species-specific details which often preclude translational predictions for clinical pharmacology. Many aspects are covered in reproduction toxicology (Neubert et al. 1999), however, without reference to changes in nuclear receptor function or steroid biosynthesis. For details of classical bioassays, consult the chapter on endocrinology (Vogel 2008c). Binding capacity of gonadotropin receptors can be added to the morphological investigation of follicular function and corpus luteum formation, with limited gain of information. In the context of endocrine safety studies, the results of segments I–III on reproduction and fertility in the regulatory toxicology protocol should be considered before deciding on any specific investigation of rat ovarian function, including vaginal cytology. Interpretation of these findings is difficult, and relevance for the clinical situation is limited.

Mammary Gland

For the evolution of histological findings, measurement of pituitary prolactin concentrations should be considered as well as inclusion of proliferation biomarkers (Ki67).

EVALUATION

For all quantitative parameters, group means are calculated, and the significance of differences is assessed by at the appropriate statistical methods. Histology may be reported either in descriptive terms or evaluated by a semiquantitative methods (histomorphometry), to provide quantitative information suitable for statistical analysis. Specific add-on methods in molecular biology of in situ hybridization and gene expression need to be considered.

MODIFICATIONS OF THE METHOD

The investigation may be restricted to female or male animals of reproductive age, targeted to prepubertal rats or to specific age groups (Sect. 14.7.2). The important component is sufficient duration of treatment of at least 2 weeks, preferably 4 weeks. Histology of the reproductive tract is essential; vaginal cytology is time consuming but may contribute. Application of ex vivo investigation (cell proliferation, in situ for hybridization, spectrum of gene expression) adds to the complexity and should be considered when the primary investigation of histology warrants detailed follow-up.

CRITICAL ASSESSMENT OF THE METHOD

The repeated-dose study of at least 14 days is an essential and recommended element in safety pharmacology, with flexible inclusion of biomarkers of endocrine function (e.g., gonadotropin receptors, nuclear receptors, steroidogenic enzymes, and proliferation markers) if the initial findings warrant follow-up by an animal study. Many endocrine effects require exposure for 14–28 days to become detectable. For any translational prediction, it is helpful to have the confirmation of a distinct weight change or a histological change in addition to the observed change of biomarkers.

Suitable modifications of this method are required for all unexpected findings concerning reproductive function in the regulatory toxicology study and in reproduction toxicology. Testing of a new compound with classical bioassays is nowadays very unusual, due to the availability of many short-term in vitro tests for receptor affinities and receptor signaling. It is therefore recommended to look for biological expression of any hormone activity predicted from early toxicology, receptor screening, and structure activity information. Frequently, unexpected effects on the reproductive system are observed in the toxicology studies in rats and dogs, requiring an explanation in relation to the predicted therapeutic dose range and supraphysiological dose selection, to confirm selection of an appropriate dose range in regulatory toxicology and to include targeted investigation in the early clinical pharmacology program.

It is advisable to investigate the reason and mechanism for the observed changes (with supraphysiological dosing), enabling prediction of the

relevance for the proposed clinical indication. There are certain areas where the prediction is very limited, for instance in relation to human reproductive function when changes in the estrous cycle of rats of observed, due to interference with luteal function. Any observation of dose-related endocrine interference is valuable for the risk assessment, concerning clinical pharmacology and future indications which are presently not considered.

The exploration of ovarian-testicular function is sometimes done in prepubertal and in young rats (Davis et al. 2001; Marty et al. 2001). Monitoring of the estrous cycle by vaginal cytology is important but rarely included in a standard protocol, as well as steroid hormone contents in relation to the estrous cycle. In all mechanistic studies, all rats should be sacrificed at the same stage of the estrous cycle. This is impractical in routine toxicology studies. Weight of the uterus and ovaries frequently indicates endocrine disruption at the pituitary or gonadal level (Owens and Ashby 2002).

Testing in animals before puberty (immature rats) often reveals pituitary-gonadal activities more readily than testing in adult animals (Kim et al. 2002). The use of in vitro methods (receptor binding, cell lines) is still burdened by many problems of interpretation of the results. The biological relevance of receptor data needs to be confirmed in each case by bioassay (Rogers and Denison 2000; Beresford et al. 2000; Fang et al. 2000). These methods are an advantage only when compounds are selected at an early stage, not for safety pharmacology and risk assessment of advanced compounds. Histology of the uterus is very important; it reflects the classical bioassay findings for estrogenic and progestational activity. Ex vivo studies with short-term incubation of ovaries are conceivable but have not been frequently investigated. Their purpose would be information on steroid biosynthesis, at specific times of the estrous cycle.

In female rats, measurement of steroid hormones is less useful due to the precise reflection by histology (publication) and the rapid fluctuations during their estrous cycle. Pituitary hormone contents are more reliable and informative. At autopsy, the neurohypophyseal part (posterior pituitary) is discarded, and the anterior pituitary is bisected to provide one-half for histology and the other half for measurement of hormone tissue content, which changes often in a dose-related manner, whereas it is difficult to quantitate the histological changes in the pituitary gland by histomorphology. LHRH (GnRH) stimulation tests are recommended near the end of each study, by a subcutaneous injection of 0.1 μg/kg measuring the LH and FSH concentrations 60 min later. These tests can also be performed once per week during the study without compromising the end result.

Basal LH and FSH concentrations may be measured 2 h after medication with the test drug or 24 h after medication. Changes are often more readily detected shortly after medication, and pharmacokinetics of the test drug should be the basis of decision for selecting the time point. In general, measurement of LH is the more sensitive parameter; hypothalamic LHRH content is rarely useful for diagnosis. Pituitary prolactin content 24 h after last medication and mammary gland histology need to be included for specific classes of drugs; the prolactin stimulation test can be performed by oral administration of monoiodotyrosine (MIT) 1 mg/kg with serum prolactin determination 20–30 min later.

In male rats, weight changes of the testes and androgen-dependent organs (seminal vesicles, ventral prostate, levator ani muscle) readily detect interference with androgen biosynthesis and secretion (Leydig cell function). The effect on spermatogenesis and Sertoli cell function is readily detected by histology but difficult to quantitate. Before going to detailed histomorphology, effects on pituitary hormones should be evaluated by measuring the tissue content of LH, FSH and prolactin (as in females), the serum concentration of testosterone, and the testosterone content in testis tissue. It is advisable to use one testis for steroid hormone analysis and the contralateral testis for histology. When there are indications for an effect on androgen biosynthesis, the testis can be studied ex vivo by incubation with human chorionic gonadotropin (pattern of androgen biosynthesis), including tissue contents at the end of the incubation period. Leydig cells isolated by collagen dispersion may also be able to perform similar stimulation tests.

In order to assess pituitary function, inclusion of the LHRH stimulation test for LH and FSH is recommended for female rats, and the monoiodotyrosine (MIT) stimulation test for prolactin secretion is recommended at least for the female animals. Pituitary content of LH, FSH, and prolactin should always be determined at autopsy (half of the pituitary for hormone assays and the other half for histology).

In our experience, many examinations described here for the rat can also be performed in dog toxicology studies, the major limitation however being the small number of animals per group in the regulatory dog studies.

Any detailed examination on intrauterine development, sex differentiation, and pubertal development is beyond the scope of this discussion. Highly specialized methods need to be applied, and there is usually no indication for such effects from the early regulatory toxicology studies (28 days in rats and dogs). The special aspects of toxicological findings with xenobiotics have been reviewed for the female reproductive tract by Creasy (1999) and for the male reproductive tract by Newbold (1999). There is now an extensive body of evidence for the interference of industrial chemicals and xenobiotics with gonadal steroid biosynthesis (Whitehead and Rice 2006) as well as studies on classical reference compounds such as androgens, antiandrogens, estrogens, and antiestrogens.

14.3.1.5 FSH Receptor Binding and Effect on FSH Receptors

PURPOSE AND RATIONALE

This evaluation can be performed as a single-dose in vitro test using, for example, cell membranes containing FSH receptor or as an ex vivo test measuring the concentration of FSH receptors in organ tissue of treated animals, after a suitable treatment period of at least 7 days. The application of ex vivo testing for gonadal tissue is an interesting extension of repeated-dose studies where changes in the target tissue need to be quantitated. The method is applicable to studies of ovarian function.

PROCEDURE

Membrane preparations from bovine testes are used according to the methods of Cheng (1975) and Andersen et al. (1983). Fresh bovine testes or testes from rats weighing 220–280 g are decapsulated and rinsed with cold 0.025-M Tris-HCl buffer at pH 7.2, containing 0.3-M sucrose, and then minced and homogenized with a Polytron homogenizer at maximum speed for 30 s at a concentration of 5-ml buffer per g of tissue. The homogenate is first filtered through four layers, and the filtrate is again filtered through eight layers of cheesecloth. The filtrate is then centrifuged at 12,000 g for 30 min at 4°C. The pellet is discarded, and the supernatant is further centrifuged at 100,000g for 1 h at 4°C. The supernatant is discarded and the pellet resuspended in cold 0.025-M Tris-HCl buffer at pH 7.2, containing 10-mM $MgCl_2$, at a concentration of 1-ml buffer per g of the original weight of the testis. The isolated membranes are stored at −70°C in aliquots of 10 ml per vial until use.

For assays, 12/75-mm glass disposable tubes are used. To each tube, 0.2 ml of 0.025-M Tris-HCl buffer at pH 7.2, containing 10-mM $MgCl_2$ and 0.1% BSA, 0.1 ml of standard FSH or unknown samples in the same buffer, 0.1 ml of ^{125}I-hFSH tracer labeled by the lactoperoxidase method (50,000 cpm, approximately 2 ng), and finally 0.1 ml of plasma membrane receptors of appropriate dilution (approximately 1–2 mg/ml) are added to reach a final volume of 500 µl per tube. The tubes are then shaken vigorously and

incubated at room temperature for 20 h. Following incubation, the reaction is stopped by adding 3.0 ml of cold 0.025-M Tris-HCl buffer containing 0.1% BSA. After centrifugation at 4,000 rpm for 30 min, the supernatant is drained. The pellet remaining at the bottom of the tube is counted in an automatic gamma counter.

EVALUATION

Specific binding to the testicular receptor (pellet) and nonspecific binding (nondisplaceable by 1,000-fold excess of unlabeled hFSH) are determined. The specific binding of 125I-hFSH in the presence of a range of standard hFSH concentrations is used for calculating a standard curve, and the sample concentrations are calculated from the FSH receptor standard curve, using suitable computer programs.

MODIFICATIONS OF THE METHOD

For the use in safety pharmacology, selection of a specific method for determination of the FSH receptor concentration is not important; however, biological validation of the method is very important. In reference experiments, the effect of a preceding treatment on the concentration of FSH receptors should be detected, for example, reduction in receptor concentration after inhibition of gonadotropin secretion.

CRITICAL ASSESSMENT OF THE METHOD

Significant differences between biological activity and receptor-binding activity of FSH preparations have been found by Marana et al. (1979), Zaidi et al. (1981), Foulds and Robertson (1983), and Burgon et al. (1993). This is attributed to the assay principle of measuring binding activity, but not subsequent intracellular signaling. Several receptor-binding assay procedures have been described, for example, Cheng (1975), Andersen et al. (1983) using bovine testes, and Reichert (1976) using rat testes tubule tissue. Interpretation of the relevance of toxicology findings in the pituitary gland (Tucker 1999), testis (Sikka 1999), comparative carcinogenesis (Gopinath 1999), and relevance for regulatory reproduction toxicology (Neubert et al. 1999) is often plausible due to defects and adaptive changes found in the 4-week treatment protocol; in some cases, longer treatment periods may be needed as well as inclusion of assessment of reversibility by extending the studies.

14.4 Hypothalamic-Pituitary-Adrenal System

Safety pharmacology of the adrenal glands is related to effects on the secretion and synthesis of glucocorticoids (Harvey 1996; Harvey et al. 2007; Harvey and Sutcliffe 2010) and mineralocorticoids (Funder 2009; 2010). In the rat toxicology studies, effects on the adrenal medulla are rare, and there is an incidence of spontaneous pheochromocytoma (Tucker 1996) not found in humans. The morphological and histological toxic reactions of the adrenal glands have been characterized (Hinson and Raven 1996, 1999; Greaves 2007a; Harvey et al. 2007; Jones 2009). The primary task in safety pharmacology is to assess whether a drug candidate can induce changes in the biosynthesis and secretion of adrenal steroids, for example, by noninvasive monitoring of adrenal steroid excretion or by dynamic tests of ACTH responsiveness (ACTH challenge).

A significant number of drugs and industrial chemicals which have toxic effects on the adrenocortical function have been evaluated in the context of programs on endocrine disruptors, for example, in several steps of the OECD 407 method development (Lahiri and Sircar 1991; Hinson and Raven 2006) and in many related in vitro studies (Molina-Molina et al. 2006; Sanderson 2008; Parmar and Rainey 2008; Parmar et al. 2008; Ziolkowska et al. 2006; Wang et al. 2012).

14.4.1 Introduction

The methods described here are applied for supplemental safety pharmacology studies (ICH S7A), if the test substance has shown indications of effects on the hypothalamic-pituitary-adrenal system in the preceding pharmacology studies. This includes effects in receptor profiling and enzyme profiling directed at, for example, the glucocorticoid receptor (GR), the mineralocorticoid receptor (MR), and characteristic steroidogenic enzymes (Wilkinson et al. 2008). The biological evaluation may also be needed as a final step of risk evaluation. There are many toxicological observations related to the unexpected interference of drugs with adrenocortical function (Ribelin 1984; Mann 1996). There are protocols for clinical assessment (Weiss and Patel 2002; Babic et al. 2011) related to adrenocortical activation by compounds with direct action on steroid biosynthesis and to suppression of adrenal steroid secretion with compensatory hypothalamic-pituitary feedback effects (Harvey and Sutcliffe 2010) masking the adrenal cortical atrophy. Several reference compounds are available for comparison and for clinical reference, for example, ketoconazol, etomidate, trilostane, and the antiglucocorticoid/antiprogestin mifepristone (Potts et al. 1971; Potts and Jüppner 2008; Albertson et al. 1994; Loose et al. 1983; Lambert et al. 1986; Weber et al. 1993; Thomas and Thomas 1999), including recent studies on industrial chemicals, for example, fungicides (Molina-Molina et al. 2006) assessed by steroid receptor profiling. Receptor profiling of NCEs is valuable in the early selection of lead compounds and profiling of candidates (Ojasoo et al. 1988; Jiang et al. 2010). The relevance of adaptive changes in the S7A d guideline has been reviewed (Valentin et al. 2005), with reference to assessing the capability of models to predict adverse events in humans. Based on recent clinical experience, this may be considered in the context of the need for preclinical evaluation of aldosterone secretion, referring to unexpected effects on inducing hypertension and cardiovascular complications in the clinical evaluation of the CEPT inhibitor, torcetrapib (Hu et al. 2009; Funder 2009; Johns et al. 2012). The related mechanistic studies (Funder and Mihailidou 2009; Funder 2010) on the effects of the compound on aldosterone secretion raised questions and provided explanations, also giving directions for the future safety evaluation of other CETP inhibitors.

The approach to a stepwise investigation of adrenal toxicology has been reviewed with reference to the sequential approach from in vitro studies to final evaluation of dose-related assessment of biological relevance in targeted animal studies (Harvey 1996; Hinson an Raven 1999; Harvey et al. 2007). The in vitro studies are generally performed with several increasing doses to investigate concentration-effect relationships (Colby 1994; Colby 1996; Colby and Longhurst 1992). The preliminary information from these in vitro studies is then compared with the biological information available from in vivo studies, to assess the need for additional in vivo animal studies based on single-dose or repeated-dose administration of the test compound. The need for noninvasive investigation of adrenocortical function including corticosterone and aldosterone excretion in rats by noninvasive methods is obvious from the recent experience with CEPT inhibitors (Forrest et al. 2008). The stepwise evaluation of hormonal parameters in the OECD 407 protocols for endocrine disruptors in a 28-day treatment protocol is helpful to appreciate the difficulties of including several parameters of hormone activity, in particular selection of time points for measurement, sampling procedure for blood samples, and selection of reference compounds for validation of reliable detection of changes (Andrews et al. 2001; Hinson and Raven 2006; Sellers et al. 2007; Ullerås et al. 2008, Ziolkowska et al. 2006). Unfortunately, noninvasive methods for adrenal steroid excretion were not assessed in the OECD-EPA studies. It should be considered here that the objectives of assessing environmental contaminants and industrial chemicals are different from those of safety pharmacology procedures, directed at screening a large number of compounds rather than going into exploration of detail.

In the endocrine safety protocol, the interaction of multiple endocrine systems in test animals is addressed. As discussed by Harvey (1996) and by Harvey and Everett (2003), effects on adrenocortical function are frequently found in toxicology studies, sometimes related to enzyme induction and effects on steroid biosynthesis (Loose et al. 1983; Weber et al. 1993; Nebert and Russell 2002; Rossol et al. 2001). Test procedures in animals are required when there is a reason for concern. Frequently, the effects observed are due to stress of toxicology procedure, rather than specific interaction with the target organ, and may involve effects on catecholamine release from the adrenal medulla (Tucker 1996). Much new evidence has been accumulated from the testing of industrial chemicals with effects on adrenal steroid biosynthesis (Cockburn and leist 1999; Harvey and Johnson 2002; Sanderson et al. 2002; Harvey and Everett 2003; Hinson and Raven 2006; Higley et al. 2010).

14.4.2 Adrenal Steroid Excretion in Rats in a Repeated Dose Study

PURPOSE AND RATIONALE

This investigation is performed in adult male and female rats. It may be applied in the context of a toxicology study as an add-on investigation or performed as a separate study to detect changes in adrenal function during treatment (satellite animals, mechanistic study). Assessment of the change in adrenal function is performed in a minimal invasive procedure, by measuring the excretion of adrenal steroid hormones in the urine during the night period. Successful application of the method critically depends on suitable housing conditions for the animals, and preliminary training and adaptation of the facility is required. The animal house should have a controlled light-dark cycle and well-controlled air-conditioning. Animals need to be adapted to metabolism cages for collection of urine (prestudy handling). An option is adaptation during the study. This can be achieved by transferring the animals twice per week for one night (e.g., 18:00–06:00) to metabolism cages, including collection of urine for control of volume, osmolarity, electrolyte concentrations, and exploratory hormone determination of corticosterone and aldosterone, the results being evaluated after correction for creatinine excretion ("creatinine correction"). This procedure allows for control of the consistent effect of handling on the reproducibility of results and for detection of a time-action profile in changes of adrenocortical function. It is important to use six rats per group, assigning two rats to each metabolism cage. The social interaction of rats is important for meaningful results. This is a general requirement for the animal facility: absence of noise and any entry of personnel during the night period. Moreover, reproducible results are obtained when rats have social contact, whereas isolation of single rats in metabolism cages produces artifacts. This consideration is also valid for studies in dogs, where the procedure of

staying in a metabolism cage is well tolerated in the presence of other dogs in the same room, whereas results become erratic during isolation of the dogs.

The final urine collection in the noninvasive rat adrenal procedure needs to be done 3–4 days before the end of the treatment period, under conditions of established adaptation. In this study, treatment of the animals needs to be done in the afternoon, before starting the collection procedure, and for a consistent protocol, it is advisable to treat the animals at the same time of the afternoon throughout the study. Selection of this procedure is preferable to obtain consistent effects even for test drugs with a short duration of action.

PROCEDURE

Male and female rats (preferably of 200 g initial body weight) are kept in a light- and temperature-controlled animal house, under standard conditions, on a pelleted rat food, with free access to drinking water. Starting 2 days after the beginning of treatment, the animals are transferred to metabolism cages for the night period (two rats per cage to avoid isolation stress). Throughout the study, treatment is administered in the afternoon. Urine is collected during the night, osmolarity and electrolytes are determined, and one volume is dispensed immediately and stored deep-frozen for the analysis of adrenal steroid hormones and creatinine.

In a toxicology study, groups of animals are randomly assigned to one control group and three treatment groups (three increasing dose levels). Treatment is administered in the morning, and animals are transferred to their metabolism cages in the evening. This procedure does not interfere with the standard protocol of regulatory studies; collection of urine samples is an add-on procedure which pertains to all animals of the study. Urine collection should be done sparingly to reduce any effects on the animals, for example, one night each during the third and fourth week of the study. Prestudy adaptation of the animals to metabolism cages can be considered to make them acquainted with the procedure and reduce stress effects. The last urine sampling should be done several days before final autopsy, such that effects on histology and clinical chemistry at the end of the study are avoided.

For evaluation and satellite groups, treatment should be given in the evening, before the onset of the dark period and before transfer to urine sampling cages. This ensures that any effects on adrenal steroid secretion of limited duration and at lower dose levels are detected in the urine procedure. For each cage and collection night, the urine volume of two rats per cage collected during the night is recorded.

At the end of the treatment period, the animals are killed by decapitation, preferably 24 h after the last treatment injection. Body weight and organ weights are recorded, and organs of interest are dissected out at autopsy for histological examination and/or measurement of hormone contents.

In male animals, weight of the adrenals, testes, seminal vesicles and ventral prostate is recorded (because the effects on steroid biosynthesis frequently involve both the adrenal and gonadal system). In female animals, weight of the adrenals, ovaries, and uterus is recorded. As an added investigation, the hypothalamus of the animals may be dissected out and shock frozen immediately for assay of corticotropin-releasing hormone (CRH), and the adenohypophysis (pituitary) is dissected out for assay of corticotropin content (ACTH) by radioimmunoassay. The pituitary tissue is stored frozen at $-20°C$ until the assay of hormone content can be performed.

During a treatment period of 7 days or up 28 days (toxicology study), the excretion of corticosterone and of aldosterone during the night period is monitored on the last 3 days of treatment or on 2 consecutive days of each week (toxicology study). This approach ensures a check on consistency of changes in adrenal steroid excretion.

EVALUATION

The following parameters are evaluated at the end of the study period by calculation of the group means and standard deviation, applying suitable methods for analysis of variance and tests for significance of differences between groups. In most instances, the significance of differences for treatment groups versus control groups is calculated at the 95% level by analysis of variance and a distribution-free rank test. Here is a list of the important parameters which are to be calculated in the evaluation of studies on adrenocortical function:

- Excretion of corticosterone, in the urine of at least six rats of control and treatment groups (pooled urine of two rats per metabolism cage)
- Excretion of aldosterone in the same samples
- Weight of adrenal glands at autopsy

- Tissue content of corticosterone and aldosterone, expressed as total content per gland (ng/adrenal) and as relative concentration (ng/g adrenal tissue)

Supplementary information about the reproductive system is obtained in the same study and should generally be obtained to investigate the possibility of interference by the test substance with the secretion and synthesis of steroid hormones of the adrenals and of the male and female gonads.

- Male rats: weight of testes, seminal vesicles, and ventral prostate
- Female rats: weight of the ovaries and uterus

Optional parameters of hypothalamic-pituitary activation or feedback effects are the hypothalamic content of CRH and the anterior pituitary content of ACTH (group means and standard deviation). Final data may be calculated as hormone content per mg or gram of organ tissue (pituitary hormone contents) or as hormone content per tissue equivalent (hypothalamic fragments).

MODIFICATIONS OF THE METHOD

It is recommended to perform this extensive investigation in rats, for comparison of the findings with the related regulatory toxicology study, alternatively in satellite groups of the regulatory toxicology (e.g., controls and high dose). Under special conditions, a similar methodology can be applied to the dog (Stolp et al. 1983; Rijnberk et al. 1988; Feldman et al. 1996; Colagiovanni and Meyer 2008). A modification for veterinary medicine concerning the 24-h determination of aldosterone excretion in dogs with creatinine correction has been developed (Gardner et al. 2007) in the context of diagnostics in cardiology; 24-h diagnostic assessment of the cortisol/creatinine ratio in canine urine has also been validated (Tidholm et al. 2005). This is important because the principal adrenal steroid in rats is corticosterone, whereas in the dog cortisol is excreted in the urine. Collection of urine samples during the night under minimum invasive conditions (in the context of pharmacokinetic studies) as well as 24-h collection has been successfully performed in dogs.

The core of this method is the assessment of adrenal steroid excretion during minimum invasive conditions, during repeated-dose daily administration of the test substance. Supplementary investigation may be an ACTH stimulation test (Feldman et al. 1996).

Modifications of the method are the duration of treatment (not less than 7 days) and timing of treatment injections (conventional regimen in the morning, or injections late in the evening shortly before transfers to metabolism cages for starting the urine collection period).

Concerning analytical methods for cortisol, corticosterone, and aldosterone in serum and urine or tissue samples, it is recommended to search the Internet at the time of planning the study for commercial sources of assays and perform the analytical validation for multiple sample matrices (serum, plasma, urine, extraction from feces, tissue extracts) before including these methods in the final study design (prestudy validation procedure).

Suppliers often indicate that their methods are applicable in a variety of animal species; there are however considerable differences in steroid metabolism and in the percentage of steroid that is detected by the analytical method envisaged. There may also be strain differences (Sarrieau and Mormède 1998) and specific details of the animal facility (Eriksson et al. 2004) which need to be considered before selecting a rat strain for a detailed investigation which is as different from the strain used for the regulatory toxicology studies of the institution.

14.4.2.1 Adrenal Steroid Content

Determination of adrenal gland steroid content may be included but is of limited value. Determination of serum concentrations of corticosterone and aldosterone may be included during up to week 3 for studies of 4 weeks duration, but needs to be performed under well-controlled conditions which reduce stress to a minimum.

14.4.2.2 Serum Corticosterone in Rats

Any sampling of serum corticosterone in rats without anesthesia will lead to highly variable and arbitrary results due to stress effects, even if performed at a standard time of the day. For this reason, either anesthesia or premedication with dexamethasone has been developed and may be applicable in a limited number of animals, for example, control animals and high-dose group for orientation, albeit with limited reliability of result. Inclusion of monitoring in serum is a matter of handling the animals, not one of analytical methods. There are reliable

methods for adrenal steroids including aldosterone (even though concentrations of aldosterone are very low). For diagnostic evaluation of serum corticosterone in groups of any months, preferably, a stimulation test with ACTH after low-dose dexamethasone blockage of spontaneous secretion may be included. Rats are injected with 0.5 mg/kg of dexamethasone 18 h before the stimulation test. The test is then performed by an injection of synthetic ACTH (1–24), which is readily available as a clinical diagnostic tool. The clinical test procedures have been reviewed (Weiss and Patel 2002). Extended investigations are the assessment of effects on other steroid-secreting organs (gonadal system) and the assessment of hypothalamic-pituitary changes at the end of the treatment period. Determination of pituitary ACTH content may be particularly useful in case of inhibitory effects on adrenal steroid biosynthesis.

14.4.2.3 Serum Cortisol in Dogs

Blood sampling for cortisol: a dexamethasone suppression tests for the diagnostic evaluation of adrenocortical function in dogs with hypercorticism or adrenal tumors has been established (Feldman et al. 1996) and may be included in the adrenal profile study for dogs.

CRITICAL ASSESSMENT OF THE METHOD

Changes in the secretion of adrenal steroids are often induced by stress effects, which need to be differentiated from drug effects on the adrenal steroid secretion (Harvey and Everett 2003). This is the reason for selecting the minimum invasive procedure of monitoring adrenal steroid excretion in urine, which avoids blood sampling and reduces the stress on animals by adequate adaptation periods for the nighttime sampling procedure.

It is always important to compare the effect of well-established drugs which affect adrenal cortical steroid secretion and synthesis (comparator drugs). The best reference compound for adrenal steroid excretion is synthetic corticotropin-24 (Synacthen), which readily induces adrenal hyperplasia at high doses or when given by sustained subcutaneous infusion (osmotic minipumps). There are many synthetics steroids with some adrenocortical activity. The problem as with other hormonal evaluations is the pronounced circadian rhythm of corticosterone secretion and excretion in the urine (Miki and Sudo 1996; Hilfenhaus and Herting 1980). To avoid these difficulties of sampling under stress conditions, in a system constantly changing and responding immediately to any stress, the night period is the most adequate selection of minimum stress and interference especially in well-controlled animal houses.

The equivalent of cortisol secreted by monkeys can also be detected by a noninvasive procedure of urine sampling (Pal 1979); many studies of this kind are available for humans. Blood sampling needs to be done during specific times of the day; for advance stimulation tests, endocrine essays have been developing based on a temporary suppression of the pituitary adrenal response by pretreatment with dexamethasone. Such tests may be included during a study of 28 days' duration, but should be done at least 7 days before the end of the study in order not to interfere with the final hormonal evaluation. Stimulation tests with synthetic corticotropin may be built into the study. For the evaluation of stimulatory drug effects, there is a noninvasive procedure for corticosterone secretion which could at the same time be applied to electrolyte balance studies (Haack et al. 1978). During the night period (14 or 16 h), the animals are placed in metabolism cages for urine collection; the amount of corticosterone and aldosterone excreted during this period is determined in the urine samples, together with the electrolyte concentration. The principle is derived from studies on electrolyte excretion after treatment with diuretics (Hilfenhaus 1977).

MODIFICATIONS OF THE METHOD

For the noninvasive exploration of adrenal steroid secretion by monitoring the excretion in fecal samples, numerous studies have been reported in pharmacology and zoology for a number of animal species (Kley et al. 1976; Ganswindt et al. 2003; Carlsson et al. 2009; Miki and Sudo 1996).

Human studies on the stimulation of adrenal steroid excretion by ACTH administration were performed (Vecsei et al. 1982; Gomez-Sanchez et al. 1988) including the evaluation of stressful procedures in human physiology (Muñoz et al. 2010). Similar procedure could be adapted for the rat to assess secretory capacity after the repeated-dose treatment (Siswanto et al. 2008).

14.4.3 Corticosterone Secretion in Dexamethasone Blocked Rats

PURPOSE AND RATIONALE

Corticotropin activity can be measured by the increase of corticosterone in venous blood of hypophysectomized or dexamethasone-blocked rats, as a single-dose test when receptor affinity for ACTH receptor is found with a test compound. The test can be used to measure time-response curves of corticotropin preparations and compounds with adrenal-stimulating activity (Vogel 1965, 1969). The use of hypophysectomized rats for evaluation of the pituitary response to compounds with corticotropin activity has been entirely replaced by the dexamethasone-blocked model.

In the context of repeated-dose studies for endocrine safety evaluation, a modification of this test is built into the procedure, as described above (Sect. 14.4.2).

PROCEDURE

For the ACTH assay, male Sprague-Dawley rats weighing 150–200 are injected subcutaneously 24 and 1 h prior to subcutaneous injection of the ACTH preparation or the standard with 5 mg/kg dexamethasone in oily solution. Eight rats are used for each dose of test preparation or standard. Various time intervals after ACTH injection, the rats are anesthetized with 60 mg/kg pentobarbital i.p., and blood is withdrawn by cardiac puncture. One-ml plasma is diluted with 2-ml distilled water and extracted (washed) with 5-ml petrolether to remove the lipids. The petrolether is discarded. Two ml of the water layer are extracted twice with 5-ml methylene chloride by vigorous shaking for 15 min. The methylene chloride phase is separated by centrifugation. Both methylene chloride extracts are unified and shaken with 1 ml ice-cold 0.1 N NaOH. The water phase is immediately removed, and the methylene chloride extracts dried by addition of dry sodium sulfate. An aliquot of 5 ml of the methylene chloride extract is mixed with 5 ml of the fluorescence reagent (seven parts concentrated sulfuric acid, three parts 96% ethanol, v/v). After vigorous shaking, the methylene chloride phase is removed, and fluorescence is measured with primary filters of 436 mm and secondary filters of 530–545 mm. For calibration, concentrations of 0, 20, 50, 100, and 250 mg/ml corticosterone are treated identically and measured in each assay. Synthetic ACTH (1–24) is used as the reference standard; this compound has full biological activity (Schuler et al. 1963) when compared with natural ACTH (1–39).

The classical analytical method of methylene chloride extraction is now entirely obsolete; there are direct assays for corticosterone and aldosterone in rat plasma. Similar analytical methods are applicable for adrenal steroid excretion in urine (Kabra 1988; Samtani and Jusko 2007; Carvalho et al. 2008; Kushnir et al. 2011). Selection of simple and reliable assay methods (RIA, ELISA) is a logistic decision. An Internet search will indicate suppliers. For the complex analytical tasks, one of the methods indicated above with clinical reference experience and validation of specificity is to be preferred.

EVALUATION

Using three doses of test compound and standard, activity ratios with confidence limits can be determined after each time interval with the 3 + 3-point assay giving evidence for the duration of action (Vogel 1965, 1969).

MODIFICATIONS OF THE METHOD

In contemporary methods, the assay of corticosterone is performed by immunoassay in unextracted serum samples or in serum and tissue extracts by HPLC. In the classical methods, fluorometry was applied. Pekkarinen (1965) used fluorometric corticosteroid

determinations in guinea pigs resulting in highly deviating activity ratios of synthetic and commercial corticotropins as compared with the international working standard of ACTH. The option now is to select a low-dose dexamethasone test or high-dose dexamethasone test consistently, depending on animal species and experience. Analytical methods depend to some extent on the number of samples to be analyzed and the expected workload.

CRITICAL ASSESSMENT OF THE METHOD

It is recommended to include these dynamic function tests during the early investigation of adrenocortical function in satellite groups of rats as well as in repeated-dose studies in dogs (Feldman et al. 1996). Pretreatment with dexamethasone is essential for reproducible results, because stressful procedure interferes with the secretion of corticosterone/cortisol during the sampling procedure, even if animals are handled carefully in a separate room of the animal facility. This is particularly the case with dogs. Due to the analytical methods now available (RIA, ELISA, IRMA, HPLC), the response of the pituitary gland and any feedback effects after repeated-dose treatment (3–7 days preferred) are readily detected.

14.4.4 Corticosteroid Release from Adrenal Cell Suspensions In Vitro

PURPOSE AND RATIONALE

The principle of this method is to assess the direct effect on adrenal cells, either by incubation of dispersed adrenal cells with ACTH preparations or with test compounds in the presence of ACTH or angiotensin II. Ideally, a homogeneous preparation of adrenocortical cells is obtained, variability is eliminated, and the number of animals required is much reduced. An in vitro assay of corticotropin was described by Saffran and Schally (1955a). This test has been modified by Van der Vies (1957) and used by several authors (Staehelin et al. 1965; Vogel 1969). Subsequently, adrenal cell lines have replaced the method when large numbers of compounds need to be evaluated. The previous analytical method using adrenal cell suspensions as an assay for corticotropin preparations is a cumbersome procedure which was replaced by RIA and ELISA methods.

PROCEDURE

There are many modifications of this method, based on incubation of small fragments of adrenal glands, or on the use of dispersed adrenal cells. Cells are incubated in a physiological buffer. The final solution is gassed with

a mixture of 95% O_2 and 5% CO_2 for 10 min. As with similar methods—for example, for pituitary cells or dispersed Leydig cells—there is a preincubation period, followed by the test incubation with corticotropin or test compound. The vessels are incubated and gassed with a mixture of 95% O_2 and 5% CO_2 at 38°C under continuous shaking for 2 h. The initial analytical procedure for corticosterone has been replaced by measuring aliquots in extracts of incubation medium by HPLC or directly in the media by specific immunoassays.

EVALUATION

The concentrations in the incubation flasks are compared (duplicates or triplicates); potency ratios with confidence limits may be calculated from a 2 + 2 design or from dose-response curves.

MODIFICATIONS OF THE METHOD

Corticosterone is now conveniently determined by RIA or HPLC, and dispersed adrenal cells are incubated instead of adrenal tissue fragments.

CRITICAL ASSESSMENT OF THE METHOD

The method is suitable to detect changes in steroid biosynthesis induced by test compounds. In endocrine safety evaluation, it is recommended to apply measurement of corticosterone and adrenal steroid in metabolites in the tissue as an ex vivo investigation to test material from animals previously treated in a repeated-dose protocol.

14.4.5 Adrenal Cell Culture, Human Cell Lines

There has been an impressive progress in the use of adrenal cell lines for the assessment of effects on steroid biosynthesis, in particular due to the programs on industrial chemicals and environmental contaminants (endocrine disruptors).

The intrinsic problem of using in vitro systems for endocrine safety pharmacology is the complexity of such systems with regard to biological interpretation. When a two-stage approach is selected of using an adrenal cell line with subsequent bioassay in rats, the evidence for designing early clinical trials becomes more reliable. Incubation of dispersed adrenal cells was the initial step leading to the development of human adrenal cell lines. The cell lines were derived from human tumors, and they enable a detailed analysis of effects on steroidogenesis. There are several examples for the importance in safety pharmacology, particularly relevant is the observation that torcetrapib showed an off-target effect on secretion of aldosterone in H295R adrenocortical cells and related test systems (Forrest et al. 2008; Capponi et al. 2008; Hu et al. 2009; Stein et al. 2009; Clerc et al. 2010).

Short-term assays have been developed with rat and bovine adrenal cells. Adrenocortical cells (BAC) were prepared by treatment of adrenocortical slices with trypsin, cells were cultured in a defined media, and treatment was started at the end of the second day of culture. LeRoy et al. (2000) investigated the time course of the response to ACTH, angiotensin II (AT2), and other proteins and examined the effects of peptides on the expression of specific genes. This approach is useful in research and for early assessment of drug candidates. In a similar manner, Ziolkowska et al. have used rat adrenocortical cells in vitro to study the effect of several compounds on secretory and proliferative activity. The parameter was basal

corticosterone production from cultured adrenocortical cells after 24-h exposure to the test compounds. The conclusion of the study was that proliferative activity of cultured adrenocortical cells exhibits great variability which depends on the dose and duration of exposure of the studied cells. The practical use in safety pharmacology is therefore limited.

An extensive program has been conducted with the human adrenocortical carcinoma cell line H295R in the context of steroidogenic response elicited by endocrine disruptors. Samandari et al. (2007) stated that the NCI-H295A and NCI-H295R cells progeny originates from tumors which produce predominantly androgens and a small amount of mineralocorticoids and glucocorticoids. It was found that the two cell lines differ markedly in their steroid profile and expression pattern of important genes involved in steroidogenesis. One cell line produces more mineralocorticoids, whereas the other line produced more androgens. Both cell lines were found to express the ACTH receptor at lower levels consistent with low stimulation of cells by ACTH. The angiotensin I receptor (AT1R) was expressed in both cell lines, and angiotensin II stimulated steroidogenesis in H295A but not in H295R cells. The studies were initially targeted at clinical questions related to disorders of adrenocortical function. Two cell lines were characterized with regard to predominant mineralocorticoid biosynthesis in one assay and androgen biosynthesis in the other system. The application of these cell lines to studies of preclinical safety pharmacology is limited, whereas these lines have their specific relevance and have been extensively used in environmental toxicology.

Ullerås et al. (2008) studied the secretion of cortisol and aldosterone in relation to disruption of adrenal function by chemicals. They screened a large selection of chemicals in this model, using specific ELISA methods for hormone production in vitro. An added test was angiotensin II-stimulated hormone secretion. The inclusion of several known toxicants was helpful to characterize profiles for aminoglutetimide, ketoconazole, and etomidate. The test system was found to be reliable and responding in a reproducible manner to established toxicants. An application for safety assessment of drug candidates is supported by these findings, for instance by selecting well-characterized toxicants as reference compounds for safety pharmacology satellite studies (Hecker et al. 2006).

Details of using the adrenocortical cell lines have been reviewed by Hinson and Raven 2006. Higley et al. (2010) performed a detailed assessment of chemical effects on aromatase activity in the H295R cell line. The reference assays are commonly used aromatase assays, including a human microsomal assay established in the EPA-EDSP program. The H295R cells were exposed to a number of known toxicants, and the response of direct, indirect, and combined effects of aromatase activity was measured. Exposure to letrozole, ketoconazole, and aminoglutethimide resulted in greater indirect aromatase activity after a 48-h exposure. The overall conclusion was that a combination of direct and indirect aromatase measurements is needed in order to predict the effects of industrial chemicals on estrogen production and the mechanism of action by aromatase activation. It was shown that direct aromatase measurements in vitro need to be interpreted with caution and a subsequent cell-based assay is required for application in safety pharmacology.

The method of evaluation in the H295R adrenocortical cell lines has also been applied to effects on mineralocorticoid secretion (aldosterone), for example, in studies on CEPT inhibitors (Capponi et al. 2008).

14.4.6 ACTH Receptor Affinity

The corticotropin receptors have been a matter of great interest concerning the regulation of adrenocortical function, and more recently, an array of functions related to energy balance, metabolism, immunology, and pigmentation which are explored in the context of melanocortin receptors, of which the ACTH receptor is now designated one of the melanocortin receptors, MC2R (Fong et al. 2012).

PURPOSE AND RATIONALE

For all new compounds which have some structural similarity or relation to the corticoid scaffold. There are now many such test systems which measure the initial membrane binding to the ACTH receptor and to define the initial steps of hormone-related activation. However, the binding affinity does not necessarily imply biological activation, for example, of adrenal cortical cells. Therefore, such tests always need to be followed up by an in vitro testing on adrenal glands or dispersed adrenal cells.

Corticotropin (ACTH) receptors have been used as the test preparations for comparison of the binding affinities of adrenocorticotropin peptides using a cloned mouse adrenocorticotropin receptor expressed in a stably transfected HeLa cell line (Kapas et al. 1996). Such assays measure the initial membrane binding but not strictly the biological activation, for example, of adrenal cells or melanocytes.

PROCEDURE

HeLa cells are seeded into 12-well culture plates at a density of 106 cells/well. On the second day of culture, the cells are washed as follows: 2× in 1 ml of ice-cold 0.9% NaCl, 1× in 1 ml of ice-cold glycine (50-mM glycine, 100-mM NaCl, pH 3.0) for 5 min, and 2× in 0.5 ml of ice-cold 0.9% NaCl. Cells are then incubated for 60 min at 20°C with increasing concentrations of nonradioactive ACTH or various ACTH analogues and the reactions initiated on the addition of [125I-iodotyrosyl23]ACTH[1–39] (2,000 Ci/mmol; final concentration 0.1 pmol/l) in DMEM. At the end of the incubation, the medium is removed and the cells washed three times with 0.9% NaCl and then dissolved in 0.5-M NaOH/0.4% sodium deoxycholate. Each point is determined in triplicate. Specific binding is determined as the difference of total radioactivity bound minus nonspecific binding radioactivity determined in the presence of an excess of 10–5 M nonradioactive ACTH.

EVALUATION

Binding parameters are calculated from computer programs, one example being the ligand program of Munson and Rodbard. Estimates of binding affinity are then compared with the binding affinity of natural corticotropin, corticotropin analogues, and more importantly with the drug concentrations of the compound to be evaluated reached in the toxicology studies or similar pharmacokinetic studies (level of exposure).

MODIFICATIONS OF THE METHOD

There are many different modifications of the method; early technology used membrane preparations and modern methods use solubilized receptors and receptor constructs which enable fast signal detection. In the early studies, ACTH receptors of rats were measured

by Buckley and Ramachandran (1981); Grunfeld et al. (1985) characterized the ACTH receptors in rat adipocytes. Subsequently, the ACTH receptor on human adrenocortical cells was measured (Catalano et al. 1986). Expression of the ACTH receptor mRNA was studied in mouse and human adrenocortical cell lines (Mountjoy et al. 1994). Extensive mechanistic studies were performed on bovine adrenal cell cultures, including the time course of the response after adding test compounds (LeRoy et al. 2000). Functional expression of the human ACTH receptor gene has been explored by molecular biology methods (Penhoat et al. 2000).

Penhoat et al. (1993) reported the identification and characterization of corticotropin receptors in bovine and human adrenals, using cultured bovine adrenal fasciculata reticular cells and crude plasma membrane fractions. Lebrethon et al. (1994) and Penhoat et al. (1991, 1995) studied the regulation of ACTH receptor mRNA and binding sites by ACTH and angiotensin II in cultured human and bovine adrenal fasciculata cells. Picard-Hagen et al. (1997) found that glucocorticoids enhance corticotropin receptor mRNA levels in ovine adrenocortical cells, as an equivalent of receptor regulation by circulating glucocorticoid concentrations.

Naville et al. (1996, 1997) developed a stable expression model in order to characterize the human ACTH receptor by binding studies and functional coupling to adenylate cyclase.

Schiöth et al. (1996) described the pharmacological distinction of the ACTH receptor from other melanocortin receptors in the mouse adrenocortical cell line Y1. Melanocortin receptors do not have a binding epitope for ACTH beyond the sequence of alpha-MSH (Schiöth et al. 1997). The human ACTH receptor (MC2R) is now investigated as part of the wide spectrum of melanocortin receptors in several animal species, which may be used in environmental toxicology, for example, for investigation of endocrine disruptors as well as for phylogenetic comparisons (Schiöth et al. 2005; Ling and Schiöth 2005; Haitina et al. 2005; Kobayashi et al. 2011).

CRITICAL ASSESSMENT OF THE METHOD

This test is to be performed if the specific pharmacology of the compound indicates the potential for interaction with the ACTH receptor. It is used to prove that the compound achieves highly specific receptor targeting (Behrens and Ramachandran 1981; Oelofsen and Ramachandran 1983) or modulates the receptor density by changing peripheral glucocorticoid concentrations. For specific compounds, the extent of safety pharmacology studies to be performed with the product is reduced (Stocco and Clark 1996; Abdel-Malek 2001; Vaisse et al. 2000).

14.4.7 ACTH Secretion and Tissue Content

The secretion of ACTH is stress related, and measuring levels in unanesthetized animals does not provide valid estimates due to wide fluctuations. For that reason, the dexamethasone pretreatment is recommended in rats as well as in dogs to establish dynamic function tests of ACTH responsiveness, whereas measurement of basal serum ACTH concentrations is impractical. The pituitary tissue content of ACTH can be measured readily; this should however be done only in the context of a search for feedback effects, for example, of adrenal inhibition (reduced glucocorticoid secretion due to inhibition of steroid biosynthesis). Measuring the ACTH receptor in tissues (MC2R) may be more appropriate, in particular for mechanistic studies.

PURPOSE AND RATIONALE

Numerous assay procedures have been developed for the measurement of serum ACTH concentrations in clinical diagnostics (e.g., in tumor-related secretion, for ectopic hormone production, Krieger 1983; Genazzani 1975; Ganong 1974). This principle can also be applied (in a limited way) to safety pharmacology studies, when a reduction in glucocorticoids secretion leads to upregulation of ACTH secretion, by removing the inhibitory feedback. This is the primary diagnostic application in repeated-dose studies with test compounds which may interfere with adrenal steroid biosynthesis.

PROCEDURE

Several methods have been described, starting with radioimmunoassay (RIA) procedures (Rees 1971; Kao 1979; Krieger 1975) and proceeding to immunoradiometric (IRMA) methods (Hodgkinson 1984; White 1987; Zahradnik 1989; Raff 1989; Gibson 1989; Fukata 1989).

EVALUATION

Hormone concentrations in serum extracts or in unextracted serum and ACTH concentrations in dilutions of pituitary homogenate are calculated from standard curves using an appropriate reference standard for pituitary corticotropin (for the biologically active sequence the ACTH analogue ACTH 1–24 may be used). Sample data are calculated as ng ACTH/ml serum, as ACTH per pituitary gland or per pituitary weight (mg).

MODIFICATIONS OF THE METHOD

For analytical determination of ACTH, a method should be selected that can be applied to unextracted serum, provided that ACTH degradation is prevented by adding an enzyme inhibitor and the time of blood collection.

CRITICAL ASSESSMENT OF THE METHOD

A very critical item has been a tendency of ACTH to fluctuate widely and rapidly under conditions of stress (Meeran 1993; Lambert 1985; Goverde 1989). This is especially a problem in studies with dogs, where the

experiments need to be performed under stress-free conditions, and even then there will be a difficulty of rapidly fluctuating concentrations.

14.4.8 Adrenal Steroid Activity

In the endocrine safety pharmacology of test compounds affecting nuclear receptors for glucocorticoids and mineralocorticoids (GR and MR), the levels to be examined after treatment of mice and rats are accessible for investigation; the information concerning risk assessment is discussed below.

PROCEDURE

Adult male and female rats are treated with the test compounds for 7–28 days, and levels of action are identified by measuring hypothalamic CRH content, ACTH secretion and synthesis, and the effect on adrenal steroid excretion, preferably at two dose levels. Test compounds are those which have been identified due to their interaction with nuclear steroid receptors and by structure-activity considerations. CRH activity, for example, hypothalamic CRF/CRH content, may be measured; the information obtained by this measurement is limited; and CRH content is controlled by the feedback action of pituitary hormone release and adrenal steroid secretion. There is always a clear response to glucocorticoids and inhibitors of adrenal steroid synthesis.

ACTH secretion and synthesis, namely, the tissue ACTH content, may be modified by compounds affecting corticotropin secretion, in particular by inhibition of glucocorticoid secretion. This information is valuable, because measurement of ACTH secretion reflects the level of secretion of glucocorticoids over several days of treatment.

Affinity for the glucocorticoid and mineralocorticoid receptors is usually known from early pharmacological profiling of the test compounds (Wilkinson et al. 2008; Houck and Kavlock 2008; Zwermann et al. 2009; Sedlak et al. 2011). For an assessment of the relevance of receptor signaling, studies in human adrenocortical cell lines are recommended (Parmar and Rainey 2008; Sanderson 2008; Pippal and Fuller 2008; Wang et al. 2012).

Clearly, compounds interacting with adrenal steroid biosynthesis by effects on enzyme and receptors will directly affect the target organ functions dependent on adrenal steroids. These activities may be detected by single-dose tests in the classical in vitro and in vivo bioassays for adrenocortical activity. The time course of effects is of interest and needs to be explored in relation to the nuclear receptor activation (GR, MR).

It is assumed here that any indications for receptor-mediated effects found in early pharmacological profiling will support the decision to perform an endocrine safety evaluation in satellite groups (Sullivan and Kinter 1995). The direct assessment of steroid activity by nuclear receptor assay is not discussed here. At the biochemical level of investigation, signaling mechanisms have often also been investigated (Wittliff and Raffelsberger 1995). The purpose of the endocrine safety pharmacology is to assess the relevance of these in vitro findings and their manifestation of biological effects in the intact animal test, by repeated-dose administration.

PURPOSE AND RATIONALE

There are numerous classical bioassays as for the glucocorticoid activity and mineralocorticoid activity of steroidal and nonsteroidal compounds. For the scope of endocrine safety pharmacology, however, it may be assumed that in the pharmacology procedures used for this selection of these compounds, modern methods were applied such as receptor screening and screening for enzyme activities (see reviews by Barnes and Adcock (1993), Berger et al. (1992), Jensen (1996), Lieberman (2001)).

CRITICAL ASSESSMENT OF THE METHOD

Direct tests for adrenal steroid activity are at the entry level of endocrine safety pharmacology; such activities are usually expressed by a feedback regulation at the pituitary level, changing the ACTH response, or by one of the multiple biological effects of the adrenal steroid hormones ranging from anti-inflammatory to immunosuppressive activity (Schimmer and Parker 1995).

14.5 Hypothalamic-Pituitary-Thyroid Function

In rodent toxicology studies, effects on the thyroid gland are frequently found in histopathology and often require an extensive retrospective evaluation. The inclusion of measurement of thyroid stimulating hormone (thyrotropin, TSH) and thyroid hormones (in particular free thyroxine) at an early stage is helpful to provide mechanistic guidance for explanation of the effects, which are often observed in rodents but not in humans. The toxicological findings in rodents, other laboratory animals, and domestic animals have been reviewed with regard to the toxicants and chemical mechanisms involved (Capen 1992, 1994), mechanistic studies and toxic endpoints (Capen 1997; Capen 1998), and specific details of the histopathological findings and their interpretation (Capen 2001).

A detailed overview of the toxicological and relevance including findings of thyroid and parathyroid glands was published (Capen et al. 2002). An extensive review of the histopathology of the thyroid and other endocrine glands was provided by Greaves (2007a). The clinical spectrum of drugs affecting thyroid function includes thyroid hormones, inhibitors of thyroid hormone synthesis (antithyroid drugs), and drugs interacting with the thyroid hormone receptor isoforms being developed for several indications in metabolic diseases (Farwell and Braverman 2006; Dong and Greenspan 2009). In regulatory toxicology studies, in particular 6-month, 12 months and carcinogenicity studies, adverse findings affecting thyroid system are frequently found and inclusion of satellite groups for analysis of TSH, T3 and T4 is advisable, as well as the inclusion of thyroid-related peptides calcitonin and parathormone in particular cases (Capen et al. 2002).

14.5.1 Pituitary Thyroid Evaluation in Rats in a Repeated Dose Study

PURPOSE AND RATIONALE

Inhibitory effects on pituitary-thyroid function are readily detected in toxicology studies by changes in thyroid weight and histology of the thyroid and pituitary gland. Their interpretation regarding relevance for human is difficult and limited, because in many cases, there are underlying mechanisms such as enzyme induction which are not found in clinical studies (Capen 1998, 1999) and in clinical epidemiology. When effects on the thyroid are suspected, the inclusion of serum concentrations of TSH, T3, and T4 is recommended, and duration of treatment should be 28 days for reliable detection of changes. A treatment period of 15 days in intact male rats has been recommended based on testing of endocrine active compounds (EAC), comparing daily treatment by a intraperitoneal injection or by gavage (O'Connor et al. 1999, 2000, 2002b). Hormones measured were TSH, T3, and T4. The endocrine safety evaluation may use the 28-day toxicology study for orientation, with findings in pituitary histology and serum TSH as the relevant and reliable source of information. These parameters can be readily built into the study design, based on blood sampling 1 or 2 days before end of the treatment period (or terminal autopsy) and determination of the pituitary TSH and prolactin content (using one-half pituitary for the hormone assay). An increase in the serum concentration of TSH is the most frequent a relevant finding; a stimulation test can be included for the secretion of TSH and prolactin, by injection of thyroid-stimulating hormone (TRH). Changes in biosynthesis of thyroid hormones due to enzyme inhibition are usually detected by the rise in TSH. Measurements of free T3 and free T4 do not contribute to diagnostic relevance in rats. The uptake of radioiodine (131-I) into the thyroid of treated animals is a very useful additional test.

PROCEDURE

Separate groups of 5–10 male and female Sprague-Dawley rats weighing 100 g are used (juvenile rats). For some compounds, rats of 200-g body weight may be required (adult rats). They are treated daily over a period of 6–12 days with the test compound by the intended route (usually orally by gavage or by subcutaneous injections, sometimes by exposure to test compounds in the feed). For toxicological studies, a treatment period of 4 weeks is preferable. A similar protocol is applied in chronic toxicity studies in rats and dogs. On the day after the last application (alternatively 2 h after the last dosing), the animals are sacrificed and weighed and the following parameters determined: pituitary weight and thyroid weight, pituitary content of thyrotropin (TSH) and prolactin (PRL), TRH content in hypothalamic tissue (optional), and serum concentrations of TSH, T3, and T4. Determination of free thyroid hormones does not contribute to diagnostic evidence in rats and is not recommended. Samples should always be taken at the same time of the day, preferably in the morning, here to avoid artifacts by diurnal fluctuation of thyroid hormones (Weeke 1973; Brabant et al. 1990).

There are nowadays numerous possibilities for additional exploration, using ex vivo or tissue samples. The classical approach is histology of the anterior pituitary gland (Tucker 1999), and this can be extended to histomorphometry, in situ hybridization for enzymes, and gene expression profiling. In general, pituitary hormone contents are sufficiently informative (pituitary TSH content and serum TSH concentration). These hormones reflect the effects on receptors and enzyme systems, including the action of hepatic enzyme-inducing drugs on thyroid hormones and related histological findings of the thyroid gland (Curran and DeGroot 1991).

EVALUATION

For each parameter, means, and standard error calculated, an analysis of variance is performed, and the appropriate tests of significance are applied. The mean values of each parameter of the treated groups are compared with the values of the vehicle control group. It is important to compare the results with reference to their use for the rat strain commonly used in the laboratory. For many studies, it may be advisable to include groups treated with reference compounds of established endocrine activity.

There are many published toxicology studies with xenobiotics, which may serve as examples and facilitate the selection of reference compounds for defined mechanisms of action (Capen and Martin 1989).

MODIFICATIONS OF THE METHOD

The main modifications are selection of the age of the animals, duration of treatment, and time of autopsy related to the last drug application.

CRITICAL ASSESSMENT OF THE METHOD

Several reference compounds have been explored in the OECD endocrine disrupters program, phenobarbital and propylthiouracil being the most frequently studied (O'Connor et al. 2002; Mellert et al. 2003; Cooke et al. 2004; Cho et al. 2003). The interpretation of positive findings in the rat concerning inhibition of thyroid function which has been frequently found presents considerable difficulty, and there are many cases where such findings in rats have been shown to be of no relevance for the human (Akhtar et al. 1996; Waritz et al. 1996; Capen 1998; Poirier et al. 1999). Many drugs that act on thyroid function in rats share a mechanism of action based the induction of microsomal enzymes, which in turn may enhance the biliary excretion of thyroid hormones (Vansell and Klaassen 2001).

The response of rats of different strains with regard to the TSH response when treated with thyroid inhibitors appears to be in a similar range (Fail et al. 1999); the commonly used Sprague-Dawley and Wistar rats also share a similar response of thyroid hormone inhibition as found with propylthiouracil. The mechanism of thyroid inhibition by interference with iodine uptake is frequently found, the reference component being perchlorate (Kyung et al. 2002). A separate mechanistic study is required to clarify this question.

14.5.2 TRH Radioimmunoassay

This is essentially a research method which was of interest during the development of TRH and TRH analogues in the context of proposed applications in neurological diseases. It may be included in the thyroid endocrine profile.

PURPOSE AND RATIONALE

In repeated-dose studies, hypothalamic tissue is readily available at autopsy of rats and can be used for the determination of hypothalamic hormone contents. It is important to take samples rapidly and stop enzyme inactivation in the tissue immediately (Griffiths et al. 1975; Jeffcoate and White 1975; Eskay et al. 1976) by the addition of suitable enzyme inhibitors. The hypothalamic TRH content has been measured by numerous groups (Mitsuma et al. 1976; Montoya et al. 1975; Pease et al. 1980; Utsumi et al. 1975).

PROCEDURE

The TRH radioimmunoassay was developed as a double antibody assay, with modifications mainly depending on the antiserum used and on the conditions of incubation. Addition of an enzyme inhibitor to the assay tubes is essential to avoid degradation of TRH in samples and of radioiodinated TRH.

EVALUATION

As with other radioimmunoassays, sample concentrations are calculated from a standard curve of synthetic TRH. Using various doses of standard and test preparation, dose-response curves can be established, allowing calculation of sample concentrations or potency ratios for tissue extracts tested at several concentrations.

MODIFICATIONS OF THE METHOD

Modifications of this assay have been applied to the measurement in serum, in hypothalamic tissue homogenates and extracts, and in human urine.

CRITICAL ASSESSMENT OF THE METHOD

The method is of interest because the results can be correlated with measurements of pituitary TSH and prolactin secretion and tissue content of these hormones. In a number of studies, it has been shown that changes in the secretion of thyroid hormone in the treated animals as well as administration of hormonally active compounds can change the hypothalamic TRH content in characteristic manner (Emerson and Utiger 1975; Schwinn et al. 1976; Simpkins et al. 1976).

Synthetic TRH is used as a diagnostic tool in animals and in humans. There is a response of the secretion of TSH as well as of prolactin (van Landehem AA and van de Wiel DF 1978; Andreassen et al. 1979). Pituitary cells in culture respond readily to the edition of TRH with the secretion both of TSH and prolactin (Queen et al. 1975; Haug and Gautvik 1976; Tal et al. 1978; Snyder et al. 1978).

14.5.3 TSH Immunoassay and TSH Receptor Assay

Traditionally, TSH activity was determined by bioassays in mice based on the release of ^{131}I by TSH injection. The concentrations of TSH in serum and tissue are now measured by RIA and ELISA methods. There is a close correlation of biological activity and results of immunoassays. Reference standards are available for rat TSH, dog TSH, and human TSH (for current diagnostics, an Internet search is recommended). Immunometric measurements of TSH are reported (Utiger 1979; Spencer 1994; Meinhold et al. 1994), there are commercially available rat TSH assays, and the wide spectrum of analytical methods for clinical purposes has been reviewed (Spencer 2010), including TSH receptor-stimulating antibodies which characteristic for clinical thyrotoxicosis. Large-scale synthesis of recombinant human thyrotropin has been reported (Cole et al. 1993; Hussain et al. 1996). The role of the thyrotropin receptor has been reviewed by Vassart and Dumont (1992). Castagiola et al. (1992) described

a binding assay for thyrotropin receptor autoantibodies using the recombinant receptor protein. A brain-derived TSH receptor has been cloned and expressed (Bockmann et al. 1997). Binding characteristics of antibodies to the TSH receptor were described by Oda et al. (1998). The diagnostic procedures used in clinical assessment of thyroid function have been reviewed (Spencer 1994; Spencer 2010).

[Internet resource Thyroid Manager: This Internet site provides a clinical overview of the analytical difficulty in application of methods for assessment of thyroid function and a review of hypothalamic-pituitary-thyroid physiology (Mariotti 2002)].

Application of the TSH receptor assay is recommended for assessment of the functional state of the pituitary gland after repeated-dose treatment, and serum TSH radioimmunoassay is important for the detection of inhibition of thyroid hormone synthesis by test compounds.

The difficulty in using TSH receptor assay is essentially that the initial step of binding of the hormone to the receptor is determined (receptor affinity), which does not change in proportion to the biological changes subsequently induced by TSH release. Receptor assay is therefore of limited relevance. There are functional assays which reflect activation of the receptor (Vitti et al. 1983; Perret et al. 1990).

PURPOSE AND RATIONALE

Determination of serum TSH concentrations is important for assessment of pituitary functional state (long-term elevation of TSH may result in goiter formation in rodents). The TSH RIA methods have replaced other methods for the quantitative assessment of changes in pituitary responsiveness. Test compounds which enhance the secretion of thyroid hormones lead to a suppression of the serum TSH concentrations, a clinical example being hyperthyroidism (Connors and Hedge 1981; Pekary et al. 1980). On the other hand, a reduction in circulating concentrations of thyroid hormones (T3 and T4) will impair feedback control of the pituitary gland, and the serum concentration of TSH may rise in an exponential manner.

There are TSH assays for research and clinical application with different sensitivity and limit of detection (Utiger 1979; Spencer 2010). In the endocrine safety protocol in rats (also applicable to dogs); the TRH test injection is a dynamic test for assessment of the serum TSH response and is useful for assessment of changes in thyroid hormone responsiveness, indicating modification of the pituitary TSH and prolactin response.

CRITICAL ASSESSMENT OF THE METHOD

Measuring serum TSH concentrations after 7–28 days of treatment is an important component of assessment in thyroid safety pharmacology. It is recommended to include these both in regulatory studies and satellite studies whenever there are any indications from receptor profiling or from in vitro assays on changes in thyroid peroxidase activity. Thyroid peroxidase is inhibited by the thioamide drugs, such as propylthiouracil and methimazole, and its inhibition in rats will result in goiter formation (Capen 2001).

Determination of TSH receptor affinity and related changes in receptor signaling are research methods which do not contribute to thyroid safety pharmacology.

14.5.4 Iodine Uptake and Release in Rats

PURPOSE AND RATIONALE

This method may be used in the context of repeated-dose treatment, on satellite groups of rats which show changes in thyroid uptake of labeled iodine (^{131}I). It is essentially a confirmation of the effect of increased TSH secretion; it may be sufficient to determine radioiodine uptake in controls and in the high-dose group.

A modification of this method was previously used for evaluation of thyrostatic drugs and responds to inhibition of the iodine transport mechanism in the thyroid gland.

For conventional drug evaluation, all rats were pretreated with the same dose of radioiodine (preloading). The release of 131-I from the preloaded thyroid in rats is inhibited by treatment with thyroxin (Wolff 1951), and the degree of inhibition is related to the dose administered (Perry 1951). This phenomenon was used to compare thyroid hormone derivatives with the standard thyroxine. It is superseded by chemical assay of thyroid hormones by RIA and HPLC and by measuring feedback inhibition directly via the decrease in serum TSH following administration of high doses of triiodothyronine and thyroxine.

PROCEDURE

Male Sprague-Dawley rats weighing 180–240 g are fed in a commercial laboratory with low concentrations of thyroid hormones, containing constant amount of unlabeled iodine. The animals are treated for at least 7 days with the test compound to be evaluated, at a pharmacologically active dose determined by previous biological studies. On the morning of the test day, rats are injected with a test dose of ^{131}I (intravenously or intraperitoneally), and that concentration of radioactivity in the thyroid glands is measured after 1–4 h. The blood concentration of ^{131}I at these time points is measured, and the tissue to blood ratios are calculated for individual animals.

EVALUATION

Statistical evaluation depends on the experimental design for such studies with prelabeling of the thyroid gland and release by thyroid-stimulating drugs or single-dose uptake of radioiodine into the pituitary of pretreated rats, for example, after several days of a thyrostatic drug.

From the dose-response curves, potency ratios and confidence limits are calculated. This approach may be selected to measure short-term uptake of ^{131}I as a parameter of thyroid peroxidase inhibition by antithyroid drugs.

MODIFICATIONS OF THE METHOD

The main modification for practical use in endocrine safety pharmacology is the application of this method to satellite groups of animals in a repeated-dose study. Most pelleted animal feeds nowadays contain a standard amount of iodine (it may be useful to check the specification). Therefore, the addition of potassium iodine to the drinking water is not required (as previously specified). In the satellite groups, the animals are injected with a standard dose of radioiodine after the last treatment, and the dose of radioactivity accumulated in the thyroid glands after a standard time interval (e.g., 2 h) is determined and evaluated.

CRITICAL ASSESSMENT OF THE METHOD

Determination of 131-I in the thyroid of rats at the end of a treatment period is a useful additional test, which can be applied to satellite groups, preferably control

and high dose. This is a sensitive test which readily detects inhibition of thyroid hormone synthesis, for example, by propylthiouracil.

14.5.5 Inhibition of Iodine Uptake into the Thyroid of Rats

This assay is applied to the study of drug candidates that inhibit thyroid peroxidase and may cause goiter in the preclinical studies due to decreased thyroid hormone synthesis, with subsequent compensatory increase in TSH secretion.

PURPOSE AND RATIONALE

Propylthiouracil (PTU) and a wide spectrum of drugs may inhibit thyroid hormone synthesis. Some of these drugs can be used for treatment of thyrotoxicosis. As a consequence of thyroid peroxidase inhibition, the iodine uptake and content of the thyroid is decreased. This phenomenon is dose-dependent and may occur at lower doses than those increasing thyroid weights in rats (McGinty and Bywater 1945). The historical parameter of measuring iodine content was replaced by measuring uptake and release of radioiodine (^{131}I).

PROCEDURE

Groups of male Wistar rats age 26–28 days, weighing 40–45 g, are placed in metabolism cages (two rates per cage). They are fed normal diet, and potassium iodide is added to the drinking water in order to minimize differences between thyroid status of the animals during treatment. Test compounds may be injected daily or added to the feed (mainly for testing of industrial chemicals. In this procedure, the test compounds and the reference standard are added in various concentrations to the diet over a period of 10 days). The amount of compound which each rat has ingested is calculated from the total food consumption over 10 days and expressed as milligram ingested daily per kilogram of body weight. After 10 days of treatment, the rats are sacrificed and the thyroids dissected free from adjacent tissue and capsule. The thyroid is weighed and iodine content determined (conventional procedure). In daily doses between 0.1 and 10.0 mg/kg, thiouracil decreases the iodine content of the thyroid dose-dependent. Definitely, higher doses are necessary to increase thyroid weight.

When the uptake of a standard dose of radioiodine is tested at the end of the treatment period, the radioactivity found in the thyroid gland is used as the parameter instead of the iodine content.

EVALUATION

Dose-response curves of test compounds are compared with those of the reference standard for calculation of potency ratios with confidence limits.

MODIFICATIONS OF THE METHOD

Walker and Levy (1989) used implantable pellets of propylthiouracil to induce thyroid dysfunction in rats. In the modification based on uptake of labeled iodine, as standard dose of radioiodine, 131-I is injected in each animal, and the amount of radioactivity in the thyroid gland is determined in a gamma counter.

Release of labeled iodine may be stimulated by injection of TRH (TSH-releasing hormone, protirelin).

CRITICAL ASSESSMENT OF THE METHOD

This test is valuable as single-dose uptake test and may be performed (after 10 days of treatment) when changes in the serum concentrations of T3 and T4 of unknown relevance have been found, with no corresponding increase or decrease in the serum TSH concentrations. It may help to differentiate changes which occur or predominantly at the level of thyroid hormone synthesis.

14.5.6 Thyroid Hormone Assays (T3 and T4)

Thyroid hormone assays are performed on serum samples, predominantly in rat studies to identify, for example, substances with goitrogenic activity.

PURPOSE AND RATIONALE

Measurement of thyroid hormone concentrations in the serum has become an important final step in the endocrine safety pharmacology procedures (Capen 1992, O'Connor et al. 2002). Basal concentrations are measured in serum samples in the morning before treatment (to avoid artifacts by the diurnal fluctuation of thyroid hormone concentrations). In contrast to the rise in TSH after a test injection of TRH (dynamic function test), there is no pronounced rise after TRH stimulation. However, in specific situations, the secretion of thyroid hormones may be stimulated by the injection of a biosynthetic TSH preparation.

PROCEDURE

Standard radioimmunoassay procedures are applied, nowadays mainly solid phase assays which can be rapidly performed and evaluated. There are also several enzyme-linked immunoassay (ELISA) procedures from commercial suppliers. It is recommended to perform an Internet check for the most appropriate method at the time of the study (for example, DSL 2005). Methods have been described for triiodothyronine (Nejad et al. 1975; Chopra et al. 1972a; Larsen 1972a, b) and for thyroxin (Chopra et al. 1971; Chopra 1972). The use of assays based on thyroxin-binding globulin (Chopra et al. 1972b) is no longer recommended and cannot be applied to the rat, because the rat does not have this binding protein. However, for the human, measurement of the thyroxine-binding globulin by radioimmunoassay has been successfully applied (Levy et al. 1971).

EVALUATION

The usual procedure for radioimmunoassay data is calculation by a computer program, from standard curves of the hormone to be measured. It is important to have a sufficient number of animals per group, to be able to perform analysis of variance and statistical evaluation by tests of significance.

CRITICAL ASSESSMENT OF THE METHOD

There are now many methods of RIA and ELISA design available for the rat and dog thyroid hormones. It is recommended that each laboratory performs an on-site validation for the methods to be selected for routine evaluation of endocrine safety pharmacology.

14.5.7 Thyroid Function in Chronic Toxicology Studies

Effects on the thyroid gland are found frequently in rodent toxicology studies. The relevance of these findings can be assessed more clearly when measurement of thyroid-related hormones and enzymes is included. There are several toxicants which may be useful as a reference compounds. Long-term studies in environmental toxicology have contributed detailed information, and 28-day rat toxicology tests with thyroid endpoints have been established in the EPA-OECD research programs.

PURPOSE AND RATIONALE

The problems of evaluating thyroid function during high-dose drug exposure are well known for several classes of compounds. In endocrine safety pharmacology, this represents a recurrent difficulty which can be resolved by early inclusion of functional parameters into the long-term toxicology studies. To take preemptive action on possible effects disclosed by long-term toxicity studies, particularly carcinogenicity, it is advised to perform hormone measurements early in the development program, namely, during 6–12-month toxicity studies and carcinogenicity studies. To start mechanistic studies at a later date may be required of if special aspects of enzyme induction and changes in pharmacokinetics need to be investigated for drugs affecting thyroid function.

14.5.7.1 Mechanistic Studies

Test should include measurement of basal concentrations for TSH, total T3, and total T4—at several time points during the study. Measurement of the free fractions of T3 and T4 is in our experience not required and does not contribute to interpretation of the organ-related findings, for example, in thyroid histology. A TRH test may be included for the stimulation of TSH secretion by subcutaneous injection of TRH.

14.5.7.2 TRH Test

The TRH test is performed in a minimal invasive manner, 24 h after dosing on the next morning. The test dose is s.c. injection of 1 ug/kg body weight synthetic TRH followed by blood sampling in unanesthetized rats 30 min later. For mechanistic studies, it is also possible to use another specific TRH test blocking basal TSH by injection of levothyronine (L-T3) 18 h 1 ug/rat s.c. before the test. On the next morning, the TRH dose is injected i.v. followed by blood sampling at 15 min or (in anesthetized rats) after 15 and 30 min.

MODIFICATIONS OF THE METHOD

In carcinogenicity studies, such minimal invasive procedures (basal hormones, TRH test for stimulated TSH) can be included in small groups of animals. In other studies (chronic toxicity), pituitary hormone contents (autopsies 24 h after last dosing) of THS, PRL, and GH are a useful parameter (median sagittal sectioning of pituitary gland with half going to histology and half to hormone assay). Iodine uptake cannot be assessed in the toxicology studies and must remain a specific item satellite groups or for a mechanistic study. The thyroid content of iodoproteins can be assessed if thyroid glands (one-half as for pituitaries) are made available at autopsies, or from added groups included in the study.

CRITICAL ASSESSMENT OF THE METHOD

Inclusion of these investigations of endocrine safety pharmacology is a useful addition to chronic toxicology studies. The inclusion of thyroid safety pharmacology can be of considerable interest because there are frequent changes induced by drugs (examples are phenobarbital and benzodiazepines). Studies including thyroid safety pharmacology have also been performed for a number of environmental toxicants and xenobiotics. In a pilot study (O'Connor et al. 1999), phenobarbital and propylthiouracil (PTU) were investigated

in two short-term in vivo tests (5-day ovariectomized female rats and 15-day intake male Sprague-Dawley rats) and an in vitro yeast transactivation system. Thyroid endpoints were serum hormone concentrations, liver and thyroid weights, thyroid histology, UDP-glucuronyltransferase, and 5′- deiodinase activity. Several thyroid-related endpoints including serum hormone concentrations and histopathology of the thyroid gland were evaluated for their utility in detecting thyroid-modulating effects after 1, 2, and 4 weeks of treatment with PB or PTU. In the Sprague-Dawley rats, phenobarbital administration increased serum TSH and decreased T3 and T4 concentrations. In female Sprague-Dawley rats, PTU administration produced an increase in TSH concentrations and decrease in T3 and T4 concentrations, associated with distinct histopathology changes of the thyroid gland. In male Sprague-Dawley rats, PTU administration caused thyroid gland hypertrophy/hyperplasia and colloid depletion together with increased TSH and decreased serum T3 and T4. These studies with the toxicants confirmed that thyroid gland histopathology coupled with decreased serum T4 concentrations was the most useful criteria for identifying thyroid toxicants in studies of 1–4 weeks' duration. Suitable chronic treatment assays were discussed by Clode (2006). The female pubertal essay was recommended by the EPA for antithyroid activity and antiestrogenic effects. The OECD recommended an enhanced version of the 28-day rat toxicity tests. The characteristic changes in thyroid function observed in the 28-day test have been established using reference toxicants phenobarbital and propylthiouracil (PTU). An early extensive study was performed with an industrial chemical of the thiourea class. This study (Biegel et al. 1995) was a 90-day gavage study and included measurement of serum T3, T4 and TSH, hepatic UDP-glucuronyltransferase activity, and cell proliferation of thyroid and liver. There were characteristic effects elicited by the compound PTI (1-methyl-3-propylimidazole-2-thiol). Due to the toxic dose, there were substantial reductions in body weight gain. The primary target organs were the thyroid and liver. Significant alterations in T3, T4, and TSH levels were found together with increased cell proliferation and UDP-glucuronyltransferase activity. There were characteristic histopathological changes in cell proliferation. The effect of the PTI thiourea on thyroid peroxidase activity was also evaluated in vitro using porcine thyroid microsomes. Findings of the study indicate that PTI enhances the excretion of T4 via induction of glucuronyltransferase and inhibits thyroid hormone synthesis via a direct effect on thyroid peroxidase. Disruption of the hypothalamic-pituitary-thyroid axis results in sustained elevation of TSH and the corresponding thyroid hypertrophy and hyperplasia. In the assessment of drug effects on the thyroid, the rise in serum TSH can be used as a paradigm for thyroid toxicants with inhibitory effects on thyroid peroxidase.

14.6 Safety Pharmacology of the Pancreas

14.6.1 General Considerations

Safety pharmacology of drugs and drug candidates affecting the pancreas is a rapidly expanding field. In the toxicologists' view, there are significant morphological changes of the exocrine pancreas and endocrine pancreas detected in regulatory toxicology studies, including the findings in carcinogenicity studies of 2 years' duration. The current pharmacologist's view is rather single minded, mainly addressing the antidiabetic class of compounds. Various effects on

the exocrine pancreas have been of limited importance. In the antidiabetic field, the main concern is compounds which induced damage to the beta cells, "diabetogenic compounds." The classical examples are alloxan and streptozotocin. There are also a number of potential environmental toxicants (endocrine disruptors), components which can induce damage to the endocrine pancreas upon long-term exposure. In the area of antidiabetic agents, there is considerable evidence from regulatory studies with sulfonylurea compounds, glinids, insulin analogues, incretin mimetics (GLP-1 analogues), and DPP-4 inhibitors. Recently, evaluated compounds have shown particular difficulties concerning risk evaluation of inducing pancreatitis and C-cell hyperplasia in the thyroid of rodents. Details of this effect have been studied, in particular, with relevance to exenatide and liraglutide where such changes have been a matter of debate and discussion concerning clinical relevance. There are a number of established and useful preclinical biomarkers in the assessment of drugs affecting the endocrine pancreas, their relevance being confirmed by application as clinical biomarkers. There are also established biomarkers for damage to the exocrine pancreas.

14.6.2 Antidiabetic Agents

Safety assessment of the pancreas is of particular relevance in the context of antidiabetic agents, of which there is now a wide range including the sulphonylurea compounds, human insulin and insulin analogues (Owens 2011; Swinnen et al. 2011), incretin mimetics for injection (GLP-1 analogues), and DPP-4 inhibitors (gliptins) for oral administration (Barnett 2011; Dicembrini et al. 2011; Forst and Pfützner 2012; Ghatak et al. 2010; Ghatak et al. 2011; Joy et al. 2005; Neumiller et al. 2010; Stephens and Bain 2007). A list of drugs with cytotoxic effects on the pancreas was compiled by Longnecker and Wilson (2002). A new class of antidiabetic is currently under investigation, SGLT2 inhibitors acting on sodium-glucose-cotransporters (e.g., dapagliflozin, Asano et al. 2004; Washburn 2009; Idris and Donnelly 2009; Abdul-Ghani et al. 2011; Kinne and Castaneda 2011). Very extensive safety evaluation was done for sulphonylurea compounds, in the context of preclinical development and later concerning clinical safety, in particular cardiovascular safety and drug interactions (Krentz et al. 1994; Krentz and Bailey 2005; Sehra et al. 2011). This was followed by long and acrimonious considerations about recombinant human insulin and difference related to the use of animal insulins (Richter and Neisser 2005), a controversy which no longer appears relevant due to the widespread development of biosimilar human insulin preparations (worldwide). The discussion about the growth effects of insulin and insulin analogues on cell proliferation was resumed in the context of in vitro studies in cell lines, including cancer-derived cell lines (Leroith 2007; Sandow 2008, 2009; Sommerfeld et al. 2010; Stammberger and Essermeant 2012). The relevance of this important approach was resolved by the conclusion that the clinical evidence from epidemiology studies was the important source of information (Simon and Balkau 2010; Muessig et al. 2011). The current task is now to develop drugs even in the presence of class preclinical findings, by finding an explanation for their toxic mechanism which may show that the adverse effects observed are not related to the proposed use in clinical conditions (Ettlin et al. 2010a, b).

Safety pharmacology of the endocrine pancreas as a target organ for drug effects is a different and specific approach by methods of toxicology (Wilson and Longnecker 1999; Thomas and Thomas 1999; Longnecker and Wilson 2002) and histopathology (Greaves 2007c). Problems arising from effects on the exocrine pancreas are also addressed by these methods; they are identified less frequently during preclinical drug evaluation but may become apparent with prolonged clinical use.

There are established reference compounds for the toxicology of the exocrine pancreas, namely, azaserine (Christophe 1994) and cerulein (Kern 1980), and of the endocrine pancreas, namely, alloxan and streptozotocin (Lenzen and Panten 1988; Szkudelski 2001), which may serve as comparators because their mechanisms of action have been elucidated.

Each of the pharmacological classes affecting the endocrine pancreas (Davis 2006; Nolte 2009) has its own history and particular problems identified during the development phase. There is now an impressive array of methods in early toxicology, based on receptor profiling, in vitro cell-based assays, and molecular biology methods directed at the development of early biomarkers suitable for preclinical toxicology

development (Dambach and Gautier 2006; Pavanello 2006, Collings and Vaidya 2008) and translation to clinical toxicology (Muller and Dieterle 2009). Some of these biomarkers may find their definitive use in regulatory toxicology (Godsaid and Frueh 2006), after validation for specific target organs such as the kidney (Vaidya et al. 2008, 2010), the endocrine pancreas, and hormone-responsive endocrine tissues, for example, the gonadal system. More recently, biomarkers have acquired an important role in the assessment of the effects on the skeletal system and connective tissue, for example, in the evaluation of bisphosphonates, calcitonin, and parathyroid hormone. Examples of established biomarkers for damage to the exocrine pancreas are the enzymes amylase and trypsin; new biomarkers are being established (Walgren et al. 2007).

The studies on mechanisms of action may be suitable for identifying new therapeutic options or specific pharmacological mechanisms, but they are not relevant for the preclinical safety evaluation for the design of phase 1 studies. There are a number of important considerations concerning the use of receptor profiling of new chemical entities as well as for compounds with established hormone activity. The test systems for receptor affinity and signaling are based on cells or cell lines which reflect only one particular organ, whereas frequently receptors are found in a number of target organs responding at different doses and with different activation kinetics. An example is compounds which act both on endocrine target organs and on the central nervous system. It is then difficult to assess which receptor category gives rise to the relevant biological effects. This needs to be clarified by targeted endocrine evaluation as well as safety evaluation of centrally mediated effects including neurotoxicity. A particular case is incretin mimetics which have clinically relevant effect on appetite control and satiety. Safety pharmacology will usually be required to assess the relevance of centrally mediated effects in contradistinction to effects mediated by the gastrointestinal tract.

In the development of new methods to assess pancreatic safety pharmacology in biological systems (which can be related to classical studies in pharmacology and regulatory toxicology), there is an increasing recourse to animal models based on transgenic animals. These models may be closely related to toxicological pathology (Longnecker 2004; Hruban et al. 2006), and they may address specific tasks of exploratory pharmacology (Srinivasan and Ramarao 2007; Kumar et al. 2012) including reproductive toxicology (Jawerbaum and White 2010).

One specific area in application of safety pharmacology to the study of chemicals and compounds in the environment ("endocrine disruptors") is the inclusion of targeted investigation in the OECD 407 protocols (Hectors et al. 2011), often including the toxicological assessment in vitro of natural compounds used as nutritional enhancement (Reiter et al. 2011) and searching for leads in drug research (Ahrén 2009). The particular relevance of this approach was that animals were treated for 10–28 days including a maximum tolerated dose; parameters of endocrine function such as measurement of hormones were included during method development and assessed for diagnostic relevance. These programs started with the exploration of defined chemical entities, mainly established drugs such as synthetic gonadal and adrenal steroids. As an example, in the context of effects on the endocrine pancreas (beta cell function), bisphenol A was addressed as an endocrine disruptor (Alonso-Magdalena et al. 2008, 2010). The involvement of estrogen receptors (ER-alpha and ER-beta) in the regulation of pancreatic beta cell function has been explored (Nadal et al. 2011) and may be a future topic of safety pharmacology.

Studies on endocrine safety pharmacology are part of the "supplemental safety pharmacology studies" described in the ICH guideline S7A. These supplemental studies are designed and performed to evaluate potential adverse effects on organ system functions (endocrine organs and target tissues of hormones) which are not addressed by the general methods of the core battery or by repeated-dose toxicity studies. The definition clearly requires that the specific pharmacology of the test substance be known starting point for supplemental safety pharmacology. This knowledge will inform the investigator about decisions related to selecting test articles of endocrine safety pharmacology. The strategic objective is to bring information from two different sources to bear on the problem and to initiate the translational dialogue of pharmacology and toxicology. The classical source of information, namely, toxicological pathology with defined methods of morphology and (more recently) molecular biology of endocrine tissues (at autopsy), and the new source of information, that is, methods for functional assessment of endocrine organs and endocrine target tissues (during the study), provide information for the interpretation (mechanistic toxicology). This is obviously a process

leading from indications in biochemistry and molecular biology to the exploration and confirmation in targeted animal studies. This can be done in parallel with toxicological pathology, in the repeated-dose toxicology studies where possible and in satellite groups when necessary. The findings at the functional level and at the morphological level are shared and compared for consistency. The best opportunity prior to clinical studies is inclusion of hormone assays and hormone-related biomarkers as well as specific endocrine organ pathology in the regulatory toxicology studies. In the majority of cases, this will mean early treatment periods of 4 weeks (as in toxicology); there remain however numerous questions which are better addressed by targeted investigation included in the 6-month or 1-year toxicology. The final and most critical step in future development will be inclusion of such parameters in the lifetime toxicology performed in rodents, whenever the additional effort and expense appears justified. The critical task of assessing the relevance of findings for future therapeutic intervention in humans has been prepared in several instances by working within a group of compounds that already has a clinical history including long-term use and epidemiological studies, for example, about the relation of preclinical findings in animal toxicology to cancer risk in humans (Scarpelli et al. 1984; Scarpelli 1989; Longnecker 1999; Germann et al. 1999; Gopinath 1999).

The general pharmacology profiling of new drugs nowadays is predominantly performed by in vitro testing, followed-up by cell-based assays and studies in endocrine-related cell lines when available for pancreatic beta cells (Poitout et al. 1995, 1996; Skelin et al. 2010). This may be quite an effective procedure for preselection of candidate compounds with hormonal activity (Houck and Kavlock 2008). It is also an interesting approach to the receptor-mediated effects which can be studied on the isolated pancreas (Barseghian and Levine 1980) and on beta cell lines in relation to the effects of glucocorticoids (Pierluissi et al. 1986; Delaunay et al. 1997) and other hormones (Lenzen and Bailey 1984; Hectors et al. 2011). These in vitro explorations will need in each case to be followed-up by animal studies, the best option being the repeated-dose studies in the toxicology program. The studies of the pancreas proceed in parallel, with more flexibility in study design and (hopefully) providing the explanations for the questions which are raised by the finding in pathology and toxicology.

14.6.3 Endocrine Pancreas Study in Rats

In the toxicology studies (2 weeks, 1 month, 3 months, etc.) morphological changes in the endocrine pancreas and less frequently in the exocrine pancreas are detected, often without an obvious relation to the pharmacological profile of the drug investigated. In general, there are predictions and early indications for a therapeutic potential, which provide direction for targeted investigation. There may be indications from receptor interaction of pancreatic beta cells, for example, with the glucocorticoid receptor (McMahon et al. 1988; Delaunay et al. 1997), of insulin-responsive tissues with the IGF-1 receptor (Sandow 2009) or with thyroid hormones and steroids (Lenzen and Bailey 1984). Any indications for interaction with the glucocorticoid receptor (GR), GLP-1, and glucagon receptor (GCGR) from early drug profiling may be followed by a search for adaptive changes during repeated-dose treatment (Brubaker and Drucker 2002; Hansotia and Drucker 2005; Drucker et al. 2012). The animal study reflects the sum of changes induced by a candidate drug, and the site of action at different levels can be investigated when characteristic analytical determinations are available. For more complex research questions of receptor signaling and receptor interaction (crosstalk), in vitro studies on cell lines will need to be added where the response in the regulatory toxicology system needs to be explored in more detail and when particular safety issues require mechanistic explanations.

In the selection of animal model, many studies are performed in adult normal rats, by including special analytical determinations and biomarkers in the regulatory toxicology studies (similar to the enhanced protocols in environmental toxicology). This approach is helpful, when necessary satellite groups are added, or separate satellite studies need to be designed. For antidiabetic compounds, pancreatic safety studies in normal rats are often inappropriate. The decision is then for diabetic animal models (Herling 2006; Mueller 2008; Tourrel et al. 2002; Srinivasan and Ramarao 2007; Kumar et al. 2012; Hempe et al. 2012; Tesch and Allen 2007; Masiello 2006; Alemzadeh et al. 2002) which may be directed more at diabetes type I by extensive destruction of beta cells or at diabetes type II by inducing insulin resistance, including the reduction of beta cell mass. Such studies often transcend the tasks of safety pharmacology, and they may be directed at identification of specific extrapancreatic effects, for example, on the vascular system (Murthy et al. 2010).

Safety issues arising from reproductive toxicology findings are addressed in specific models in, for example, pregnant animals (Jawerbaum and White 2010). In recent submissions for marketing authorization of incretin mimetics, diabetic animals were included in the primary pharmacology studies of exenatide and liraglutide (Byetta 2006; Victoza 2009) and also in the primary pharmacology of DPP4 inhibitors (Galvus 2007; Onglyza 2009; Trajenta 2011). The advantage of diabetic animals is that pharmacodynamic effects are more readily characterized and the preclinical chemistry is more characteristic of the mechanism of action.

Another species for diabetic animal models in toxicology is the mouse, including a large number of transgenic animal models (Longnecker 2004; Hruban et al. 2006). The situation is more complex for diabetes models in dogs. Previously, pancreatectomized dogs were used for insulin studies, whereas now, the rodent models are considered sufficient for safety assessment. In regulatory toxicology, the dog is the second species for long-term studies; it is also shown chosen for verification of specific issues (e.g., saxagliptin) and for the pharmacokinetic analysis.

14.6.3.1 Analytical Methods for Pancreas Functions

There are a number of analytical determinations which can be built into pancreatic safety pharmacology in animals. Evaluation of beta cell function is similar to clinical protocols (Weinstock and Zygmont 2010), fasting blood glucose, and the change after drug administration characterized the activity pattern (antidiabetic, hyperglycemic). The plasma concentrations of insulin and glucagon can be measured; measurement of C-peptide is an index of pancreatic secretory capacity which may change with loss of beta cells. The noninvasive C-peptide measurement using the urinary C-peptide/creatinine ratio is clinically validated and may be applied to any mouse in a similar manner (Bowman et al. 2012; Besser et al. 2011). The change in glycated hemoglobin (A1c) may be determined after 1 month or longer intervals of treatment as an index of efficient glycemic control or loss of control. Description for specific analytics suitable for incretin mimetics and gliptins is found in a number of publications (Gedulin et al. 2005; Pérez-Arana et al. 2010; Gil-Lozano et al. 2010; Nachnani

et al. 2010; Wu et al. 2012) and in the assessment reports of the European Medicines Agency (EMA). These documents are particularly valuable because the primary animal pharmacology of antidiabetic compounds is of not described in sufficient detail, whereas the clinical reports are very extensive for incretin mimetics (Byetta 2006; Victoza 2009) and for gliptins (Galvus 2007; Onglyza 2009; Trajenta 2011).

Dynamic function test may be included in satellite studies, in a similar manner as for clinical protocols (Weinstock and Zygmont 2010), namely, the glucose challenge (OGT) and insulin challenge, also including euglycemic clamp studies in rats.

PURPOSE AND RATIONALE

The study of endocrine pancreas function may be performed in normal rats or—in case of specific pharmacological knowledge about the mechanism of action—in rat models of type II diabetes and other related models (Tourrel et al. 2002; Masiello 2006). Assuming that there is no prior knowledge, young male or female rats (100 g initial body weight) or adult rats (2–300 g BW) are selected for the study.

PROCEDURE

Male and female rats of the same age are assigned to control and treatment groups (six animals per group), preferably at two dose sizes related to the toxicology studies.

Choice of animal models for the incretin mimetics (exenatide, liraglutide) are often diabetic rats because insulin release in these models is dependent on glucose levels.

The animals are treated in the same way as in the toxicology study, either by gavage or daily injections, up to 4 weeks. At intervals of 7 days, a test procedure is performed for the endocrine pancreas which may be blood sampling at the same time of the day (preferably in the morning) for the determination of hormone and metabolic parameters. The animals may have free access to feed or may be kept without feed during the night, prior to sampling.

Parameters to be investigated are blood glucose, insulin and proinsulin, glucagon, GLP-1 (total and active GLP-1), somatostatin, and other hormonal parameters (e.g., ghrelin). When an effect on glucose regulation is known or anticipated from pharmacology studies and early toxicology, glucose and insulin are determined prior to drug administration and 1–2 h after treatment. A time-action profile for glucose regulation at the higher dose level is recommended, when there are consistent effects on glucose regulation (duration of the effect). In any long-term study of 3 or 6 months duration, the assay of glycated hemoglobin (HbA1c) needs to be included. There are species-specific methods for the rat, dog, and mouse. It is recommended to perform an initial validation of the analytical methods for glucose-regulating hormones and related parameters, when performing studies in mice and dogs. There is a wide spectrum of suppliers and reagents, from which assays may be selected either in the form of single hormone assays or multiplex assays. There is also an array of commercially available biomarkers for metabolic and toxicology studies (websites of suppliers).

Biomarkers may also be determined during this study, depending on the drug-receptor profile, results of in vitro investigations, and cell-based studies which have been performed prior to development decision. Effects on the endocrine pancreas are much more frequent, and the related examinations take precedence. There is also the option of monitoring parameters of exocrine pancreas function, for example, enzyme levels and biomarkers related to exocrine pancreas function (Muller and Dieterle 2009, Walgren et al. 2007).

All specific investigations of blood sampling at particular days of the study, and urine samples when appropriate, place an additional burden on the animals and may interfere to a significant extent with the protocol of a regulatory toxicology study (Redfern and Wakefied 2006). The results of the satellite study need to be reviewed in the context of the regulatory toxicology which needs to follow an established protocol.

At the end of the treatment period, autopsies are performed, and tissue samples are processed for determination of hormone contents, for molecular biology studies, and for targeted histology and histomorphometry.

EVALUATION

For all quantitative parameters such as organ weights and hormone concentrations, group means are calculated, and the significance of differences is assessed by the appropriate statistical methods. The aim is to show that the drug was tested at doses which achieve biologically effective concentrations (later to be followed-up by pharmacokinetics). In relation to the regulatory

toxicology studies, this will provide proof of relevance and enable prediction of anticipated adverse events (AE) in phase 2 clinical pharmacology (early risk management plan).

Histology may be reported in descriptive terms, evaluated by a semiquantitative method, or by computer-assisted histomorphometric methods (to be used for quantitative statistical analysis). For advanced methods of in situ hybridization and gene expression, a description of the observed changes is generally appropriate together with quantitative data generated by computer-assisted analysis of gene expression profiles.

MODIFICATIONS OF THE METHOD

In the development of a drug candidate, there may be an established profile, for example, for an antidiabetic agent or a general project plan based on indications of receptor profiling. Studies on endocrine pancreas profiling with modern methods of endocrine evaluation have been performed, for example, with insulin analogues (insulin lispro, insulin aspart, insulin detemir, insulin glargine), GLP-1 agonists (exenatide, liraglutide), and DPP-4 inhibitors (vildagliptin, sitagliptin, saxagliptin, linagliptin). The classical compounds, for example, sulphonylureas, do not have the advanced methodology of hormonal assays but contribute considerably to the knowledge of biochemical mechanisms and toxicological evidence. They have in particular contributed to the study of mechanisms of action on ATP-sensiive K^+ channels (Inagaki et al. 1995, 1996; Miki et al. 1998; Quast et al. 2004; Thomas and Smart 2005; Gloyn et al. 2004).

CRITICAL ASSESSMENT OF THE METHOD

The endocrine pancreas safety study of rats is a satellite investigation providing additional evidence for understanding of results of the regulatory toxicology study is an important element, because it integrates the biological response of several systems including the currently important incretin hormone system.

14.6.4 Exocrine Pancreas Function

Effects on the exocrine pancreas are occasionally detected in studies with rats and mice; there are also a number of observations in carcinogenicity studies with currently used drugs and toxicants in evaluation of chemicals and environmental contaminants. Drug-metabolizing enzymes in endocrine, exocrine, and pancreatic tissue are inducible by certain chemicals. Many observations have been made in histopathology (Greaves 2007c); changes in pancreatic enzyme reactivity have been found in patients with chronic pancreatitis and pancreatic cancer. The current discussion about the risk of acute pancreatitis during treatment with exenatide and incretin mimetics shows that there is a need for evaluation and safety pharmacology, in particular for new development compounds of similar class. Acute pancreatitis has been found after administration of, for example, corticosteroids, diuretics, antidiabetics, and analgesic or anti-inflammatory agents (paracetamol, indomethacin, salicylates). It is therefore of interest to include monitoring of exocrine pancreas function in all regulatory toxicology studies related to the derived or related drug classes.

PURPOSE

Diabetic rat strains are predisposed to the development of acute and chronic pancreatitis (a characteristic toxicant in rats is in the cholecystokinin analogue cerulein, a compound which may cause maximum pancreatic secretion). Cerulein is also used as a diagnostic agent. Acute pancreatitis has been observed with several anxiolytic and antipsychotic drug candidates. Whereas the development of acute pancreatitis may be detected by changes in pancreatic enzyme excretion, chronic pancreatitis is more difficult to detect; focal tissue chronic inflammation with or without fibrosis has been described as a common finding in the exocrine pancreas of aged rats, to some extent also found in mice, hamsters, and beagle dogs (Greaves 2007c). The increasing prevalence in aged rats already indicates the impending problems in carcinogenicity studies, where chronic pancreatitis is a very frequent finding in histopathology. The finding of changes in endocrine pancreas function (controlled by glucose tolerance, serum insulin, and histology of pancreatic beta cells) was found to be associated with atrophy of pancreatic acinar cells in dogs and monkeys. Interestingly, long-term treatment with phenobarbital induced proliferation of pancreatic acinar cells together with that of endocrine pancreatic cells (Jones and Clark year?). The findings were associated with a distinct change in drug-metabolizing capacity of the pancreas and distribution of CP 450 enzymes.

PROCEDURE

Animal study of rats and dogs, biomarkers, and dynamic function test

14.6.4.1 Details of the Method

Pancreatic growth is regulated by cholecystokinin; there is a negative feedback mechanism on CCK by stimulation of intestinal trypsin. As a consequence, feeding with raw soy flour containing a trypsin inhibitor will remove endogenous trypsin and may stimulate the release of CCK with resultant pancreatic proliferation. A number of soy derivatives have been investigated in OECD studies for environmental toxicants. Studies with pentagastrin administration have shown an increase in pancreatic size and enzyme secretion, principally characterized by hypertrophy of acinar cells. A number of such studies were performed in the context of evaluating carcinogen and hamster treatment with nitrosamines (505). The continuous administration of CCK-8 induced increase in pancreatic weight, protein and DNA content, and thymidine labeling index. As a consequence, CCK-8 may be used as a model toxicant in studies on proliferation and apoptosis of the pancreas. Injections of isoprenaline have been shown to increase pancreatic weight. This confirms the relevance of including safety pharmacology of the exocrine pancreas when there are structural indications for effects on pancreatic enzymes. Characteristic changes in histopathology have been reviewed (Greaves 2007c), among them duct proliferation in rabbits treated with corticosteroids. There were also zones of exocrine pancreatic cells with increased eosinophilic staining of the cell cytoplasm. The future objective for safety pharmacology is to validate biomarkers of pancreatic enzyme secretion which can be monitored in long-term toxicology studies. In the presence of focal lesions and neoplasia of the exocrine pancreas found in carcinogenicity studies, functional assessment is important for risk assessment. The pancreatic acinar cell hypertrophy, hyperplasia, and adenoma in rats were modified by a number of therapeutic agents such as testosterone, estradiol, and cholecystokinin as well as cholecystokinin analogues. CCK is an important growth factor for normal pancreas; new drugs acting on gastrointestinal hormones may stimulate neoplastic growth of acinar cells by a CCK-related mechanism. One of the established toxicants is azaserine. Alterations of the exocrine pancreas may also be found in chronic toxicity studies with mice.

CRITICAL ASSESSMENT OF THE METHOD

Among the established compounds inducing pancreatic proliferation, there is ciprofibrate, a peroxisome proliferator tested in Fischer 344 rats. There are some indications that an increase in prolactin secretion may contribute to pancreatic tumor development. Prolactin secretion is one possible biomarker which may be detected by analytical studies in rodent toxicology. A mechanistic explanation for the development of pancreatic acinar carcinoma in Fischer 344 rats has been an effect on decreasing bile acid synthesis and changing bile composition during treatment with peroxisome proliferators (e.g., clofibrate). The change in bile acid synthesis may increase CCK secretion and stimulate acinar cell proliferation by CCK-A receptors (IUPHAR database). Human safety studies of hypolipidemic agents have not disclosed any similar development for peroxisome proliferators. In nonhuman primates, beta cells are

the main cell population, glucagon cells comprise about 10%, and somatostatin-secreting D cells are a much smaller population. The technical analysis by immunohistochemistry of the prevalent cell types in rat pancreas is time consuming and difficult; it would be helpful to have hormone measurements which could replace risk assessment by histomorphometry. Particular factors to be monitored are glucagon and somatostatin, which might be measured in the circulation (basal levels and dynamic function tests), or by molecular biology methods for the glucagon and somatostatin-related receptor proteins. Such methods ex vivo might contribute to replace the time-consuming histomorphometry.

14.6.5 Pancreatic Cell Lines and Ion Channels

Pancreatic ion channel signaling has been studied in HEK293 cells and many other models. The in vitro effects of sulfonylureas and glinides, as an example of using safety assays, have focused on the function of ion channels in the beta cell membrane, an example for continuing the work on sulphonylureas (Müller and Geisen 1996; Kramer et al. 1996) which require mechanistic implications for the site of action. Much of this work on classical bioassays, pharmacological assays, and biochemical methods has been summarized (Herling 2006; Mueller 2008). The examples of glimepiride, nateglinide, and repaglinide are of particular relevance for the studies on ion channels in pancreatic cells. These compounds have been tested on rat pancreatic ductal cells, concerning their interaction with the K(ATP) channels and the sulphonylurea receptor one (SUR1). The KATP channel is an octameric complex of the inward-rectifier potassium ion channel Kir6.2 and sulfonylurea receptor SUR1 which associate with a stoichiometry of Kir6.24/SUR14. The HEK 293 cell line has been discussed as a vehicle for isolated receptor channels, including the sulphonylurea channel (Thomas and Smart 2005). Application of the HEK-293 cell system to studies of sulphonylureas and glinides has been reported (Hu et al. 2000). In these studies, the direct interaction of nateglinide with K(ATP) channels in rat pancreatic beta cells was investigated as a suitable test system for orally active antidiabetic agents. Methods and concepts for the pancreatic sulphonylurea channels are discussed in the IUPHAR database of ion channels (Inagaki et al. 1995, 1996; Miki et al. 1997, 1998). The selectivity of ion channels for insulin secretagogues (sulphonylureas and glinides) have been discussed by Quast et al. (2004) in relation to the effect on pancreatic beta cells and the presence of KATP channels in coronary myocytes. They found a different selectivity for the pancreatic beta cell membrane over the cardiovascular KATP channels when comparing long sulphonylureas (glibenclamide) and short sulphonylureas (nateglinide). For the safety pharmacology evaluation, this means that oral antidiabetic agents need a specific profiling with regard to their effects on ion channels. The mechanisms of insulin signaling in pancreatic beta cells have been elucidated by studies with tissue-specific knockout animal models of the insulin receptor (Kulkarni et al. 1999a) and related studies on the insulin signaling in cultured beta cell lines (Kulkarni et al. 1999b). Due to the intrinsic differences of these models when compared with the situation in toxicological studies in rats and mice, studies in cultured cell lines and animals with

targeted knockout have remained a scientific approach; there is currently no direct relation to safety pharmacology.

14.6.6 Animal Models of Antidiabetic Activity

There are some specific issues related to safety evaluation of GLP agonists and gliptins by pancreatic toxicology in repeated-dose studies. Evidence is in part summarized by the EMA assessment reports and the related scientific discussion; the specific questions concerning safety evaluation are reviewed. The preliminary test is whether any dose-related response can be obtained in the animal species used in toxicology or whether a different animal species is to be select. One example is the evaluation of exenatide in repeated-dose studies where the response of the mouse is similar to that of the intended therapeutic use, whereas the paradoxical response of the nondiabetic rat is probably due to the release of catecholamines. This precludes the use of the rat in conventional toxicology studies with exenatide, because the response is different and gives rise to different histological findings.

Selection of normal rats for safety pharmacology may not always be appropriate. This has developed for single-dose studies and repeated-dose protocols. In studies with exenatide, nondiabetic mice and rabbits were suitable. The injection of exenatide reduced plasma glucose in both species. Nondiabetic rats

however showed a paradoxical hypoglycemic response, and studies were therefore performed in *diabetic* mice and rats. There is a wide selection of models for diabetic rats and with a considerable range of sensitivity to drug effects. In the exenatide studies, a reduction in fasting glucose and an acute increase in insulin secretion were shown in the diabetic models in the presence of elevated glucose levels. One-month treatment was associated with a decrease in A1c. In these studies, the effects observed were increased insulin secretion, suppressed basal and postprandial glucagon secretion, and improved insulin sensitivity. Specific effects on the adrenocortical steroid secretion were investigated (Gil-Lozano et al. 2010). A once-a-month depot injection for exenatide has been evaluated in rats (Gedulin et al. 2005). Effects on the gastrointestinal tract are not usually investigated in safety pharmacology studies. They are however relevant for the pharmacological profile of GLP analogues (Nachnani et al. 2010). In the case of incretin mimetics, in particular of the GLP-1 agonists, inclusion of studies on gastrointestinal gastric emptying has shown consistent drug effects and is recommended for safety pharmacology evaluation of new compounds in this class.

In this context of safety pharmacology of GLP analogues, the evaluation of pancreatic exocrine secretion is of relevance (Kern 1980; Greaves 2007). This was done in some animal studies with exenatide and liraglutide (Malhotra et al. 1992; Vrang et al. 2012). Exenatide was examined for its effect on cholecystokinin-stimulated secretion of amylase and lipase in the rat. CCK-8 injection is a test of exocrine pancreas function. Another test was pentagastrin-stimulated gastric acid secretion in cannulated rats.

There were some specific issues in the safety pharmacology of the gliptins. Gliptins are small molecules which require extensive profiling. The primary screening procedure for saxagliptin was its ability of binding of appropriate radioligands to 42 receptors and ion channels or to inhibit the action of 14 different proteases. No significant effects were observed in this initial screen. This test of receptors and enzyme profiling is important because effects on GLP-1 receptors have been found with liraglutide, effects which were different from those anticipated. In rodents, GLP-1 receptors were found on C cells of the thyroid, and receptor activation was shown, in a species-specific manner different from human and monkey receptor activation.

The safety evaluation for *saxagliptin* as a selective DPP-4 inhibitor (DPP4) was done by in vivo efficacy testing in Sprague-Dawley and Zucker rats and in the Zucker FA/FA rats, a model for type II diabetes with several pharmacodynamic endpoints: plasma GLP-1, insulin and glucose levels postglucose challenge, and fasting glucose levels. It is important to note that the testing needs to be done in the presence of increased glucose concentrations, because both the gliptins and the GLP agonists are active in the presence of increased glucose concentrations, but not when glucose levels are in the normal range (Augeri et al. 2005; Tahara et al. 2009; Gallwitz 2008).

The single-dose toxicology studies were performed including the monitoring for 2 weeks after a single dose (standard toxicology procedure). In principle, hormone parameters could be included in such a protocol, in parallel to the regulatory toxicology. Repeated dose toxicity was evaluated in mice, rats, dogs, and cynomolgus monkeys at exposure markedly higher than the therapeutic exposure in a number of nonclinical toxicology studies.

Vildagliptin as a small molecule and DPP4 inhibitor was initially studied for its biochemical activity and subsequently by in vivo studies in rats and monkeys. Studies in diabetic rats and insulin-resistant monkeys (cynomolgus) demonstrate a dose-related glucose lowering effect. Chronic effects were studied in *prediabetic* insulin-treated monkeys (the specific model is discussed by Ahrén (2006)). The particular details were discussed with regard to an increase in beta cell mass in neonatal rats and improved beta cell function in streptozotocin-induced diabetic mice. The effects on the gastrointestinal tract were examined in relation to the established effects of an incretin mimetics. Vildagliptin and the other gliptins have no significant effect on gastric emptying in experimental models, for example, in monkeys. One safety issue different from that of other gliptins was modulation of immune function; this effect is outside the scope of endocrine-mediated effects but has considerable relevance for risk assessment. An interesting aspect is the safety assessment of drug combinations in the primary drug application. Vildagliptin was administered to Zucker fatty rats together with nateglinide, and additive effects on glucose parameters were found. The evaluation was complicated by findings of gastrointestinal symptoms in dogs which were however unrelated to the characteristic effect of incretin mimetics on a delay in gastric

emptying and decreased gastrointestinal motility. The dogs in this vildagliptin study had diarrhea and soft feces. Carcinogenicity studies were performed in mice and rats with no findings that gave rise to concern. In particular, there was no effect reported on the exocrine pancreas after long-term treatment. A matter of concern with tumors is noted in the mouse carcinogenicity study which might be the result of an effect on the pituitary-gonadal axis. There was an upregulation of genes related to milk production, suggesting that hormone-initiated changes are occurring in the mammary gland of mice. These findings are not of relevance for humans.

Another well-documented oral antidiabetic agent is *linagliptin*. The DPP4 inhibition after a single dose is long-lasting making this a once-a-day medication. As with the other members of this class, linagliptin can stimulate glucose-dependent insulin secretion, achieve suppression of glucagon secretion, and to a limited extent delay gastric emptying (not confirmed in humans). Linagliptin was tested both in normal and diabetic rats, with characteristic glucose-induced elevations of insulin and prolonged elevations of endogenous GLP-1. It was found that the effect on blood glucose in diabetic rats was dependent on the severity of insulin resistance. Animal models were Zucker diabetic fatty rats. Another antidiabetic model was treatment of cynomolgus monkeys, a monkey model with similarities to type 2 diabetes. Cynomolgus monkeys have been used as an animal model for other antidiabetic compounds with reproducible results; the diabetic condition depends on the increased food intake of the animals in captivity (insulin resitance and diabetes associated with obesity). Diabetic mice were treated for 14 and 28 days with a consistent effect on glycated hemoglobin (A1c). In the secondary pharmacodynamic studies on gastrointestinal function in rats, there was no decrease of gastric emptying. The effect of pharmacodynamic drug interactions was studied combining linagliptin with metformin. This combination acts by different mechanisms, and there was an added effect on glycemic control when comparing monotherapy and combination therapy. In pharmacokinetics studies, there was no indication that linagliptin does cross the blood-brain barrier. The studies were performed because centrally mediated effects of incretin medics on food intake have been suggested from studies with, for example, exenatide. In the repeated-dose toxicity studies in rats, there were effects on reproductive organs, thyroid, and lymphoid organs at high concentrations, conceivably by interaction with hormone-related enzyme systems. After initial testing, no repeated-dose toxicity studies were performed in dogs because of secondary cardiovascular changes which were considered species-specific and preclude the use in toxicology. Repeated dose toxicology was therefore done in cynomolgus monkeys. Intravenous administration of linagliptin was associated with atrioventricular block and symptoms of pseudo-allergy. These studies were not further pursued because the route of administration will not be used in clinical therapy. In the 2-year carcinogenic rodent studies, there were no carcinogenic effects in either mice or rats.

In summary, the primary pharmacology of the gliptins (vildagliptin, saxagliptin, and linagliptin) is extensively studied and documented. The results confirm that both pancreatic safety studies and inclusion of endocrine parameters are advisable, in particular referring to findings with linagliptin. There were no indications that the general principle of DPP4 inhibition has any characteristic effect on hormone systems other than the endocrine pancreas. The findings described as pseudo-allergy merit a more detailed discussion. Pseudo-allergic reaction became apparent without prior sensitization and was associated with significantly increased plasma histamine levels. This is reminiscent of nonspecific histamine-releasing effects observed with LHRH antagonists which contain multiple basic amino acids. The structural reason for the pseudo-allergy observed with linagliptin has not been followed-up. Clinical study results indicate that pseudo-allergic found with linagliptin is not of relevance for humans. The interest of monitoring plasma histamine levels as a biomarker for pseudo-allergy is evident from these studies.

14.7 Pharmacology of Bone

14.7.1 General Considerations

With increasing knowledge of the regulation of bone as a hormone-dependent organ system, hormones involved have been characterized in biochemical and functional detail, with regard to calcitonin, parathormone, and calciferols (vitamin D group). A number of validated biomarkers are available for the structural changes occurring in bone, referring in particular to osteoporosis and metastatic bone disease also to changes in end-stage renal failure (ESRF). A detailed discussion of biomarkers which may be included in animal studies for safety pharmacology of bone is presented there.

The task of this section on endocrine safety pharmacology is to evaluate the use of existing methods for early investigation of effects on bone, to be detected prior to planning studies in clinical pharmacology for a drug candidate. This may be a new chemical entity (NCE) or an established compound with effects on bone predicted from early experiments but not well characterized. The critical question is how studies can be included in the preclinical profile, in particular whether they can be added to the regulatory toxicology studies. Any dose-related effects on bone are likely to have an effect on compound development and need to be detected at an early stage whenever there are safety concerns and open questions.

Bone is an endocrine-dependent organ tissue that may undergo profound changes with prolonged therapy. One aspect is the structural change and loss of mineral content after ovariectomy in animals and the related situation in aging humans that affects both men and women (fracture risk). Another aspect is the prevention of such changes in the bone, for example, by antiresorptive agents (e.g., bisphosphonates and steroidal compounds). Endocrine safety pharmacology can contribute during the early phase of drug evaluation, to recognize the need for targeted studies in phase 2 clinical development.

A number of drugs are known to affect bone metabolism to some extent and different mechanisms, among them are heparin, warfarin, cyclosporine, glucocorticoids, medroxyprogesterone acetate, thyroid hormones, selective estrogen receptor modulators (SERM), atypical antipsychotics (clozapin), and certain antibiotics.

As outlined further by the FDA and EMEA, supplemental studies must be conducted outside the safety pharmacology core battery, when there is a cause for concern. This includes effects of the test substance on renal/urinary parameters, on parameters of the autonomic nervous system, the gastrointestinal systems, and other organ systems such as skeletal muscle, immune, and endocrine functions. In this context, Henriksen et al. (2010) have reviewed the options for targeted investigation of effects on the bone by using specific biomarkers which are validated for research on animal models and in a similar manner have been applied in clinical studies. In preclinical studies and regulatory toxicology, the task is to identify indications for a potential effect on bone in clinical studies. The application of such methods is justified by the gain in information, using established animal models extending their predictive power. In the clinical application, biomarkers are helpful as an initial indication for clinical efficacy which subsequently has to be supported and confirmed by clinical outcome studies. During the early development of bisphosphonates, biomarkers of bone resorption were the leading indicators for a consistent clinical effect and at that time were designated "surrogate endpoints."

Safety pharmacology of the skeletal system is related to the secretion of calcitonin, parathormone, calciferols, the electrolyte balance of calcium and phosphate, and finally to the manifestations of the effect of drugs and hormones on bone structure. The characteristic findings in toxicological pathology (Woodard et al. 2002) and histopathology have been reviewed (Greaves 2007b). There are a number of therapeutic drugs with indications in diseases with manifestations on bone diseases (ICD-10), for example, osteitis deformans, postmenopausal osteoporosis, and end-stage kidney disease (Friedman 2006; Bikle 2009). In safety pharmacology of the bone, assays related to hormonal regulation of bone and cartilage as an endocrine-dependent organ system are performed in a search for preclinical evidence for mechanisms induced by drug candidates or investigational drugs. The classical regulatory toxicology studies often detect changes in bone formation in reproductive toxicology, with no direct relation to a signal for future clinical use. Studies in normal mice and rats will often miss skeletal changes which are difficult to assess and may require histomorphometry of the bone. Direct hormone assays for

calcitonin and parathormone are difficult to perform and interpret. There are some enzyme assays in conventional clinical chemistry which may indicate that the specific pharmacology needs to be extended and/or reinvestigated and the inclusion of biomarkers of bone turnover is certainly to be recommended.

This situation has improved considerably with the introduction of bone-related biomarkers which may be easily included in regular toxicology and in targeted satellite investigation in animals. There are some interesting examples for well-documented drugs, for example, calcitonin, parathormone, teriparatide, several bisphosphonates (Licata 2005), and calcimimetic cinacalcet, and there are of course the classical observations of steroid-induced osteoporosis related to the effects of chronic therapy with glucocorticoids and their derivatives in asthma, chronic obstructive pulmonary disease (COPD), and related indications. In the early profiling of a drug candidate, interaction with a particular set of receptors, for example, steroid receptors or the calcium-sensing receptor (Theman and Collins 2009), may have been found and give rise to a more detailed safety assessment.

Duration of treatment in rats is based on bone remodeling cycles (six cycles recommended). The ovariectomized rat (OVX) is frequently used for such studies (Lelovas et al. 2008).

14.7.2 Bone Safety Study in Rats

In the context of regulatory studies, there are two problems which need to be considered concerning the standard inclusion of biomarkers for increased bone turnover. There are a number of therapeutic agents which are known to affect bone turnover; therefore, drug candidates might be addressed if they belong to one of the classes already known to affect bone turnover (Rosen 2012).

PURPOSE

The specific bone safety model in adult female rats is the ovariectomized rat (OVX).

The intact female rat is not suitable to detect subtle changes. Moreover, male rats are not adequate models for bone turnover studies, even if antiandrogens would cause an interesting change in bone turnover.

PROCEDURE

The preferred selection for a bone safety study is therefore based on adult ovariectomized female rats, preferably treatment to be started at least 4 weeks after ovariectomy. Inclusion of two dose levels may be sufficient; preferred duration of treatment is 6 or 12 weeks. This model is particularly useful for compounds with antiresorptive activity (calcitonin, parathormone, calciferols, bisphosphonates, etc.).

EVALUATION

The result of finding a significant change indicated by the selected biomarkers needs to be assessed with regard to dose-related changes and a follow-up by histomorphometry. It depends on the extent of the biomarker change whether histomorphometry of specific bone areas is to be included (for details, see Bagi et al. 2011) or whether the result is translated to inclusion of similar biomarkers in the proposed clinical trial.

14.7.2.1 Biomarkers of Bone Turnover

An extensive review for clinically validated biomarkers for osteoporosis management is provided by Garnero (2008). In this review, the urinary osteocalcin fragments are addressed, the tartrate-resistant acid phosphatase, regulators of osteoclastic and osteoblastic activity currently under investigation, and markers for the posttranslational modification of bone matrix proteins (type I collagen).

There is a wide selection of analytical methods available; biomarkers following increased bone turnover have been characterized extensively in clinical studies, and the general principle of investigating biomarkers as an exploratory approach with a high probability of relevance is well established (Calvo et al. 1996; Henriksen et al. 2010; Frank and Hargreaves 2003; Dambach and Gautier 2006; Williams et al. 2006; Garnero 2008; Wagner 2009). Selection of an analytical method at the time of planning a safety study is based on an Internet research to collect some experience with the sample acquisition and determination in a small preliminary study (Leeming et al. 2006; Bay-Jensen et al. 2010; Herrmann and Seibel 2008).

CRITICAL ASSESSMENT OF THE METHOD

A detailed discussion of parameters related to the ovariectomized model is provided by Lelovas et al. (2008). The histomorphometry methods are reviewed with reference for specific sites to be investigated. For limited safety pharmacology, the application of biochemical markers is of practical interest. For the biomarkers, there are numerous assay methods available. Markers of bone formation are alkaline phosphatase and osteocalcin, and markers of bone resorption for the rats are pyridinolin, tartrate-resistant acid phosphatase, and urinary type I collagen cross-linked in telopeptides (CTX-I). The markers of bone turnover represent bone metabolism changes in the whole skeleton; they are not suitable for regional assessment. The markers of bone turnover are very valuable for the assessment of drug candidates with indications for hormone effects on bone (due to structural considerations or by receptor screening). Densitometry is a precise noninvasive method, but requires special equipment and cannot be recommended for toxicology studies. Histomorphometry remains limited for detailed information of regional bone changes. Although a description for methods applying

mechanical stress is available, these methods are outside the scope of safety pharmacology. The review by Lelovas et al. (2008) provides an excellent assessment of the options in extended mechanistic studies. A similar review for the pharmacology, pathology, and preclinical studies with ibandronate is provided by Russell (2006). The species included are rats, dogs, and monkeys. The review shows that evaluation of bone changes in the rat requires treatment periods of preferably 6 months; ovariectomy is performed in adult rats aged 10–12 months.

Given the complexity of bone turnover, any studies in cell culture, for example, with neonatal rep osteoblasts, have the disadvantage of being with no direct relation to the practical therapy (Yan et al. 2009). The bone safety study and rats is to be preferred as a practical satellite study enhancing the interpretation of any findings in long-term regulatory in rats.

14.7.2.2 Parathormone and Teriparatide

There are some practical examples where inclusion of safety pharmacology studies for the effects on hormonal-dependent bone may be appropriate (Forsteo 2004). Detailed indications for clinically established compounds are provided by the EMA assessment reports. The human parathyroid hormone sequence (1–34), teriparatide, was evaluated in animal models in rats, mice, rabbits, and monkeys. Monkeys and rabbits are considered remodeling species but in bone physiology do not mimic that seen in humans. Endpoints in skeletal changes were analysis of bone mass (DXA absorptometry), bone architecture by histomorphometry, and mechanical testing. For the practical application in safety pharmacology, studies in ovariectomized rats are relevant. It was summarized that teriparatide stimulated both modeling and remodeling of bone in adult animals. In drug interactions, selective estrogen receptor modulators (SERM) administered with teriparatide increased bone mineral density in trabecular bone. For the assessment of drug interaction studies in mechanistic studies, biomarkers and bone imaging are suitable; however, interaction studies are rarely part of endocrine safety pharmacology. Interaction studies with vitamin D3 were performed in rat, rabbits, and monkey and showed similar bone responses. The safety pharmacology may then turn to specific questions such as the effect of excessive calcium mobilization on kidney function. Teriparatide is an interesting example for limited relevance of carcinogenicity detected in a lifetime studies. There was formation of osteosarcoma in lifetime studies in rats, but not when the study duration was limited to 12 months in the rat.

14.7.2.3 Bisphosphonates

Studies on bone quality have been performed with several antiresorptive bisphosphonates. Models used in the evaluation of ibandronate were reviewed (Bauss and Dempster 2007). Studies were directed at bone mass, strength, and architecture. Biomarker determinations were also applied in these studies. Intermittent and daily regimens of bisphosphonates have frequently been compared, and there are clinical preparations administered once a week, once a month, or by infusion (in the treatment of metastatic bone disease). The details of studies with alendronate in osteoporosis with regard to the supporting preclinical data were summarized (Bauss and Russell 2004). The animal models of preclinical studies included for animal models the rat, dog, mini pig, and monkey. In the rats, dogs, and monkeys, the osteoporosis-like condition was initiated by ovariectomy (estrogen depletion). In mini pigs, bone loss was induced by glucocorticoid treatment. Corticoid treatment is a clinically relevant risk condition, where osteoporosis has been frequently observed as a critical adverse long-term effect. The studies compared the continuous and intermittent treatment, in particular with regard to developing preparations for intermittent use (once a month). Additional models of secondary hyperparathyroidism and bone loss induced by immobilization (both models in rats) were applied. In clinical studies, ibandronate was found to reduce the risk of vertebral fractures, and the studies also support the use in metastatic bone disease.

14.7.3 Animal Models

14.7.3.1 Animal Tests of Bone Structure and Drug-Induced Changes

An early study was performed by Balena et al. (1993) with alendronate using a rat model of hyperthyroidism. Alendronate was tested for prevention of thyroid hormone-induced bone loss. Ten-week-old Sprague-Dawley rats were treated with thyroxine 250 μg per kilogram per day, to induce bone changes. After 3 weeks of treatment, histomorphometry parameters of cancellous bone remodeling were assessed in the tibia and in vertebra. Thyroxine treatment caused significant bone loss associated with increased bone turnover. At the time of the study (1993), the authors did not apply any of the biomarkers for bone turnover currently used to describe bone metabolism changes. Thyroid hormone in this model induces high bone turnover and bone loss in the tibia which can be prevented by alendronate through an inhibition of osteoclast activity. After 3 weeks' treatment, there was no significant change in the vertebral bone (spinal column). The consequence is that studies need to be performed for a longer time when distinct changes in histomorphology of vertebral bone are to be induced in the model.

There are several well-established animal models for the effect of calcitonin on skeletal metabolism (Wallach et al. 1999). The methods for evaluation of the response of bone to the hormone generally include histomorphometry in rats. Similar models were applied to the evaluation of parathormone (full sequence and active sequence). In these models, calcitonin and parathormone as well as calciferols were assessed (Peppone et al. 2010). Bone density was assessed by a variety of methods, and studies of mechanical properties of connective tissue with regard to breaking strength and tensile strength were sometimes included. Many models are based on time-consuming evaluation and complex endpoints; the studies were subsequently extended and refined by enhancement with validated biomarkers. The initial animal models were focused on detailed examination of the bone and cartilage, with a view to treating postmenopausal osteoporosis and more recently also targeting osteoarthritis. A recent update of the methods used in rodent models of aging bone was provided by Syed and Melim (2011). There are now comprehensive research models in mice and rats which evaluated hormone concentrations,

biochemical effects, inflammatory cytokines, oxidative stress, nutrition, and the effect of exercise on the skeleton. The segment suitable for safety pharmacology is based on the response of adult ovariectomized rats preferably with 3-month treatment. The research methods for new factors involved in bone pathophysiology ("bone is an endocrine organ") are in general not suitable for safety evaluation of drug candidates, due to their limited predictive power. They do provide an outlook for future development of animal models to osteoblasts and osteoclasts activity separately and include adipocyte cells. The step of translation to the clinical situation for the effects of salmon calcitonin treatment was reviewed by Karsdal et al. (2009a). They reviewed the use of biomarkers of bone turnover in postmenopausal women. The analytical determinations included measurement of plasma calcitonin levels and changes in the bone resorption marker serum CTX-I and the urinary cartilage degradation marker CTX-II measured up to 5 h after treatment. Bone resorption and cartilage degradation markers displayed a comparable response, during the early posttreatment observation period. The parameters were applied to evaluation of recombinant calcitonin injections and new oral calcitonin formulations. Karsdal et al. (2009b) also discussed the specific value of biochemical markers for the development of a better understanding of pathophysiology. There is currently an FDA Critical Path Initiative of improving the validation of specific markers for drug discovery.

14.7.3.2 Calcitonin

The ovariectomized rat model of postmenopausal bone loss was described by Kalu (1991) and subsequently frequently applied for the assessment of antiresorptive agents including calcitonin and the bisphosphonates. At this time, the antiresorptive activity of calcitonin was extensively evaluated, and research indicated that there are calcitonin-related peptides which might have similar therapeutic activity. It turned out that the specific antiresorptive activity is closely associated with the calcitonin structure (Zaidi et al. 1987). Research on the molecular pharmacology of the calcitonin receptor family is continuing (Purdue et al. 2002); the methods are currently not applicable to safety evaluation. The complexity of the calcitonin receptor family needs to be further explored, and therapeutic activity is currently restricted to calcitonin formulations.

14.7.3.3 Recombinant Human PTH

In the context of osteoporosis research, animal models have been reviewed and discussed by several groups, including Kimmel (Kimmel et al. 1993; Kimmel 2002). This group has evaluated the effects of recombinant human parathormone full sequence (1–84) and active sequence (1–34), synthetic parathormone teriparatide. In many of these studies, the ovariectomized rat model (OVX) was applied.

Cheong et al. (2011) investigated the use of tetracycline bone-seeking label in rats after ovariectomy and found that the excretion of label followed the presence in the skeleton over a period of 3 months after injection of the probe. This method may be suitable in satellite groups, in parallel to the toxicology studies if there is a question of a drug effect on accelerated bone turnover.

14.7.4 Bone-Related Hormone Analytical Methods

The concentrations of calcitonin, parathormone related peptides and partial sequences and calciferols may be measured in satellite studies in rats, dogs and monkeys. There is considerable selection of analytical methods for the determination of calcitonin, procalcitonin, parathormone (intact sequence and partial sequences), and the calciferols (vitamin D group). Methods for calcitonin assay may be directed at monitoring pharmacokinetic concentrations after treatment and endogenous secretion in animal studies. Recently, the importance of thyrocalcitonin as an indicator of thyroid cancer (Rosai 2003; Kratzsch et al. 2011) has become a very controversial issue, when thyroid C-cell proliferation was found with an incretin mimetic and studies are required to assess the relevance of these findings for human risk assessment (Bjerre Knudsen et al. 2010). Reference ranges for the clinical assay are established (D'Herbomez et al. 2007). Interestingly, pro-calcitonin is used as a biomarker for inflammation in sepsis and has acquired clinical relevance (Maruna et al. 2000; Kratzsch et al. 2011).

There are several assay methods for intact parathormone (1–84) and partial sequences including the active sequence (1–34), teriparatide (Carter and Howanitz 2003; Fuleihan and Jüppner 2012). The group of assays for calciferol (vitamin D3) is characterized by a number of different methods which have been recently reviewed due to problems of sensitivity and specificity (Lensmeyer et al. 2006; Glendenning et al. 2006).

Application to safety pharmacology studies of hormone-dependent bone is certainly an approach which may extend the information provided by biomarkers of bone turnover. Considering the complexity of the analytical methods and their problems of specificity and handling of samples, these hormone determinations will only be included in very specific situations and for pharmacokinetic monitoring.

15.1 In Vivo Percutaneous Absorption Assays

PURPOSE AND RATIONALE

Percutaneous absorption, also known as dermal or skin absorption, is a term that refers to the transport of a chemical from the outermost layer of the skin (stratum corneum) to the systemic circulation. Percutaneous absorption assays are essential for the safety assessment of chemicals making contact with the skin surface, such as pesticides, topically applied pharmaceuticals, industrial chemicals, and cosmetics, as well as in the development of drugs for dermal or transdermal application.

PROCEDURE

Percutaneous absorption can be determined by applying a known amount of chemical to a specified surface area of laboratory animals or human volunteers. Radiolabeled chemicals, usually carbon-14 (^{14}C) or tritium (^{3}H), are widely used for analytic convenience. When the study is performed in laboratory animals, the amount of chemical and/or metabolites recovered from urine, feces, cage washing, blood, skin bound residues*, and the remaining carcass are added, and the percutaneous absorption is expressed as the total percentage recovery from the applied dose. Expired air should be collected when volatile metabolite is excreted in quantity $>5\%$ of applied dose.

If the animals are not sacrificed, or the study is conducted with human volunteers, an indirect measure of absorption is performed by monitoring urine, feces, and blood. The amount of chemical that is absorbed, but not measured in the monitored fluids, is corrected for by determining the amount of chemical excreted

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_17, © Springer-Verlag Berlin Heidelberg 2013

following parenteral administration. The percutaneous absorption is calculated by the amount excreted after topical application divided by the amount excreted after parenteral administration of the chemical and is expressed in terms of percentage of applied dose. In the absence of intravenous studies, the average percutaneous absorption rate can be estimated by mass balance. It is calculated by the amount excreted divided by the amount applied.

At the end of the experiment, a full mass balance of the applied dose should be performed. An adequate mean recovery is in the range of 90–110% (OECD).

Note: *According to OECD (2008), skin bound residues (residues recovered from the application site after it has been washed) should be added to the absorbed dose depending on the bioavailability of skin bound radioactivity. If bioavailability cannot be determined, skin bound residues should be considered absorbed.

EVALUATION

The advantage of in vivo assays is that it relies on a physiologically and metabolically intact system (OECD 2004a). In vivo studies in humans are the gold standard and provide definitive data for the assessment of the absorption of chemicals through human skin.

Percutaneous absorption rates in rat, rabbit, and mouse are generally higher than in humans while the skin permeability of pig and monkey more closely resembles humans. There are interspecies differences in routes of excretion of some chemicals as well. These knowledge should be considered when selecting an animal model and designing the experiment. If the objective of the assay is to predict human percutaneous absorption, then the rate and extent of skin absorption in the laboratory animal should be quantitatively the same as in man or consistently related to the absorption in humans by a constant ratio.

CRITICAL ASSESSMENT OF THE METHOD

As monkey and pigs are comparatively more difficult and expensive to maintain, rat is the most commonly used species for animal in vivo studies, having the advantage that information from other toxicity studies is mostly obtained from this species and is therefore directly comparable and the disadvantage of overestimation of human percutaneous absorption. Increasing resistance from animal protection organizations to the use of live animals in testing of chemicals associated with the difficulties in conducting these pharmacokinetic assays—collecting excrement for relatively long period of time (24 h +), requirements for specialized cages, for specialized protective apparatus to avoid ingestion of the chemical or contact with the cage, and space requirements for housing animals individually—constitutes the major limitations of animal in vivo assays. The major limitations of human in vivo assays are the possible systemic and local toxicity of applied chemicals and the fact that their conducts are subject to strictly ethical considerations and conditions.

Radiolabeled chemicals are widely used for analytic convenience; however, they may not provide accurate estimates of bioavailability. For example, a comparison of the bioavailability of nitroglycerin and the level of radioactive tracer indicates the overestimation of available drug by as much as 20%. This corresponds to the metabolism of the drug to an inactive form.

MODIFICATIONS OF THE METHOD

15.1.1 Tape Stripping

Rougier et al. observed a linear relationship between the amounts of chemical present in the stratum corneum that has been washed 30 min after application and the total amounts excreted in the urine within a 4-day period. The good correlation between the two measurements suggested the value of the tape-stripping approach as a simple and minimally invasive method for estimating percutaneous absorption in laboratory animals and humans. In this assay, the stratum corneum of the skin exposed to the chemical is removed sequentially by successive application of adhesive tape. The amount of chemical present in the stratum corneum recovered by the tape is then determined. This method has been used to estimate bioequivalence of topically applied chemicals. However, it does not have a regulatory imprimatur.

15.1.2 Residual Analysis Methods

The determination of the material "lost" from the skin surface may also be considered as a measure of

percutaneous absorption. Two approaches have been described. (A) Single-point measurements of drug disappearance: The difference between the applied dose and the recovered residue from the application site is assumed to be the amount of drug absorbed. The disadvantages of this method are that recovery of the chemical is difficult and total recovery from the skin is not guaranteed. Volatile materials may leave the surface without penetrating. In addition, skin may retain a reservoir of the chemical that has not entered the circulation. (B) Continuous monitoring of drug uptake: The chemical (radiolabeled or containing a spectrophotometric marker) in the outer skin layers is monitored over time for the disappearance of radioactivity or of spectral signal, and absorption is assessed from the decay of the respective signal.

15.1.3 Cutaneous Microdialysis

Cutaneous microdialysis measures the amount of a chemical in the extracellular space beneath the skin of human volunteers or laboratory animals using perfused dialysis. The microdialysis probe may be implanted into the dermis or into the subcutaneous tissue. The blood flow underneath the skin application site of the chemical is mimicked by continuously passing a receptor fluid (perfusate) through a microdialysis tubing (a thin hollow tube formed by a semipermeable membrane) and collecting it in a collector (dialysate). The technique is based on the passive diffusion of the chemical across the microdialysis tubing, and the amount absorbed into the receptor fluid is then measured, and the results are usually expressed in terms of relative recovery. Microdialysis may be useful to assess local bioequivalence/bioavailability after topical application of a chemical. The challenge of the assay is the measurement of lipophilic chemicals and those with high protein binding, which are poorly diffused into the receptor fluid (perfusate). A limitation rests in the inability to quantitatively collect all of the dialysate and obtain mass balance data.

15.1.4 Whole-Body Autoradiography

The whole-body distribution of a topically applied radiolabeled chemical in the laboratory animal skin is determined in frozen cross sections of the entire carcass. Whole-body cross sections include representative samples of all major tissues and are evaluated qualitatively and/or quantitatively for radioactive content using autoradiography or autoradioluminographical techniques.

15.1.5 Pharmacodynamic Method

Pharmacodynamic responses in skin function can be used to assess absorption of topical dermatological products. The method is rather qualitative than quantitative. It represents an accepted approach to establish bioequivalence between different formulations of certain topical drugs, e.g., the vasoconstriction or “blanching” to evaluate topically applied corticosteroids.

15.1.6 Skin Biopsy

Despite the advantage of offering a “snapshot” of chemical disposition in the different skin layers, the invasive nature of the biopsy makes the method less useful.

15.2 In Vitro Percutaneous Absorption Assays

PURPOSE AND RATIONALE

Recently, many efforts have been made to replace percutaneous absorption assays in the animal by in vitro assays. The excised skin from humans and/or laboratory animals are used to measure absorption of chemicals based on the assumption that stratum corneum is the principal diffusion barrier for percutaneous absorption, and as it is composed of nonviable cells, the permeability properties of skin are maintained after its excision from the body.

PROCEDURE

Most common methods of in vitro percutaneous absorption assays are performed with diffusion cells, which consist of a donor compartment (upper compartment) and a receptor compartment (lower compartment), between which a disc-shaped fragment of the chosen skin sample is stretched, epidermal side up. The underside of the skin is bathed with a receptor fluid, which for hydrophilic chemicals can be saline or an isotonic buffered saline. For lipophilic chemicals, a solvent mixture such as ethanol or bovine serum albumin should be added. Two types of diffusion cells may be used: the static or Franz diffusion cell (samples of the fluid from the receptor compartment are manually withdrawn periodically for analysis) or the flow-through diffusion cell (automatic sampling of the fluid that flows continuously through the receptor compartment).

The chemical to be studied, which may be radiolabeled, is applied to the epidermis for a specified time under specified conditions and then is removed by an appropriate cleansing procedure. Skin barrier integrity should be previously checked by an appropriate method. The fluid from the receptor compartment is sampled at time points throughout the experiment and analyzed for the test chemical and/or metabolites by liquid scintillation counting (LSC) or high-performance liquid chromatography (HPLC). The amount found in the receptor fluid at the end of the experiment is considered to be systemically available. For studies performed in accordance with the OECD methodology (2008), the residue in the skin is counted as absorbed.

At the end of the experiment, a full mass balance should be performed. An adequate mean recovery is in the range of 90–110% (OECD) or 85–115% (SCCP). Lower or higher recovery rates should be investigated and/or explained.

The choice of the skin model depends on the purpose of the study, the chemical under investigation, and also on the availability of the skin sample. Human viable skin (female abdominal or breast skin obtained from cosmetic surgery) is preferred, but alternatively, human nonviable skin (cadaver skin) may be used. Either split-thickness skin (stratum corneum+epidermis+upper dermis), prepared with a dermatome or epidermal sheets (stratum corneum+epidermis), prepared enzymatically by heat or chemically, are acceptable. The use of full-thickness skin (stratum corneum+epidermis+dermis) should be justified, as the lack of a functioning microcirculation below the in vitro epidermis leads the dermis to participate in the absorptive process, functioning as a permeability barrier to lipophilic chemicals. Frozen and/or cadaver skin preparations may lack enzymatic activity; therefore, it is not recommended for chemicals that undergo significant biotransformation in the skin.

Skin from laboratory animals may also be used. Pigskin is accepted and validated for cosmetic assays by the SCCP. Although rodent skin overestimates

human percutaneous absorption, it is used for toxicological studies because the majority of the studies in vivo were conducted in this species.

EVALUATION

In vitro assays offer some advantages over in vivo assays. Highly toxic chemicals can be studied in human skin, and large number of diffusion cells can be run simultaneously. In addition, these assays may be less expensive and easier to conduct.

Van de Sandt et al. (2000) and Cnubben et al. (2002) demonstrated that in vitro assays using viable human full-thickness skin samples correlated reasonably well with human in vivo percutaneous absorption of propoxur and ortho-phenylphenol, respectively, on the basis of the potential absorbed dose and the amount systemically available. For propoxur (solubility in water 1,900 mg/L), human full-thickness skin samples slightly overestimated the amount systemically available after 24 h. For *ortho*-phenylphenol (solubility in water 700 mg/L), full-thickness skin samples significantly underestimated the amount systemically available at the earlier time points, but after 48 h, it predicted very well the amount systemically available. This could be explained by the fact that lipophilic chemicals (*ortho*-phenylphenol) are partially retained in the dermis and are only slowly released into the receptor fluid. The epidermal sheet samples significantly overestimated human in vivo data in both studies. Perhaps, a better correlation would have been found if split-thickness skin were used instead of full-thickness skin or epidermal sheets.

CRITICAL ASSESSMENT OF THE METHOD

The disadvantages of in vitro assays include the many variables that must be standardized for results to be comparable between studies and conclusions to be made reliably. Variations of experimental parameters such as thickness and types of skin, amount applied, exposure duration, vehicles, type of diffusion cell, perfusate flow, air temperature, relative humidity, air flow, type of receptor fluid, and extent of chemical solubility in the receptor fluid have all shown to result in significant changes in chemicals absorption rates.

Van de Sandt et al. (2004) described an interlaboratory study where the in vitro absorption rates of benzoic acid, caffeine, and testosterone were compared. A major effort was made to standardize the study performance, but not all variables were controlled (skin thickness, diffusion cell type, and receptor compartment volumes). All laboratories assigned the absorption of benzoic acid the highest ranking of the three chemicals, but only seven out of nine laboratories utilizing human skin ranked the maximum absorption of caffeine to be higher than testosterone. The variation observed was attributed to human variability in dermal absorption and to the skin thickness. Skin thickness had a great influence on testosterone (most lipophilic chemical) absorption, and the maximum absorption rates were clearly higher in the laboratories using thin, dermatomed skin samples.

MODIFICATION OF THE METHOD

To overcome the legal and ethical limitations concerning the use of human and animal skin samples in in vitro assays, several artificial human skin models have been developed, and some of these are commercially available: Epiderm®, SkinEthic®, and Episkin®, which are reconstructed human epidermis (RHE) models. More recently, full-thickness models were also introduced to the market: EpiDermFT® and Phenion® full-thickness skin model.

Schäfer-Korting et al. reported a validation study that aimed to evaluate whether the commercially available reconstructed human epidermis (RHE) models, Epiderm®, SkinEthic®, and Episkin®, were suitable for in vitro percutaneous absorption assays. Nine chemicals, covering a wide spectrum of physicochemical properties, were tested in ten laboratories, under strictly controlled conditions having human epidermis sheets and 1-mm thickness pigskin as references. In general, permeation of the RHE models exceeded that of human epidermis and pigskin (SkinEthic was found to be the most permeable), but the ranking of the permeation through the three tested RHE models and the pigskin reflected permeation through human epidermis sheets. According to the authors, additional experiments employing at least 30 test chemicals should be performed to estimate the prediction of systemic human exposure by permeation experiments with RHE models. The major limitation of all three models is the still relatively weak barrier function, and when used in percutaneous absorption assays as alternatives to human and pigskin, product-specific overpredictability should be taken into account.

According to the OECD Guidance Document N° 28 for the conduct of skin absorption studies (2004a), reconstructed human skin models can be used if

obtained data from reference chemicals are consistent with those in the published literature. On the other hand, considering the insufficient barrier function of reconstructed skin models, SCCP (2006) recommends the use only of samples of natural origin for in vitro testing.

15.3 Guinea Pig Sensitization Tests

PURPOSE AND RATIONALE

The prediction of the sensitizing potential of individual chemicals or finished products (capacity of inducing proliferation of specific memory T lymphocytes that can lead to cutaneous inflammatory reaction in subsequent exposures of susceptible individuals) can be investigated by animal test methods using guinea pigs. These assays are valuable in the safety assessment of chemicals coming in contact with the skin such as cosmetics, household products, pharmaceuticals for topical use, those present in the occupational environment, or any other with which humans my come into contact. Several tests will be described here.

PROCEDURE

15.3.1 General Principles

Male and/or female healthy young guinea pigs of the Hartley or Pirbright White strains with a starting body weight of 300–450 g have been shown to be optimal. If females are used, they should be nulliparous and nonpregnant. Animals are maintained in the facilities with temperature of 20 ± 3°C, relative humidity of 30–70%, and 12-h automatic light cycle. For feeding, conventional laboratory diets may be used with an unlimited supply of drinking water. It is essential that guinea pigs receive an adequate amount of vitamin C. Test sites are cleared of hair by clipping, shaving, or possibly by chemical depilation, depending on the test protocol used. Care should be taken to avoid abrading the skin.

The test animals are initially exposed to the test substance by intradermal injection and/or topical application with the intention of stimulating the immune system (induction exposure—simulates the first contact). Following a rest period, during which an immune response may develop, a subsequent exposure (challenge exposure—simulates subsequent exposures) to the test substance in a virgin skin area of the previously treated guinea pigs checks if the animals show allergic reactions to the tested substance.

A control group is necessary to ensure that the positive challenge reactions are of allergic origin and not due to skin irritancy. The guinea pigs of this group are treated in the same manner as the test animals, except that during the induction exposure, the use of the test substance is omitted. If it is necessary to clarify the results obtained, a second challenge (a rechallenge) should be considered approximately 1 week after the first one, and it is essential to incorporate a new set of control animals.

Skin reactions are evaluated by visual scoring and palpation of erythema, edema, and other skin clinical changes using various grading scales, e.g., the Magnusson and Kligman grading scale (0 = no visible change, 1 = discrete or patchy erythema, 2 = moderate and confluent erythema, 3 = intense erythema and swelling). An exceptional case is the optimization test, in which "reaction volume" serves as the parameter for evaluation of skin reactions. Reactions are considered positive when they are more intense in the test group than in the controls. The incidence of positives in the test group compared to the control group is used to classify the test substance as a sensitizer or not.

The sensitivity and reliability of the chosen technique should be assessed twice a year using substances known to have mild-to-moderate skin sensitization properties such as hexyl cinnamic aldehyde, mercaptobenzothiazole, and benzocaine. In a properly conducted test, a response of at least 30% in an adjuvant test and at least 15% in a nonadjuvant test should be expected.

The tests differ significantly in route of exposure, use of adjuvants, induction interval, and number of exposures. The principal features of the most commonly used assays to predict sensitization are summarized in Table 15.1.

15.3.1.1 The Draize Test (DT)

This test employs intradermal injections for the induction and challenge exposure. A minimum of 20 animals is required for the treatment group and for the control group (OECD 1981). Days 0 to 20—Induction exposure through intradermal injections: One flank of the animals is cleared of hair. One intradermal injection (0.05 mL) at 0.1% of the test substance in an appropriate vehicle is given in the anterior flank. Then, nine subsequent intradermal injections (0.1 mL) at 0.1% of the test substance are given every other day into a new site on the same flank. The control group is injected only with vehicle. Day 34—Challenge exposure through intradermal injection: The contralateral flank of the animals is cleared of hair. One intradermal injection (0.05 mL) at 0.1% of test the substance is given in the anterior flank of both groups. Days 35 and 36—Assessment of sensitization: The test sites are visually evaluated and graded at 24 and 48 h after challenging. Although largely abandoned—largely because of the intradermal—rather than topical dosing, the method in experienced hands identifies many known human allergens.

15.3.1.2 Open Epicutaneous Test (OET)

This test employs open topical application for the induction and challenge exposure. A minimum of 6–8 animals is required for each treatment group (usually six groups) and also for the control group (OECD 1981). Days 0–20 or 28—Induction exposure through open topical applications: One flank of the animals is

FCA Freund's complete adjuvant, *SLS* sodium lauryl sulfate, *TS* test substance, *V* vehicle; *id* intendermal. Reproduced from Maibach and Patrick (2001) with permission

cleared of hair. A volume of 0.10 mL of the test substance in an appropriate vehicle is applied to an 8 cm^2 area of the flank of each treatment group for 20 consecutive days or 5 times a week for 4 weeks. Each treatment group is treated with different concentrations of the test substance (100%, 30%, 10%, 3%, 1%, and 0.3%). The test substance is applied to the same site daily unless a moderate to strong skin reaction occurs, requiring the change of application site. The control group is treated only with vehicle. Days 21 and 35 or 29 and 43—Challenge exposure through open topical application: The contralateral flank of the animals is cleared of hair. Twenty-four hours after the last induction treatment, 0.025 mL of the test substance at the minimal irritant concentration, the maximum nonirritant concentration, and some lower

concentrations is applied to a 2 cm^2 area of all animals. The same procedure is repeated 2 weeks after. Vehicle may also be involved at challenge, if indicated. Days 36, 37, and 38 or 44, 45, and 46—Assessment of sensitization: The test sites are visually evaluated and graded at 24, 48, and 72 h after challenging. This assay provides not only irritation and sensitizing data but also dose-response evaluation.

15.3.1.3 Buehler Test

This test employs an occluded topical patch technique for the induction and challenge exposure. A minimum of 20 animals is required for the treatment group and a minimum of 10 animals for the control group (OECD 1992). Days 0, 7, and 14—Induction exposure through occluded topical application: One flank of the animals is cleared of hair. An occlusive patch (2 × 2 cm) or chamber loaded with the test substance in a suitable vehicle is placed on the test area and is held in contact to the skin for 6 h. This procedure is repeated on day 7 and 14 on the same test area. The concentration of the test substance for each induction exposure should be the highest to cause mild irritation. The control group is treated only with vehicle. Day 28—Challenge exposure through occluded topical application: The contralateral flank of the animals is cleared of hair. An occlusive patch (2 × 2 cm) or chamber loaded with the test substance in a suitable vehicle is placed on the contralateral flank of both groups and is held in contact to the skin for 6 h. An occlusive patch or chamber with only the vehicle may also be applied when relevant. The concentration of the test substance should be the highest nonirritating dose. During the induction and challenge exposure, the patch is held in place by keeping the animals in a special restrainer, which prevents their movement and enables attachment of the occlusive patch with a rubber dam, slightly pulled and fastened to the restrainer. Days 29 and 30—Assessment of sensitization: 24 and 48 h after removal of the patch, the reactions are visually evaluated and graded. Widely utilized for a generation, this method as with the other assays requires meticulous attention to the original protocol.

15.3.1.4 Freund's Complete Adjuvant Test (FCAT)

This test employs intradermal injections (with adjuvant) for the induction exposure and open topical applications for the challenge exposure. A minimum of 8–10 animals is required for the treatment group and also for the control group (OECD 1981). Day 0, 4 and 8—Induction exposure through intradermal injections: A 6 × 2-cm area across the shoulders of the animals is cleared of hair. An intradermal injection (0.1 mL) of 1:1 FCA and the dissolved test substance at a concentration of 5% are given on days 0, 4, and 8. The control group is injected only with FCA. Days 21 and 35—Challenge exposure through open topical application: One flank of the animals is cleared of hair. A volume of 0.025 mL at up to six concentrations (including the minimal irritant concentration and the maximum nonirritant concentration and lower concentrations) is applied to a 2-cm^2 area of the flank. The same procedure is repeated 2 weeks later. Days 36, 37, and 38—Assessment of the sensitization: The test site is visually evaluated and graded 24, 48, and 72 h after challenging.

15.3.1.5 Optimization Test

This test employs intradermal injections (with and without adjuvant) for the induction exposure and both intradermal and occlusive topical application for the challenge exposure. A minimum of 10 animals is required for the treatment group and also for the control group (OECD 1981). Day 0 to 21—Induction exposure through intradermal injections: One flank, back, and shoulder regions of the animals is cleared of hair. One intradermal injection (0.1 mL) at 0.1% of test substance in 0.9% saline is given three times a week into the back area for 1 week. On the day of the first injection, an intradermal injection is also given to one flank. During the second and third weeks, intradermal injections (0.1 mL) at 0.1% of test substance in 1:1, FCA/saline, are given three times a week to the area across the shoulders (total of ten intradermal injections). Controls are injected only with saline during week 1 and FCA/saline during weeks 2 and 3. Day 35—Challenge exposure through intradermal application: The contralateral flank of the animals is cleared of hair. Two weeks after the last induction application, all the animals are given an intradermal injection (0.1 mL) at 0.1% of test substance in 0.9% saline in the contralateral flank. Day 45—Challenge exposure through occlusive topical application: The back region of the animals is cleared of hair. After a rest period of 10 days, an occlusive patch loaded with the maximum nonirritant concentration of the test substance is placed on the back area and is held in contact to the skin for

24 h. Assessment of the sensitization after intradermal and topical challenges is done 24 h after the intradermal injections during the first induction week as well as 24 h after the intradermal challenge injection, skin reactions are measured by multiplying the two greatest perpendicular diameters and the skinfold thickness (with a skinfold caliper) to obtain a "reaction volume" for each animal. If the reaction volume of the challenge injection is greater than the reaction volume of the first induction week, the animal is considered sensitized (positive). For final evaluation, the number of "positive" animals in the test group is statistically compared with the number of animals in the control group that showed nonspecific reactions of comparable intensity. After 24, 48, and 72 h of the removal of the occlusive patch, the skin reactions are evaluated according to a standard rating scale. The significance of differences in the number of positive animals between the treated group and the controls are again assessed.

15.3.1.6 The Split Adjuvant Test

This test employs pretreatment of induction site, occlusive topical application combined with intradermal injection (with adjuvant) for the induction exposure, and occlusive topical application for the challenge exposure. A minimum of 10–20 animals is required for the treatment group and also for the control group (OECD 1981). Days 0 to 9—Induction exposure through occlusive topical application and intradermal injection: The skin of the shoulder region is shaved to the glistening layer and then treated with dry ice for 5–10 s. A dressing with a 2-cm^2 opening window is fixed over the test area. On day 0, 0.2 mL semisolid or 0.1 mL liquid test substance is spread over the test area and covered with filter paper, fixed with adhesive tape, and kept under occlusion for 48 h. On day 2, the filter paper is lifted from the test site, the test material (0.2 mL semisolid or 0.1 mL liquid) is reapplied, and the filter paper covering is replaced. On day 4, two intradermal injections (0.1 mL) of FCA are given symmetrically into the induction area, followed by application of the test material (0.2 mL semisolid or 0.1 mL liquid). On day 7, the procedure of day 2 is repeated. On day 9, the dressing is removed. Day 21—Challenge exposure through occlusive topical application: An area of 2 cm^2 of the dorsal back region of animals is cleared of hair. A volume of 0.5 mL semisolid or 0.1 mL liquid test substance, in a concentration half of the induction, is spread over the test site and covered with filter paper, fixed with adhesive tape, and held in contact to the skin for 24 h. Days 22, 23, and 24—Assessment of the sensitization: The test site is visually evaluated and graded 24, 48, and 72 h after challenging.

15.3.1.7 Guinea Pig Maximization Test (GPMT)

The guinea pig maximization test employs intradermal injections (with adjuvant) combined with occlusive topical application for the induction exposure and occlusive topical application for the challenge exposure. A minimum of ten animals is required for the treatment group and at least five animals for the control group (OECD 1992). Day 0—Induction exposure through intradermal injections: The shoulder region of the animals is cleared of hair. One pair of intradermal injection (0.1 mL) of a mixture of 1:1 FCA/water of the test substance at the highest concentration to cause mild-moderate irritation in an appropriate vehicle and of the test substance at the highest concentration to cause mild-moderate irritation formulated in 1:1 FCA/water is given in the shoulder region. One of each pair lies on each side of the midline. Control animals are injected only with FCA/water, undiluted vehicle, and vehicle/FCA/water. Day 7—Induction exposure through occluded topical application: The shoulder region is again cleared of hair. A filter paper (2 × 4 cm) loaded with the test substance in a suitable vehicle at the highest concentration to cause mild-moderate irritation is placed on the injection site and is then covered with approximately 4 × 8-cm occlusive surgical tape and secured in place with an elastic bandage wrapped around the animal. It is held in contact to the test area for 48 h. If the test substance is nonirritating, the test site is pretreated with 10% sodium lauryl sulfate in petrolatum 24 h before the topical induction application (day 6) to provoke an irritant reaction. Control animals are patched only with the vehicle. Day 21—Challenge exposure through occluded topical application: The flank region of the animals is cleared of hair. A patch loaded with the test substance at the highest nonirritating concentration is applied to one flank, and a patch with the vehicle may also be applied to the other flank when relevant. It is held in contact to the test area for 24 h. Days 23 and 24—Assessment of sensitization: 24 and 48 h after removal of the patch, the reactions are visually evaluated and graded. This assay mandates extensive operator background knowledge of its complexity and training.

EVALUATION

The first guinea pig sensitization method was developed by Draize in 1944. However, the sensitivity of the method to detect known human sensitizers such as benzocaine, mercaptobenzothiazole, neomycin, and nickel sulfate was very low. The sensitivity of the further developed methods was increased by enhancing the immune system through the addition of Freund's complete adjuvant during the induction period. Methods with topical application were also developed to simulate the exposure situation in humans.

In the original OECD guideline of 1981, seven tests were considered to be acceptable (the Draize test, open epicutaneous test, Buehler test, Freund's complete adjuvant test, optimization test, split adjuvant test, and the guinea pig maximization test). In the updated version of 1992, the guinea pig maximization test (GPMT) and the Buehler test were given preference over the other methods, whose use was left to special occasions. The GPMT is a highly sensitive adjuvant method for hazard allergenicity screening of chemicals. It may overestimate the sensitization hazard of many chemicals, but on the other hand, a negative GPMT gives a large safety margin. The Buehler test was designed to detect moderate to strong sensitizers prior to testing in man. It is less sensitive than the GPMT and may underestimate the sensitization potential of chemicals.

The advantage of the guinea pig tests is the inclusion of induction and elicitation phases (challenge exposure) in the assay. Also, the long tradition for using the guinea pig as an animal model has given extensive experience with this laboratory animal, and the performance of the various test methods is documented. Marzulli and Maguire Jr. evaluated several guinea pig test methods by analyzing the frequency with which their results agreed with those obtained with the human Draize test, using ten chemicals. Three rounds of each test were carried out on each of the ten chemicals (i.e., a total of 30 evaluations/tests). An agreement between guinea pig and human data was observed in 14 cases with the Draize test, in 10 cases with the Buehler test, in 29 cases with the guinea pig maximization test, and in 22 cases with the split adjuvant test. The adjuvant techniques (GPMT and split adjuvant test) showed significantly greater agreement with human predictive findings than the nonadjuvant techniques (Draize and Buehler). Comparing the adjuvant techniques one with another, the GPMT test was superior. False-negative results showed the highest frequency with the Draize and Buehler methods and the lowest frequency with the GPMT.

CRITICAL ASSESSMENT OF THE METHOD

Many factors may influence the outcome of guinea pig assays, leading to considerable interlaboratory variation. Interpretation of test results may vary widely, as the visual evaluation of skin reactions may be subjective, and in case of testing colored materials, the reaction evaluation may be impaired. Intradermal injections have to be given carefully, as deep injections (subcutaneous or intramuscular) can lead to a lower sensitivity of the guinea pig tests. Other disadvantage of guinea pig assays is that, with the exception of the open epicutaneous test (OET), dose-response relationships are not included in the standard protocols. Dose-response relationship assessment is important because the induction and the elicitation of allergic reactions is concentration dependent, and there is a threshold dose below which no significant effects are seen. Moreover, guinea pig assays are usually time consuming. The time required for a full test varies from 3 to 6 weeks.

MODIFICATIONS OF THE METHOD

The Draize test has undergone modifications to enhance the sensitivity of this animal assay. In the modified (Sharpe 1985), the concentration of the test substance was increased both in the intradermal induction exposure (2.5 times the intradermal challenge concentration) and in the challenge exposure (maximum nonirritant concentration). An open topical application was included on the challenge exposure with the test substance at maximum nonirritant concentration. The guinea pig maximization test was modified to study materials unsuitable for testing by intradermal injection. In the modified guinea pig maximization test (1985), the FCA was injected intradermally, but an occluded topical application instead of intradermal injection of the test substance was performed in the induction exposure. Andersen et al. (1995) refined the GPMT by applying a multiple dose design at the induction exposure in order to provide information of the relative sensitizing potency of six chemicals. The scientist motivated to seek detail will find this in Andersen et al. (1995) and Marzulli and Maibach's Dermatotoxicology (Klecak 2008).

15.4 Sensitization Tests in Mice

15.4.1 Local Lymph Node Assay (LLNA)

PURPOSE AND RATIONALE

The local lymph node assay (LLNA) is based on the knowledge that the induction phase of skin sensitization is associated with, and dependent upon, proliferation of lymphocytes in the lymph nodes draining the site of test substance application.

PROCEDURE

Healthy female mice of CBA/Ca or CBA/J strain (nulliparous and nonpregnant), 8–12 weeks of age are selected. Other strains and males may be used when sufficient data can demonstrate that strain and/or gender-specific differences in the LLNA response do not exist. Animals are maintained in the facilities with temperature of 22 ± 3°C, relative humidity of 30–70%, and 12-h automatic light cycle. For feeding, conventional laboratory diets may be used with an unlimited supply of drinking water.

At least three concentrations of the test substance are evaluated in separate groups with a minimum of four animals each. A control group is treated only with the vehicle (VC). Positive controls (PC) are used to assess the reliability of the assay by performing it with sensitizing test substances for which the response is well known, such as 25% hexyl cinnamic aldehyde in acetone, olive oil (4:1), or 5% mercaptobenzothiazole in *N*,*N*-dimethylformamide.

Solid test substances should be dissolved or suspended in an appropriate vehicle and diluted if appropriate. Liquid test substances may be applied neat or diluted. Recommended vehicles are 4:1 acetone/olive oil, methyl ethyl ketone, *N,N*-dimethylformamide, propylene glycol, and dimethyl sulfoxide.

Three consecutive concentrations from the series 100%, 50%, 25%, 10%, 5%, 2.5%, 1.0%, 0.5%, etc. are tested. The highest concentration from the three to be tested should be the maximum that does not induce systemic toxicity and/or excessive local skin irritation. In the absence of this information, an initial pretest is necessary.

Twenty-five microliters of the appropriate dilution of the test substance is applied to the dorsal surface of each ear for 3 consecutive days. The control group is treated only with the vehicle (VC). Five days after the first exposure, 250 μL of sterile phosphate-buffered saline (PBS) containing 20 μCi (7.4 × 105 Bq) of tritiated (3H)-methyl thymidine is injected into all test and control animals via the tail vein. Five hours after injection, animals are humanely killed. Draining auricular lymph nodes from each mouse are excised and placed in PBS individually (individual animal approach) or placed in PBS pooled with lymph nodes from other animals of the same group (pooled treatment group approach).

A single-cell suspension of lymph node cells (LNC) is prepared by gently passing the nodes through 200-μ m-mesh stainless steel gauze. The LNC are washed twice with an excess of PBS, and the DNA is precipitated with 5% trichloroacetic acid (TCA) at 4°C for 18 h. Pellets are resuspended in 1 mL TCA and transferred to scintillation vials containing 10 mL of scintillation fluid for 3H counting.

Lymphocyte proliferation is measured by estimation of DNA synthesis, which involves the incorporation of the labeled nucleoside [tritiated thymidine ([3H]dT)] into genomic DNA. Incorporation of 3H-methyl thymidine is measured by a β-scintillation counter as disintegrations per minute (DPM). Depending on the approach used, the incorporation is expressed as DPM/mouse (individual animal approach) or DPM/treatment group (pooled treatment group approach).

The ratio of tritiated (3H)-methyl thymidine incorporation into each treated group and into the vehicle treated control group (VC), termed the stimulation index (SI), is calculated. When using the individual animal approach, the SI is derived by dividing the mean DPM/mouse within each test substance group by the mean DPM/mouse for the VC group. When using the pooled treatment group approach, the SI is obtained by dividing the DPM/treatment group within each test substance group by DPM/VC group. The material is considered a sensitizer when SI $\geq$ 3 (OECD 2010a).

The relative potency (defined as a function of the amount of chemical required for skin sensitization) of contact allergens can be measured by deriving from dose responses in the LLNA an EC3 value, which is the concentration of the chemical required to provoke a threefold increase in the proliferation of LNC compared with controls (i.e., an SI of 3). Additional details are found in the ICCVAM website.

EVALUATION

LLNA offers advantages in the lower number of animals used, lower cost, an objective and quantitative end-point measurement, and less time required for conducting the assay in comparison to various guinea pig assays. Moreover, the LLNA provides advantages with regard to animal welfare. The nonrequirement of a challenge exposure and the nonuse of adjuvant reduce animal pain and distress. The inclusion of several concentrations tested during the induction exposure provides opportunity to combine hazard identification with quantitative estimation of relative sensitizing potency.

Warbrick et al. (1999) examined the stability and consistency of LLNA responses induced by the contact allergen paraphenylenediamine (PPD). Analyses were conducted once a month over a 4-month period in each of two independent laboratories. In all assays and in both laboratories, PPD elicited a positive response, with minor differences, confirming the stability of LLNA responses both with time and between laboratories.

The LLNA EC3 values (the concentration of chemical necessary to obtain a threefold stimulation of proliferative activity in draining lymph nodes) have been reported to correlate well with the sensitization potencies of human contact allergens. Gerberick et al. (2001) assigned five potency rankings [(strong, moderate, weak, extremely weak, and nonsensitizing) for 21 chemicals based on quantitative data from human repeat patch test studies reported in the literature [human maximization test (HMT) and the human

repeat insult patch test (HRIPT)] together with their clinical experience and compared these with the potency rankings derived from LLNA EC3 values. They showed that the potency of 12 out of the 15 chemical allergens was similarly classified. For the nonsensitizers, each of the six chemicals evaluated and classified as nonsensitizers for humans were classified identically in the LLNA.

The local lymph node assay (LLNA) is currently recognized as a stand-alone test method for the purposes of hazard identification (i.e., a method that can be used not only for the identification of skin sensitization hazard but also for confirmation of the absence of such hazard), and it has now been adopted formally by several regulatory agencies in the USA.

CRITICAL ASSESSMENT OF THE METHOD

The main disadvantages of the LLNA are the need for radioactive material and the restriction of the evaluation to the induction phase. As shown in previous publications, false-positive results to certain nonsensitizing skin irritants [e.g., sodium lauryl sulfate (SLS)] and false-negative results to metal allergens (in particular nickel) may be obtained.

MODIFICATIONS OF THE METHOD

15.4.1.1 The Reduced LLNA (rLLNA)

The protocol for the rLLNA is identical to that of the traditional LLNA, with the exception that instead of testing three concentrations of each test substance, only the highest concentration that does not induce systemic toxicity and/or excessive skin irritation is tested. This way, it is possible to reduce the number of animals used to perform the test in up to 40%. The rLLNA is recommended to distinguish between skin sensitizers and nonsensitizers in cases that do not require dose-response information (ICCVAM 2009).

15.4.1.2 Nonradioactive LLNA Methods

The LLNA: DA is a similar method to the LLNA that measures the adenosine triphosphate (ATP) content as an indicator of lymphocyte proliferation, instead of the incorporation of the labeled nucleoside [tritiated thymidine ([3H]dT)] into genomic DNA. The ATP content in the lymph nodes (known to correlate with living cell number) is measured by the bioluminescence method, which utilizes the luciferase enzyme to catalyze the formation of light from ATP and luciferin. The emitted light intensity, which is related to the ATP concentration, is given in relative luminescence units (RLU). The SI is derived by dividing the mean RLU/mouse within each test substance group by the mean RLU/mouse for the vehicle-treated control group (VC).The material is considered a sensitizer when SI $\geq$ 1.8 (OECD 2010).

The LLNA: BrdU-ELISA (enzyme-linked immunosorbent Assay) is also an alternative method similar to the LLNA that measures the incorporation of 5-bromo-2-deoxyuridine (BrdU) into genomic DNA as an indicator of lymphocyte proliferation. BrdU is an analogue of thymidine and is similarly incorporated into the DNA of proliferating cells. Its incorporation is measured by ELISA (utilizes anti-BrdU antibody labeled with peroxidase, which reacts with BrdU to produce a colored product, whose absorbance at 370 nm is determined with a microplate reader with a reference wavelength of 492), and the result is given as BrdU labeling index. The SI is derived by dividing the mean BrdU labeling index/mouse within each test substance group by the mean BrdU labeling index/mouse for the vehicle-treated control group (VC). The material is considered a sensitizer when SI $\geq$ 1.6 (OECD 2010). Taken together, the LLNA is a precise assay for hazard identification. Its use in risk assessment requires many strategies and interpretation—to minimize withdrawing many chemicals from potential use by man because of the many compounds that are so identified as allergens, but with appropriate concentrations of use may be well tolerated in man.

15.4.2 Mouse Ear Swelling Test (MEST)

PURPOSE AND RATIONALE

The basic principle of the mouse ear swelling test (MEST) is the assessment of skin sensitization by quantitatively and objectively measuring the increase in mouse ear thickness with a micrometer following the challenge exposure with potential sensitizers.

PROCEDURE

Healthy, 6–8-week-old female CF-1 or Balb/c mice are fed with a diet supplemented with vitamin A acetate at 250 IU/g of feed for 2 weeks prior the beginning of the assay. A minimum of ten animals is required for the test and control group and at least eight for the pretest group. A pretest is performed in order to establish the minimal irritating concentration to the abdomen and the highest nonirritating concentration to the ear of the animals. Two mice are used to test each concentration of the test substance, and this way, at least four concentrations are evaluated. Acetone, methyl ethyl ketone, and 70%, 80%, and 95% ethanol in water have been shown to be acceptable vehicles based on solubility and chemical compatibility with the test substance. Days 0, 1, 3, and 5—Induction exposure: The abdomen of the animals is clipped free of hair. Next, two intradermal injections of FCA (20 μL) are given at separate sites along the borders of the test area that is then tape-stripped until the skin appears glossy. A volume of 100 μL of the test substance at the minimal irritating concentration is topically applied to the test area of the test group. Control group receives 100 μL of the vehicle. On days 1, 3, and 5, the tape stripping and application of test material (test group) and vehicle (control group) are repeated. Day 10—Challenge exposure: 20 μL of the test material at the highest nonirritating concentration is applied to the ventral and dorsal surfaces of the left ear of all test group animals and to five control animals. A volume of 20 μL of 100% vehicle is applied to the ventral and dorsal surfaces of the right ear. Days 11 and 12—Assessment of skin sensitization: Ear thickness is measured 24 and 48 h after challenging using an Oditest spring-loaded caliper. Positive results are defined as animals whose test ear is at least 20% thicker than the control ear. The percentage of respondents in the test group is then calculated. The degree of ear swelling of the test group should also be calculated by dividing the thickness of the ear to which the test material was applied by the thickness of the vehicle-treated control ear. One or more positive responses (20% or greater swelling compared to the control ear) in a group of 10 animals indicate that the test substance is a sensitizer. A negative response indicates that the substance is not a moderate or strong sensitizer. Day 17—Rechallenge: It can be performed using the five remaining naïve control group, if it is desired to clarify ambiguous findings. A positive control is recommended and should show 0.05% dinitrochlorobenzene (DNCB) in 70% ethanol to be a strong sensitizer. The procedure presented here was based on the description of Gad (1994), modified from Gad et al. (1985, 1986).

EVALUATION

The mouse ear swelling test (MEST) was developed to overcome the disadvantages of the existing guinea pig based tests. It provides a lower cost, shorter length of test, and an objectively graded end point (making unnecessary the subjectively grading skin erythema). The possibility of rechallenging is an advantage from the other murine test, the LLNA.

Gad et al. (1986) published a large study, in which a MEST was employed to evaluate a battery of 72 test substances [for which the sensitizing potential in the guinea pig maximization test (GMPT) and/or in humans was already known].These included 49 known positives and 23 known negatives. Only one known positive sensitizer was not properly identified, giving a false-negative rate of 1/49 or 2%. All 23 nonsensitizers, including contact irritants such as benzoic acid and sodium lauryl sulfate (SLS), were correctly identified.

CRITICAL ASSESSMENT OF THE METHOD

The sensitivity of the MEST has been questioned. Dunn et al. (1990) conducted an investigation at two independent laboratories for the purpose of evaluating

the ability of the mouse ear swelling test (MEST) developed and validated by Gad et al. (1986) to detect contact sensitization induced by 26 chemicals. They found a high incidence of false negatives for either weak (HS, PABA, Sudan III, methyl methacrylate, croton oil) or moderate (benzoyl peroxide, nickel sulfate, ethylenediamine, monothioglycerol) human contact sensitizers. Contrary to results reported by Gad et al., their findings suggested that MEST is a useful model for identifying strong contact sensitizers but is not reliable for detecting weak and moderate ones.

Although the MEST is quantitative, it has a degree of variability based on individual interpretation of caliper measurements. The type of micrometer used may also affect interpretation of the test results. When van Loveren et al. (1984) compared the spring-loaded caliper, the screw with friction thimble micrometer, and the sliding caliper, the spring-loaded instrument, which applies the least pressure to the ears, was considered to give the most accurate measurements of the thickness of the ears at different times after challenge.

MODIFICATIONS OF THE METHOD

Sailstad et al. (1993) evaluated four protocols with variations of the mouse ear swelling test (MEST) using the strong sensitizer 2,4-dinitrofluorobenzene (DNFB) and three weaker sensitizers, glutaraldehyde, formalin, and an *azo* dye (Solvent Red 1 [SRl]). For one of the groups, the protocol required all animals to be fed a supplemented diet with 0.477 g/kg of vitamin A acetate (approximately 15 times the amount found in standard chow) for 4 weeks prior to sensitization. All four protocols of the MEST detected the strong sensitizer (DNFB); however, only the vitamin A–supplemented protocol detected the weaker sensitizers. They concluded that feeding the animals with a vitamin A–supplemented diet proved to be the best procedure to enhance the test sensitivity for weak sensitizers. Other previous studies (Miller et al. 1984; Maisey and Miller 1986; Thorne et al. 1991) demonstrated similar effects of vitamin A–supplemented diet. It is believed that a vitamin A–supplemented diet has an adjuvant effect that enhances cell-mediated immune responsiveness. With this knowledge, the MEST protocol was optimized. On the original MEST design of Gad et al. (1986), mice were fed with conventional diet. However, on the current version of the protocol (Gad 1994), mice are fed with a diet supplemented with 250 IU/g of vitamin A acetate, starting 2 weeks before the induction exposure.

Studies have tried to turn the assessment of sensitization response on the MEST more objective by measuring cellular proliferation on the mouse ear instead of measuring skin thickness. Cornacoff et al. (1988) compared the sensitization response on the mouse ear by measurement of the influx of inflammatory cells which have been prelabeled (125[I]-iododeoxyuridine) with the classical measurement of increase in tissue thickness. The study demonstrated that both the radioisotopic method and the classical method detected significant reactivity to the strong sensitizer oxazolone and DNFB. Both methods were capable of detecting reactivity to only one of the three weak sensitizers tested. The authors concluded that the radioisotopic approach was comparable to the classical approach and also more sensitive and less subjective. Lee et al. (2003) attempted to assess sensitization response on the mouse ear using a nonradioisotopic end point (BrdU incorporation into DNA as an alternative to labeling proliferating cells with radioisotopes). However, the method failed to find a significant difference in ear response between the mice treated with allergens and those treated with irritant. This, like the LLNA, is a useful screening assay and, like the LLNA, requires many other steps for risk assessment.

15.5 Human Sensitization Assays

PURPOSE AND RATIONALE

Provided that the risk of inducing contact sensitization in volunteers is judged to be minimal (based on assessment of preclinical sensitization data), human sensitization assays may be conducted for premarketing safety assessment of new cosmetics or household products to confirm that humans will not respond adversely to chemicals contained therein. Sensitization assays should be conducted in accordance with accepted codes of ethics for the conduct of human testing [e.g., The Declaration of Helsinki, Good Clinical Practice (GCP) guidelines] and conform to any applicable national regulatory requirements and legislation. Volunteers should be informed of the purposes and the potential risks of the test and sign an informed consent.

PROCEDURE

There are several human sensitization tests available. They vary with regard to the number of induction patch tests, the placing of the patches, the grading scale, the scheme of induction exposure (continuous or with rest intervals), and the use of a maximization step. Basically, each test is divided into three consecutive phases: An initial or induction phase, during which repeated patches insult the skin; a period of rest, during which an immune response may develop; and a final challenge or elicitation phase to determine whether sensitization has occurred. Subjects are randomly selected, and each protocol has a standard list of inclusion or exclusion criteria. Volunteers with clinically active dermatitis, immunological disease, routine use of anti-inflammatory drugs, immunosuppressive drug therapy, or with a known preexisting sensitization to the chemical being tested are usually excluded. The concentration at which the chemical is evaluated is determined by integrating prior sensitization test results in animals, the desire to exaggerate use concentrations, and prior experience. There are three basic predictive human sensitization tests in current use: (1) the human repeat insult patch test (HRIPT), (2) the modified Draize human sensitization test, and (3) the maximization test. Principal features of human sensitization assays are summarized in Table 15.2.

15.5.1 Human Repeat Insult Patch Test (HRIPT)

The three most used HRIPTs include (1) the Draize human sensitization test (1955, 1959), (2) the Shelanski/Shelanski test (1953), and (3) the Voss/Griffith test (1969, 1976).

In the Draize human sensitization test, an occlusive patch containing the test substance is applied to the upper arms or back of the volunteers and is held in contact with the skin for 24 h. The patch is then removed, and the skin is allowed to rest for 24 h. Then, a second patch test is applied to a new skin site. This process is repeated every other day three times a week until 10 induction patches are applied. Each induction site is evaluated for erythema and edema after removal of the patch. Ten to 14 days after application of the last induction patch, a challenge patch is applied to a new site for 24 h and subsequently evaluated for erythema and edema. The response after challenge is compared to the responses reported after the early induction patches and the incidence of sensitization are reported.

In the Shelanski/Shelanski test, an occlusive patch is applied on the upper arm for 24 h in a similar fashion (24-h contact and 24-h rest) to the Draize RIPT described above. However, the patch is placed on the same test site each time, and a total of 15 induction patches are applied. The test site is evaluated before application of the new patch, and if inflammation has developed, the patch is placed on an adjacent uninflamed site. The induction site is evaluated for erythema and edema after removal of the patch. Two to 3 weeks after application of the last induction patch, a challenge patch is applied on a new site of the upper arm for 48 h and subsequently evaluated for erythema and edema. The response after

challenge is compared to the responses reported after the early induction patches and the incidence of sensitization is reported.

In the Voss/Griffith test, quadruple occlusive patches are applied to the same site of the upper arm for 24 h in a similar fashion (24-h contact and 24-h rest) to the Draize RIPT described above. This process is repeated on 3 consecutive weeks for a total of nine induction applications of each material per subject. If primary irritation occurs, the succeeding patch is applied adjacent to the original site. Twenty-four hours after removal of the patches, the induction site is evaluated for erythema and edema. Seventeen days after application of the last induction patch, a challenge patch is applied on the original test sites and on the opposite virgin arm. Patches are removed after 24 h, and the test sites are evaluated for erythema and edema after 48 and 96 h.

Stotts (1980) presented detailed examples of proper interpretation of human repeat insult patch tests. Sensitization is characterized by delayed appearance of response, by challenge reactions stronger than reactions early in the induction phase, and by persistence and/or increased responses through delayed readings. Weak responses in a few subjects when the material has not produced irritation in the panel suggest a weak sensitizer and a sudden increase in intensity of reactions during the second or third week of the test (following the fourth or fifth application) can be indicative of a strong sensitizer with a short induction period. A very strong reaction by one subject following the first or second patch

application suggests a preexisting sensitization. Jordan and King (1977) proposed modifying the challenge procedure to two consecutive 48-h patch periods, and Marzulli and Maibach (2003) proposed that the investigator, rather than the volunteers, remove the patches.

15.5.2 Modified Draize Human Sensitization Test

The HRIPT was modified by Marzulli and Maibach (1974) to provide for continuous induction patch exposure (without rest period between patches). Occlusive patches with the test material (at use concentration as well as at higher concentrations) are applied three times weekly (Monday, Wednesday, and Friday) for 48 or 72 h (weekends) to the same site of the upper lateral portion of the arm until ten patches have been applied. The patches remain in place until approximately 30 min before the application of the new one, and skin reactions are graded (1 = erythema, 2 = erythema and induration, 3 = vesiculation, 4 = bulla formation) during this interval. If moderate inflammation has developed, the next patch is moved to an adjacent skin site. This produces a continuous exposure of 504–552 h compared to a total exposure period of 216–240 h for HRIPT of comparable induction applications. Following a rest period of approximately 2 weeks, the challenge patch (at nonirritant concentration) is applied to a new site and allowed to remain for 72 h. Test sites are evaluated at patch removal and after 24 h.

15.5.3 Human Maximization Test

The human maximization test, designed and later modified by Kligman et al. (1966, 1975), employs irritancy as an adjuvant. Test materials are tested during induction at a concentration that produces a moderate erythema within 48 h. If materials are nonirritating, the test site is pretreated with a 24 h patch of 5% sodium lauryl sulfate (SLS). Additional SLS patches may be applied before each patch application until a brisk erythema is achieved. The induction concentrations should be at least five times higher than use levels. Patches are applied to the upper arm or lower back, and up to four different materials can be tested at once. Five sets of patches are applied on the same site for 48 h each, with a 24-h rest period between removal and reapplication. Following a 2-week rest period, a new site is pretreated with SLS patch for 1 h followed by a 48-h patch application with the test substance. Test sites are evaluated at patch removal and then reexamined 24 and 48 h after. The number of subjects developing a positive response is reported, and a sensitization index based on percentage of subjects responding is assigned to the test material. The assay is rarely employed today.

EVALUATION

The advantages of experimental induction of skin sensitization in human volunteers are that exposures are controlled, several doses can be tested, and extrapolation of the test results from one species to another is not needed. The FDA developed a guidance document (1999) for evaluating skin sensitization to chemicals in natural rubber products and selected the modified Draize test as the test of choice.

Because no standardized test guidelines are available for the human sensitization assays, methods may vary from laboratory to laboratory. When reporting test data, it should contain a brief description of the test protocol, the scoring criteria used, and the method used for rating skin responses.

CRITICAL ASSESSMENT OF THE METHOD

Human skin sensitization assays have the disadvantages that large cohorts of volunteers are needed to give a reliable result and a number of them may drop out during the course of the test (usually for reasons unrelated to the test). Studies conducted in human volunteers are subject to stringent ethical considerations, and the investigator is required to obtain approval from an Institutional Review Board (IRB) (USA) or Ethics Committee (Europe). Because the human maximization test may produce strong skin reactions, it may be considered unacceptable nowadays.

Skin responses are evaluated by subjective visual scoring, and consequently, the degree of reliability with which the available signs are read and interpreted is dependent on the experience and judgment of the investigator. The greatest demand is the investigator ability in distinguishing between primary irritation and sensitization. Positive assays require careful

interpretation—to extrapolate from hazard—to risk for a given use situation.

MODIFICATIONS OF THE METHOD
In the interest of reducing animal use, in vitro alternatives for skin sensitization assays are under development.

15.5.4 Peptide Reactivity Assay

One characteristic of a sensitizer chemical is its ability to react with proteins prior to the induction of skin sensitization. Measuring chemical reactivity to peptides has a potential utility for evaluating skin sensitization hazard (Gerberick et al. 2004). In order to determine whether and to what extent reactivity correlates with sensitization potential, Gerberick et al. (2007) evaluated 82 chemicals (sensitizers of different potencies and nonsensitizers) for their ability to react with reduced glutathione (GSH) or with two synthetic peptides containing either a single cysteine or lysine. The test chemical was mixed with the two synthetic peptides and with glutathione, in separate reactions. Following a time allowed for reaction, the samples were analyzed by high-performance liquid chromatography (HPLC) to monitor the depletion of glutathione or of the two peptides. Generally, nonsensitizers and weak sensitizers demonstrated minimal to low peptide reactivity, whereas moderate to extremely potent sensitizers displayed moderate to high peptide reactivity. Classifying minimal reactivity as nonsensitizers and low, moderate, and high reactivity as sensitizers, it was determined that the method gave a prediction accuracy of 89%.

15.5.5 Immune Cell Activation Assays

Based on the knowledge that skin sensitization is dependent upon recognition of the sensitizer chemical in the skin by Langerhans cells (LC), many efforts have been done to exploit LC responses to chemicals in vitro (chemical-induced changes in phenotype or function of these cells) for the identification of sensitization hazard. After skin contact with immunogenic chemicals, LC are activated and upregulated a set of cell surface markers (e.g., CD83 or CD86), secrete various cytokines, such as interleukin (IL)-1b, and downregulate proteins involved in antigen uptake such as aquaporins.

However, since Langerhans cells (LC) constitute only 1–3% of all epidermal cells, human peripheral blood mononuclear cell-derived DC (PBMC-DC), THP-1 cells (human monocytic leukemia cell line), and U-937 (human histiocytic lymphoma cell line) are being used as surrogates of LC in the development of in vitro model systems for predictive skin sensitization tests.

Aeby et al. (2004) reported the use of a human peripheral blood mononuclear cell-derived DC (PBMC-DC) test system to assess skin sensitization potential based on the measurement of cell surface CD86 expression by flow cytometry and interleukin (IL)-1b and aquaporin 3 gene expressions by quantitative real-time polymerase chain reaction (QRT-PCR). In presence of the sensitizer 2, 4, 6-trinitrobenzenesulfonic acid (TNBS), the percentage of the CD86 bright cells increased up to approximately 200% of control at 30 h. On the other hand, the irritant sodium lauryl sulfate (SDS) did not induce relevant modification of the CD86 bright population after 24 or 30 h. A similar effect was observed on the modulation of IL-1b gene expression. Incubation with TNBS for more than 6 h induced relevant increases in IL-1b gene expression and reached 800% of control after 30 h. Exposure to SDS induced 80% of control after 30 h. Analysis of AQP3 gene expression demonstrated a pronounced decrease of AQP3 expression (down to 25% of control at 30 h in the cells exposed to TNBS). SDS did not affect AQP3 gene expression at any of the tested time points.

Uchino et al. (2009) described the development a three-dimensional human skin model composed of dendritic cells, keratinocytes, and fibroblasts (VG-KDF-Skin). This type of culture system develops a fully differentiated epidermis with a stratum corneum, which besides evaluating skin sensitization, allows for the topical application of test materials and provides a barrier system for skin penetration. Sensitizers and nonsensitizers were applied to the surface of the skin model for 1 h. When 2, 4-dinitrochrolobenzen (DNCB), α-hexyl cinnamic aldehyde (HCA), and 2, 4-dinitrofuruolobenzen (DNFB) were applied, the VG-KDF-Skin induced the expression of CD86 and significantly induced IL-1α and IL-4 release. On the other hand, DMSO and isopropanol (nonsensitizers) did not induce the expression of CD86 or cytokine release. Sodium dodecyl sulfate (SDS, an irritant but

a nonsensitizer) did not induce the expression of CD86 or IL-4 release but did significantly induce IL-1α release.

15.6 Irritation Tests in Animals

15.6.1 Draize-Type Tests

PURPOSE AND RATIONALE

Draize et al. (1944) described a method to evaluate the potential for skin irritation (reversible local inflammatory changes without the involvement of an immunological mechanism) and corrosivity (irreversible tissue damage) that might result from intended or accidental exposures to chemicals and finished products. It has been modified to varying extents by regulatory authorities over time; however, all Draize-type tests evaluate skin primary irritation based on an occluded *single application* of the test material on albino rabbits.

PROCEDURE

According to Draize et al. (1944), the backs of six albino rabbits are clipped free of hair. Four areas of the back of each animal, placed approximately 10 cm apart, are designated for the position of the patches. Two of them are abraded by making four epidermal incisions (two perpendicular to two others in the area

of the patch). The compound is applied so that there are three applications to intact skin and three to abraded skin. This way, four compounds can be tested per series of six animals. The material (0.5 mL in the case of liquids or 0.5 g in the case of solids) to be tested is introduced under the patches, which consist of two layers of light gauze cut in squares (2.5 cm on the side). These are secured to the area by thin bands of adhesive tape. The entire trunk of the animal is then wrapped with rubberized cloth or other occlusive impervious material to retard evaporation of the compound and hold the patches in position. The wrappings are removed 24 h after application, and the test sites are evaluated according to the Draize scoring system for erythema (very slight erythema = 1, well-defined erythema = 2, moderate to severe erythema = 3, and severe erythema to slight eschar formation = 4) and edema (very slight edema = 1, slight edema = 2, moderate edema = 3, and severe edema = 4). This way, the total possible score for primary irritation is 8. Test sites are evaluated again 72 h after application using the same scale, and the final score is the average of the 24-h and the 72-h readings. Evaluations of abraded and intact sites are recorded separately. The combined averages of the 24-h and 72-h scores for the intact and for the abraded skin are referred as "the primary irritation index." Compounds producing primary irritation index of 2 or less are considered mildly irritating, whereas those with index from 2 to 5 are moderate irritants and those above 6 are considered severe irritants.

EVALUATION

The Draize test provides tremendous value in warning consumers, workers, and manufacturers of potential dangers associated with specific chemicals so that appropriate precautions can be taken. It can be done prior to human testing to offer guidance and reduce the risks of testing on man. Its predictive validity for the human response was assessed by Phillips et al. (1972). They compared the relative irritancy of 12 chemicals in man and rabbit utilizing a variation of the standard Draize rabbit irritancy test. The Draize rabbit test accurately predicted the severe human skin irritants and nonirritants but failed to separate the mild and moderate skin irritants. Several chemicals considered unsafe by the rabbit test proved nonirritating to human skin. Rabbit skin generally tends to be more easily irritated than human skin under similar conditions. An inherent difference in the permeability of rabbit and human skin probably accounts for a major portion of the increased irritation observed in the rabbit testing. However, there are a few examples of instances in which irritancy testing on animals has failed to indicate human irritancy (Nixon et al. 1975). Anatomical, physiological, and biochemical differences between the rabbit and humans may have prevented direct prediction of the expected irritancy in man from data on experimental animals.

CRITICAL ASSESSMENT OF THE METHOD

All Draize-type tests are used to evaluate corrosion as well as irritation; however, vesiculation, ulceration, and severe eschar formations are not included in the Draize scoring scales. When chemicals that are severe dessicants or severe escharotics are tested, dilute solutions in a bland nonirritating solvent should be done. Sufficient dilution needs to be made so that the responses elicited may be graded by the scale.

The subjectiveness of the scoring system and difficulties in the interpretation of the results contribute to intra- and interlaboratory variability, making comparison between different laboratories difficult. Animal welfare is another point of criticism. Animal welfare groups have long targeted the Draize test procedures as inhumane and unnecessary.

MODIFICATIONS OF THE METHOD

Modifications of the Draize test are currently required by regulatory authorities worldwide. The modifications relate to the number of animals tested, the duration of test material exposure, the application on intact versus abraded skin, and the number and frequency of skin evaluations. The Federal Hazardous Substance Act (FHSA), Department of Transportation (DOT), Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), and OECD guidelines are contrasted to the original Draize methods in Table 15.3.

The Organization for Economic Co-operation and Development (OECD 2002) guidelines and the United States Environmental Protection Agency acute dermal irritation guidelines (EPA 1998) give special attention to animal welfare improvements and to the evaluation of all existing information on the test substance prior to animal testing. It is important to avoid the unnecessary use of animals and to minimize any testing that

Table 15.3 Comparison of skin irritation test based on the Draize method

Feature	Draize	FHSA	DOT	FIFRA	OECD[a]
Number of animals	3[b]	6	6	6	3
Abrasion	Abraded and intact	Abraded and intact	Intact	2 abraded and 2 intact	Intact

is likely to produce severe responses in animals. It is recommended that prior to undertaking the described in vivo test for corrosion/irritation of the substance, a weight-of-the-evidence analysis be performed on the existing relevant data: human and animal data; results of testing of structurally related substances, physicochemical properties, and chemical reactivity (substances exhibiting pH extremes such as 2.0 and 11.5 may have strong local effects); and results from in vitro or ex vivo tests. Substances that have demonstrated corrosive or severe irritant properties need not be tested in animals. It can be presumed that such substances will produce similar severe effects in vivo. When determination of corrosivity or irritation cannot be made using a weight-of-the-evidence analysis, an in vivo sequential testing strategy is recommended. It begins with an initial test using one animal and up to three test patches are applied sequentially. The first patch is removed after 3 min. If no serious skin reaction is observed, a second patch is applied at a different site and removed after 1 h. If the observations indicate that exposure can humanely be allowed to extend to 4 h, a third patch is applied and removed after 4 h, and the response is graded. If the results of this test indicate the substance to be corrosive to the skin, further testing should not be performed. If a corrosive effect is not observed in the initial test, the irritant or negative response should be confirmed using up to two additional animals for an exposure period of 4 h. Other modifications are that the skin of the rabbits are not abraded, the exposure period is reduced to 4 h, the responses are scored at 60 min, and then at 24, 48, and 72 h after patch removal, animals should be observed up to 14 days after removal of the patches to determine the reversibility of effects. The grading of skin responses is similar to the Draize scale. Chew et al. provided extensive clinical background that adds to the clinical implications of such testing. Dermatotoxicology background is found in Marzulli et al. (ref) [7th edition—Dermatotoxicology].

15.6.1.1 Non-Draize Animal Studies

PURPOSE AND RATIONALE

These are animal assays that evaluate the ability of chemicals to produce cumulative irritation and is based on *repeated applications* of the test material. Many such tests have been described in the literature, but only a few have been studied extensively enough to mention. Even those used more often are not as well standardized as Draize-type tests, and many variables have been introduced by multiple investigators.

PROCEDURE

1. Repeat animal patch (RAP) test—Justice et al. (1961) compared the irritation potential of surfactants. Solutions are applied to the clipped back of immobilized albino mice with a saturated cotton-tipped applicator. The test site is covered with a rubber dam to prevent evaporation. This process is repeated seven times at intervals of 10 min and then the skin is subsequently microscopically evaluated for epidermal erosion.
2. A 16-day cumulative irritation test in rabbits—Marzulli and Maibach (1975) presented a new animal test for evaluating the skin-irritant capacity of cosmetics, drug preparations, and ingredients intended for repeated application. Substances are applied 14 times (uncovered) to the skin of six rabbits over a 3-week period on Mondays to Fridays, except for the last Friday. Each test site is scored every subsequent day, except Sundays (16 readings). The two parameters evaluated throughout the test as indices of skin irritation are redness (cumulative irritation score) and fluid accumulation (changes in skinfold thickness). The score used is 0 for no erythema, 1 for barely perceptible erythema, 2 for well-defined erythema, 3 for moderate to severe erythema, and 4 for beet-red erythema to slight eschar and/or disruption of epidermal intactness. At the conclusion of the test the cumulative irritation score for each animal (maximum $16 \times 4 = 64$) is obtained, and the mean cumulative score for six rabbits is recorded as an index of skin irritation. Changes in skinfold thickness are evaluated by deriving the mean difference from the daily differences between test and control-site readings on each rabbit and using the average of these mean differences for six rabbits as an index of skin irritation.
3. A 5-day dermal irritation test—performed in rabbits to compare various consumer products (MacMillan et al. 1975). The back of the animals are shaved, and 0.5 mL of the test material is spread over a 5×4.5-cm skin area. The test sites are protected from grooming by placing the animal in a leather harness or Elizabethan collar. After 4 h, sites are cleaned and graded using the Draize scoring system. The procedure is repeated every day for 5 days. The authors showed good agreement between the assay and the 21-day human patch tests of liquid detergents, after bath colognes, and hair preparations; the technique was less satisfactory for other types of materials.
4. The guinea pig immersion assay—used to evaluate the irritancy of aqueous detergent solutions and other surfactant-based products. Ten guinea pigs are placed in restraining devices that are immersed in a 40°C test solution for 4 h. The apparatus is designed to maintain the guinea pig's head above the solution. Immersion is repeated daily for three treatments. Twenty-four hours after the final immersion, the flank is shaved, and the skin is evaluated for erythema, edema, and fissures. A photographic grading scale for this assay was presented in MacMillan et al. (1975). Only materials of limited toxic potential are suitable for this assay because systemic absorption of a lethal dose

is possible. Concentration of test materials varies somewhat but is usually below 10% to limit systemic toxicity of the agents. A second group of animals is usually tested with a reference material as a control for the material of interest.

5. Open application procedure in guinea pigs—irritant skin reactions from repeated open applications of organic solvents are studied macroscopically and microscopically (Anderson et al. 1986). Aqueous solution of sodium lauryl sulfate (SLS) in low concentrations is used as the reference irritant substance to rank the solvents. Ten microliters of solvent or 5 μL of aqueous solution of SLS are applied openly three times daily for 3 days in 1-cm^2 areas of the shaved flank. Sites are than evaluated visually for erythema and edema. Biopsies samples are taken, stained with May-Grunward-Giemsa and assessed under oil immersion for epidermal thickness and dermal infiltration. A composite score reflecting the day of first visible reaction (day 1 = 3 points, day 2 = 2 points, day 3 = 1 point, no response = 0 point) and the macroscopic evaluation, the epidermal thickness, and the cellular response (response as for 2% SLS = 3 points, response as for 1% = 2 points, response less than 1% SLS = 1 point, no response = 0 point) are used to rank the chemicals. This method provides information on the pathogenesis of the response to each chemical, but the extensive processing may limit its application to special studies.
6. The mouse ear test—Uttley and Van Abbey (1973) applied undiluted shampoos to one ear of mice daily for 4 days. The degree of inflammation was quantified visually as vessel dilation, erythema, and edema. A reference material was tested on another group of mice, and the two were compared.
7. Finkelstein and colleagues (1963, 1965) test—they described a method to test for low-irritancy compounds using rabbits, rats, or guinea pigs. Application sites are pretreated with an irritant to make them more reactive. The animal is anesthetized, its abdomen is shaved, and circular areas of 1 in. in diameter are marked out. These areas are painted with a 20% solution of formaldehyde and then are allowed to dry for 5 min. This is repeated three times and then the test materials are impregnated on circular white cotton flannel pads of 1 in. in diameter and placed over the presensitized test sites. A control substance of known irritancy is tested in each study. Pads are secured in place and then the entire trunk is wrapped in polyethylene. A 0.5% solution of trypan blue is then injected subcutaneously away from the test sites to enhance visualization of the response by increasing test sensitivity. The dye serves as a marker for plasma leakage because it spontaneously binds albumin. After 16 h, patches are removed, and the accumulation of blue dye in the various areas can be estimated on a scale from 0% to 100%.
8. Brown (1971)—both open and closed exposures are used to rank surfactants for skin irritation potential. Tests ranged from 6-h patch exposures each day for 3 consecutive days in rabbits to daily open applications to the skin of rabbits, guinea pigs, or hairless mice for up to 4.5 weeks.

EVALUATION

The Draize-type tests for skin irritation consist of a single application of the test material on rabbits under occlusion. These tests may be most useful in identifying substances that may irritate skin after accidental contact. Since topical drug preparations are applied for days or even weeks, and cosmetics may be applied for a lifetime, it was felt the importance to develop animal tests based on repeated application to establish the safety of preparations intended for prolonged use. Marzulli and Maibach (1975) compared the response obtained on rabbits after a single occluded application (Draize method) and after 16 uncovered applications (cumulative irritation). The results suggested that the multiple-application technique can provide more definitive information about chronically applied substances that have a relatively mild irritation potential. They also compared the results obtained by this method with data from a 21-day occlusive test conducted in man. Results on 60 test materials showed a significant correlation between the cumulative irritation scores obtained on rabbits and those obtained on man.

CRITICAL ASSESSMENT OF THE METHOD

As the Draize-type tests, non-Draize animal studies are criticized regarding animal welfare concerns.

MODIFICATIONS OF THE METHOD

Some animal assays have been developed to quantify irritant response. Humphrey et al. (1993) measured

Evans blue dye recovered from rat skin after exposing the skin to inflammatory agents. Trush et al. (1994) described a procedure for the assessment of the dermal inflammatory response to numerous irritants by measuring the level of myeloperoxidase (MPO) enzyme in polymorphonuclear leukocytes of young CD-1 mice 16 h after application of the test agent on the shaved back. Chew et al. provided extensive documentation that aid in the clinical interpretation of such assays. Dermatotoxicology background is found in Marzulli et al. [7th edition—Dermatotoxicology].

15.7 Human Irritation Tests

15.7.1 Single-Application Irritation Patch Tests

PURPOSE AND RATIONALE

Following a screening test in animals (for materials of unknown or unfamiliar composition) and with proper attention to ethics, irritation tests on human volunteers are preferred to animal tests if it is important to avoid the uncertainties of interspecies extrapolation. Single-application irritation patch tests measures acute skin irritation potential and is relevant to the identification of skin irritation hazards to humans.

PROCEDURE

The National Academy of Sciences (National Academy of Sciences and Committee for the Revision of NAS Publication 1138 1977) recommends a 4-h single-application patch test protocol for routine testing of skin irritation in humans. Ten volunteers are selected, and patches may be applied to the interscapular area of the back or to the dorsal surface of the upper arms. Eight to ten patches can be applied to each volunteer. Abrasion is not recommended. Instead of the wrapping around the body of the animals, a large piece of porous adhesive tape can be used to hold patches on the volunteers. A single exposure of 4 h is suggested, though it may be sufficient to use shorter exposures with strong irritants or very volatile materials. Volunteers are instructed to remove patches immediately if pain or discomfort occurs. After the exposure period, patches are removed and the skin is cleansed. Test sites are evaluated 30 min to 1 h, and 24 h after patch removal. Persistent reactions may be evaluated for 3–4 days. The Draize scale for redness and swelling can be used or an integrated scale based on the scale of Marzulli and Maibach: 0 = no response, 1/2 or + = questionable or faint, indistinct erythema, 1 = well-defined erythema, 2 = erythema with slight to moderate edema, 3 = vesicules or papules, 4 = bullous, spreading, or other severe reaction.

EVALUATION

The human 4-h patch test provides an opportunity to identify chemical acute skin irritation potential, providing data which are inherently superior to that given

by a surrogate model, such as the rabbit. It requires no species or system extrapolation of data for prediction of skin irritation potential as it is performed on the relevant species.

CRITICAL ASSESSMENT OF THE METHOD

Human testing is subject to strict ethical approval. This requires adherence to rigorous testing guidelines and overall protection of the well-being of the volunteers. They must read, understand, and sign an informed consent form prior to entry into the study. They should also be informed of all possible adverse reactions such as skin irritation and the possibility of postinflammatory hyperpigmentation. Ethical questioning comes from the fact that in human toxicological tests like this, some degree of intention knowingly "adverse" reaction may be produced without any direct health benefit to participants. However, these reactions are almost always mild or moderate in severity, are limited to small sites of chemical or product exposure, and quickly recover. In practice, the 4-h human patch test has been shown to be inherently low in risk, a fact well documented by an extensive published literature.

Single-application irritation patch tests measure acute skin irritation potential; however, for prediction of the cumulative or chronic skin irritation potential of ingredients or products intended for prolonged use, the repeat application irritation patch tests are more appropriate.

MODIFICATIONS OF THE METHOD

A standardized procedure for evaluating the irritation potential of new chemicals in man as a replacement for the Draize rabbit test has been proposed by Basketter et al. (1994). The method has been tested in several different laboratories, and results seem to be reproducible (Griffiths et al. 1997). The central tenet of this protocol is that skin responses to test materials are compared with the ones obtained after application of a meaningful positive control (20% SLS). It is then possible to determine statistically whether the test material has produced a level of skin irritation which is similar to, greater, or lower than the positive control (for the evaluation of the results of the test, what is measured is the number of subjects who had a positive irritant reaction after an exposure of up to 4 h. It is the incidence of positive responses, not the severity that is the basis for evaluation). Test materials showing statistically greater incidences of response (or no statistically significant difference versus the control) would be classified as "irritating to skin." Each test subject is exposed to the undiluted test material in occlusive chambers (Hill Top Chambers) and to a 20% solution of sodium laurel sulfate. The length of exposure begins with a 15-min exposure with evaluation at removal and at 24 and 48 h. If no response is observed, then another set of patches are applied for 30 min. This process of patching, evaluation, and patching for a longer exposure interval is repeated until the subject responds to the SLS exposure or until a 4-h exposure has been completed.

In a series of patch testing experiments to compare interspecies skin irritancy, Nixon et al. (1975) applied a 4-h Draize-type procedure (including abrasion) to evaluate a range of household products. Skin responses were evaluated for erythema and edema at 4, 34, and 48 h after application of the patches. Detail is provided by (Chew and Maibach 2006).

15.7.2 Repeat Application Irritation Patch Tests

PURPOSE AND RATIONALE

Kligman and Wooding (1967) described a new method for bioassaying substances intended for chronic exposure, as a means of evaluating any irritant effects that

may be cumulative with repeated exposure. As with single-application patch tests, many investigators (e.g., Lanman et al. 1968; Phillips et al. 1972) developed their own version of the repeat application patch test.

PROCEDURE

For weak irritants, Kligman and Wooding (1967) determined the IT50, which is the estimated number of days of continuous exposure which would produce a threshold reaction in 50% of the population. For strong irritants, they determined the ID50, which is the estimated concentration needed to produce a discernible irritant reaction in 50% of the population in 24 h.

The IT50 procedure: A minimum of ten subjects are included in the study. The patches consist of one centimeter square of Wcbril®, a highly absorbent nonwoven fabric, loaded with the test material. Occlusion is obtainable by securing the patches under overlapping strips of impermeable plastic tape (Blenderm®). The appropriate volume is that which is just sufficient to load the patch completely without overrun, approximately 0.05 mL per sq cm. The patches are reapplied once daily at exactly the same site of the back, and the end point is the number of days required for an unmistakable erythema to develop. When this threshold is reached, no further patches are applied at that site. Ten days of continuous exposure is the minimum required. For very mild materials, extension to 20 days may be necessary to obtain more than 50% of reactors in the sample. Sometimes, 50% or more of the subjects will have failed to react even after 20 days. Many products are so innocuous that none or only one or two subjects may react; these include the common vehicles such as lanolin, hydrophilic ointment USP, baby oils, and others. One may simply conclude that the products are essentially nonirritating. The Litchfield and Wilcoxon probit analysis is used to estimate the IT 50 value. For particular purposes, one may use either more subjects or a greater number of days of exposure.

The ID50 procedure: The minimum number of subjects is ten, as before. A pilot study is done to select a range of at least five concentrations which may be either evenly spaced or arranged in geometric progression, depending upon the material. Patches are applied as before, every subject being exposed to the entire range of concentrations. The patches are left on for a standard period and are not reapplied. Usually, 1-day exposure with immediate readings is performed, but contact time for strong irritants may be as low as 2–8 h. In such cases, the readings should be made at 24 h. The ID50 value is estimated trough the Litchfield and Wilcoxon probit analysis.

EVALUATION

Extensive experience with this assay indicates that it is most useful in evaluating low-grade irritants and compounds which have frequent and intimate exposure to human skin. The end points of Kligman and Wooding's (1967) method are "all or none" choices (quantal responses). The observer has only to decide whether there is or is not a reaction; he/she need not estimate its intensity. Furthermore, the all-or-none reaction depends upon a single quality, erythema, which is the common denominator of all irritation reactions.

CRITICAL ASSESSMENT OF THE METHOD

Besides all the ethic questions related to human studies (reported in the single application tests), these type of tests have a higher cost and are more time demanding. Laboratory personnel and subjects must be available for three consecutive weeks, including weekends. The subjects can leave the study without completing it. Another issue is whether the trauma or irritation to the skin from applying and reapplying adhesive patches for 21 days interferes with the proper evaluation of irritancy for the compositions being studied.

MODIFICATIONS OF THE METHOD

Modifications of the cumulative irritation assay have been reported. Intensity of response has been evaluated using other evaluation schemes, the interval between applications of fresh patches has been varied, and other methods of data evaluation have been proposed. The newer chamber devices have replaced Webril® with occlusive tape in some laboratories. Some investigators currently use cumulative scores to compare test materials and do not calculate the IT50. Kligman and Wooding performed their studies on surfactants in 10 days. Lanman et al. (1968) needed 21 applications to discriminate between baby lotions. Finkelstein et al. (1963, 1965) described tests using either a 5–6 or a 17–18-h exposure each day for 4 days. Test sites were evaluated 1 h after patch removal.

15.7.2.1 The Chamber Escarification Test

Repeated application patch tests on intact skin fail to predict some adverse reactions due to repeated application of materials to damaged skin (i.e., acne, shaved underarms, or sensitive areas such as the face). The chamber scarification test was developed to evaluate materials that would normally be applied to damaged skin. Light-skinned whites who developed severe erythema with edema and vesicles following a 24-h exposure to 5% sodium lauryl sulfate in Duhring chambers applied to the inner forearm are preselected as subjects. Five to ten volunteers constitute a test panel. Six to eight 10-mm^2 areas on midvolar forearm are scarified with eight crisscross scratches made with a 30-gauge needle. Four scratches are parallel, with another four at right angles. The test material is applied once daily for 3 days with readings made at 72 h. The reactions are graded on a five-point scale from 0 to 4.

15.7.2.2 Immersion Tests

Small differences in the mildness of soap cannot be demonstrated readily by means of normal usage tests with normal persons. It is consequently necessary to exaggerate the conditions in some manner so that the differences which exist may be magnified and determined objectively. In this manner, Kooyman and Snyder developed the arm immersion technique to compare the relative irritancy of two soaps or detergent products (Kooyman and Snyder 1942). In this procedure, solutions of two soaps are prepared and placed in pans or troughs in which the temperature is maintained at a constant level of 41°C (105°F). In order to simulate practical dishwashing conditions more closely, concentrations of 0.35% are used. One hand and arm of the subject is placed in each solution for a given period (10–15 min) and is then rinsed and patted dry with a soft towel. This immersion process is carried out three times a day at convenient intervals, and the test is continued until observable irritation is produced on one or both arms. The relative mildness of the two soaps may then be determined by an arbitrary scale for grading the degree of irritation. More recently, variations on the arm immersion technique have developed so that the antecubital fossa and the hands are separately tested. Variations incorporate different dosing regimens or measuring different end points.

15.7.2.3 Soap Chamber Technique

The "chapping" potential of bar soaps is evaluated with the soap chamber technique, developed by Frosch and Kligman (1979). While patch testing is useful in predicting erythema, it does not address the dryness, flaking, and fissuring observed with bar soap use. Using this method, 100 μL of an 8% soap solution is applied to the forearm via Duhring chambers fitted with Webril pads. Nonocclusive tape is used to secure the chambers. The exposure encompasses 5 weekdays, the first one for 24 h beginning on Monday morning. Fresh solutions are applied to the same sites for 6 h daily for the next 4 days. The sites are read on the Monday morning following removal of the chambers on Friday afternoon. During this 36-h interval, "chapping" becomes more noticeable, while erythema tends to moderate. If severe erythema at the test site occurs, the investigator must discontinue the study. Skin responses are evaluated with visual scoring of erythema, scaling, and fissures.

15.7.2.4 Bioengineering Methods

Bioengineering methods utilized to quantify test results include transepidermal water loss (TEWL), capacitance, ultrasound, laser Doppler flowmetry (LDF), spectroscopy, and chromametry (colorimetry). Most of the assays described were developed before the introduction of these bioengineering methods. These methods allow a more precise quantification of test results.

15.7.2.5 In Vitro Assays

There are three validated in vitro test methods that may be used to determine the skin irritancy of chemicals. They are based on a reconstructed human epidermis (RhE) model, which is comprised of nontransformed human-derived epidermal keratinocytes that have been cultured to form a multilayered, highly differentiated model of the human epidermis. It consists of organized basal, spinous and granular layers, and a multilayered stratum corneum containing intercellular lamellar lipid layers representing main lipid classes analogous to those found in vivo and are commercially available as EpiSkin™, EpiDerm™ SIT (EPI-200), and SkinEthic™ RHE test methods (OECD Test Guideline 439). The test material is applied to the three-dimensional RhE model, and irritant chemicals are identified by their ability to decrease cell viability below a defined threshold level.

Three validated in vitro test methods have been adopted as OECD Test Guidelines to be used for skin corrosivity testing. OECD Test Guideline 435 (2006) provides an in vitro membrane barrier test method, commercially available as Corrositex®. The test system is composed of two components, a synthetic macromolecular biobarrier (a proteinaceous macromolecular aqueous gel and a permeable supporting membrane) and a chemical detection system (CDS). The test substance is layered onto the upper surface of the membrane barrier, and penetration of the membrane barrier (or breakthrough) might be measured by a pH indicator dye or combination of dyes will show a color change in response to the presence of the test substance. OECD Test Guideline 431 (2004e) is based on a reconstructed human epidermis (RhE) model, comprised with the same material of that used for skin irritation that are commercially available as EpiDerm™ and EPISKIN™. The principle of the method is based on the premise that corrosive chemicals are able to penetrate the stratum corneum by diffusion or erosion and are cytotoxic to the cells in the underlying layers. Corrosive chemicals are identified by their ability to decrease cell viability below defined threshold levels. The OECD Test Guideline 430 (2004d) is the in vitro skin transcutaneous electrical resistance (TER) test. The test substance is applied for up to 24 h to the epidermal surface of skin discs (prepared from humanely killed 28–30-day-old rats) in a two-compartment test system in which the skin discs function as the separation between the compartments. Corrosive substances are identified by their ability to produce a loss of normal stratum corneum integrity and barrier function, which are measured as a reduction in the TER below a specified level. For rat skin TER, a cutoff value of 5 kΩ has been selected. Details are found in Rougier et al.

16.1 Introduction

Since the approval of the first recombinant protein therapeutic (insulin) in 1982, the number of biopharmaceuticals that have been approved as new medicines has grown steadily (Gosse et al. 1996; Lowe and Jones 2007). In one decade (1992–2002), 56 biopharmaceuticals were approved by FDA (Schwieterman 2006) and more than 170 biopharmaceuticals have been approved for clinical use worldwide (Giezen et al. 2008; Leader et al. 2008). Biopharmaceuticals have been successful as new therapeutics because of their high specificity for a given molecular target, favorable pharmacokinetic properties such as long half-life, low volume of distribution that provide better target coverage, and low "off-target" liability. This latter property translates into fewer non-clinical and clinical failures due to toxicity, when compared to small molecule therapeutics. A recent review of regulatory actions for safety concerns for all approved biopharmaceuticals in USA/EU (total: 174) indicated that the most frequent warnings (41 products) were related to immunomodulatory effects such as injection site reactions and infections, but none of these biopharmaceuticals have been withdrawn from human use (Giezen et al. 2008). However, recently two biopharmaceuticals were withdrawn from market - efalizumab (2009) because of increased risk of progressive multifocal leukoencephalopathy and gemtuzumab ozogamicin (2010) due to lack of efficacy and safety concerns (FDA.gov). This is in stark contrast with a large number of conventional "small molecule" drugs withdrawn from medical use because of safety issues, especially cardiovascular toxicity (Guengerich 2011).

The safety pharmacology assessment of drug candidates is based on the International Conference on Harmonization (ICH) guidelines S6(R1) (2011), S7A (2000) and S7B (2005). The primary goal of these safety guidelines is to provide a framework for the functional evaluation of candidate drugs, thus assuring their safety for first use in humans. This is achieved by assessing the undesirable pharmacological effects of drug candidates on various organ systems. The general approaches toward safety pharmacology assessment of small molecules and biopharmaceuticals are basically the same in that the effects of a drug candidate on cardiovascular, central nervous (CNS), and respiratory systems should be investigated prior to first use in humans. However, they could differ in practice. Safety pharmacology evaluation of small molecules is typically conducted in dedicated studies. In contrast, for biopharmaceuticals, incorporation of safety pharmacology endpoints into repeat-dose toxicity and/or pharmacodynamic studies is recommended. In this chapter, we review the special consideration for safety pharmacology assessment of biopharmaceuticals.

16.2 Regulatory Guidelines for Safety Pharmacology Assessment

In contrast to traditional chemically synthesized drugs, biopharmaceuticals are therapeutics derived from biological processes or organisms. Typical examples of biopharmaceuticals are proteins such as monoclonal antibodies (mAbs), recombinant proteins, cytokines, growth factors, fusion proteins, and peptides (ICH S6(R1) (2011)). In the ICH S6(R1) guideline, a wide variety of biopharmaceuticals are broadly referred to as biotechnology-derived pharmaceuticals, but other synonyms include biotherapeutics, protein therapeutics, and "large molecules." The designation "large molecule" is a reference to the high molecular weight (1 to >140 kDa) and complex secondary, tertiary, and quaternary structural characteristics of proteins (Crommelin et al. 2003), compared to classical "small molecule" drugs whose molecular weight is typically less than 500 Da (Ghose et al. 1999).

Biopharmaceuticals such as mAbs are engineered to specifically interact or modulate human cellular targets of diseases; as a result, this can make the non-clinical safety evaluation of protein therapeutics challenging, especially, the choice of the species to use for safety studies (Chapman et al. 2007; Bussiere et al. 2009). Such challenges can directly impact the in vivo safety pharmacology strategy used to assess biopharmaceuticals, especially if only a non-rodent species, such as the non-human primates (NHPs, i.e., cynomolgus monkey), is considered pharmacologically relevant (Green 1997; Chapman et al. 2007).

In this regard, the ICH S7A guideline (2000) recognizes that the traditional core battery of safety pharmacology studies may be inappropriate for biotechnology-derived products given their high specificity for human targets. For such agents, the guideline suggests inclusion of safety pharmacology endpoints in repeat-dose toxicity studies. It states that "For biotechnology-derived products that achieve highly specific receptor targeting, it is often sufficient to evaluate safety pharmacology endpoints as part of toxicology and/or pharmacodynamic studies, and therefore safety pharmacology studies can be reduced or eliminated for these products." While it is recognized that some safety pharmacology endpoints such as electrocardiographic parameters (ECG) can be collected from non-rodent toxicity studies, capturing high-quality safety pharmacology data requires skilful integration (i.e., right endpoint at the right time) and attention to the limitations of repeat-dose toxicity studies (i.e., small group size; interpretation of physiological/functional changes secondary to drug-induced toxicity) that may compromise the safety pharmacology assessment.

16.3 Integrated Safety Pharmacology Assessment

Because of limitation in the choice of animal test species for biopharmaceuticals, it is appropriate to monitor their potential undesirable pharmacological effects in repeat-dose toxicity studies. For biopharmaceuticals, there are several advantages of integrating safety pharmacology endpoints into a repeat-dose toxicity study including: ability to monitor acute (e.g., onset of delayed cardiac repolarization) and chronic effects (e.g., dysfunction due to myocardial structural alterations and QTc prolongation secondary to reduced hERG expression); opportunity to observe gender differences and whether there is recovery from toxicity after dosing stops; ability to relate toxicity; safety pharmacology and pharmacokinetic data from the

same animal (maximized data collection); and reduction in the total number of animals used, especially NHPs. This latter point is critical since NHPs tend to be used exclusively for toxicity studies for many types of biopharmaceuticals. Therefore, the opportunities to reduce NHPs use during non-clinical drug development should be considered (Chapman et al. 2007).

The integration of safety pharmacology endpoints into toxicity studies requires careful planning and thought to insure that best practices are used and that key toxicity and safety pharmacology endpoints are not jeopardized or compromised as a result of data collection. Another key point to consider is whether the pharmacokinetic profile of biopharmaceuticals is affected by antidrug antibodies which could alter their clearance and consequently the interpretation of study findings (Tabrizi et al. 2006). Depending on the safety concern with a novel biopharmaceutical, a dedicated and optimally designed safety pharmacology study may be needed in some cases (Vargas et al. 2008).

16.4 Cardiovascular Safety Pharmacology Assessment

Because biopharmaceuticals may require case-by-case safety pharmacology assessment during non-clinical development, alternative safety pharmacology approaches and experimental designs can be considered. Given that biopharmaceuticals generally have long half-lives, evaluations of cardiovascular effects that emerge after acute and chronic exposure are important to consider. Thus, a rational and cost-effective approach for biopharmaceuticals is the integration of cardiovascular endpoints into a repeat-dose toxicity study. For example, noninvasive ECG telemetry systems can enable a high-quality assessment of cardiac electrical activity in non-rodents and can be integrated into repeat-dose toxicity studies to optimize the evaluation of drug-induced changes in cardiac conduction and repolarization (Chui et al. 2009; Guth et al. 2009; Derakhchan et al. 2011). Such an approach can be used to collect high-fidelity multi-lead ECG data in long-term NHPs studies from 1 to 6 months duration (Vargas et al. 2010; Chui et al. 2011), particularly because NHPs are the common species used for biopharmaceuticals safety assessment.

Arterial blood pressure changes associated with the administration of biopharmaceuticals can be tracked using conventional implant telemetry in the cynomolgus monkey (Santostefano et al. 2012). Telemetric evaluation of arterial pressure using invasive or minimally invasive approaches enable the assessment of acute and chronic changes in blood pressure, are suitable for use in repeat-dose toxicity studies (Kaiser et al. 2010; McMahon et al. 2010), and would be a practical method to assess blood pressure changes associated with biopharmaceuticals. Lastly, blood pressure can be assessed using noninvasive approaches such as high-definition oscillometry (Schmelting et al. 2009), but such methods may not be ideal to assess drug-related effects because they require animal restraint, cause stress-associated elevation in blood pressure, and lack sensitivity to detect small changes in blood pressure (Kurtz et al. 2005; Wernick et al. 2012).

A key consideration with biopharmaceuticals is whether there is value-added safety in performing a voltage-clamp hERG assay to comply with the ICH S7B guideline. In contrast with “small drug” inhibitors of the hERG channel, large therapeutic molecules are not expected to interact with or inhibit hERG channel function directly or indirectly. A scientific review examined the hERG liability and QTc prolongation risk of biopharmaceuticals and concluded that mAbs and other protein that have very high target selectivity have low risk for blocking the channel, thus it is not appropriate to conduct the hERG assay as part of the non-clinical QT prolongation risk assessment (Vargas et al. 2008). Rather, the assay should be considered if there is a need to determine the mechanism of an in vivo QTc prolongation signal. The low likelihood of delayed cardiac repolarization with biopharmaceuticals is based primarily on the physical size and pharmacological characteristics of these agents which make them unable to cross the plasma membrane to interact with and inhibit the central pore or nonspecifically block the external “toxin-binding site” of the hERG channel. The recent demonstration that two specific anti-hERG polyclonal antibodies bind to epitopes on the hERG channel but do not interact with the external pore region further supports the low QTc prolongation risk of large molecule therapeutics (Qu et al. 2011). A recent perspective on safety assessment of biopharmaceuticals by Nakazawa et al. (2008) also recommends that the decision to conduct an in vitro hERG assay should be based on the results of an in vivo ECG evaluation.

16.5 Central Nervous System Safety Pharmacology Assessment

The potential undesirable pharmacological effects of biopharmaceuticals on the CNS can be evaluated in repeat-dose toxicity studies in accord with regulatory guideline (ICH S7A (2000). In traditional core battery safety pharmacology studies, rodents are typically used in the functional neurobehavioral assays conducted to support small-molecule drug development (see Chap. 3 "Central Nervous System (CNS) Safety Pharmacology Studies" and Chap. 6 "Respiratory Function Assays in Safety Pharmacology"), but for many types of biopharmaceuticals, rodents may not be a pharmacologically relevant species. Thus, if NHPs are the most relevant test species for safety assessment of biopharmaceuticals, then it is appropriate to assess CNS function during the repeat-dose toxicity studies in this species.

Behavioral changes indicative of adverse CNS effects, such as altered locomotor activity (e.g., hyper- or hypoactivity), changes in motor tone or mental alertness, and convulsion are generally detectable in non-rodent toxicity studies. Therefore, serious CNS adverse events associated with the administration of biopharmaceuticals can be identified from NHPs toxicity studies and used to support CNS risk assessment after acute and chronic exposure. This is advantageous because it eliminates the need to perform a dedicated neurobehavioral safety pharmacology study in this higher species. Specific testing methods have been developed and are available to improve neurobehavioral risk assessment in the cynomolgus monkey (Korte et al. 2007) and these evaluations could be conducted at various times during a regulatory toxicity study to assess the impact of a biopharmaceutical on CNS function.

However, based on their molecular size and physicochemical properties, biopharmaceuticals are not expected to penetrate into the brain and spinal cord, due to the restrictive nature of the blood-brain barrier (Pardridge 2005). As a result, biopharmaceuticals may have an inherently lower risk for causing undesirable pharmacological effects in the CNS (Pardridge 2005). In a recent internal survey (142 studies on 33 compounds) that examined convulsion incidence in neurobehavioral safety pharmacology and repeat-dose toxicity studies in rodents, we sought to assess the occurrence of CNS risk with a broad range of biopharmaceuticals and small molecules. None of the large molecules (0/11) caused convulsion in any repeat-dose toxicity study, whereas 14% of small molecules (3/22) caused convulsion in neurobehavioral safety pharmacology or toxicity studies (Amouzadeh and Vargas 2012). Overall, the physiochemical properties and results from internal data review supports the hypothesis that biopharmaceuticals have low potential to cause adverse neurobehavioral effects. The poor ability of biopharmaceuticals to access the CNS suggests that these agents may also have low inherent risk for inducing drug dependency and abuse. If a convulsion risk was detected during a NHPs toxicity study with biopharmaceuticals, which would be an unusual finding, a follow-up study using electroencephalography (EEG) may be needed to assess whether the adverse effect originated in the brain (e.g., CNS-mediated seizure) or had another cause (e.g., altered clinical chemistry or body temperature). The findings from such a specialized study could be a critical component of the CNS risk assessment and inform the decision to advance the compound into clinical development (see Chap. 2 "Safety Pharmacology: Introduction").

16.6 Respiratory Safety Pharmacology Assessment

The potential for biopharmaceuticals to affect the respiratory system can also be evaluated in repeat-dose non-rodent toxicity studies. Respiratory endpoints such as dyspnea, labored breathing, and breathing rate estimates can be monitored during cage-side clinical observations in NHPs. However, cage-side assessments are subjective, and may only have the sensitivity to detect clinically observable events like overt respiratory toxicity, and will be limited to the evaluation times designated in the study protocol. If a more detailed functional assessment of respiratory ventilation and mechanics is needed to support the risk assessment for biopharmaceuticals (e.g., triggered by an assessment of target liability), classic methods such as head-only or whole-body plethysmography can be adapted for use in the restrained or unrestrained NHPs (Foster et al. 2008; Iizuka et al. 2010; see Chap. 6 "Respiratory Function Assays in Safety Pharmacology"). In this latter scenario, a dedicated respiratory safety pharmacology study would be needed to evaluate the hypothetical

liability, given the need for special equipment, acclimation procedure, and staff expertise to conduct the NHPs respiratory function evaluation. In the future, it may be possible to introduce quantitative respiratory measurements into non-rodent toxicity studies, which would maximize animal use and allow for respiratory hazard identification of biopharmaceuticals. The use of jacket-based inductive plethysmography is an emerging noninvasive technology that can capture respiratory endpoints (breathing rate and tidal volume) continuously from unrestrained animals and has the potential to be fully integrated into long-term toxicity studies (see Chap. 6 "Respiratory Function Assays in Safety Pharmacology"), like jacket-based ECG evaluation.

16.7 Other Organ System Safety Pharmacology Assessment

The need for assessment of the undesirable pharmacological effects of biopharmaceuticals on systems other than cardiovascular, central nervous, and respiratory systems depends on a theoretical basis for potential adverse functional effects associated with the target, the organ distribution of the target receptor, and empirical observation during exploratory toxicity studies, including histopathological evidence. Therefore, supplemental safety pharmacology studies should be considered for biopharmaceuticals whenever there is an indication of a potential functional adverse effect. Similar to evaluation of the core battery of safety pharmacology studies, supplemental safety pharmacology endpoints may be integrated into multiple-dose toxicity studies, or they could be performed separately. For example, serum creatinine and blood urea nitrogen are biomarkers that are normally evaluated during toxicity studies and are used to monitor renal function. An important caveat to remember is that valid safety pharmacology methods in the NHPs model may be limited and available only in some key areas with established endpoints (e.g., renal or endocrine function and plasma catecholamines as an index of sympathetic nervous system tone). The future development of new biomarker approaches (e.g., KIM-1 for nephrotoxicity) and non-invasive methods (e.g., SmartPill® for GI transit) for application to NHPs studies represent new opportunities to integrate supplemental safety pharmacology endpoints into toxicity studies.

16.8 Summary

The goal of safety pharmacology evaluation of new drug candidates is to assess effects on cardiovascular, central nervous, and respiratory systems prior to first human exposure. This is guided by the ICH guidelines S6(R1) (2011), ICH S7A (2000) and S7B (2005). Although the general approaches toward safety pharmacology assessment of biopharmaceuticals and small molecules are similar, they differ in practice in that safety pharmacology of small molecules is usually evaluated in dedicated studies optimized to assess drug-induced functional effects, whereas the approach for biopharmaceuticals is case dependent and reliant upon the incorporation of safety pharmacology endpoints in repeat-dose toxicity studies. Overall, the safety pharmacology evaluation of biopharmaceuticals is driven by their unique pharmacological properties, specificity of action, and the choice of test species. In most cases, NHPs are the most appropriate test species for safety pharmacology and toxicity assessment. Since there is a desire to reduce NHP use during non-clinical development, especially in safety assessment studies, there will be an ongoing impetus to maximize the collection of important safety pharmacology endpoints in toxicity studies. This can be achieved by the careful integration of improved safety pharmacology methods (e.g., noninvasive cardiovascular and respiratory methodologies) into the design of toxicity studies used for regulatory filings.

17.1 Introduction

The high rate of attrition of drug projects through the pharmaceutical pipeline is a significant contributor to the increasing R&D costs seen in recent years. In 2004, the FDA released a report entitled "Innovation or Stagnation, Challenge and Opportunity on the Critical Path to New Medical Products" in which the alarm was raised that only 8% of the molecules that enter clinical development were successfully registered (http://www.fda.gov/oc/initiatives/criticalpath/whitepaper.html). Recent data suggests that this figure had fallen to 4% by 2010 (Bunnage 2011). Many more fail in the preclinical stages of development. There is an urgent need for new tools to improve drug development and the critical path document specifically highlights imaging as one of the new technologies that has a potential to contribute. One quote from the report is particularly telling, "Often, developers are forced to use the tools of the last century to evaluate this century's advances."

Despite the explosion of potential biomarkers due to the "-omics" approaches, there is an acknowledged need to find and establish more sensitive, specific, and predictive biomarkers (Wehling 2006). ICI (now AstraZeneca) and Sandoz (now Novartis) introduced MRI into the pharmaceutical industry in 1983, and the use of imaging biomarkers to accelerate drug discovery and development has been well documented (Chandra et al. 2005; Pien et al. 2005; Beckmann et al. 2007). MRI has been successful in the pharmaceutical industry for the same reasons that it is popular in clinical practice; it is a noninvasive imaging technique with superb soft tissue contrast capable of delivering quantitative 3D information on organ anatomy and function (Beckmann et al. 2004;

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_19, © Springer-Verlag Berlin Heidelberg 2013

Maronpot et al. 2004). Because it is noninvasive, aside from the need to anesthetize animals to immobilize them during image acquisition, animals can be imaged on multiple occasions and studies can be designed so that each animal serves as its own control increasing the statistical power of experiments and allowing group sizes to be reduced. However, despite penetration into preclinical and clinical drug efficacy studies, there are relatively few reports of the use of MRI in drug safety studies. Toxicology accounts for approximately one third of attrition in development and is thus a major cost in the pharmaceutical industry. An informal survey of a number of preclinical imaging groups in the pharmaceutical industry showed that approximately 5% of effort (range 0–20%) was devoted to safety imaging studies. This seems a disproportionally small effort considering that MRI is a powerful tool that could potentially be used to reduce attrition in the late pipeline where it is most expensive. It is important to understand why MRI has not been more widely used in the drug safety arena before describing in detail a few of the MRI assays appropriate for preclinical safety studies.

There are three types of safety pharmacology studies conducted in the pharmaceutical industry: (1) single-dose core portfolio preclinical safety studies conducted to good laboratory practice (GLP), (2) supplemental studies of compound specific effects after chronic dosing that are conducted when results from the core battery of tests raise concern, and (3) "front-loading" safety studies conducted in the drug discovery function with the aim of designing safety liabilities out of the lead compound series.

The first type of study forms part of the legally required activities toward the registration of a pharmaceutical product. The International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) safety pharmacology guidelines recommend the use of unanesthetized animals, which is incompatible with the standard MRI experiment in which animals are anesthetized to prevent motion interfering with image quality. It is certainly feasible to habituate animals to the MRI environment; however, in practice, the results may not warrant the effort involved. In addition, it is unlikely that MRI assays will replace conventional endpoints or shorten the study duration. Thus, there is little incentive to routinely incorporate MRI assays in the core package.

The second type of study is investigational and is conducted when results from the core battery of tests raise concern (Ettlin et al. 2010). In almost all cases, the pharmaceutical industry prepares a comprehensive package of studies for the regulatory authorities that include effects after chronic dosing. The chronic-dosing regimen encourages the design of imaging experiments in which each animal acts as its own control, increasing statistical power with smaller group sizes and allowing longitudinal studies without the need to kill groups of animals at each time point; two factors that both separately and combined offer dramatic sparing of laboratory animals. In these investigational studies, there are no guidelines against anesthesia, although clearly one must consider the impact of anesthesia on each individual experiment. One of the most significant obstacles in incorporating MRI assays into investigational safety studies is that these studies are often on the critical path for drug development, and therefore there is an urgency that leaves little time to develop and evaluate sophisticated new assays. Thus, MRI is most appropriate to investigate adverse events that recur regularly in safety assessment departments so that the appropriate validation work with positive and negative controls can be in place before the technique is needed in earnest.

The third type of study is not designed with regulators in mind or conducted within dedicated safety assessment functions. It is now widely recognized that the pharmaceutical industry can no longer afford to start safety evaluation only after candidate selection, knowing that many candidates will quickly fail due to safety issues. The pressure is on to reduce attrition in the late pipeline by introducing safety screens in the early pipeline when it is still possible to design known safety liabilities out of the lead series. In future, we expect to see increased numbers of these early pipeline non-GLP safety pharmacology studies of pre-candidates conducted in the drug discovery functions for purely internal decision-making purposes. These "front-loading" studies are likely to be the most amenable to MRI as the drug project lifetime is sufficient to discover and develop the appropriate MRI assays.

Good laboratory practice is often considered a major hurdle in the use of MRI in safety assessment studies. GLP ensures that the data produced from nonclinical studies are of high quality, reliable, and valid. Since regulators use these data to authorize clinical trials and marketing of the end product,

it is important that they are correctly recorded and reproducible. An experienced, multidisciplined, and dedicated function is needed to ensure that such work is in compliance with legal requirements. The current generation of preclinical MRI scanners are not equipped with GLP software tools that would guarantee consistent spectrometer operation or data transfer in compliance with GLP. In principle, there is no reason why collaboration between MRI scanner manufacturers and the pharmaceutical industry could not produce GLP compliant MRI assays; however, the burden of GLP documentation makes compliance for complex and innovative assays impractical. In practice, regulatory agencies do accept investigatory studies not to GLP if the work is critical to a scientifically based risk assessment and has been conducted to an acceptable standard. In this case, there is still a definite advantage if protocols, data acquisition, transfer, archival, staff records, and so on are in accord with GLP principles.

Despite the obstacles mentioned above, the advantages of noninvasive imaging techniques to drug safety studies are obvious. It is possible to design longitudinal studies in which the same animal is studied at baseline and then at several time points while on study. Changes in individual animals can be quantitated and compared with baseline measurements either in simple percentage terms or, for example, using more sophisticated linear mixed-effect models (Brown and Prescott 1999), leading to a reduction in group size and obviating the need to sacrifice animals at each time point. Baseline data can be used either to select or deselect animals to be included in a study or as a basis for randomization between groups. And, of course, at the end of the study, the animal is still available for other, complimentary, analysis techniques. In general, the readout time for MRI endpoints is faster than that for histology leading to faster management go/no-go decisions. Some biomarkers are only amenable via MRI, for example, quantitation of intramyocellular lipid (IMCL) is straightforward with MR spectroscopy (MRS) but time-consuming with traditional microdissection techniques.

Further, the imaging biomarkers identified in preclinical safety assessment studies can also be used in clinical drug safety studies, as MRI is widely available and safe to use in volunteer studies. This can be an advantage for the preclinical safety assessment function as it provides feedback on translation of animal safety assessment studies to humans using the same endpoint. Clearly, one would not run MRI on all clinical safety studies but in those cases where there is no cheaper, simpler safety biomarker available and there is doubt about the degree of risk posed in man, for example, because of species differences or because the effect size in the placebo group is expected to be very high.

The conclusion is perhaps best put in a recent posting on the FDA website, “Imaging technologies provide powerful insights into the distribution, binding, and other biological effects of pharmaceuticals. As part of its Critical Path initiative, FDA has joined the National Cancer Institute (NCI), the pharmaceutical industry, and academia in a number of activities that will facilitate the development of new imaging agents and the use of medical imaging during product development. We believe that with a little effort on the part of all of us, imaging agents and technologies can contribute important biomarkers and surrogate endpoints during disease progression and contribute to the development of new therapies to treat disease” (http://www.fda.gov/cder/regulatory/medImaging/default.htm).

17.2 Liver Volume Measurement

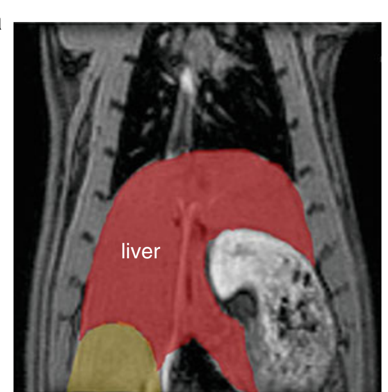
PURPOSE AND RATIONALE

Liver hypertrophy is a frequent side effect in drug development caused by a wide variety of compounds. Because it is often the first indication of the hepatocarcinogenic potential of a drug candidate, liver weight is routinely monitored in safety assessment studies (Ou et al. 2001; Shoda et al. 2000). This is necessarily a terminal procedure so that longitudinal evaluation of hypertrophy must involve serial kills of groups of animals at the time points of interest. Assuming that the compound administered does not significantly change liver density, liver volume changes should be at least as sensitive as liver weight changes. Noninvasive serial MRI measurements of liver volume can reduce animal usage by following the same groups of animals over the time points of interest. In addition, the ability to measure difference from baseline instead of a single time-point liver volume usually increases the precision of treatment measurements, and the resulting increase in statistical power can be used to reduce group sizes.

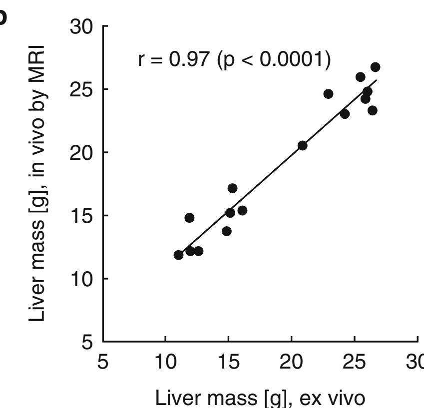
PROCEDURE

Rats are anesthetized with isoflurane (1.5–2%, 0.6–1 l/min), and then MR images are acquired.

High resolution 3D MRI permits in vivo assessment of liver volume



High resolution 3D MRI image through the rat abdomen allows easy delineation of the liver



Correlation between post mortem liver mass and in vivo MRI liver mass

Fig. 17.1 MRI coronal section through a rat liver showing good contrast from surrounding tissues (**a**) and correlation with ex vivo wet weight (**b**) (Abdel Wahad Bidar, AstraZeneca, personal communication 2007)

A high-resolution 3D FISP scan is acquired (TE/TR 1.7/3.3 ms, FOV 50 × 50 × 50 mm, reconstruction size 256 × 192 × 192, NA 1, FA 20°). Individual 3D images take approximately 6 min to acquire. Spectrometer triggering is set such that data acquisition occurs during the expiratory phase of the respiratory cycle.

EVALUATION

Images can be evaluated with Analyze (Biomedical Imaging Resource, MN, USA). Liver volume is determined by manual segmentation of each slice using the ROI spline tool (Fig. 17.1). There is no loss in accuracy in liver volume estimation if only a subset of at least 6 evenly spaced slices are segmented instead of the full 60 slices through the liver. To improve liver segmentation at later time points, follow-up scans can be registered to the baseline scans (Hajnal et al. 1995).

MODIFICATIONS OF THE METHOD

Cockman et al. (1993) used a multislice spin-echo method and reported that respiratory triggering increased the accuracy of rat liver volume measurements. Hockings et al. (2002) and Hockings et al. (2003a) reported rat liver volumes obtained with a respiratory triggered segmented 3D fat suppressed inversion recovery snapshot readout sequence at both 7 T and 2 T and reported a correlation coefficient between in vivo MRI liver volume and post-mortem liver wet weight of 0.96 and 0.99, respectively. Tang et al. (2002) used a non-respiratory triggered multislice spin-echo method in rats and reported a correlation coefficient of 0.9 against liver wet weight with a systematic overestimation of MRI liver volume. The coefficient of variability of MRI precision was 2.3% and operator reliability for segmentation 2.9%. Garbow et al. (2004a) measured liver volume in mice with MRI at 4.7 T using an intraperitoneal injection of contrast reagent to increase contrast between liver and surrounding organs. The correlation coefficient between MRI volume and wet weight was 0.94.

CRITICAL ASSESSMENT OF THE METHOD

The correlation between MRI liver volume and liver weight has been established by a number of groups using a variety of MRI methods indicating the robustness of the technique. Its advantage over the direct measurement of liver weight is the dramatic sparing of animals as groups of animals no longer need to be sacrificed at each time point and because the ability to make within animal comparisons leads to greater precision and a reduction in group sizes. Hockings et al. (2002) reported a reduction in animal usage from 120 to 6 with the same level of precision. In order to measure liver volume with precision, it is necessary to produce good contrast between liver and surrounding tissues such as intercostal muscle, fat, spleen, stomach wall, and kidney. This can be done through judicious optimization of the MRI pulse sequence and timings. In addition, some researchers have used fat suppression pulses to null the signal from fat to enhance contrast to surrounding organs. Image

acquisition normally takes several minutes so motion from breathing and peristalsis in the GI tract can produce artifacts and blurring of the images. Fast imaging, averaging, breath holding, or respiratory triggering strategies can reduce motion artifacts from respiration. The respiratory-triggering strategy synchronizes data acquisition to the respiratory cycle and is the most widely applied strategy for preclinical liver volume determination. Peristaltic motility can be reduced by overnight starvation or the application of antispasmodics such as Buscopan; however, neither approach is usually necessary.

One possible confound for this experiment is that liver weight changes by up to 15% during the day as glycogen levels drop (Latour et al. 1999), and so care must be taken in longitudinal studies that animals are always imaged at the same time of day to reduce within animal variance. In addition, care must be exercised with the choice of anesthetic as anesthetics such as halothane are hepatotoxic and may influence the outcome of the study when there are several imaging sessions.

17.3 Cardiac Hypertrophy

PURPOSE AND RATIONALE

Measurement of cardiac function and morphology is a key part of the preclinical evaluation of experimental medicinal compounds. Blood pressure, heart rate, and electrocardiogram evaluation are part of the core portfolio of safety pharmacology studies carried out in conscious telemetry dogs. If results from the core battery of tests raise concern, then supplemental studies are conducted to measure endpoints such as left ventricular pressure, pulmonary arterial pressure, heart rate variability, baroreflex, cardiac output, ventricular contractility, and vascular resistance. However, many of these endpoints involve invasive surgery and so are only appropriate for acute single time-point studies. To date, there have been relatively few preclinical studies using MRI to measure cardiovascular function, especially in the dog which is a large animal species widely used in toxicology. MRI can be used to determine myocardial volume, wall thickness, and left ventricular (LV) and right ventricular (RV) end-diastolic and end-systolic lumen volumes (EDV and ESV, respectively). These parameters can be subsequently used to derive functional indices such as wall stress, degree of eccentric hypertrophy, stroke volume (SV), *cardiac output* (CO), and ejection fraction (EF). MRI studies are particularly suited to chronic-dosing regimen with multiple imaging time points in the same animals.

PROCEDURE

Adult male beagle dogs (Harlan UK) weighing between 9 and 14 kg are used. On days prior to scanning, food is withheld from approximately 4 p.m. Dogs are anesthetized with a bolus intravenous dose of propofol (approx. 10 mg/kg) followed by propofol (32–42 mg/kg/h) maintenance anesthesia and ventilated with medical air via an endotracheal tube. The dorsal metatarsal or femoral artery is cannulated for blood pressure measurements and to enable sampling of arterial blood for monitoring blood gasses to ensure adequate ventilation. ECG, capnography, pulse oximetry, body temperature, and arterial blood pressure are monitored throughout the scanning sessions on a Bruker Maglife C (Wissembourg, France). Body temperature is maintained with the aid of a thermostatically controlled heating blanket.

MRI scanning is performed in a 1 meter bore 2 T Bruker Medspec (Ettlingen, Germany) using a 28-cm transmit/receive birdcage resonator. ECG triggered segmented gradient-echo cine images are acquired during the expiration phase of the respiratory cycle as measured directly from the ventilator. An average of 16 frames per heart cine traverses approximately 80% of the cardiac cycle starting from end diastole. Other relevant imaging parameters are gradient-echo flip angle 20°, TE 3 ms, TR 8 ms, 1–3 averages, SW 100 kHz, image matrix 128 × 128, in-plane field of view 200 mm, four phase-encoding steps per frame, and linear traverse of k-space. Hence, the time resolution per cine frame is 32 ms. Each individual slice cine is acquired in about one to one and a half minutes depending on heart rate, so each set of multislice cines takes about 15–20 min.

To obtain true short axis views, scout imaging commenced with a mid-ventricular coronal slice allowing the vertical long axis (VLA) to be located by aligning another scout through the apex and mid-mitral valve, thus allowing for the leftward angle of the heart. From the VLA, the downward inclination of the heart is allowed for by taking a further scout lining up the apex and mid-mitral valve to generate the horizontal long axis plane (HLA). The scouts are acquired at end diastole (0 ms delay after the QRS wave) so that the

atrioventricular (AV) ring, which descends apically in systole, is in its most basal position. The first short-axis cine is then placed just forward of the AV ring on the HLA image, to cover the most basal portions of the right and left ventricles. Approximately 15 contiguous 5-mm-thick segmented gradient echo cines with no interslice gap are then sequentially acquired moving toward the apex and including the apical tip. In this way, the entire ventricle is imaged.

EVALUATION

Frames corresponding to end diastole and end systole are identified from each cine sequence and regions-of-interest (ROI) drawn around the left ventricular (LV) epi- and endocardial borders using ParaVision software (Bruker). The area of the ROIs is summed and multiplied by the interslice distance (5 mm) to calculate the end-diastolic and end-systolic volumes (EDV and ESV) of the whole ventricle and lumen. Other cardiac parameters are calculated as follows:

Stroke volume: $SV = EDV_{Lumen} - ESV_{Lumen}$
Cardiac output: $CO = SV \times \text{heart rate}$
Ejection fraction: $EF = (SV/EDV_{Lumen}) \times 100$

Left ventricle myocardial mass at end systole is calculated as:

$$\text{MassLV} = (ESV_{Ventricle} - ESV_{Lumen}) \times D$$

where D is the density of the myocardium (1.05 g/mL) (Hoffmann et al. 2001).

Left ventricle myocardial wall thickness in diastole is calculated from the epi- and endocardial areas at the slice where the epicardial area is maximum as follows:

$$\text{LVwall thickness} = \sqrt{\frac{\text{Area}_{LV}}{\pi}} - \sqrt{\frac{\text{Area}_{Lumen}}{\pi}}$$

The two ROIs used are assumed to be concentric and circular.

MODIFICATIONS OF THE METHOD

Markiewicz et al. (1987) examined eight pentobarbital anesthetized dogs and reported that cardiac output and stroke volume measured by ECG-triggered MRI correlated significantly with thermodilution measurements ($r = 0.73$ and 0.93, respectively). Shapiro et al. (1989) also used ECG-triggered MRI in dogs subjected to myocardial infarction and found excellent correlation between MRI-derived myocardial mass and wet weight ($r = 0.97$) and that MRI-derived myocardial mass measured in systole and diastole correlated closely ($r = 0.95$). Bambach et al. (1991) examined carbon monoxide–induced ventricular hypertrophy in rats using scan averaging instead of triggering to reduce artifacts from cardiac motion. They found that the mean outside diameter of the left ventricle plus interventricular septum (LV + S) showed a strong correlation with the duration of CO ($r = 0.73$, $p < 0.01$) and to the hematocrit ($r = 0.72$, $p < 0.05$). Rudin et al. (1991) used a dual respiratory-gated and ECG-triggered approach in two models of cardiac hypertrophy in rats. The correlation coefficient between LV mass determined by MRI and post-mortem LV weight was 0.99 and LV volume, SV, and EF in control animals showed statistically significant differences from cardiac hypertrophy animals. Siri et al. (1997) applied ECG-triggered MRI to murine hearts and found LV mass determined by MRI correlated well with LV weight ($r = 0.87$). This data demonstrated the dependence of LV mass estimates in the mouse on the geometric model of the heart used and show that MRI provides more accurate estimates of LV mass in mice than does two-dimensional-directed M-mode echocardiography. Slawson et al. (1998) used a dual respiratory- and cardiac-gated MR sequence in mice and obtained a correlation coefficient of 0.99 between MRI and post-mortem heart weight. Hockings et al. (2003b) used the method described above to measure dobutamine- and minoxidil-induced changes in cardiac function in dogs. They showed good correlation between cardiac output measured by MRI and cardiac output measured by thermodilution ($r = 0.94$) and that MRI could reliably detect acute changes in cardiac output induced by dobutamine infusion ($p = 0.01$) in small groups of animals ($n = 7$). Furthermore, they showed that MRI could detect LV enlargement induced by chronic administration of minoxidil and that the increase in EDV without an accompanying change in LV wall thickness indicated a preload-induced hypertrophy. Interestingly, the MRI technique was able to detect small amounts of pericardial effusion.

CRITICAL ASSESSMENT OF THE METHOD

MRI has become the gold standard imaging technique for the study of the human heart. The main advantages are that it is noninvasive and has pronounced contrast

between myocardium and blood and good temporal resolution allowing images to be acquired at any phase of the cardiac cycle. Thus, it is an accurate technique for measuring ventricular volumes independent of geometric assumptions, although clearly the precision with which myocardial geometry can be characterized depends on the number of image slices acquired through the heart and on the in-plane resolution. Image acquisition during end diastole and end systole allows the calculation of functional parameters such as stroke volume, ejection fraction, and cardiac output. One of the most important factors in the acquisition of artifact-free images is the quality of the MRI system's ECG and respiratory triggering. Cardiac exams in the clinic are usually conducted using breathhold rather than with respiratory gating because of the difficulty of obtaining a regular breathing cycle in conscious volunteers and patients. However, in anesthetized animals, breathing irregularities are not usually a significant problem and complications due to the increase in heart rate with hypercapnia during breathhold usually outweigh the time penalty involved in waiting for the respiratory gate. The studies described above indicate that combined respiratory gating and ECG triggering improve the precision of measurements.

Alternatives to MRI include echocardiography to measure LV wall thickness, lumen volume, and cardiac output (Coatney 2001; Collins et al. 2003; de Simone et al. 1990; Zhou et al. 2004), dye-dilution techniques such as bolus thermodilution to measure cardiac output (Siren and Feuerstein 1990), and implanted pressure transducers and flow probes to measure left ventricular pressure and blood flow parameters. Like MRI, echocardiography is noninvasive and has the further advantages that it provides low cost, real-time images with structural, functional, and hemodynamic information. Functional information is usually acquired in M-mode, and hence it is necessary to make geometrical assumptions that may not be applicable if heart morphology changes. In addition, the superior inter-study reproducibility of MRI in comparison with 2D echo leads to better reliability of observed changes and thus greatly reduced patient numbers in clinical trials (Grothues et al. 2002). Both dye-dilution and implanted pressure and flow probes are invasive techniques.

When planning functional studies, it is important to consider that most anesthetics cause cardiac and respiratory depression. For chronic studies, it may only be important to ensure that the depth of anesthesia is reproducible from imaging session to imaging session; however, for acute studies, it is necessary to consider interactions between the anesthetic and the test substance. The complexity of cardiac structure and function needs to be understood to devise a well-planned imaging protocol.

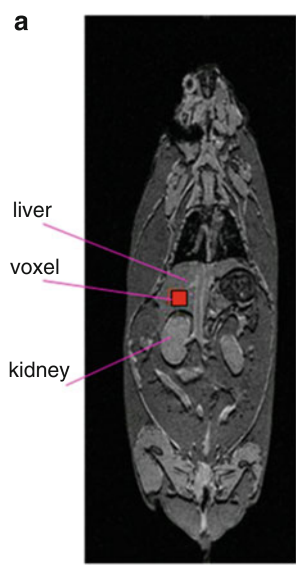
17.4 Hepatic Steatosis

PURPOSE AND RATIONALE

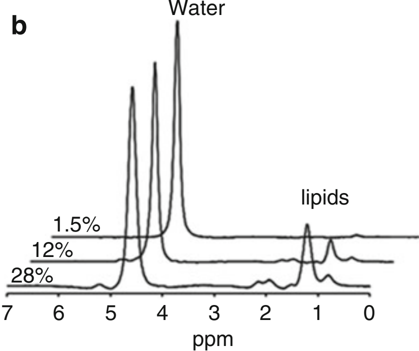
Hepatic steatosis is a side effect associated with a number of classes of compounds including some metal compounds, cytostatic drugs, antibiotics, and estrogens. In some cases, drug-induced hepatic steatosis patients can present with a rapid evolution of severe hepatic failure, lactic acidosis, and ultimately death (Diehl 1999). The absence of predictable correlation between abnormalities in liver enzymes and histologic lesions led Clark et al. (2002) to conclude that localized magnetic resonance spectroscopy (MRS) was the best noninvasive way to quantify liver fat in patients. This approach was favored because it avoids the risks associated with invasive liver biopsy. Lee et al. (1984) demonstrated that MRI can detect fatty infiltration of the liver clinically, and Longo et al. (1993) demonstrated that MRS is a reliable noninvasive method, comparable to computerized tomography (CT), for quantifying clinical liver steatosis in humans. Recently, Szczepaniak et al. (2005) used localized MRS to show a strikingly high prevalence of hepatic steatosis in the US population, and Cuchel et al. (2007) showed that treatment with BMS-201038 was associated with hepatic fat accumulation, a potentially serious adverse event. A trend toward increased hepatic fat was also seen by Visser et al. (2010) after treatment with mipomersen.

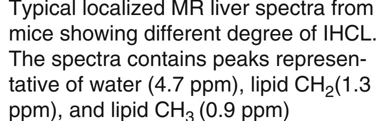
For 20 years, localized MRS has been used in medicine and biomedical research to obtain noninvasive biochemical information from living tissue (Koretsky and Williams 1992). The spectra obtained possess the very valuable property that the intensity of a given peak is proportional to the number of nuclei contributing to that peak provided that certain experimental precautions are taken. This allows a quantitative determination of a substance if there is an appropriate internal or external reference. In the case of localized in vivo 1 H spectroscopy, the water

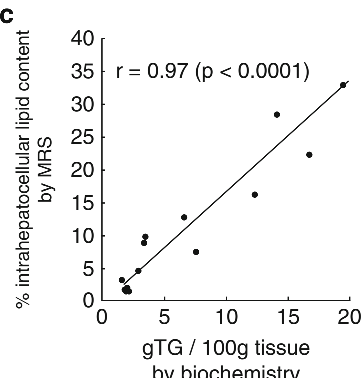
Localized MR spectroscopy (MRS) allows non-invasive measurement of intrahepatocellular lipids (%IHCL) in vivo



A spectra is obtained from a voxel placed in the right liver lobe







Correlation between in vivo MRS IHCL and ex vivo liver triglyceride content

Fig. 17.2 (**a**) Coronal view through the liver of a Café diet mouse showing the position of the 2 × 2 × 2-mm-localized MRS voxel in the right lateral lobe of the liver, (**b**) in vivo–localized PRESS spectrum from three mice with different degrees of hepatic steatosis, and (**c**) correlation between in vivo MRS and ex vivo triglyceride measurements (Abdel Wahad Bidar, AstraZeneca, personal communication 2007)

signal is usually chosen as internal standard as the proportion of body water to ash and protein is relatively invariant. Single-voxel localized MRS allows spectra to be obtained with spatial resolutions down to 8 μL in some circumstances allowing localization of a volume of interest entirely within the liver in animals as small as mice (Fig. 17.2).

PROCEDURE

Isoflurane anesthetized mice or rats can be scanned in a dedicated small animal MRI system with a transmit/receive radiofrequency birdcage-design resonator. MRI and MRS acquisition are synchronized with the respiratory cycle to minimize artifacts (Schwarz and Leach 2000; Wilson et al. 1993). Scout multislice spin-echo images through the liver are used to determine voxel placement. Localized 1 H PRESS spectra (Bottomley 1987) with, for example, TE/TR 6/3,000 ms and 64 averages can be obtained. For the mouse, a 2 × 2 × 2-mm cube in the right lateral lobe adjacent to the portal vein and well removed from the surface of the liver and distinct hyperintense fatty deposits is appropriate to provide sufficient signal to noise.

EVALUATION

Quantification was accomplished by simulating the water signal (which was used as a chemical shift reference) at 4.7 ppm, and the fat signals at 2.1, 1.3, and 0.9 ppm, with an 80:20 Gaussian–Lorentzian lineshape using the Bruker XWINNMR package. Without knowing the average lipid chain length and degree of unsaturation, it is impossible to calculate a valid molar fat–water ratio, so the intrahepatocellular lipid (IHCL) content is expressed as the percentage of the sum of the fitted peak areas of the three fat peaks to the fitted water peak area.

$$\%\ \mathrm{IHCL} = 100 * \left(\frac{A_{(\mathrm{lipid})}}{A_{H_2O} + A_{(\mathrm{lipid})}} \right)$$

MODIFICATIONS OF THE METHOD

Hazle et al. (1991) used MRS to follow the time course of ethanol-induced liver steatosis in rats. Spectra were acquired without respiratory triggering, and lipid signal was normalized to signal from an external reference sample. Correlation between MRS normalized lipid signal and biochemically determined lipids

was moderate ($r = 0.52$). Ling and Brauer (1992) used respiratory-triggered MRS to examine the same model and were able to show that a 5.5-fold increase in lipid signal on treatment was matched by ex vivo analysis although a correlation coefficient was not given. Szczepaniak et al. (1999) used two animal models to show a close correlation between hepatic triglyceride measured by in vivo MRS and liver biopsy ($r = 0.93$). These researchers converted the MRS fat–water signal ratio to micromoles triglyceride/gram wet tissue by correcting for NMR relaxation and triglyceride proton density relative to water. Daubioul et al. (2002) used non-triggered localized MRS to show a reduction in hepatic steatosis in Zucker rats fed a dietary supplement with non-digestible carbohydrates. The spectra presented showed artifacts consistent with respiratory motion during acquisition. Hockings et al. (2003a) measured the MRS fat–water ratio in the livers of Zucker rats. They found a good correlation between MRS fat–water ratio and the fractional volume of intrahepatic fat determined by histology ($r = 0.89$) and were able to show that rosiglitazone treatment reduced liver fat content. Kuhlmann et al. (2003) reported similar findings in Zucker diabetic rats treated with rosiglitazone. Liver lipid levels in mice were examined by Garbow et al. (2004b). They reported that respiratory-triggered acquisition of spectra was important to remove the deleterious effects of respiratory motion and that the variation in MRS lipid content across the liver was typically less than 10%. The correlation coefficient between in vivo MRS and ex vivo wet chemistry lipid measurements was 0.95. Zhang et al. (2004) reported the use of a respiratory-triggered 3D three-point Dixon MRI method to determine liver fat–water ratio in rats treated with a microsomal transfer protein inhibitor known to produce hepatic steatosis. They reported a high level of reproducibility in in vivo measurements and were able to detect drug-induced steatosis, but the correlation coefficient against liver triglyceride and information on spatial inhomogeneity of lipid accumulation in the liver were not given.

CRITICAL ASSESSMENT OF THE METHOD

A number of both clinical and preclinical studies have shown a robust correlation between liver fat–water signal ratio measured by in vivo–localized MRS and ex vivo analysis. Most groups have used a short echo time PRESS sequence with respiratory triggering to reduce motion artifacts and water as an internal standard. Both liver biopsy and single-voxel localized MRS are hampered by sampling errors if fatty infiltrations are inhomogeneously distributed in the liver. In the clinical setting, alternative MRI or spectroscopic imaging techniques have been used to measure lipid content across the entire liver where there is a risk of fatty infiltrations. Preclinically, Ling and Brauer (1992) have shown that fat is distributed homogeneously throughout the liver in rats with ethanol-induced hepatic steatosis, and Garbow et al. (2004b) reported similar findings for wild-type and two transgenic strains of mice on low-fat or high-fat diets. Most researchers avoided the problem of potential inhomogeneous lipid distribution by selecting one region of the liver and always returning to the same region in serial time-point studies. For preclinical studies, it is clearly possible to kill groups of animals at each time point, but particularly when the within group variability is large in comparison to the measurement precision, the introduction of a noninvasive technology can result in a dramatic sparing of animals.

18.1 General Considerations

The development of anticancer pharmaceuticals and safety evaluation of such agents for human use is strongly dictated by the nature of the disease being treated. Cancer is a complex and heterogenic genetic disease involving an almost infinite number and combination of cellular and molecular perturbations. Unlike many other diseases, in its early stages cancer is often asymptomatic and remains hidden, with the problem only being identified later in the process once the cancer has become symptomatic and noticeable by the patient. Unfortunately, by this stage the cancer is commonly aggressive and in many cases has disseminated to other sites within the body. As a consequence cancer is often life-threatening with patients having a poor prognosis and significantly reduced life expectancy, factors which significantly alter the risk-benefit balance in this therapeutic area. Therefore the successful development of new treatments for cancer can have an immediate impact upon patient survival.

Until recently, the vast majority of agents used within the clinic were cytotoxics targeting nucleic acid replication or synthesis, many of which have been approved for clinical use since the 1960s. Due to the desire to obtain maximum efficacy, this class of drug are administered at or close to their maximum tolerated dose. Mechanistically these agents do not exclusively target cancer cells, and will also attack any rapidly proliferating cell type such as those in the digestive tract and bone marrow, commonly resulting in toxicity. As a consequence of this inherent toxicity, there is a high level of attrition during development of this class of agent (Walker and Newell 2009; Westhouse 2010). Despite a high prevalence of

DOI 10.1007/978-3-642-25240-2_20, © Springer-Verlag Berlin Heidelberg 2013

toxicity, a lack of alternative therapeutic avenues meant that the benefit of cancer treatment was deemed to be far superior to the unrequired toxic side-effects. Consequently, until recently, nonclinical safety evaluation studies were deemed of minor significance compared to therapeutic efficacy and rarely prevented progression of these drugs into first-in-human studies. In recent years, there has been a considerable shift in development of cancer therapeutics, particularly in terms of their safety evaluation.

Over the past decade, increased understanding of the molecular basis of cancer has advanced cancer therapy into an era of "targeted molecular therapeutics" (Collins and Workman 2006; Newell 2005). These new targeted drugs exhibit a broad range of therapeutic mechanisms, including inhibition of extracellular growth receptors, activation of cell death pathways, retardation of cell motility, kinase inhibition, and toxin delivery, to name a few. Despite many of these drugs significantly improving cancer treatment and patient survival, their targeted nature offers a set of potential liabilities and safety issues different to that of the cytotoxic genre.

The development of therapeutics to treat cancer is conceptually more difficult than for other non-life threatening diseases for two particular reasons; (1) The majority of cancer therapeutics have been developed to either kill the cancer cell or at least inhibit its proliferation, and thus have inherently high toxicity. (2) Initial clinical trials of new cancer therapeutics involve administration of the drug to the cancer patient population rather than healthy volunteers, due to the intended mechanism of action of these therapeutics. These patients would previously have received all current therapeutic strategies without success, are highly likely to be ill, and their disease will have been classified as terminal. Consequently, determination of safety of these drugs has several inherent complications, not least the drug mechanism and the intended clinical population.

Historically, the rationale for preclinical evaluation of any new pharmaceutical was determined by the potential risks the therapeutic posed to humans. For the reasons outlined above, such a framework is inappropriate for cancer drug development as it inadequately considers the short-life expectancy of the patient, the life threatening nature of the disease and the lack of efficacious therapeutics. In contrast to other therapeutic areas, more emphasis is required on potential benefits of new treatments for advanced cancer balanced by a requirement to manage any resulting toxicity. In order to reduce safety-related attrition of cancer therapeutics and simultaneously improve cancer treatment it is important that compounds with the greatest safety margin in nonclinical studies, involving significant efficacy and minimal toxicity, are identified and progressed. Taken together this supports the fact that the type and timing of nonclinical safety studies for anticancer therapeutics has significantly different goals and required outcomes relative to non-oncology therapeutics. These issues and requirements resulted in development of the ICH S9 guidelines, "Nonclinical Evaluation for Anticancer Pharmaceuticals" (ICH 2010a), announced in the Federal Registry. These are the only ICH guidance devoted to a specific therapeutic area.

The ICH S9 guidelines are not currently legally binding, but provide a minimum standard for harmonization of nonclinical study requirements in support of oncology therapeutics across the European Union, Japan, and the United States. The guidelines emphasize improved evaluation of pharmacological efficacy, and incorporation of toxicity endpoints which can reflect acceptable toxicity for this class of agent as a basis for clinical starting dose selection. The principle objectives of the S9 guidelines are to: (1) decrease the attrition rate of new cancer therapeutics, (2) increase the clinical dose escalation rate to attain an active dose, (3) reduce, refine and replace animal use for drug development studies, in line with international efforts, and (4) ultimately reduce the time taken for a cancer drug to enter the clinic.

The guidelines are strict with regards therapeutic area and relate specifically to the development of both small molecule drugs and biotechnology-derived therapeutics (including antibodies and peptides) for the treatment of cancer. Excluded from the guidelines are medicines for cancer prevention, vaccines, cellular therapeutics, and pharmaceuticals developed to treat the symptoms or side effects of cancer therapy. Specifically, the ICH S9 guidelines cover the development of therapeutics for "patients with advanced cancer whose diseases is refractory or resistant to current therapy, or where current therapy is not considered to be providing benefit" (ICH 2010a). A major underlying principle for the S9 guidelines is that, relative to non-cancer therapies, a higher health risk for a patient with advanced cancer is likely to be acceptable in light

of their limited life-expectancy. Accordingly, the S9 guidelines are not applicable to pharmaceuticals intended for patients with a long life expectancy. In this regard, the guidelines are non-prescriptive with the definition of advanced cancer or life-expectancy, implying that additional data requirements maybe applicable for patients with longer life-expectancy (Ponce 2011). Although not explicitly defined within the S9 guidelines, short life-expectancy is defined within the ICH S1A guidelines, in the context of nonclinical carcinogenicity studies, as < 2–3 years (ICH 1998). Therefore, defining patients with advanced cancer as being those with a median life-expectancy of less than 3 years appears a reasonable basis for application of the ICH S9 guidelines (Ponce 2011).

In principle, the nonclinical safety requirements outlined in the ICH safety guidelines, ICH S1A to ICH S8, are still applicable to the development of cancer pharmaceuticals and the submission of an IND application prior to clinical evaluation. However, as detailed in the ICH S9 guidelines, the counterproductive nature of a protracted drug development process for life-prolonging cancer pharmaceuticals led to modifications of the standard "safety package" such that long-term effects of the pharmaceutical is now defined unnecessary (or at least deferrable) for oncology therapeutics. Accordingly, the majority of assays and methodologies for evaluation of safety of cancer pharmaceuticals are covered in detail elsewhere in this book. This chapter specifically describes screening methodology of particular relevance to oncology therapeutics, not covered in detail in other chapters, and defines the ICH S9 guideline modifications and alterations from general drug screening practices suggested for oncology therapeutics.

18.2 Nonclinical In Vitro Assessment of Toxicity

Conventional cancer therapeutics, principally antiproliferative or cytotoxic agents, are effective agents, with the downside in that they also demonstrate significant toxicities due to their effect upon cells and tissues with a high turnover (e.g., cells of gastrointestinal tract and the bone marrow) and those with metabolic or excretory functions (e.g., liver and kidney). Although the new generation of cancer therapeutics are designed to target specific molecular irregularities of cancer, many have also been shown to demonstrate a toxic effect upon other cell types. To reduce the high level of drug attrition with cancer therapeutics, significant effort has been placed on predicting likely toxicities and identifying therapeutics with high efficacy coupled to low toxicity as early as possible within the drug development cycle. Several methodologies have been developed for such goals.

18.2.1 Assessment of Cellular Toxicity: MTT Assay

PURPOSE AND RATIONALE

One of the initial stages of pharmacological screening within cancer therapeutic drug programmes is to determine the anticancer potential of a test therapeutic against cancer cells in vitro. At early stages in the drug discovery process the putative therapeutics are screened against a panel of human cancer cell lines to evaluate both patterns of tumor selectivity and potency (Shoemaker 2006). To improve screening efficiency and increase study throughput, the US National Cancer Institute (NCI) developed a 60 human tumor cell line screen (NCI60) to fulfill this objective (Shoemaker 2006). In these screens, therapeutics with common mechanisms of action demonstrate similar profiles of growth inhibition (Holbeck et al. 2010). In addition to

ascertaining the therapeutic potential and confirming proof of drug-target interaction, the same assays as used for efficacy can also be utilized to determine the effect of the therapeutic on non-cancer cell types, as either a secondary or off-target pharmacological effect.

In contrast to cancer cells, normal cells often have a lower proliferative index, are reliant on the heterogenous cellular nature of their host tissue for survival, and have a finite number of cellular divisions, making their in vitro culture very challenging. Over recent years, significant advances have been made with characterization of in vitro growth conditions for toxicological assessment of several human primary cell types, including renal, hepatic and haematological cells (Gomez-Lechon et al. 2010; Krishna et al. 2009; Li et al. 2003; McKim 2010; Valente et al. 2011). In addition, several laboratories have also developed toxicity assays using stem cells, characterized by their capacity to differentiate into many different cell lineages (Lee et al. 2011; Shuga et al. 2007, 2010). Despite these improvements, it is still common practice to utilize immortalized cell lines, such as HepG2 and HuH7 (liver), or HEK293 (kidney). An important benefit of the latter approach is that these cell lines are generally fully characterized in terms of morphology, behavior and biochemistry. On the downside, many of these cell lines do not recapitulate the full metabolic or differentiated status of the organ they represent.

Many screening tests have been developed for in vitro evaluation of cytotoxicity over the years, ranging from dye exclusion techniques of vital stains such as trypan blue or neutral red (Cavanaugh et al. 1990), to bioluminescent detection of released intracellular proteases following loss of membrane integrity (Cho et al. 2008) or quantitation of cellular ATP levels (Crouch et al. 1993; Shukla et al. 2010), to the most widespread technique which involves metabolism of tetrazolium salts by intracellular organelles of viable cells (Mosmann 1983; Shoemaker 2006). The most popular of these assays, the MTT assay, measures the reduction of the yellow MTT tetrazolium salt (3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) to dark purple formazan by succinate dehydrogenase present in mitochondria of metabolically active cells, with the amount of formazan created being directly proportional to the viable cell number. Importantly, no interference of the product with the substrate is observed with this assay, allowing it to be conducted in a 96-well plate format with spectrophotometric detection (Mosmann 1983; Shoemaker 2006).

PROCEDURE

The method for the MTT assay developed by Mossmann et al. is described below (Mosmann 1983; Shoemaker 2006). Cells are seeded into 96-well cell culture plates at a density dependent upon the cell-type and intended duration of therapeutic exposure, with the target of approximately 70% cell confluence at time of analysis. In the case of primary cells, the plate may be pre-coated with a matrix protein to aid attachment, if necessary. Following a period of monolayer establishment, normally 24 h, cells are then exposed to a dose range of the therapeutic for the experimental duration, which can range from 1 to 72 h dependent upon the objective of the study. After this exposure period, the MTT solution is added to each well, and the plate incubated at 37°C for 4 h. The insoluble formazan (purple) is then solubilized in dimethyl sulphoxide (DMSO) and the well absorbance read at 540 nm. The color generated is stable for a few hours at room temperature, but can be read directly following the crystal solubilization. Since the reduction of MTT varies from one cell type to another, standard curves showing the different metabolic activities must be determined for each cell type.

EVALUATION

The MTT assay is selective for metabolically active cells, showing a direct correlation between formazan absorbance at 540 nm and viable cell number (Mosmann 1983; Shoemaker 2006). From this data, dose-response relationships can be determined, as well as the IC_{50} (dose causing 50% reduction in cell number). In this context, an in vitro therapeutic index of a putative cancer therapeutic can be determined, through comparison of the IC_{50} of cancer cells versus that of normal cells. Ideally, a clear differential in cytotoxicity between the cancer and non-cancer cells is required, since agents anticipated to reach therapeutic plasma concentrations that are greater than or equal to the toxicity IC_{50} of the non-cancer cells have a high probability of dose limiting in vivo toxicity (McKim 2010).

MODIFICATIONS OF THE METHOD

One limitation of the MTT assay is the production of an insoluble formazan product, requiring solubilization

in DMSO prior to spectrophotometric measurement. Consequently, water soluble analogues of MTT have been developed, such as XTT (2,3-bis-(2-methoxy-4-nitro-5-sulfophenyl)-2H-tetrazolium-5-carboxanilide) (Scudiero et al. 1988). These water soluble variants do not require solubilization in organic solvents prior to colorimetric analysis, allowing immediate reading of cell number in the culture well without the requirement for further processing. Relative to MTT, the use of XTT also offers the advantages of being suitable for automation, and being more reproducible. On a negative note, a high background is obtained with XTT and this substrate is not reduced as easily as MTT by mitochondrial enzymes, often requiring electron couplers such as phenazinemethosulfate to promote rapid electron transport to XTT. Consequently, convenience must be balanced with lack of sensitivity when considering XTT versus MTT for this option.

The relative lack of stability of MTT and XTT and consequent requirement for preparation immediately prior to use, coupled with the fact that they have inherent toxicity, resulted in the development of several further improvements to this methodology, such as Alamar blue (Hamid et al. 2004). Whereas MTT was colorimetric, Alamar blue is converted by reduction in viable cells from a non-fluorescent substrate to a fluorescent pink non-toxic product (λ_{ex} 530 nm, λ_{em} 590 nm). Consequently, the Alamar Blue assay is both sensitive and highly reproducible (Hamid et al. 2004). The disadvantage to this method is the requirement for a fluorescence plate reader, rather than a spectrophotometer.

CRITICAL ASSESSMENT OF THE METHOD

The use of cytotoxicity assays, such as the MTT assay, is widespread across the drug discovery and development sector and is a valuable tool for initial evaluation of a therapeutic index. In order to interpret this data and relate it to the in vivo situation it is important that reference factors are also taken into consideration, including compound solubility and metabolic stability, and not just the value obtained from the MTT assay. Additionally, it is important to remember that the MTT assay, along with the majority of in vitro cytotoxicity assays, do not fully recapitulate the in vivo situation, in that they often do not address protein binding, metabolite activation and stability, and systemic pharmacology. These limitations must always be borne in mind or resolved when attempting to directly extrapolate in vitro observations to the in vivo setting (McKim 2010).

In order to improve assessment of drug efficacy and safety, it is strongly suggested that the MTT assay be integrated into a multiple parameter package of in vitro cytotoxicity assays (for instance, addition of a membrane integrity screen) (McKim 2010). This is especially important when appreciating that therapeutics can affect several subcellular targets, with varying exposure concentrations and times. The reliance specifically on the MTT assay (or any other single in vitro cytotoxicity assay) for predicting in vivo toxicity is beholding to the toxicity mechanism itself. For example, a therapeutic which inhibited mitochondrial reductases would provide erroneous results in the MTT assay (Hamid et al. 2004).

18.2.2 Assessment of Haematological Toxicity: Colony Forming Unit Assay

PURPOSE AND RATIONALE

A major dose limiting toxicity of both conventional and molecular-targeted cancer therapy is myelosuppression. The rapid proliferation of haematopoietic stem cells and the motile and invasive nature of cells within the bloodstream results in this cell population being sensitive to a wide range of cancer therapeutics. Haematopoietic stem cells are pluripotent and can generate into almost all cell types of the immune system, generating cells of both lymphoid and myeloid lineages. In addition, these stem cells have the capability of self-renewal meaning that following division one cell replaces the stem cell whilst the other is committed to differentiate. An important goal for the successful development of cancer therapeutics is to predict whether it will be clinically toxic to the bone marrow, whether the toxicity will be specific to one cell lineage (lymphocytes, neutrophils, megakaryocytes, or erythrocytes), at what dose or exposure level the drug will be toxic, and when the onset and recovery are likely to occur. The assay which is currently used to predict myelosuppression, both clinically and nonclinically, is the colony-forming unit assay (CFU). Although several iterations of the CFU assay exist, each focusing on a specific haematopoietic cell type, assays focusing on granulocyte-macrophage precursors (CFU-GM) are routinely used to predict neutropenia, the commonest type of myelosuppression. In contrast to the majority of in vitro toxicity assays which report activity as an IC_{50}, the CFU-GM assay reports its activity based upon the IC_{90} value (Concentration inhibiting proliferation by 90%) as this has been demonstrated to be an accurate predictor of concentrations that produce dose-limiting haematological toxicity (grade 3 or 4 neutropenia) in the clinic (Parchment et al. 1998; Pessina et al. 2002, 2005). Following validation, the CFU-GM assay for predicting acute neutropenia using human derived cells was shown to be a valid substitute to the use of a second species, such as dog, for this purpose (Pessina et al. 2007). Importantly, the toxic concentrations calculated from the mouse and human in vitro CFU-GM studies have been shown to be predictive of human maximum tolerated doses in the clinic, through extrapolation of in vivo mouse toxicity data (Pessina et al. 2003; Pessina and Bonomi 2007).

PROCEDURE

The standardized protocol of the CFU-GM assay for evaluation of potential drug myelotoxicity developed by Pessina and Bonomi is described below (Pessina et al. 2007).

Bone Marrow cells (mu-BMC) are isolated from femur bone marrow of sacrificed mice (8–12 week old), with cells from three mice pooled together per experiment. For human studies, cryopreserved human cord blood mononuclear cells (hu-CBMNC) are used, since these are known to contain a high number of primitive haemopoietic progenitor cells. Each experiment normally consists of a linearity control (cells alone), therapeutic-vehicle control and six concentrations of therapeutic agent. Cells are cultured in a semi-solid methylcellulose-containing culture medium (MCM); primarily Iscove's modified Dulbecco's medium containing 1% Methylcellulose, 30% Fetal Bovine Serum, 1% Bovine Serum Albumin, 2 mM L-Glutamine and 10 ng/ml murine or human GM-CSF. Prior to cell addition, the respective volume of drug stock or drug-solvent (vehicle) is mixed with MCM. Cells are then added to each mixture, at 4×10^4 and 7.5×10^4 cells per dish for mu-BMC and hu-CBMNC, respectively. For the linearity controls, comparison plates should also be created containing 2.5×10^3 and 1×10^4 cells for mu-BMC and hu-CBMNC, respectively. The cell medium mixture (maximum volume

1 ml) is then added to 35 mm petri dishes, in triplicate. Cultures are placed in a humidified incubator maintained at 37°C, 5% CO_2, for 7 (murine) or 14 (human) days.

In many studies a preliminary dose finding study is first performed in order to identify both the Maximum Tolerated Concentration (MTC; complete inhibition of CFU-GM) and the Highest Non-Toxic Concentration (HNTC; highest dose that did not inhibit CFU-GM), with a secondary study performed at concentrations between these two values to identify the IC_{50} and IC_{90} values.

EVALUATION

Colonies are counted after 7 days (murine) or 14 days (human cells) by scanning the whole petri dish at low magnification for colonies. Aggregates containing 50 or more cells are defined as CFU-GM colonies, whereas smaller aggregates are termed clusters. Several different types of colonies will be present and should be counted as single colonies; Compact colonies (defined dense shape with few spread cells), Multifocal colonies (aggregates with potential halo of spread cells), diffuse and spread colonies (without apparent nucleus), and multicentric colonies (two or more central dense nuclei with common peripheral halo) (Pessina et al. 2003, Pessina and Bonomi 2007). It is advised that all dishes should be counted in a random fashion to reduce experimental bias. In order to determine the lower limits of acceptability for aggregates considered as a colony, it is advised that the highest drug level be examined first, since these colonies will be smallest and most difficult to define because of toxicity. Verification of colony growth linearity should be determined by comparison of the ratios between the number of colonies formed in low cell number control (2.5×10^3 or 1×10^4 cells per dish) and high cell number control (4×10^4 and 7.5×10^4 cells per dish for mouse and human, respectively) and testing the null hypothesis that the slope is equal to zero.

The IC_{90} value for the CFU-GM assay for both the mouse and human cells are calculated relative to vehicle control. The prediction of human Maximum Tolerated Dose (P-HuMTD) is calculated using the equation:

$$\mathrm{P-HuMTD} = \mathrm{Murine\ MTD} \times (\mathrm{Human\ CFU} - GM\ IC_{90}/\mathrm{Murine\ CFU-GM\ IC_{90}}).$$

Since pharmacokinetic differences across species may contribute to as much as fourfold difference in MTD, an accurate prediction of the myelosuppressive MTD is defined as that which lies within fourfold of the actual human MTD value (Parchment et al. 1998; Pessina and Bonomi 2007).

MODIFICATIONS OF THE METHOD

This CFU assay is primarily used to predict neutropenia, but can also be modified to predict clinical toxicity against other haematopoietic cell lineages, including lymphocytes, megakaryocytes and erthrocytes. The main differences between assays being the cytokine cocktail used to stimulate the progenitor cells. Drug-induced thrombocytopenia, a common toxicity of several anticancer therapeutics, is clinically defined as a dramatic decrease of platelet counts below 10^9/l, although this can be the result of bone marrow suppression or damage to circulating platelets. Since platelets are derived from proliferation and differentiation of megakaryocyte progenitors, the effect of therapeutics upon progenitor cells and consequent thrombocytopenia can be predicted using these cells in the CFU assay (CFU-Mk), with the standardized protocol previously reported (Pessina et al. 2009b). Comparison of the IC_{10}, IC_{50} and IC_{90} with maximal plasma drug concentrations (Cmax) in the mouse allows a robust prediction of the presence and degree of thrombocytopenia (Pessina et al. 2009b).

In light of the fact that the rat is the preferred species for nonclinical toxicology studies, the in vitro CFU-GM assay has now also been refined and optimized for this species, including the use of cryopreserved bone-marrow cells (Pessina and Bonomi 2007; Pessina et al. 2009a).

To determine potential haematological toxicity on a larger scale or for an increased throughput format, further assays have been developed using undifferentiated haematopoietic cells in liquid culture, in the presence of the respective cytokines and regulatory factors (Dal Negro et al. 2006a). Quantification of toxicity in these assays is performed either by manual counting of stained colonies, using flow cytometry, or through 96-well format luminescence assays which report intracellular ATP levels (Dal Negro et al. 2006a; Rich and Hall 2005).

A limitation of the standard CFU assay is that it only predicts direct toxicity and does not take into account a requirement for systemic or metabolic activation

(Dal Negro et al. 2006b). To achieve this goal, the methodology can be modified to include a metabolic activation step (liver microsomes, liver slices or isolated hepatocytes) to generate the relevant metabolites and determine their toxicity parameters, whether they result in synergistic or antagonistic effect upon haematotoxicity, and the effect of their detoxification (Dal Negro et al. 2006b). This new approach appears promising but has yet to be fully validated (Dal Negro et al. 2006b). In a further iteration of this assay, in vivo xenograft models have been developed containing humanized bone marrow to monitor haematotoxicity in a whole body system, with consequent reduced potential for interspecies differences (Cai et al. 2011). This humanized bone marrow mouse model was shown to be a feasible and physiologically appropriate tool with the potential to aid and improve screening for haematotoxicity (Cai et al. 2011).

CRITICAL ASSESSMENT OF THE METHOD

The CFU assay has great versatility for prediction of haematopoietic toxicity of cells from different lineages and shows a high level of correlation to the respective clinical toxicity. However, quantification of colony formation is still reliant upon manual observer interpretation of cell colonies and as such can be relatively subjective in nature. Alterations in the methodology toward liquid culture, as opposed to growth in semisolid medium, have allowed the progression of the assay toward higher throughput screening of therapeutic agents and automated detection of colonies through technologies such as luminescent detection (Dal Negro et al. 2006a, b; Rich and Hall 2005). Although these modifications should in theory improve throughput and quality of data, methodological validation and comparison to the conventional CFU assay is still required to confirm the predictive value and benefits of these approaches.

It is well reported using in vitro clonogenic assays that interspecies differences exist with regards response of haematopietic cells to anticancer therapeutics (Kurtzberg et al. 2009; Masubuchi et al. 2004; Pessina et al. 2005). For example, mouse bone marrow is less responsive to several cancer therapeutics relative to human bone marrow, resulting in blood levels in nonclinical studies often been unattainable in human clinical trials (Cai et al. 2011; Kurtzberg et al. 2009). Therefore nonclinical assessments should be based on the results of several species (particularly human) prior to identifying a safe starting dose for clinical trial. As described above and in terms of neutropenia, the ratio of mouse to human CFU-GM IC_{90} has now been shown to adjust for the interspecies differences and has been accepted as a good predictor of human Maximum Tolerated Dose (MTD) (Pessina and Bonomi 2007).

18.3 Nonclinical In Vivo Assessment of Toxicity

In reflection of the intended patient population, the severity and terminal nature of the disease, and the mode of action of cancer therapeutics, the selection of a clinical starting dose for cancer therapeutics has to be safe but must also be high enough to offer potential therapeutic efficacy. Consequently IND applications for cancer therapeutics must provide nonclinical data with clear translatability to clinical trials, as well as satisfying the other regulatory requirements. The main difficulty is in choice of the actual clinical starting dose, which must be balanced between choosing one which is low and thus safe, and one which is high enough to achieve as few dose escalations as possible to reach clinical maximum tolerated dose (MTD) or biologically effective dose.

Integrated evaluation of efficacy and toxicity for cancer pharmaceuticals has now led to many drug development organizations, particularly the National Cancer Institute (NCI), and several major pharmaceutical companies adopting a two phase cost-effective strategy to appraise potential safety aspects of cancer therapeutics; the first being a preliminary nonclinical assessment of toxicity in one or often two animal models, focused on identification of MTD, drug pharmacokinetics and identification of the potential therapeutic index. Successful fulfillment of program progression criteria then permits full-scale development, including comprehensive toxicity evaluation using the intended route, schedule and duration as the proposed clinical protocol and satisfaction of the regulatory requirements outlined in the ICH S9 guidelines.

In the majority of cases, the procedure and methodologies for evaluating safety of cancer pharmaceuticals is in agreement with other types of therapeutic and is addressed elsewhere in this book. Areas where there is deviance from the standard protocol are, (1) the modification of nonclinical rodent safety studies to facilitate attainment of maximum tolerated efficacious dose rather than the maximum effective dose, (2) the suggested modifications to the standard safety studies to accelerate development of this class of agent to the clinic, and (3) the mechanism by which the clinical starting dose is calculated, as outlined in the ICH S9 guidelines. These three areas will be discussed in the next section.

18.3.1 Determination of Nonclinical Maximum Tolerable Dose

PURPOSE AND RATIONALE

Many different types of nonclinical in vivo mouse model have been developed for efficacy assessment of cancer therapeutics, with the ever challenging goal of using a model which captures and is highly predictable for the clinical situation. These models range from autochthonous and spontaneous occurring tumor models, to human tumor xenografts in immunodeficient mice, to orthotopic tumor models, to genetically modified tumor and host models (Talmadge et al. 2007). The details of the advantages and disadvantages of these models with regards efficacy assessment is beyond the scope of this chapter, but is adequately reviewed elsewhere (Bibby 2004; Firestone 2010; Talmadge et al. 2007).

A comprehensive set of guidelines for the welfare and use of animals in cancer research have been compiled as a collaborative venture between academia, the pharmaceutical industry and government representatives, covering all aspects of developmental and therapeutic studies (Workman et al. 2010). All such studies are also still bound by the respective national legislation: USA Institute for Laboratory Animal Research (ILAR) Guide for the Care and Use of Laboratory Animals; UK Animals (Scientific Procedures) Act 1986; Public Health Service Policy on Human Care and Use of Laboratory Animals (Office of Laboratory Animal Welfare, National Institutes of Health, 2002), amongst others.

In addition to evaluating therapeutic efficacy, nonclinical animal models are also valuable for information relating to pathology, toxicity and ultimately

drug safety. Determination of efficacy and safety of small-molecule drugs or biopharmaceuticals (e.g., antibodies, protein therapeutics) targeted against cancer cells is initially conducted in rodents, prior to regulatory studies outlined in the ICH S9 guidelines.

PROCEDURE

Initial evaluation of maximum tolerated dose for the investigative agent should be conducted in mice. The maximum tolerated dose (MTD), in respect of cancer pharmaceuticals, being defined as the highest dose of a therapeutic in which the clinical condition of the animal is maintained, and which is independent of the mechanism of drug action (Workman et al. 2010). These tolerability studies must be conducted using the same strain as will be employed for efficacy studies, which in the majority of cases will be an immunocompromised model such as nude or SCID mice. With a few exceptions, these mice must also be non-tumor bearing.

Although these studies are not tightly prescriptive in terms of their design, the consensus across several groups and organizations is the use of two mice per dose level with a doubling dose-escalation or dose-halving de-escalation design (Workman et al. 2010). Such a study design agrees with the suggested guidelines for nonclinical rodent studies and fulfils a major aim of the S9 guidelines to reduce and refine experimental animal numbers (ICH 2010a; Russell and Burch 1959; Workman et al. 2010).

An important criterion when conducting these tolerability studies is to characterize the efficacy and more importantly the safety profile within the therapeutic dose range of the therapeutic, using a schedule which reflects that intended for the clinic, particularly the duration of treatment. The suggested dose schedules, as outlined in the ICH S9 guidelines, are identified in Table 18.1.

In the majority of cases for a new therapeutic, whereby the ideal dosing regimen is not yet identified, the starting point for MTD assessment should be set as a single dosing event. In these cases, escalation to a second dose level requires a minimal interval of 24 h, to allow acute toxic or safety concerns to be identified. For therapeutics intended to be delivered chronically or over a longer time period (e.g., daily for a month, orally or intravenously) the interval is suggested to increase to at least 5 days (Workman et al. 2010).

Table 18.1 Example schedules for oncology therapeutics to support clinical trials, adapted from ICH S9 guidelines (ICH 2010a). These schedules are intended for evaluation of conventional cancer therapeutics and should be modified accordingly for biopharmaceuticals with extended pharmacodynamics or half-lives, and potential for immunogenicity. In addition, the schedules outlined in this table do not identify recovery periods which should be incorporated into study design

Clinical schedule	Nonclinical study schedule
Single dose every 3 weeks	Single dose
Daily for 3 days, Repeated every 3 weeks	Daily for 3 days
Daily for 5 days, Repeated every 3 weeks	Daily for 5 days
Daily for 7 days, Repeat alternating weeks	Daily for 7 days, Repeat week 3
Single dose every 2 weeks	Repeat dose, 14 days apart
Single weekly dose for 3 weeks, 1 week rest	Once a week for 3 weeks
Two doses per week	Two doses per week for 4 weeks
Continuous daily	Daily for 28 days
Continuous weekly	Once a week for 4–5 doses

Additional to the dosing route and treatment schedule, toleration is also dependent upon the composition of the therapeutic solution being administered. Delivery of the therapeutic as an acidic or basic solution commonly is associated with complications due to the irritant nature of the vehicle, limiting the maximum deliverable dose. Therefore, the vehicle in which the therapeutic is delivered should be as close to physiological pH as possible, for example 0.9% saline or 5% dextrose/saline. In cases where the therapeutic is poorly soluble in aqueous solution, a vehicle comprising low concentration organic solvent, not exceeding 10% (or 5 ml kg^{-1}) of the total administered volume, could be used. A common used example being dimethylsulphoxide (DMSO). Chemical composition of the therapeutic may also necessitate inclusion of a detergent (such as Tween), an emulsifier, or a solubilizer, although these shouldn't exceed 20% of the total delivered volume. Additionally, cyclodextrin to a maximum of 45% total volume is also an accepted inclusion for drug administration of poorly soluble therapeutics, although use of this compound necessitates that the animals be rehydrated 2–4 h post-treatment (Workman et al. 2010).

The volume of therapeutic solution to be administered is also of consideration for assessment of tolerability, with the smallest possible volume being used in order to keep solvent related issues and subsequent

toxicity to a minimum. Although no definitive guidelines are available, the following suggestions are widely accepted as standard; oral/intraperitoneal dosing in mice of 10 ml kg^{-1} and intravenous dosing in mice of 5 ml kg^{-1} (equating to 200 and 100 µl for a 20 g mouse, respectively) (Workman et al. 2010).

EVALUATION

Clinical signs of toxicity observed during these nonclinical rodent tolerability and efficacy studies may manifest as either a behavioral, physiological or pathological change. In agreement with the guidelines for the welfare and use of animals in cancer research, all mice should be visually examined twice daily as a minimum (Workman et al. 2010). In addition to the legislative requirements for evaluation of animal physical and psychological distress or suffering, mice should be weighed frequently (i.e., daily) and their behavior observed. A median body weight loss of 15–20% of the weight prior to treatment requires cessation of dosing and monitoring of the mouse for weight recovery. Mice with weight loss exceeding 20% should be sacrificed.

The MTD for the therapeutic is the highest dose of a drug in which the clinical condition of the experimental animal is maintained and no significant drug-induced adverse effects are observed. Specifically, a dose of the drug causing weight loss less than 15% of the weight before treatment, not causing death due to toxicity events, or causing significant detrimental changes in animal wellbeing within 1 week after administration. The dosing schedule should reflect that used for the proposed efficacy studies.

MODIFICATIONS OF THE METHOD

The conventional methodology for evaluation of the MTD is to use healthy non-tumor bearing immunocompromized mice, which in the vast majority of cases is applicable. Despite this, the advent of "targeted molecular therapeutics" will in some cases require the additional use of tumor-bearing or immunocompetent mice for tolerability studies. Studies requiring immunocompetent mice include those involving biotechnologically derived peptides and antibodies. The use of tumor-bearing mice is potentially necessary for determination of the tolerability of tumor-activated prodrugs, although an alternative strategy maybe to evaluate the active moiety in the "standard" tolerability model.

As opposed to evaluation of therapeutic tolerability in non-tumor bearing mice (or for non-oncological conditions), care should be adopted when identifying apparent drug-induced adverse effects in tumor-bearing models as these maybe a result of tumor presence or response rather than a true drug safety concern. Although such events are rare and avoidable by appropriately designed experimental studies they should not be overlooked and should be appraised within all studies as standard. For example, dermal distension and ulceration, and cachexia can both be the result of tumor presence.

CRITICAL ASSESSMENT OF THE METHOD

The MTD in mice provides the foundation for calculating the first in human starting dose for the therapeutic, indicating the significant importance of this approach. The downside to this methodology is that the majority of clinical signs indicative of toxicity do not provide mechanistic information, but simply identify the presence of a toxicity either warranting further investigation or in severe cases animal termination.

18.3.2 Evaluation of Oral Mucositis: Hamster Cheek Pouch Model

PURPOSE AND RATIONALE

Oral mucostosis is a major toxicity of non-surgical cancer therapy, particularly chemoradiation treatment

of cancers of the head and neck (Sonis 2004). Over the years, the screening of oral mucotoxic therapeutics and the effect of cancer therapeutics has been performed in several rodent models, particularly mice, rats and hamsters. Of these the male golden Syrian hamster model has proved most useful, through use of the buccal cheek pouch, a structure not found in other rodent models (Sonis et al. 1990). Using this model, a five-stage hypothesis of mucositis was developed; initiation, primary tissue response, signal amplification, ulceration and healing (Sonis 2004). Advantages of the hamster cheek over other rodent models are that the check pouch has a similar epithelial structure to the human oral cavity, the oral bacterial flora in the hamster is similar to humans, hamsters demonstrate a similar chemosensitivity profile to humans, and mucositis development in the hamster follows a predictable course. In addition, from an experimental perspective, the check pouch mucosa provides a large mucosal surface accessible for easy examination (Sonis 2004; Sonis et al. 1990). Although the commonest use of the oral mucositis models are to identify and assess agents to treat or prevent this adverse effect of cancer treatment, this model can also be used to evaluate the induction of mucositis in its own right (Bowen et al. 2011; Sonis et al. 1990).

PROCEDURE

The following methodology is based upon that of Sonis and colleagues (1990). Golden Syrian hamsters, aged 5–6 weeks and weighing 80–100 g should be used for this assay. Animals should be housed in small groups, fed standard chow and watered ad libitum. The dose and treatment schedule for administration of the experimental therapeutic should be chosen based on the nonclinical MTD, pharmacokinetic profile and intended clinical treatment regimen. An initial dose of the therapeutic should be administered systemically, through the intended (intravenous or intraperitoneal) route, on day 0 of the study. Since the cheek pouch mucosa is anatomically protected from functional trauma as occurs in humans, superficial irritation of the mucosa (a mechanically induced scratch) on the following day (Day 1) and for up to 3 days is performed. Therapeutic treatment is continued, using the predetermined schedule, and toxicity observed for a minimum of 14 days. The cheek pouch should be inspected on a daily basis for overt toxicity, and histological or morphological changes, such as erythematous changes indicative of mucositis (Sonis et al. 1990).

Table 18.2 Grading scale for mucositis severity in the hamster model

Grade	Mucosal appearance
0.	Pouch completely healthy, No erythema or ulceration
1.	Erythema and vasodilation, but mucosa intact
2.	Severe erythema with superficial mucosal erosion
3.	Mucosal ulceration with a cumulative size of about 25% of the pouch's surface
4.	Ulceration with a cumulative size of about 50% of pouch surface area
5.	Contiguous ulceration involving almost entire surface area of the mucosa

EVALUATION

The following 6-point scale for assessment of the severity of mucositis in the hamster check mucosa has been developed to grade mucositis (Table 18.2) (Sonis et al. 1990). This scale is analogous to that used for clinical scoring (National Cancer Institute-Common Toxicity Criteria).

MODIFICATIONS OF THE METHOD

The hamster cheek model has been used primarily as a tool for assessing anti-mucositis therepeutics, using the methodology described above. If information is required regarding the molecular basis of the toxicity or to further evaluate target cell populations, the check pouch can be readily excised from the hamster and evaluated using other technologies. In the case of histological evaluation, a single layer of tissue is optimal, created following surgical excision from the hamster.

This model is also amenable to the evaluation of chemoradiotherapeutic treatment strategies, using direct focal exposure of the cheek pouch to single dose or fractionated radiation (Alvarez et al. 2003; Watkins et al. 2010).

CRITICAL ASSESSMENT OF THE METHOD

In contrast to the human situation, induction of a "wound" or "irritation" in the hamster cheek pouch is required during the procedure. This can result in complications for toxicity analysis, particularly as result of induction of the wound healing response and consequent alteration in cellular and molecular signaling pathways.

Dose and schedule administered in the nonclinical model must be reflective of those expected clinically with the therapeutic, ideally with doses based on body surface area rather than dose per kilogram. Furthermore, species differences in susceptibility and metabolic capacity must also be borne in mind when translating results of these studies to the clinical situation.

18.3.3 Evaluation of Gastrointestinal Mucositis: Dark Agouti (DA) Rat Model

PURPOSE AND RATIONALE

Mucositis can affect the whole gastrointestinal (GI) tract from mouth to anus, but differences are observed between the effects observed in the upper GI tract (oral and oesophageal) and lower GI tract (Bowen et al. 2011; Keefe et al. 2004). Whereas the epithelia in the upper tract is developed to resist abrasion and is therefore a squamous mucosa, that of the lower tract is focused on secretion, digestion and absorption and is predominantly columnar epithelia. Consequently, therapeutic exposure, function and kinetics of mucositis are different in the two sites. Mechanistically, mucositis is the same throughout the GI tract, with the specialized function and cellular differentiation status being responsible for the different susceptibilities of mucositis observed (Bowen et al. 2011; Keefe et al. 2004).

The Dark Agouti (DA) rat mammary adenocarcinoma model of gastrointestinal (GI) mucositis was developed by Keefe and colleagues in the mid-90s (Bowen et al. 2011; Gibson et al. 2003; Keefe et al. 2000). This model uses rats bearing a subcutaneously implanted isogenic mammary adenocarcinoma, specific to the DA rat, which arose spontaneously in the 1970s and has been subsequently passaged (Gibson et al. 2003; Keefe et al. 2000). This model is unique as it reflects the human GI tract changes that occur in humans following chemotherapy (Bowen et al. 2011; Keefe et al. 2000).

PROCEDURE

The model and methodology for assessment of mucositis using the DA rat model developed by Keefe and colleagues is described below:

Female dark agouti rats weighing between 150 and 170 g and bearing the mammary adenocarcinoma tumor are assigned into treatment and control groups. Immediately prior to therapeutic dosing, animals should be injected subcutaneously with 0.01 mg kg^{-1} atropine to reduce any resulting cholinergic reaction. The therapeutic to be evaluated should then be administered intraperitonealy (for the reasons outlined later), at a dose based upon nonclinical efficacy, tolerability and pharmacokinetics, and following the intended clinical therapeutic schedule (Table 18.1). Control animals should receive therapeutic vehicle, following the same route and schedule as for the therapeutic.

Animals should be examined at least three times a day for the development of diarrhea and physical signs of mucositis related toxicity. Rats presenting with severe diarrhea or mucositis related symptoms should be terminated, with physical signs being a dull ruffled coat with accompanying dull and sunken eyes, or being cold to the touch with a hunched appearance and no spontaneous movement.

The presence of toxicity and GI mucositis should be evaluated for 7 days (or as dictated by dosing duration) via monitoring of physiological signs of toxicity, and via examination of the GI tract from euthanized animals. The GI tract (from pyloric sphincter to rectum) should be dissected out, flushed with chilled isotonic saline (0.9% w/v) to remove contents, and the wet weights of small and large intestines recorded. Samples (1–2 cm in length) of small intestine (taken at 25% of the length of the small intestine from the pylorus) and the colon (taken at mid-colon position) should be

transferred to either Clarke's fixative (60% w/v ethanol, 40% w/v acetic acid) for subsequent intestinal morphometry analysis, or to 10% neutral buffered formalin for histopathologic assessment. In addition, it is advisable to also excise, weigh, and formalin fix and evaluate accessory organs of the GI tract, such as liver and spleen. Histopathological assessment of the GI tract should be used to evaluate changes in tissue structure and pathology, determine the proliferative and apoptotic index, with TdT-mediated dUTP nick end labelling (TUNEL) commonly used for apoptosis analysis.

For intestinal morphometry, sections (1 cm) of small intestine (jejunum, corresponding to 25% of the jejuno-ileum) and large intestine (colon, 50% of total length) should be opened onto cardboard, fixed in Clarke's fixative for 24 h and then stored in 70% ethanol at room temperature. For analysis, samples are rehydrated through an ethanol gradient, hydrolyzsed in hydrochloric acid (1 M) for 7 min at 60°C, washed, stained using Schiff's reagent, microdissected, and mounted in 45% (v/v) acetic acid prior to microscopic evaluation.

EVALUATION

Therapeutic-induced changes in intestinal pathology and morphometry should be determined by light microscopic analysis of the formalin-fixed and Schiff reagent stained microdissected intestinal samples. Using a calibrated graticule, the length, apical width, and basal width of at least 15 villi (jejunum) in the small intestine should be measured in the microdissected samples. Additionally, the length of at least 15 crypts in both the jejunum and colonic specimens should also be determined. Using these dimensions a trapezoid approximation should be used to calculate the villus area, with the crypt length and villus area correlating with crypt and villus epithelial cell populations, respectively (Gibson et al. 2003; Keefe et al. 2000). Comparisons between treatment and control, as well as temporal effects of the therapeutic can then be determined.

The presence and severity of diarrhea in the rats should be recorded using a four point scale, as described by Gibson et al. (2003) (Table 18.3).

Table 18.3 Grading scale for diarrhea severity in the mucositis model

Grade	Severity	Appearance of staining
0.	None	No diarrhea
1.	Mild	Anus staining
2.	Moderate	Over top of legs and lower abdomen
3.	Severe	Over legs and higher abdomen, often associated with continual oozing

MODIFICATIONS OF THE METHOD

The DA model uses tumor-bearing rats, which can have both advantages and disadvantages in terms of assessing toxicity due to the effects of tumor burden, immunological response and cost of the model. Non-tumor bearing models of mucositis have now been developed, the commonest of which is that developed by Howarth and colleagues (Bowen et al. 2011; Howarth et al. 1996). In this tumor-free model, chemotherapy has been used to induce intestinal damage prior to the assessment of anti-mucositis approaches, indicating its utility for evaluation cancer therapeutics (Bowen et al. 2011; Howarth et al. 1996). The caveat to the tumor-free approach is that response to chemotherapy has been shown to be worse in tumor-bearing compared to tumor-naïve rats, indicating that the tumor adds to the comorbidity following therapy (Gibson et al. 2007).

Molecular targeted therapeutics, such as the tyrosine kinase inhibitors TKIs, have been demonstrated to show some level of GI tract mucositis in the clinic. Bowen et al. have developed a new model for assessment of these agents, using the albino Wistar rat, chosen for the fact that this strain has an appropriate drug metabolising profile for assessing such therapeutics (Bowen et al. 2011). Results to date with this model have appeared to reflect the clinical scenario.

CRITICAL ASSESSMENT OF THE METHOD

As with several other methodologies for assessment of efficacy and toxicity, the route of therapeutic administration has a significant influence on the outcome of the study. In the Dark Agouti rat model, intravenous administration is particularly difficult due to the skin pigmentation of this rodent model. Consequently, therapeutics screened using this model are very rarely given by the intravenous route.

Another disadvantage of rat models of GI tract mucositis is caused by their lack of an emetogenic reflex, known to be a contributing factor to GI mucosal injury. However, it has been suggested that pica can be used a an indirect marker for nausea (Bowen et al. 2011; Vera et al. 2006).

18.4 Application of ICH Guidelines to Oncology Therapeutics

PURPOSE AND RATIONALE

The ICH S9 guidelines were developed to reduce the attrition rate of cancer drug development with the specific goals of facilitating and accelerating development of new cancer therapeutics, whilst at the same time refining and reducing animal use and protecting patients from unnecessary side effects (ICH 2010a). The focus is on providing guidance on the design of nonclinical testing studies for the development of therapeutics for use in patients with advanced disease and limited therapeutic options. Specifically, nonclinical evaluation studies of therapeutics to identify and interpret the toxicological profile, pharmacological properties of cancer therapeutics, with the ultimate aim of establishing a safe starting dose for Phase I clinical trial (ICH 2010a). These guidelines apply to therapeutics, specifically small chemical chemotherapeutics and biotechnology-derived agents, intended to treat cancer in patients with life-threatening disease and a comparative short life expectancy, as described earlier in the introduction to this chapter.

The guidelines identify the type and timing of nonclinical studies required for progression of these new therapeutic entities into the clinic. The detail provided in the guidelines clearly indicates modifications required to the "standard" nonclinical screening programme in order to specifically address the specific mechanism of the cancer therapeutic or the manner in which it would be administered to patients. The guidelines clearly state the point during the development process when other ICH guidelines should be adopted, specific studies required to support development of cancer therapeutics, and rationale for inclusion or exclusion of specific safety studies. As a consequence of their mechanisms and intended disease, many of the longer-term effects of drugs addressed within general nonclinical evaluation studies are identified as being dispensable, deferrable or not-applicable in this case of cancer therapeutics. As such, it often means that other ICH guidelines are not applicable to development of cancer therapeutics unless specifically referred to in ICH S9. For instance, the guidelines do not include inclusion of healthy volunteers in a trial, indicating that the ICH M3 guidelines (ICH 2010a) should be followed.

Throughout the ICH S9 guidelines there is a clear statement of intent to develop therapeutics with a greater tolerance for risk in terms of cancer treatment, exemplified by modification, elimination or deferral of "standard" nonclinical studies (relative to ICH S6 for biotherapeutics and ICH M3 for non-oncological conditions), and use of nonclinical doses associated with adverse effects as the starting point for first in human clinical trial therapeutic starting dose.

PROCEDURE

Nonclinical safety studies to support clinical progression of an anticancer pharmaceutical should be conducted in accordance with Good Laboratory Practises. The following section identifies the specific study requirements as identified in the ICH S9 guidelines (ICH 2010a). An overview of the requirement for particular studies is indicated in Table 18.4.

18.4.1 Drug Efficacy

Preliminary characterization of mechanism of action, resistance and schedule dependencies in addition to cancer therapeutic efficacy are required as part of the nonclinical package. This should utilize appropriate models based on the target and mechanism of action of the therapeutic, but does not necessarily require evaluation in the same tumor type as intended for the

Table 18.4 Overview of the requirement for particular studies for oncology therapeutics, as described in the ICH S9 guidelines (ICH 2010a)

ICH safety guideline	Requirements for evaluation of oncology therapeutics
S1A-S1C: Carcinogenicity studies	Not required for marketing
S2: Genotoxicity studies	Not required for clinical trials, but data maybe required for marketing
S3A: Toxicokinetic study	S3A: Conducted as appropriate
S3B: Pharmacokinetic study	S3B: Partial requirements prior to clinical trial, with further data required for marketing
S4: Chronic toxicity testing	Shorter duration studies (3 months) are generally sufficient for marketing.
	Assessment of potential to recover from toxicity is required.
S5: Reproductive toxicology studies	No requirement prior to clinical trials, but partial requirements required for marketing
S6: Safety evaluation of biotechnology-derived products	Only required for biotechnology-derived therapeutics
S7A: Safety pharmacology for human pharmaceuticals	Requirement for marketing, but not specifically prior to clinical trial
S7B: The Non-clinical evaluation of the potential for delayed ventricular repolarization	
S8: Immunotoxicity studies	General toxicology studies are considered sufficient, unless immunomodulatory pharmaceutical
S10: Photosafety evaluation	Only required if potential risk is identified
M3: Nonclinical safety studies for the conduct of human clinical trials and marketing authorization for pharmaceuticals	Requirement dependent upon route of administration, proposed mechanism of action

clinic. Pharmacodynamic (primary and secondary) studies should also be evaluated, as appropriate.

18.4.2 Nonclinical Drug Safety Evaluation Studies

The screening of cancer pharmaceuticals will usually require evaluation in two species (rodent and non-rodent), as indicated in the ICH S9 guidelines (ICH 2010a). An exception to this being the development of genotoxic therapeutics, targeting rapidly dividing cells, in which safety studies in one rodent species may suffice (Newell et al. 1999). If the anticancer therapeutic is biotechnology-derived then ICH S6 guidelines are referred to with respect the choice and number of species to be screened (ICH 1997). If the initial short-term toxicity studies are comparable between rodent and non-rodent then longer-term studies can be conducted using only the rodent, on the condition that the rodent is a relevant species.

18.4.3 Safety Pharmacology

An assessment of vital organ function, including cardiovascular, respiratory and central nervous systems, is required prior to initiation of clinical trials. In contrast to other therapeutic classes, stand alone safety pharmacology studies are not required to support clinical studies in patients with late stage cancer or advanced disease. Safety parameters should be integrated and included in general toxicology studies.

18.4.4 Pharmacokinetics

A limited set of kinetic parameters identified in nonclinical studies, with the objective of facilitating clinical dose-escalation are required for commencement of clinical studies. These parameters include peak plasma levels, exposure levels and AUC, and therapeutic half-life. Studies in support of drug absorption, distribution, metabolism and excretion, conducted nonclinically, are required for later stage clinical trials and should be progressed in parallel to clinical development.

18.4.5 General Toxicity Studies

Toxicology studies must be conducted using a dosing schedule in agreement with the intended clinical trial design, as identified in Table 18.1. These studies have to be conducted in light of the intended clinical progression of the therapeutic. Accordingly, it must be remembered that the primary goal of Phase I clinical trial is to ascertain safety of the pharmaceutical in

humans, that these agents are generally administered at or close to their maximum tolerable dose, and that administration until dose-limiting toxicity is identified is the norm. Therefore, determination of a no-observable adverse effect level (NOAEL) or no effect level (NOEL) in toxicology studies is unwarranted for clinical trial support.

The assessment and prediction of toxicity recovery and delayed toxicity should also be included within the study to support the clinical trial, although it is not required to demonstrate complete reversibility within these studies before clinical progression.

18.4.6 Reproductive Toxicology

Therapeutics targeting cell division or which belong to a class of agent with known toxic effects upon embryofoetal development do not require embryofoetal toxicity evaluation. Similarly, such studies may not be feasible for biopharmaceuticals, but in principle could be performed during the period of organogenesis, in line with the requirements outlined in the ICH S6 guidelines (ICH 1996, 1997, 2010a).

Assessment of embryofoetal toxicity is only required to identify risks for the developing embryo and to communicate such potential risk to patients who are or may become pregnant. Results from these studies are required prior to marketing, but not for initiating clinical development for patients with cancer. These studies should be conducted in two species, but if found positive for teratogenicity or embryofetal lethality in the first species, a second species is not warranted.

In general, a fertility study is not required to support the treatment of patients with late stage or advanced cancer. Relevant information could be obtained from general toxicity studies, particularly the effect of the therapeutic upon the reproductive organs. Similarly, a peri- and postnatal toxicology assessment is generally not required for evaluation of therapeutics intended for use in cancer patients (ICH 2010a).

18.4.7 Genotoxicity Studies

These studies are not deemed essential to support clinical trials for therapeutics intended to treat patients with late stage or advanced cancer, but should be assessed prior to marketing. In the case of "conventional" cancer therapeutics, in which their mechanism of action is to target DNA replication and repair, a subsequent genotoxicity study is normally not warranted. Additionally, a positive genotoxicity signal from in vitro studies would indicate an in vivo study is not required. For assessment of biopharmaceuticals, the guidance provided in the ICH S6 guidelines should be followed (ICH 1997).

18.4.8 Carcinogenicity Studies

Such studies are normally not required to support either clinical trial or marketing of therapeutics intended to treat patients with late stage or advance cancer. The appropriateness of a carcinogenicity evaluation of an anticancer therapeutic is identified in the ICH S1A guidelines (ICH 1995).

18.4.9 Immunotoxicity Studies

For most therapeutics, no dedicated immunotoxicity study is required, with the design of the general toxicity study being sufficient to assess this toxicity. In the case of therapeutics with known effects in this area, such as immunomodulatory drugs and cytokines, further studies and immunophenotyping evaluation may be required.

18.4.10 Phototoxicity

The photochemical properties of the therapeutic (or chemical class) should be appraised during the nonclinical study period. A potential for phototoxicity would indicate protective measures should be adopted during clinical trial. A specific phototoxicity study is only required if photosafety risk cannot be evaluated from nonclinical or early clinical studies. In these cases, a study as identified in the ICH M3 and ICH S10 guidelines should be followed (ICH 2010b, c).

18.4.11 Assessment of the ICH S9 Guidelines

The ICH S9 guidelines are prescriptive in terms of the "core" studies required, but are limited with regards

their requirements for recovery and reversibility data. The guidelines do not identify a requirement to demonstrate complete recovery, but state "assessment of the potential to recover from toxicity should be provided to understand whether serious adverse effects are reversible" and specific data on reversibility may be expected "if there is severe toxicity at approximate clinical exposure and recovery cannot be predicted by scientific assessment." The primary purpose of inclusion of a recovery group is to ascertain whether any observed toxicity may progress to a more severe state. Irreversibility, or toxicity progression during recovery, may significantly alter clinical trial design due to duration of post-treatment monitoring and reappraisal of drug tolerability and toxicity. The advantage to inclusion of recovery groups are that toxicities developing post-treatment, their severity and clinical impact can be identified. Similarly, reversibility data can be utilized to prevent overestimation of observed toxicities and subsequent under-dosing of patients during clinical trial. Advantages of not including a recovery group would be fulfillment of the ICH S9 objectives to reduce the numbers of animals required per study and accelerate the translation of therapeutics to the clinic. In addition, the study package would be considerably less expensive. Recovery may not be required when the toxicity is predicted from the drugs mechanism, such as conventional DNA-damaging cancer therapeutics, where toxicities and their reversibility are well known. Similarly, a non-reversible toxicity, such as organ necrosis, would not necessitate a recovery group. Consequently, such information would be required on a case by case basis for regulatory submissions, particularly in the situation where no standard for reversibility potential is identified (Ponce 2011).

18.5 Extrapolation of Nonclinical Data to Support Clinical Trial Design

PURPOSE AND RATIONALE

The major objective of all preclinical and nonclinical safety studies is to identify the toxicity risks and liabilities, by which to make an informed decision and progress (or not) therapeutics to the clinic.

The relationship between animal and humans with respect to identifying effective and tolerable doses and the subsequent identification of a clinical starting dose has been studied over many decades, with mixed results dependent upon the type of therapeutic being evaluated. Conventionally, the safe starting dose for clinical trial of cytotoxic agents has been defined as one tenth the lethal dose to 10% of mice (LD10) (Newell et al. 1999). However, if the toxicology studies in the non-rodent species demonstrate significant toxicity, it is suggested that the starting dose be defined as one sixth to one third of the lowest dose that results in toxicity in the more sensitive species (Le Tourneau et al. 2010; Newell et al. 1999; Rozencweig et al. 1981). In the case of "molecular targeted therapeutics" whereby optimal therapeutic effects occur at doses below the maximum tolerated dose, an option is to use inhibition of the subcellular target and plasma levels rather than toxicity as an endpoint. Although appealing, this approach is difficult to adopt because of a need for serial tissue samples and larger patient cohorts, and consequently the "conventional" toxicity approach is used to guide clinical dosing. For biopharmaceuticals, a safe starting dose depends upon good understanding of the therapeutics pharmacology and anticipated safety profile, a choice frequently complicated by the specificity of the therapeutic for a human protein (with rats, mice and non-primate species often unsuitable as test systems).

Accordingly, the ICH S9 guidelines state that the starting dose should be scientifically justified from all the available nonclinical study data and its selection based on the proposed clinical study design and treatment duration (ICH 2010a). In this context, data obtained from nonclinical pharmacokinetic studies of cancer therapeutics is now reliably used to extrapolate toxic effects from animal to humans, by relating drug exposure and peak plasma levels to the occurrence and degree of systemic toxicity. These processes and strategies are embedded in the ICH S9 guidelines, particularly in terms of the objective to decrease the attrition rate of new cancer therapeutics.

PROCEDURE

Retrospective analysis of animal and human data by Freireich, Rozencweig and colleagues demonstrated that maximum tolerated dose in animals and humans was very close when normalised to body surface area (mg/m^2) but differential when normalized on a body weight (mg/kg) basis, requiring a species specific conversion factor in the latter case (Freireich et al. 1966; Rozencweig et al. 1981). The ICH S9 guidelines state that for most small molecule therapeutics the clinical dose should be determined by allometric scaling of the animal doses to the equivalent human dose, based on normalization of body surface area (ICH 2010a). These principles are also applicable for biopharmaceuticals which are either antagonists of the intended target/ligand or are without agnostic activity. In the case of therapeutics where allometric scaling is inappropriate or inadequate, particularly biopharmaceuticals, the starting dose maybe calculated by extrapolation from animals to humans based on other parameters, such as body weight. However, an exception to this approach are protein therapeutics with agonistic properties, whereby selection of the starting dose using an identified, minimally anticipated biological effect level (MABEL) should be considered (ICH 2010a). Facilitation of faster progression to the clinic necessitates that the design of nonclinical studies should mirror the route and dosing schedule proposed for clinical trial. The suggested preclinical study schedules to support clinical trials, as outlined in the ICH S9 guidelines, are shown in Table 18.1.

In the clinic, treatment for the majority of patients and cancer types involves combination of several therapeutics with different mechanisms of action. The pharmaceuticals involved in such combinations will of course have undergone individual toxicological investigations in their own right. Therefore, an informed decision should be made as to the requirement for further toxicology studies of the therapeutic combination prior to commencement of clinical trial. This decision must be based on both the toxicity profiles of the therapeutics in question and there being a pharmacological rationale for such combination therapy, supported by previous preclinical studies. Generally, toxicology studies to ascertain the safety profile of combination therapies intended to treat patients with advanced or aggressive cancer are not warranted.

MODIFICATIONS OF THE METHOD

In line with the objectives to increase the clinical dose escalation rate toward an active dose, attain the most therapeutically active dose, and reduce the time taken for new therapeutics to enter the clinic, the ICH S9 guidelines specify modifications to clinical trial of oncology therapeutics. Primarily, the guidelines state that dose-escalation or the highest dose investigated in an oncology clinical trial should not be limited by the highest dose tested in the nonclinical studies. The majority of cancer therapeutics will show comparability between toxicity response in nonclinical and clinical studies and thus adopt a standard process for dose escalation. In situations whereby a steep dose-response curve is obtained in nonclinical toxicology studies and no preceding marker of toxicity is available, particularly with regards biopharmaceuticals and therapeutics with a novel mechanism of action, consideration should be given to a slower than normal dose-escalation.

In contrast with other types of therapeutic, the ICH guidelines state that treatment should not cease whilst the patient is showing a response and can continue beyond the proposed end of the trial. This continuation beyond the duration of the completed toxicology studies would not require a new toxicology study. An exception to this being if the continuation of treatment is associated with a major change in the clinical schedule, such as alteration in treatment to a more intense clinical schedule (e.g., from one to three treatments per week), which is beyond the scope of the completed preclinical toxicology study. Such a situation would require further toxicological evaluation, with a single species study being deemed sufficient (ICH 2010a).

19.1 Introduction

Safety pharmacology studies are defined as:

> "Those studies that investigate the potential undesirable pharmacodynamic effects of a substance on physiological functions in relation to exposure in the therapeutic range and above." (ICH S7A International Guidelines on Safety Pharmacology Studies; Anon 2001)

The ICH S7A document also lists the principal aims of safety pharmacology as being:

1. To identify undesirable pharmacodynamic properties of a substance that may have relevance to its human safety.
2. To evaluate adverse pharmacodynamic and/or pathophysiological effects of a substance observed in toxicology and/or clinical studies.
3. To investigate the mechanism of the adverse pharmacodynamic effects observed and/or suspected.

Safety pharmacology is distinct from general toxicology in many ways, primarily in being focused on adverse functional *responses* to drugs, rather than on pathological cellular damage. Assessing functional responses involves measuring biochemical, physiological, and behavioral changes, using both in vitro and in vivo approaches. Safety pharmacology tends to focus on five organ functions for which functional responses are readily observable and quantifiable, namely, the cardiovascular system, nervous system, respiratory system, gastrointestinal system, and renal system. Compromising the function of any of the first three of these could be immediately life threatening, and these are classed as "vital organ functions" by ICH S7A.

Safety pharmacology is a dynamic discipline, with new technologies, new approaches, and new

regulatory guidelines arriving in quick succession (Redfern et al. 2002; Redfern and Wakefield 2006; Valentin and Hammond 2008; Bass et al. 2011). Rather than being viewed as merely a regulatory requirement, an increasingly broader range of techniques is being deployed in safety pharmacology to de-risk compounds early, thereby contributing to reducing candidate drug attrition at later, more expensive stages of drug development (Bass et al. 2011). However, one technique that has not been widely adopted is that of genetically modified animals, which are applied to differing extents in other areas of drug discovery, including toxicology (Wolf and Henderson 1998; Törnell and Snaith 2002; Bolon 2004; Lin 2008). This chapter explores why there has been limited uptake of transgenic animals into safety pharmacology, how they are being used and could be used, and recent technological changes that will facilitate their use to address safety pharmacology problems.

19.2 Reasons Limiting Use of Genetically Modified Animals in Safety Pharmacology Thus Far

The primary reason is that the rodent species of choice in safety pharmacology investigations is the rat, whereas the vast majority of genetically modified rodents are mice. Specifically:

1. Regulatory repeat-dose toxicity studies require evaluation of the candidate drug in a rodent and a non-rodent mammalian species (Anon 2009); the default rodent species is the rat, and the default non-rodent species for conventional pharmaceuticals (i.e., small molecules) is the dog (Keller and Banks 2006). To facilitate comparison between safety pharmacology and toxicology studies, including dose selection, systemic exposure, and maximal tolerated dose, it makes sense to confine the species used in the majority of safety pharmacology studies to the same two species used in toxicology studies: rat and dog (Redfern et al. 2002).
2. Several types of rodent studies conducted in safety pharmacology are more suited to the rat (or guinea pig) than to the mouse. These include cardiovascular assessments in anesthetized animals (guinea pig and rat), cardiovascular telemetry (rat and guinea pig), and certain operant behavioral techniques (rat). Nonetheless, mice are commonly used in safety pharmacology in earlier stages of drug discovery, specifically as this reduces compound requirements by approximately tenfold. Each mainstream safety pharmacology technique used to address the five organ functions in rats has been scaled down for use in mice (Redfern and Wakefield 2006). Even telemetry technology to record physiological variables (e.g., blood pressure, heart rate, body temperature, EEG), miniaturized so as to be suitable for use in freely moving mice, has been available for over a decade (Kramer et al. 2001).

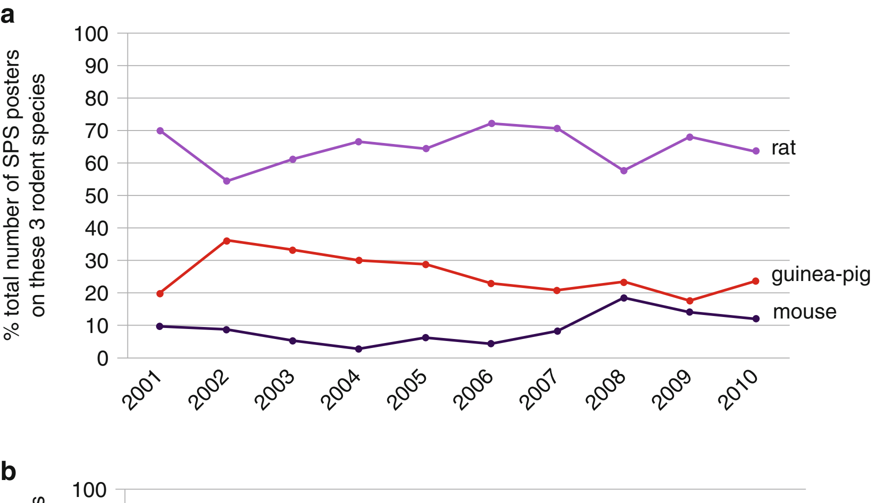
Figure 19.1 shows a plot of posters arising from work on mice and rats as a percentage of the total across all species, as presented at the annual meeting of the Safety Pharmacology Society (SPS) over a 10-year period since its inaugural meeting in 2001 (Redfern and Valentin 2011), compared to the published literature across the whole of bioscience over the same period. Although posters and publications may not reflect actual usage, nonetheless the proportion of mice as the rodent species in SPS posters is low and static, compared to an increase in their appearance in bioscience publications, generally over the same time period. In terms of the number of SPS posters on transgenic animals, there were only 5 out of a total of 1,180 posters; all of them since 2007 (Odening et al. 2008; Sun et al. 2008; Hassanain 2009a, b; Banfor et al. 2011; Redfern and Valentin 2011).

The development of techniques for genetically modified rats (Tesson et al. 2005, 2011 Geurts et al. 2009; Tong et al. 2010; Normile 2010), and their increasing availability (e.g., SAGE™ Labs; www.sageresearchmodels.com), is likely to result in an increased deployment in safety pharmacology. Safety pharmacologists are already utilizing genetic modifications in other species, including rabbit (Odening et al. 2008) and mini-pig (Forster et al. 2010).

19.3 Potential Applications of Genetically Modified Animals in Safety Pharmacology

These fall under six main themes:

1. *Target safety risk assessment*: Knockout (or conditional knockout) of the target of interest to study the impact on each of the five organ functions studied in safety pharmacology (cardiovascular, nervous system, respiratory, gastrointestinal, and renal).



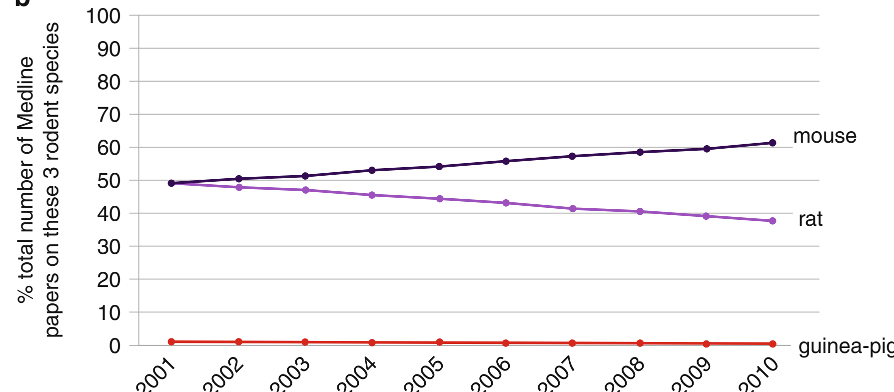


Fig. 19.1 (**a**) Posters on three rodent species presented at the annual meetings of the Safety Pharmacology Society since its inauguration in 2001. Plotted as % total posters involving rat, guinea pig, or mouse. Includes both in vivo and in vitro methodology. Various other species not plotted. Note the relative lack of research on mice presented throughout this 10-year period. Total SPS posters in 2010: mouse 11; rat 56; guinea pig 21) (Adapted from Redfem & Valentin (2011)). (**b**) Publications on the same three rodent species in the wider bioscience literature since 2001. Includes both in vivo and in vitro methodology. Note the steady rise in the publications on mice over the decade, with a corresponding reduction in publications on rats. Total publications in 2010: mouse 59, 607; rat 36, 756; guinea pig 575 (Source: Medline)

2. *Pharmacodynamic modification*: Knockout of the primary target receptor (or an off-target receptor) to determine the mechanism of an observed adverse effect with a compound or series of compounds.
3. *Pharmacokinetic modification*: Knockout of a transport mechanism/P450 enzyme to assess the modification of an observed adverse effect with a compound or series of compounds.
4. *Humanization*: Insertion of a human receptor to assess any potential adverse effects of a compound or series of compounds.
5. *Altered physiological/pathophysiological state*: Genetic modification to mimic aspects of a human disease, to enable the safety pharmacology evaluation in a "disease model."
6. *Bioluminescent/fluorescent reporter genes*: Insertion to indicate molecular mechanisms/pathways activated by an adverse effect of a compound or series of compounds.

19.3.1 Target Safety Risk Assessment

For a new molecular target, this can begin before any probe compounds have been synthesized. The purpose is to assess what happens to each of the five organ functions when the molecular target is disabled (by gene knockout), thereby mimicking what might happen if the same target is inhibited pharmacologically (by a receptor antagonist in the case of a cell surface or nuclear receptor; an inhibitor in the case of an ion channel, enzyme, or transporter). This approach is valid for the majority of drug discovery programs, as only a small proportion are designing agonists or activators. The three main problems with this approach are that some gene deletions are embryolethal, secondly, that the observed phenotypes may be due to developmental effects and not due to the acute absence of the receptor (Stark et al. 2007), and thirdly, that adaptive changes during development can provide

a "workaround" to circumvent the missing gene. One way round these problems is to use conditional knockouts. In these animals, a specific drug is administered at the time of the experiment, which causes inactivation of the targeted gene by inhibiting binding of an inserted transactivator to a gene promoter (e.g., the Cre-lox system), thereby switching off expression of the targeted gene. This can also be restricted to specific organs or tissues, for example, the brain (Aiba and Nakao 2007), by placing the transgene under a tissue-specific promotor. The first drug trigger used in the production of conditional knockouts was tetracycline (Gossen and Bujard 1992; Gossen et al. 1993; Aiba and Nakao 2007; Stark et al. 2007). Other approaches have included the use of the estrogen receptor antagonist tamoxifen, for example (Aiba and Nakao 2007; Lau et al. 2011; Friedel et al. 2011).

Currently, if knockout animals are not available for the gene of interest, there can be a significant delay until they are produced (e.g., >12 months), by which time probe compounds may become available within a drug discovery project. However, the availability of receptor knockouts is likely to increase from various sources, for example, the Mutant Mouse Regional Resource Centers (www.mmrrc.org) and the Wellcome Trust Sanger Institute (www.sanger.ac.uk); the latter is aiming to produce a knockout strain for every gene in the mouse genome. This will greatly facilitate target safety risk assessment by phenotyping, and provides an opportunity for safety pharmacologists to become more involved at this early stage of drug discovery projects, by applying more focused, safety pharmacology-related techniques than are currently used in phenotyping test batteries (Bailey et al. 2006; Crawley 2008).

19.3.2 Pharmacodynamic Modification

Table 19.1 shows the main causes of adverse effects in safety pharmacology investigations.

When such adverse effects occur, at any stage of drug discovery, a key question is whether this is mediated by the primary target. For the cardiovascular and central nervous system, adverse effects in humans are related to the primary target for ~50% of candidate drugs; for gastrointestinal adverse effects this is slightly lower (Olson et al. 2000). In early stages of drug discovery, evidence against an involvement of the primary target in the adverse safety pharmacology finding would be if the effect was not observed in all compounds interacting with the primary target that were tested. However, this is not always definitive. For example, the different ligands could interact with the primary target in subtly different ways; their cellular uptake could differ; and in the case of adverse effects mediated by the central nervous system, the different compounds could vary in their penetration of the blood–brain barrier. Using a knockout animal can help settle the argument. It is important to include a reference compound causing the same (or closely similar) adverse effect by a different mechanism, and to demonstrate that the gene knockout does not affect either the baseline control level or the response to the reference compound. If it does, the outcome is difficult to deconvolute, as shown in Fig. 19.2.

Published examples of this approach in safety pharmacology-related areas include elucidation of target- and off-target-mediated adverse effects of selective glucocorticoid receptor agonists (Kleiman and Tuckermann 2007). However, it is likely that its use is more widespread than this within the pharmaceutical industry; the paucity of publications may reflect commercial sensitivity, and if so, publications may ensue in due course.

Table 19.1 Causes of adverse effects in safety pharmacology studies and of Type A adverse drug reactions (ADRs) in humans. Type A effects are dose-dependent, pharmacology-related effects, comprising approximately 75% of human ADRs (Redfern et al. 2002).

Mechanism	Example
Augmented ("supratherapeutic") effect of interaction with the primary target	Pronounced bradycardia with a beta-blocker
Interactions with the primary target present in nontarget tissues	Sedation caused by antihistamines
Interactions with nontarget receptors	QT interval prolongation by blocking hERG channel
Inhibition of synthesis/ trafficking of receptors	Inhibition of hERG channel trafficking by pentamidine, leading to QT interval prolongation
Nonspecific effects	Gastric irritation leading to emesis
Pharmacologically active metabolites	Seizurogenic properties of bupropion metabolite

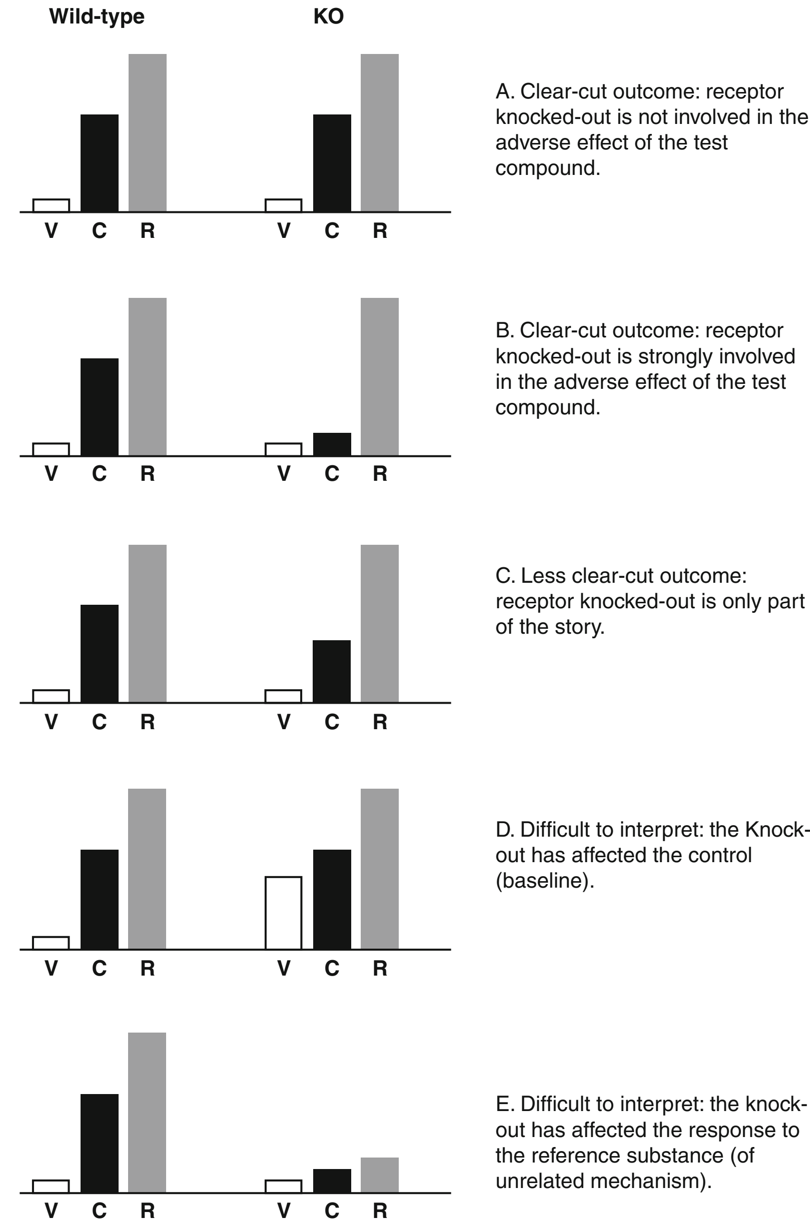

Fig 19.2 Five potential outcomes of safety pharmacology evaluations of the effects of a gene knockout on the adverse effects of a test compound (in vivo or in vitro). *V* vehicle control (baseline), *C* test compound, *R* reference compound acting via an unrelated mechanism

19.3.3 Pharmacokinetic Modification

This refers to a genetic modification to a protein involved in drug absorption, metabolism, distribution, or elimination. Such approaches can help to define where and how an adverse effect is occurring (Wolf and Henderson 1998). For example, deletion/reduction of a key cytochrome P450 enzyme can help determine whether an adverse effect is due to the parent compound or its metabolite; deletion/reduction of key drug transporters can point out which organ is involved in mediating an adverse effect, or whether such an effect is due to direct access of the compound to that organ. An example includes reduction of p-glycoprotein, an important efflux carrier protein in the blood–brain barrier. This has been used to elevate brain concentrations of a compound under evaluation, to determine whether its cardiovascular adverse effects were centrally mediated (Banfor et al. 2011).

19.3.4 Humanization

This category refers to the insertion of a human transgene into a laboratory animal species. This approach has been widely used in studying disease pathophysiology; however, its use in safety pharmacology has been minimal thus far. It would be particularly useful for safety pharmacology applications where the laboratory species differ significantly from humans in expression, homology, or ligand-binding characteristics of a particular target protein of interest, be it pharmacodynamic or pharmacokinetic (Cheung and Gonzalez 2008; Stanley et al. 2009; Strom et al. 2010; Jiang et al. 2011). Examples include mice expressing a humanized CYP3A4 enzyme, which is a key enzyme in the metabolism of drugs (Cheng et al. 2011). This approach has also been used to explain the carcinogenic effect of PPARα ligands in rodents (an effect not observed in humans), by generating a PPARα-humanized mouse line. A species-specific gene expression profile was observed with PPARα ligands between the transgenic mice and their wild-type counterparts, which explained the carcinogenic proclivity of rodents to this class of drug (Gonzalez 2007).

In safety pharmacology applications, this technique of "humanised" transgenic animals probably has most benefit in the area of biotechnology-derived therapeutics (biopharmaceuticals), especially human-specific proteins such as monoclonal antibodies. Transgenic rodents expressing the human form of the antibody's target receptor could have value in assessing target-related adverse effects in safety pharmacology studies for this class of biopharmaceuticals.

19.3.5 Altered Physiological/ Pathophysiological State

The primary purpose of safety pharmacology evaluations is to protect healthy human volunteers in Phase I clinical trials from harm due to adverse effects of new medical entities. Therefore, it is obvious that we would conduct the safety pharmacology evaluations in healthy animals. However, an aspiration of safety pharmacologists is to predict Type A adverse effects (i.e., adverse effects related to the primary or secondary pharmacology; Table 19.1) in the larger patient population. Arguments have been proffered in support of running safety pharmacology studies in animal models of the targeted disease. Counter arguments include the fact that disease models in animals only model one aspect of the human disease; the time course of the pathophysiology in the disease model (for some chronic diseases) is usually much faster; and that anatomical, biochemical, physiological, and behavioral differences between the test species and humans degrade the translation from the aspirational 1:1 relationship. Moreover, the translation of safety pharmacology findings (in healthy animals) to Phase I readouts (in healthy humans) is less than perfect (Valentin et al. 2009), so factoring in the above caveats as well would further diminish the confidence in translation of safety pharmacology findings in an animal disease model.

Notwithstanding these caveats, there may be specific situations where a strategy of using a model of the targeted disease would be relevant to the safety pharmacology evaluation (e.g., Hamlin and Kijtawornrat 2008). Also, there are other situations where the adverse effect of a test compound in normal animals is far worse (even dose limiting) than in a disease model. An example of this would be in the case of hypoglycemic agents, which may lower blood glucose to levels resulting in adverse physiological or behavioral effects in normal animals, whereas in rodent models of type 2 diabetes they merely restore the elevated blood glucose to normoglycemic levels. In both these areas, transgenic rodent models of human diseases may be appropriate for safety pharmacology applications.

19.3.6 Bioluminescent/Fluorescent Reporter Genes

The predominant fluorescent marker used in transgenic animals is green fluorescent protein (GFP), a naturally occurring protein found in *Aequorea victoria*, a species of jellyfish (Chalfie 2009). It can be coupled to proteins of interest by inserting tags on the transgene. This enables real-time monitoring of the localization of the protein of interest (e.g., a drug receptor) in live tissue (Spergel et al. 2001). It can also be used to identify individual cells (expressing a protein of interest) within a cell culture or tissue slice for

electrophysiological or biochemical assessments (Spergel et al. 2001).

It has potential applications for in vivo, ex vivo, and in vitro techniques in safety pharmacology, and GFP transgenic rats have been developed as well as mice (Remy et al. 2010; Ueta et al. 2011; Moore et al. 2012). As there are no published examples of its use in safety pharmacology applications, examples of analogous applications include cochlear hair cell loss following ototoxic treatment in vitro (Yorgason et al. 2010), ex vivo measurement of the hypothalamic vasopressin response to various physiological stimuli (Ueta et al. 2011), and in vivo assessment of nerve injury and regeneration (Moore et al. 2012). Realistically, for safety pharmacology applications, visualization (or imaging) of GFP expression in mammalian species in vivo would probably be too invasive for longitudinal studies in any of the five organ functions studied, and would therefore generally require terminal anesthesia. An exception to this could be in vivo retinal imaging by confocal scanning laser ophthalmoscopy in GFP-tagged mice (Seeliger et al. 2005). However, for in vitro applications in safety pharmacology, this technique could be quite useful, which is also the case for larval zebrafish, which are transparent, and potentially valuable as frontloaded assays for some aspects of safety pharmacology (Redfern et al. 2008).

19.4 Caveats and Pitfalls of Using Transgenic Animals for Safety Pharmacology Applications

Limitations on the application of genetically engineered animals in toxicology (Bolon 2004; Lin 2008) also apply to safety pharmacology. Both the genotype and phenotype of the transgenic model need to be well characterized. The genetic background of the animal strain used can greatly affect phenotypic expression, and some strains develop spontaneous conditions that could be misinterpreted as relating to the altered gene function. Compensatory changes in other biochemical/physiological pathways can lead to misinterpretation of the role of the altered gene function (although the use of conditional knockouts should mitigate against this). Conversely, gene functions may be missed because specific challenge conditions were required, and were not applied.

19.5 Concluding Remarks

Applications of genetically modified animals in safety pharmacology currently lags behind other areas within drug discovery, especially target validation, disease biology, drug metabolism and pharmacokinetics, and (to a lesser extent) toxicology. Part of the reason for this is the reduction in quality of physiological and behavioral data obtained from the mouse compared to the rat. The increasing availability of transgenic rats may help overcome the prevailing view in safety pharmacology that, for most of our requirements, this is still a solution awaiting a problem.

20.1 General Overview

20.1.1 Need for Alternative Models for Safety Assessment

Nonclinical safety and toxicity assessment of new chemical entities can be a labor intensive and expensive endeavor which can lead to the loss of large numbers of drug candidates. However, any toxic pharmaceutical agent not successfully identified can prove much more costly as the potential monetary loss caused by a failure associated with any major human safety concern escalates as the drug development process continues. Late-stage clinical failures account for a significant proportion of costs incurred by the drug discovery industry (Schachter and Ramoni 2007), and alongside efficacy, toxicity and safety liability remain the most likely causes of candidate drug failure (Kola and Landis 2004). Discovery and development costs required to successfully introduce a single new pharmaceutical agent to the market have previously been cited at over $1 billion USD (DiMasi et al. 2003) and, given the recent lack of productivity in the pharmaceutical industry in the last decade, these projected development costs are undoubtedly much higher.

Currently, a multitude of possibilities exist for today's safety pharmacologists to help identify compounds with the least potential liabilities, but nevertheless, drugs still enter the market with lethal consequences. This demonstrates the battery of screens and regulated studies commonly in use are insufficient for determining all possible risks; although one could argue that with the complexity of drug–drug interactions, genetic diversity and various environmental factors, no drug can be considered 100% safe even

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_22, © Springer-Verlag Berlin Heidelberg 2013

after "extensive" clinical trials. What can be concluded is that all models have their limitations and that predictivity, speed, and correct positioning of relevant screening assays can be of utmost importance to limit expenditure and prioritize the best quality candidates.

On the whole, in vitro assays are less likely to be representative when compared to in vivo models but have the advantage of being low cost, rapid to perform, and require small amounts of compound. To help demonstrate this point, the cardiovascular system can be used as an example. Manual and automated patch clamp assays are now well established for evaluating the hERG channel, but without the combined interactions with other cardiac ion channels, the induction of QT-prolongation and potentially TdP cannot be fully predicted (Lawrence et al. 2005). Ex vivo assays, such as the Langendorff preparation (perfused rabbit heart model), fair a little better with regard to predictivity but is certainly more costly and time consuming than cellular assays. At the other end of the scale, mammalian models utilizing noninvasive external telemetry to monitor, collect, and analyze a number of physiological parameters including ECG, respiration, body temperature, and activity, are the most reliable option prior to commencing human trials. But again, these come at a premium price; the typical animals (dogs) are highly regulated and generally limited in subjected number, thereby making data analysis problematic (Aylott et al. 2011), and can be the target for animal activists. Therefore, an urgent need exists for a relatively cheap, medium-high throughput, in vivo, predictive vertebrate model to help drive candidate selection earlier in drug discovery.

20.1.2 Introduction to Zebrafish and Positioning of Larval Screening in Drug Discovery

The pioneers of zebrafish research mainly focused their attention on genetics, neurobiology, and development and soon discovered a high degree of conservation compared to man, especially with regard to the embryonic vertebrate body plan (Kimmel et al. 1995; Postlethwait et al. 2000; Goldsmith 2004; Zon and Peterson 2005). Over a period of four decades, the number of academic groups working in this field grew rapidly and further similarities to mammals were established including mechanisms of toxicity and disease. As such, a series of zebrafish models were created for both efficacy and safety assessment (Grunwald and Eisen 2002; Hill et al. 2005; Zon and Peterson 2005; Lieschke and Currie 2007; Barros et al. 2008; Hill 2008a). Today, the zebrafish has become one of the most funded models by agencies such as the NIH (National Institute of Health), and over the past 5 years, an average of 3,600 zebrafish peer reviewed publications have been released annually.

As a consequence of zebrafish becoming a recognized research tool, they have also recently gained attention from the pharmaceutical sector as models for evaluating novel drug candidates. In particular, the use of larval zebrafish for assessing compounds for toxicity and safety liabilities early in the drug discovery process has been actively investigated. When treated with different toxicants, the zebrafish has comparable benefits as well as various advantages over alternative cell-based toxicity and safety assays. Measuring a mere 1–4 mm in length, a full dose-response study using embryonic or larval forms of the zebrafish can be performed in microtiter plates with only single milligrams of compound (Hill 2008a). These assays therefore share the key benefits of an in vitro assay platform, namely, the ability to screen novel compounds, usually in limited supply, before significant compound scale-up is required, and potentially in an automated fashion. In contrast, as an in vivo vertebrate model, physiological, morphological, and histological similarities to mammals and man can be observed, potentially making extrapolation of data of greater value. In addition, as a whole organism, the zebrafish larva also enables adverse physiological effects and toxicity associated with toxic metabolites to be captured (Hill 2008a), which are unlikely to be synthesized in basic in vitro screens lacking metabolic activation and necessary cell–cell interactions. However, although these zebrafish assays are very predictive in their own right, the greatest utility of such a model is as part of a front-loaded battery of assays, ideally positioned alongside or immediately after classic cell-based screens, to take full advantage of throughput, cost, and focused readouts for each assay, prior to making a fully informed decision.

Many zebrafish safety assays are relatively quick to prepare and assess, both with respect to animal sourcing and compound screening. In contrast to other vertebrates, embryogenesis is complete in just a few days and organ dysfunction can be evaluated from between 3 and 5 days postfertilization (dpf) (Westerfield 1995).

Also, with the addition of enhanced automated platforms, including liquid handling, fish recognition software, and image acquisition, data can now be compiled more efficiently. Endpoints typically assessed by monitoring changes in movement such as heartbeat (contraction of the atrium and ventricle), eye flicker (vision), and locomotion (swimming behavior, convulsion/seizure, and sedation) have been gaining support (Barros et al. 2008).

Whether assessed in a manual or fully automated assay, the zebrafish larva lends itself to being the first in vivo vertebrate model in drug discovery for studying safety pharmacology and toxicity and has the potential to bridge the gap between traditional cell assays and regulated mammalian screens. Adult zebrafish screens can also be used for focused CNS readouts and to add support to larval evaluations. Fulfilling the 3 R's principle (replace, reduce, refine) for animal testing, the use of zebrafish may help decrease the numbers of rodents needlessly treated with toxic compounds which have a safe in vitro profile and also has the potential to decrease the cost of drug development to the pharmaceutical industry by reducing late-stage attrition commonly related to drug toxicity and safety liabilities. As such, although predominantly still in a validation phase for most companies, the pharmaceutical industry is beginning to embrace the zebrafish to help advance their drug discovery programs in a cost-efficient manner.

20.1.3 Common Assay Design and Larval Maintenance

Fertilized eggs, typically obtained from paired or group breeding of AB or Tübingen strain adult zebrafish, are staged for uniform development and reared in a suitable salt-buffered media such as E3 (5 mM NaCl, 0.17 mM KCl, 0.33 mM $MgSO_4$, 0.33 mM $CaCl_2$; Westerfield 1995) or 0.3× Danieau's solution (17.4 mM NaCl, 0.21 mM KCl, 0.12 mM $MgSO_4$, 0.18 mM $Ca(NO_3)_2$, 1.5 mM HEPES, pH 7.1) in a humidified incubator at 28.5°C ± 0.5°C. Embryos or larvae can be arrayed to 384-, 96-, or 24-well microtiter plates until the desired age is reached, when test compound is added to the supporting medium in a suitable vehicle like DMSO (use of 0.5–2% final concentration has been reported). Each assay is optimized for duration and timing of exposure, although for safety-related assays, these typically begin between 2 and 10 days postfertilization (dpf) and last for 1–48 h.

Larvae can be raised in commercially available aquaria, fed on brine shrimp and common flake food, and removed as juveniles or adults as required for other kinds of safety assessment, such as ECG recording or behavioral (CNS) readouts.

All procedures must be performed in accordance with local legislation such as the UK Home Office Animals Scientific Procedures Act (1986), although certain early embryonic and larval stages of development are not currently subject to Directive 86/609/EEC which regulates the use of animals in scientific experiments.

20.1.4 How Toxicity May Impact Safety Evaluation

One of the major advantages of this model is that the zebrafish larvae are virtually transparent and develop ex utero, thereby allowing assessments of both exterior features (including the eye, fins, and jaw extension) and internal organs and tissues. Many zebrafish studies have hence concentrated on creating medium throughput assays based on phenotypic morphological aberrations which are assessable using transmitted light without the need for dissection, such as for screening hepatotoxicity (Jones et al. 2009; Hill et al. 2012) and developmental toxicity (Janaitis et al. 2007; Chapin et al. 2008; Brannen et al. 2010; Van den Bulck et al. 2011). Although toxicity models are beyond the scope of this review, chemically induced alteration to tissues or organs can have deleterious effects on various physiological processes, induce stress and secondary toxicity, and in particular can adversely affect neurological and cardiovascular function, so any evidence of necrosis, abnormal development, and acute toxicity must also be considered when evaluating more functional safety-related endpoints.

20.1.5 Compound Absorption and Metabolism

A possible complication to the zebrafish model is the typical route of exposure, namely, passive diffusion through the skin via the surrounding medium (aka aqueous exposure). Although effective levels are

commonly reached in target tissues, this will be dictated by the physicochemical properties of each compound and may result in either poor absorption and a false-negative result, or potentially rapid absorption to "overdose levels" and false-positive effects (Doshna et al. 2009). Microinjection of compound into the yolk or cardiovasculature is feasible and can be performed in a reasonably high-throughput manner in experienced hands to help control the level of exposure to larvae and adults, but this would not be as efficient as using the aqueous exposure method and without knowing how readily the compounds are circulated and deposited around the body, or metabolized and excreted, could lead to misleading results. Bioanalysis, an LCMS-MS approach, has been utilized effectively alongside aqueous exposure to evaluate the uptake of each test compound by the larvae and help rule out such complications, although this too has some limitations, especially if metabolites of test compounds are unknown. Nevertheless, this has become a valuable addition to zebrafish screening, especially as it also helps to rank compounds for toxicity and safety liabilities. A further advantage of bioanalysis is that it allows zebrafish metabolism to be investigated. This is a key factor to understand as extensive metabolism of parent compound could lead to reduced activity whereas the creation of active metabolites or metabolites with a different pharmacological spectrum of activity could lead to increased or competing/off-target pharmacology, respectively (Alderton et al. 2010). Determining the amount of compound in both dosing medium and zebrafish tissue is also important, as for some compounds metabolism can be significant and therefore mass balance needs to be established. For instance, in one study, only 35% of the testosterone exposed to larvae was recovered as unchanged parent compound after just 4 h (Alderton et al. 2010).

20.1.6 Conservation of Metabolic Pathways

One of the best known detoxification mechanisms in zebrafish is the aryl hydrocarbon receptor (AHR) pathway, mainly attributed to extensive research on dioxins and PCBs (Hill et al. 2005), but much is also known about a number of drug metabolizing enzymes, transcription factors, and transporters. For example, pregnane X receptor (PXR)-mediated induction of CYP3A and multiple drug resistance 1 (MDR1) has been demonstrated in zebrafish treated with clotrimazole, nifedipine, and synthetic steroid pregnenolone 16alpha-carboninitrile (Bresolin et al. 2005), and liver X receptors (LXRs), transcription factors activated by oxysterols with essential roles in lipid and glucose metabolism, have been characterized (Archer et al. 2008). ATP-binding cassette (ABC) protein subfamilies found in zebrafish were also found to correspond to the human subfamilies, although a single ABCH subfamily gene was unique to zebrafish (Annilo et al. 2006). Essential for the activation or inactivation of many endogenous and exogenous chemicals, with roles also associated with development and disease, cytochrome P450 (CYP) enzymes are diverse. Many of the 94 zebrafish CYP genes are direct orthologs of their human counterpart, especially those belonging to CYP families 5–51, as well as some in CYP 1, 2, and 3 with specific relevance for drug and pollutant detoxification (Mattingly et al. 2001; Tseng et al. 2005; Goldstone et al. 2010). However, only two of the 47 CYP2 genes (CYP2R1 and CYP2U1) are considered orthologs when sequences were compared to the 16 in humans (Goldstone et al. 2010). Using a variety of substrates, it has been clearly demonstrated that zebrafish embryos have the ability to perform both phase I (oxidation, *n*-demethylation, *o*-demethylation, and *n*-dealkylation) and phase II (sulfation and glucuronidation) drug metabolism reactions, thereby indicating the strong potential for this model in drug testing. Specifically, acetyltransferases (Zok et al. 1991), aldehyde and alcohol dehydrogenases (Lassen et al. 2005; Dasmahapatra et al. 2001; Reimers et al. 2004; Song et al. 2006), epoxide hydrolase (Thompson et al. 2010), glucuronyltransferases (Iannelli et al. 1994; George and Taylor 2002), glutathione *S*-transferases (Suzuki et al. 2005; Thompson et al. 2010), sulfotransferases (Liu et al. 2010), and monoamine oxidase (Anichtchik et al. 2006) have all been reported in zebrafish. However, although in many cases zebrafish metabolic profiles may be similar to mammals, such as for verapamil (Alderton et al. 2010), they may not be identical. As some atypical metabolites have also been identified, these subtle differences in metabolic pathways may therefore need further evaluation. For example, although conjugation of cisapride with glucuronic acid in mammals gives rise to cisapride *N*-glucuronide (rat, dog, and man: Meuldermans et al. 1988a, b) or cisapride *N*-sulfate

(dog: Meuldermans et al. 1988b), in 7-day-old zebrafish, only cisapride *N*-sulfate was detected following a 3-h incubation and no typical phase I metabolites (norcisapride and hydroxycisapride) were identified (Alderton et al. 2010).

20.2 Core Zebrafish Safety Assays

Included in this review are a series of the more common larval and adult zebrafish safety screens that have been developed over the past decade. As such, this is not a comprehensive list but aims to highlight benefits, advances, and pitfalls of key screens related solely to the cardiovascular system and CNS, as well as provide comparisons to earlier models and alternative in vitro and in vivo screens.

20.2.1 Cardiac Function

Various techniques, biomarkers, and models are currently available or under evaluation as surrogates for the assessment of proarrhythmia risk in humans (Joshi et al. 2004), but initially, insight into potential cardiac risk can be gained from automated patch clamp screening and concentration-response assays, especially when a comprehensive survey of cardiac channels, potentially including but not exclusive to hERG, calcium (Cav1.2, Cav3.2), potassium (HCN2, Kir2.1, Kv1.5, Kv4.3, KvLQT1/mink), and sodium (Nav1.5) channels, is undertaken. These are typically performed with mammalian cells, but studies with zebrafish myocytes have demonstrated that zebrafish also possess the majority of the known cardiac currents (Baker et al. 1997). However, these high-throughput in vitro assays are generally focused on determining the effects of compounds on specific rather than multiple cardiac channels, potentially using a single concentration instead of establishing an $IC_{50.}$ In particular, identification of potent hERG (human ether-a-go-go-related gene) blockers has typically been prioritized (Redfern et al. 2008), due to the association of hERG with some headlining withdrawals of marketed drugs in recent years, but this overdependence on the hERG assay as a preclinical cardiac risk indicator could lead to the loss of potentially useful compounds that nonselectively block hERG and other compensatory channels (e.g. voltage-gated Na^+ and Ca^{2+}). In contrast, compounds that prolong repolarization via interactions with non-hERG cardiac channels may be advanced that pose a safety risk. It is hence important to understand that the heart requires a delicate balance of multiple factors, including numerous ion channels, and therefore additional ex vivo and in vivo methods may need to be employed to verify any finding, even though these are typically expensive and time consuming (Yang et al. 2001). However, in order to predict safety concerns in man, these too need interpretation and have been difficult to develop due to complexity arising from heterogeneity within the myocardium

(Antzelevitch 2004), failure to identify effects induced only after drug–drug interaction, interspecies variation, and any individual genetic variation that potentially alters the predisposition to developing such arrhythmias (Yang et al. 2002). Nevertheless, the effect of any new drug candidate must been screened for hERG activity in vitro and for causing QT-prolongation in vivo prior to initiating human trials (FDA 2005).

In order to help identify some of these liabilities and potentially bridge the gap between in vitro and in vivo testing, various zebrafish in vivo assays have been designed and validated based on different parameters.

20.2.1.1 Cardiac Imaging and Heartbeat Assessment

PURPOSE AND RATIONALE

The potential for a drug intended for noncardiovascular indications to cause drug-induced QT interval prolongations or fatal arrhythmias, known as Torsades de Pointes (TdP), is a significant public health issue (Friedrichs et al. 2005) and remains a leading concern when screening compounds for safety pharmacology liability, especially as these adverse reactions can occur with drugs from a variety of therapeutic areas including antihistamines (Woosley 1996; Yap and Cammet 1999), antipsychotics (Glassman and Bigger 2001), and antimicrobials (Darpö 2001) as well as antiarrhythmics (Raehl et al. 1985).

hERG potassium channels conduct the rapid component of the delayed rectifier potassium current, IK_r, which is crucial for repolarization of cardiac action potentials. hERG and its zebrafish homolog (zERG) show a high degree of amino acid conservation in the S6 and pore domain (99% identity) suggesting an evolutionary conserved role (Langheinrich et al. 2003). *zERG* is expressed specifically in both heart chambers of zebrafish embryos, and when the *zERG* gene is knocked down, a distinct atrioventricular (AV) decoupling or "block" is observed (Langheinrich et al. 2003). AV decoupling is also induced when larvae are treated with compounds (hERG blockers) known to prolong QT (Langheinrich et al. 2003; Milan et al. 2003; Hill et al. 2007; Berghmans et al. 2008). A relatively simple measurement of heart rate in zebrafish larvae can hence be a rapid in vivo method to identify potential hERG liabilities as well as compounds that cause other arrhythmias.

PROCEDURE

Staged zebrafish larvae are arrayed to 96- or 24-well microtiter plates and allowed to develop in a suitable salt-buffered media until either 2 or 3 dpf, depending on the desired protocol. One to five larvae per well are treated in a dose-response format with each compound for a relatively short period, typically 1, 3, or 24 h, after which they are imaged in lateral view with a charge coupled device (CCD) or video camera, capable of a fast rate of image acquisition. For large-scale assessments of multiple blinded compounds, larvae can be screened using an automated platform.

EVALUATION

Measurements of heartbeat (number of atrial and ventricular contractions) over a period of 15–20 s are determined either manually (by eye) (Berghmans et al. 2008) or using customized software applications. In the latter scenario, video imaging using transmitted light with wild-type larvae (Langheinrich et al. 2003; Hill et al. 2009) or fluorescence imaging with transgenic larvae expressing green fluorescent protein in the myocardium (Burns et al. 2005) has been reported. Both software applications offer relatively high-throughput readouts by identifying changes in average pixel density in the region of the atrium and ventricle, and when plotted over time, the number of contractions for each chamber and average heart rate is automatically determined.

CRITICAL ASSESSMENT OF THE METHOD

The 2:1 atrial (A) to ventricular (V) contraction ratio is a surrogate for QT-prolongation and has been successfully reproduced in 2–3-day-old zebrafish larvae when exposed for 1–24 h to a variety of compounds known to prolong QT (Langheinrich et al. 2003; Milan et al. 2003; Hill et al. 2007; Berghmans et al. 2008). In addition to adverse effects on heart rate caused by hERG blockers, zebrafish also respond similarly to man when treated with classic cardioactive drugs that cause bradycardia and tachycardia (Fig. 20.1) including adrenergic or muscarinic receptor agonists and antagonist, calcium and sodium channel blockers, NO donors, and beta blockers. Classic cardiac drug–drug interactions resulting in impaired metabolic detoxification, such as with erythromycin and cisapride caused via CYP3A4 inhibition, have also been demonstrated (Milan et al. 2003).

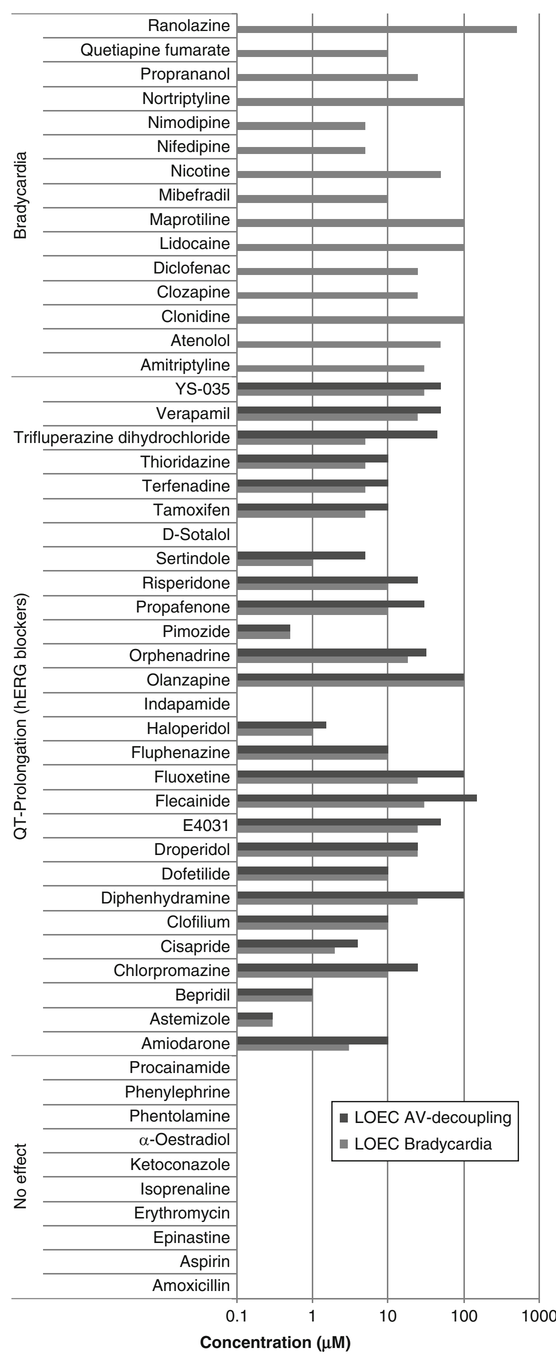

Fig. 20.1 Lowest observed effect concentrations (LOEC) in zebrafish larvae at 3 dpf for compounds causing altered cardiac function in humans. Larvae were treated in a dose-response assay for 3 h prior to imaging the heart. Compounds causing a decrease in heart rate (HR) (0–85% compared to the mean control HR) were classified as inducing bradycardia. Compounds known to cause QT-prolongation in humans elicited a greater effect on the ventricle compared to the atrium, atrioventricular (AV) decoupling, typically observed as a 2:1 AV ratio

As a whole organism, zebrafish may offer certain advantages over existing cell-based safety pharmacology assays such as the patch clamp, as in vitro screens are not considered fully predictive since they do not allow for affects on trafficking of hERG channels or effects on other/multiple ion channels to be taken into account (Kinter et al. 2004). However, more studies are required before this is fully understood in zebrafish, especially with regard to hERG trafficking as compounds such as Chromanol 293B, a specific IK_s blocker, failed to cause an adverse effect (Hill et al. 2009) whereas linopiridine and XE991, reasonably selective IK_M blockers (associated with modulating neuronal excitability) but also with activity against KCNQ1 (KCNQ1 forms the IK_s channel with KCNE1), induce bradycardia, and bepridil and clofilium, both with activity against IK_s and IK_r, cause AV decoupling (unpublished).

MODIFICATION OF THE METHOD

Correct classification of toxic compounds based purely on heart rate is generally reproducible regardless of the exact methodology, age of larvae, and duration of exposure, but in order to achieve comparable results, such as the lowest observed effect concentration, and to make the screen more widely accepted by the pharmaceutical industry, a standardized protocol should be agreed. Firstly, the use of 3-day-old larvae for these assays currently appears more common and should have the most supporting validation data. Also, as larvae can respond to certain compounds like adrenalin within just 3 min and the majority of active compounds cause an effect within 1–3 h, a 3-h period of exposure should be suitable for most cardiac assessments in this context.

As mentioned previously, a possible complication to the zebrafish model is the typical route of exposure. To investigate this possibility, Milan and colleagues (2003) microinjected hERG blockers previously classified as false-negatives with the aqueous exposure method and reported AV decoupling, and in later studies, bioanalysis, an LCMS-MS approach, has been utilized to evaluate the uptake of each test compound by the larvae and help rule out such complications (Berghmans et al. 2007a, 2008; Hill 2008a, b; Hill et al. 2009, 2012). In one such cardiac study undertaken by Novartis, three hERG blockers and one negative control compound remained unclassified due to poor uptake, thereby helping to explain the

false-negative rate. Nevertheless, of the 20 blind compounds tested, all five compounds that cause bradycardia were correctly identified along with the majority of those inducing QT-prolongation, resulting in an overall predictivity of 94% (Hill et al. 2009). In addition, with the exception of haloperidol, bioanalysis demonstrated that compounds could potentially be ranked for potency using this model with the zebrafish AV LOEC (lowest observed effect concentration) for E4031, astemizole, haloperidol, terfenadine, thioridazine, amiodarone determined as 1.0, 8.8, 50.8, 12.7, 50.6, and 182.0 ng/larva, respectively, versus the mammalian plasma LOEC for these compounds that correspondingly ranged between 0.01 and 1.8 μg/mL.

In conclusion, although this zebrafish heartbeat screen can be used to rank compounds for potency and identify those that can affect the hERG channel, as a basic readout, heart rate lacks the complexity of other methods of assessment like the ECG, and thereby the potential value of the assay is diminished when compared like with like. However, in the context of a high-throughput assay intended for use early in the drug discovery process, this in vivo model may be used to help prioritize drug candidates when in vitro assays have identified potential liabilities for hERG and other cardiac channels, or especially when liabilities have been identified for structurally similar compounds in animal models but missed previously in vitro. Notwithstanding this point, further applications have also been devised to optimize the value of such digital recordings of the beating heart.

By implementing a series of additional analytical tools, researchers have successfully assessed cardiovascular physiology in a quantitative manner by means of applying measurements for cardiac size and myocardial function (Shin et al. 2010). One such parameter, the diameter of the ventricle, can be determined at end systole and end diastole, and thereby, based on the assumption that the ventricle is a prolate spheroid, the ventricular area and volume can be calculated. Finally, by subtracting the volume of the blood in the ventricle at the end of a beat (end-systolic volume) from the volume of blood just prior to the beat (end-diastolic volume), the stroke volume can be determined, calculated for wild-type larvae as 0.16 nL (Shin et al. 2010). In addition, the potential exists with enhanced imaging capabilities for identifying drug-induced cardiac valve anomalies and regurgitation without the need for an echocardiogram as with mammals, such as demonstrated with dioxin exposure (Mehta et al. 2008). However, this has not been investigated in depth, and the translatable readout when compared to the human four-chambered heart may be somewhat limited by the embryonic larval morphology; a two chambered heart adjoined to the bulbus arteriosus and sinus venosus.

20.2.1.2 Flow Velocity

PURPOSE AND RATIONALE

In addition to measurements focused specifically on the heart, zebrafish are also amenable to imaging the cardiovascular system. As reviewed previously by Hove (2004), numerous methods of in vivo biofluid dynamic imaging have been reported. For example, by tracking the movement of blood cells with specialized video image capture systems and confocal microscopy, the blood vessel diameter can be established and blood flow (cell velocity) determined (Schwerte and Pelster 2000). These parameters are useful as they allow the calculation of cardiac output, vascular resistance, and contractility. However, the use of Doppler ultrasound with adult zebrafish (Ho et al. 2002) marked a significant advancement in imaging the heart and blood vessels, especially as ultrasound biomicroscopy (UBM) systems provided an estimation of blood flow in the microcirculation at a sensitivity of a few millimeters per second (Foster et al. 2002). This was later developed further for the assessment of adults as a high-frequency ultrasonic system (Sun et al. 2008) offering valuable insight into the cardiovascular system.

PROCEDURE

According to Sun et al. (2008), wild-type adult zebrafish of similar size (1 year old) were anesthetized by submersion in 0.08% MS-222 for 30 s before scales were gently removed at the ventral side between the gills. While under anesthetic (0.04% MS222) and maintained at 27.5°C, fish were positioned for precise imaging of the ventricle and bulbus arteriosus with an ultrasound probe. The probe was lowered into the MS222 solution until it reached a distance of 3 mm from the skin and rotated and fixed, as required, to obtain Doppler waveform images along various planes in real time. Fish were euthanized in a 1% MS222 (submersion for 15 min) after completing the assessment of cardiac size and blood flow measurements.

During imaging, an area (4 mm by 4 mm) was scanned at a frame rate up to 200 images per second. A 115-µm sample volume length was chosen, and a pulse repetition frequency of 11 KHz was utilized.

EVALUATION

Doppler waveforms were estimated using a method previously described (Jensen 1996). Further detailed information regarding the equipment settings can be obtained from Sun et al. (2008).

CRITICAL ASSESSMENT OF THE METHOD

Using this method, Sun et al. (2008) determined the dimensions of the atrium and ventricle as 0.81 × 0.58 mm and 1.19 × 0.62 mm, respectively, and found the cardiac cycle and corresponding heart rate to be 650 ± 175 ms and 93 ± 25 beats per minute (mean ± SD). The peak E and A velocities, where (E) represents early diastolic filling and (A) late diastolic filling, were 3.6 cm/s and 14.4 cm/s, respectively. In agreement with Ho et al. (2002), the E/A ratio was calculated as 0.25. UBM was therefore validated as a suitable method for real-time assessments of the heart, allowing dimensions of each chamber to be taken and measurements for cardiac function and blood flow to be established in vivo (Sun et al. 2008).

Dual-beam Fourier domain optical Doppler tomography (FD-ODT) has also been used to analyze blood velocity in zebrafish, but in contrast to the previous studies, this was undertaken in larvae. In addition to the typical advantages of using larvae instead of adults, in comparison to UBM, this generated high-resolution three-dimensional images and accurately measured absolute flow rates in major vessels of the larvae (Iftimia et al. 2008).

However, other ways of assessing cardiac function and blood flow velocity have also been made possible through technological advancements in the field of microscopy. For example, cell velocity has also been evaluated by laser-scanning velocimetry (Malone et al. 2007). In addition, as analytical and imaging tools have recently been developed that can identify and track individual blood cells, frame by frame, in a series of sequential still images with a high-speed camera at high temporal resolution (Shin et al. 2010), this may offer a significant advantage over Doppler imaging in terms of throughput and the decreased need for specialized equipment. As such, custom algorithms using the coordinates of these cells over a set time, determined by the number of frames, can be processed and normalized to establish erythrocyte flow velocity (FV). In one study, image analysis was undertaken from at least ten frames prior to the onset of systole and continued until at least ten frames into the second systolic acceleration, thereby encompassing an entire cardiac cycle (Shin et al. 2010). They determined a mean FV value of 685 μm/s (peak systolic and diastolic FV, 1,644 and 206 μm/s, respectively), which is comparable to a mean FV of between 291 and 766 μm/s previously reported (Bagatto et al. 2006).

20.2.1.3 ECG

PURPOSE AND RATIONALE

As the electrocardiogram (ECG) is a common diagnostic tool for humans, any model species that can successfully reproduce or mimic the ECG trace would be considered in preference to other safety cardiac assays by the pharmaceutical industry and regulatory bodies. A typical ECG of the human heart has five deflections, arbitrarily named “P” to “T” waves. The Q, R, and S waves occur in rapid

succession and appear centrally as the most prominent part of the ECG trace. This QRS complex corresponds to the depolarization of the right and left ventricles whereas the T wave represents the repolarization. Therefore, the time between the start of the Q wave and the end of the T wave in the heart's electrical cycle, known as the QT interval, represents electrical depolarization and repolarization of the left and right ventricles. The P wave corresponds to the depolarization of the atria.

In zebrafish studies, two electrodes can be placed either side of the heart to detect and amplify tiny rises and falls in the voltage during each contraction. Depolarization can therefore be traced as it is initiated in the sinoatrial node, progresses as a wave through the atrium, before passing through into and over the ventricles. Therefore, in addition to being a sensitive device for monitoring the overall rhythm of the heart, the zebrafish ECG can also help identify weaknesses in different parts of the heart muscle.

PROCEDURE

Electrocardiograms on adult zebrafish have previously been undertaken (Milan et al. 2006). In brief, zebrafish of the same strain were selected with similar mass and heart size. Two needle electrodes were inserted through the ventral epidermis of each paralyzed adult, one between the pectoral fins and the other at two thirds of the body length away from the head. Zebrafish were orally perfused with 10 mM HEPES (pH 7.5) in E3 medium for 10 min before taking baseline recordings and exposing the fish with test compound diluted from DMSO stocks in E3. To help match the traces with each contraction, the beating heart was simultaneously imaged with a CCD camera. This was synchronized with the electrical recording by pulsing a light-emitting diode in the optical field and recording the electrical stimulus artifact.

EVALUATION

All recordings were processed offline and were accepted only if they met a defined criteria including achieving a minimum amplitude and maintaining signal stability (Milan et al. 2006). Unpaired two-tailed t-tests were used to compare the means of normally distributed continuous variables (P values ≤ 0.05). The observed QT interval was also corrected for variations in heart rate by applying a mathematical calculation.

CRITICAL ASSESSMENT OF THE METHOD

Two distinct issues discussed by the authors were overcome for this study. Firstly, as hypoxia was shown to cause bradycardia and more severe phenotypes within 30 min, the use of a perfusion system to maintain fish hydration and oxygenation was implemented to allow sufficient time for stable ECG recordings. Secondly, as identified for other ECG studies (Egorouchkina et al. 2005), due to the nature of these kinds of readouts, extensive computerized processing of the electrical recordings was necessary, especially with regard to filtering out noise from the signal. Appropriate screening criteria and algorithms developed for offline data processing were hence devised. Signal averaging helped reduce electromyographic noise, although Milan and colleagues demonstrated that skeletal muscle paralysis with an intraperitoneal injection of CTX was necessary to achieve optimal noise reduction. Finally, it was noted that subtle differences in the settings for the ECG, such as reducing the cut-off frequency, and precise electrode placement and heart orientation was required to achieve successful and reproducible recordings.

MODIFICATION OF THE METHOD

No distinct modifications are considered necessary to this assay, although the need for data processing, correct use of the equipment, and likelihood for further adjustments on a case-by-case basis may indicate this assay may be better suited for researchers experienced in this field.

The adult zebrafish ECG has been shown by Milan and colleagues (2006) to be an efficient way to investigate drug-induced adverse effects on heart function, including QT-prolongation, and can add value to supporting the zebrafish as a comparable model species to other vertebrates. In addition, based on the similarity of the mean QTc for adult wild-type zebrafish (416 ± 8 ms) compared to the normal value for humans (typical range 300–450 ms) (Arnaout et al. 2007), these readouts may also be easily translatable to man. However, in terms of throughput and difficulty, one should consider whether small savings in cost and time would warrant the use of zebrafish instead of proceeding directly to well-established mammalian ECG models. Larval ECGs have also been attempted (Forouhar et al. 2004), but contrary to other larval-based screens, this method too has some limitations associated with assay throughput. In addition, although

these studies have successfully recapitulated the adverse effects of certain hERG blockers shown in man, these studies have only assessed a relatively small set of compounds, so it remains to be determined whether other compounds known to affect the heart can be identified.

Finally, as specific electrocardiographic approaches are required for humans in order to diagnose different conditions, for example, ST-elevation myocardial infarctions can be detected using the resting ECG, whereas exercise ECG is better suited for the diagnosis of stable coronary artery disease (Huebner et al. 2010), the zebrafish ECG in its current form may or may not be a suitable model for studying or modeling other cardiac disorders. However, in the future, there may be alternative uses for the zebrafish ECG for investigating heart phenotypes related to toxicity or disease, possibly in concert with transgenic or mutant lines of zebrafish.

20.2.1.4 High Resolution Voltage Detection: Action Potential Evaluation

PURPOSE AND RATIONALE

In contrast to ECG, more technical and cutting-edge molecular technologies have also been utilized in order to investigate the intrinsic electrical conduction of the embryonic and larval heart. These tend to utilize either transgenic larvae or fluorescent markers and can visualize electrical activity in certain regions of the heart or characterize the temporal-spatial pattern of activity throughout the whole atrium and ventricle. One such example is high-resolution optical mapping with voltage-sensitive dyes such as di-4 ANEPPS, a fluorescent reporter of transmembrane potential, that allowed a comprehensive assessment of cardiac repolarization throughout the heart (Milan et al. 2009; Peal et al. 2011).

PROCEDURE

In the study described by Milan et al. (2009), the hearts from embryos obtained from pairwise crosses of AB zebrafish were excised at 48 hpf by microdissection in modified Tyrode's solution (136 mM NaCl, 5.4 mM KCl, 0.3 mM NaH_2PO_4, 1.8 mM $CaCl_2$, 1 mM $MgCl_2$, 5 mM glucose, 10 mM HEPES, 2% BSA). Those exhibiting spontaneous beating were treated with 15–17 mM 2,3-butanedione monoxime, a myofibrillar ATPase inhibitor, in order to stop cardiac motion and then bathed in a 7-μM solution of di-4-ANEPPS for 10 min immediately prior to imaging. Hearts were field paced at 60 min^{-1}, and electrical activity of the isolated hearts was captured in a customized chamber using a CCD camera with appropriate fluorescence illumination.

EVALUATION

The authors used Cardioplex software to perform analyses including exponential subtraction of baseline photobleaching. Action potential durations (APDs) were determined from an average of three or more successive heartbeats (calculated at 90% repolarization). Signal averaging of five successive action potentials was performed using Clampfit to reduce signal noise.

CRITICAL ASSESSMENT OF THE METHOD

This method was used to help investigate the underlying biology of AV-decoupling and a network of genes that regulate cardiac repolarization. For instance, it was determined that wild-type embryos exposed to the hERG blocker dofetilide and homozygous breakdance mutants (possessing a KCNH2 mutation that phenocopies long QT (LQT) type 2 syndrome, the life-threatening disorder in humans associated with prolongation of cardiac repolarization) exhibited the typical 2:1 AV block due to marked prolongation of ventricular refractory periods (Milan et al. 2009). Furthermore, as part of a pharmacogenetic screen

investigating myocardial repolarization, Milan and colleagues used this method to identify 15 out of nearly 300 insertional mutants not exhibiting AV block after being sensitized with 12 μM dofetilide, thereby successfully identifying novel genes that modify the cardiac response to IK_r blockade. Also, using this approach, a small-molecule screen of 1,200 compounds was undertaken with the breakdance mutant zebrafish, resulting in the identification of two molecules that rescued the LQT type 2 phenotype by shortening the ventricular action potential duration (Peal et al. 2011). These included flurandrenolide that was claimed to function via the glucocorticoid receptor-mediated pathway. In addition, compounds like verapamil that act on hERG and the Ca^{2+} channel tended not to have any effects on arrhythmia risk even if QT was prolonged. This method thereby offered the next level of complexity to zebrafish cardiac readouts at higher resolution than ECG and led to several scientific achievements.

As this model requires hearts to be excised prior to staining and assessment, this adds an additional level of technical expertise and processing time to the assay. A potential alternative noninvasive method was previously reported by Arnaout et al. (2007) who demonstrated how monitoring Ca^{2+} release as a surrogate in vivo readout could be used to assess atrial and ventricular conduction. In this study, calcium cycling was captured using a cardiac-specific transgenic line of zebrafish (Tg(cmlc2:gCaMP)^{s878}) that expressed a voltage-sensitive fluorescent calcium indicator know as gCaMP (Nakai et al. 2001). At 48 hpf, systolic Ca^{2+} release, recorded as repetitive waves of fluorescence, could be observed transferring from atrium into the ventricle via the atrioventricular junction (Arnaout et al. 2007). However, as selective plane illumination microscopy (SPIM) (Huisken et al. 2004) was used to image the conduction waves, these were only visible in the chosen plane of view (a thin slice of the heart chambers), not the whole heart. It was also necessary to prevent contraction of the heart by injecting a silent heart cardiac troponin (tnnt2) morpholino at the 1-cell stage. Therefore, in conclusion, the potential benefits of the ex vivo optical mapping method should outweigh that of the in vivo calcium indicator model.

MODIFICATION OF THE METHOD

No modifications are as yet identified.

20.3 CNS

Zebrafish possess comparable brain morphology and signaling pathways as with other vertebrates and have therefore been a key model for investigating both neurobiology and neurological disease (Guo 2004; Mathur and Guo 2010; Rinkwitz et al. 2011). Importantly, dopaminergic, noradrenergic, cholinergic, and serotonergic neurotransmitter pathways have been mapped (Rink and Wullimann 2004; Wullimann and Mueller 2004; Maximino and Herculano 2010; Lillesaar 2011 in press), and a blood-brain barrier can be observed in larvae between 3 and 10 days postfertilization (dpf) (Goldsmith and Fleming 2007). In particular, endothelial cells exhibiting tight junctions in cerebral microvessels can be observed from 3 dpf by implementing permeability studies with horseradish peroxidase and fluorescent tracers (Jeong et al. 2008). Zebrafish should therefore be suitable as an alternative in vivo vertebrate CNS model for assessing the safety and efficacy of new neurological drug candidates.

20.3.1 Locomotor Assays

PURPOSE AND RATIONALE

Zebrafish are amenable to relatively high throughput neurobehavioral screening via locomotor-based

tracking assays from 96 hpf when they are free swimming (Drapeau et al. 2002), and as such can be used to monitor various drug-induced effects on activity including sedation, stimulation, and convulsion (Zhdanova et al. 2001; Barros et al. 2008; Bate et al. 2010), as well as sleep patterns, learning, and potential drug addiction (Zhdanova et al. 2001; Cahill 2002; Guo 2004; Orger et al. 2004; Ninkovic et al. 2006; Mathur and Guo 2010; Stewart et al. 2011). These semiautomated screens can simultaneously quantify parameters such as distance moved, speed, number of movements over time, and even response to startle stimuli, similar to those used in rodent safety pharmacology assessments.

PROCEDURE

One of the first automated locomotor assays was used to investigate the activity of larval zebrafish on a circadian time scale (Cahill et al. 1998). They demonstrated that time-lapse video image analysis could be performed simultaneously on 100 larvae using a single recording system with custom specimen plates, temperature controlled imaging system, and analytical software. In this study, larvae from the AB strain of zebrafish were arrayed 1 per well and assessed for 130 h from 10 dpf at 28.5°C. A series of 60 images was collected every 4–5 min at a rate of 1 per second. No food was provided during the recording period. In order to enhance the contrast of the fish for imaging with a CCD camera, the larvae were backlit by placing a mirror beneath the specimen plate. This allowed a pixel value threshold to be used to distinguish the fish from the lighter background and monitor movement frame by frame. To allow movement to be tracked throughout the day and night, an infrared (IR) camera was used to record the images.

A few years later, this method was modified by Zhdanova et al. (2001) who assessed Tubingen strain larval zebrafish between 7 and 14 days old in constant darkness, also using an infrared camera. In this case, larvae were backlit by an 880-nm IR source, and a custom software program designated "FishWatch" captured the movements of 60 fish. After a 2-h basal recording, larvae were treated with different compounds (melatonin, diazepam, and pentobarbital) and then imaged for a further 2 h in consecutive 15-s intervals. It was noted that the onset of behavioral effects caused by exposure to the test compounds typically occurred within 20 min after treatment (Zhdanova et al. 2001).

Since these early studies, imaging hardware and software based on these methods has become commercially available for the purpose of tracking small organisms such as zebrafish larvae. For example, Berghmans et al. (2007) captured and assessed the locomotor activity of larvae from the WIK zebrafish strain from 6 dpf using EthoVision 3.1 locomotion tracking software (Noldus, Wageningen, The Netherlands) and imaging apparatus containing a high-resolution digital video camera and IR light source for image capture in the dark. In this study, larvae were arrayed in 96-well plates, 1 per well, 12 larvae per treatment group, and co-treated for 24 h with defined concentrations of test compound and pentylenetetrazole (PTZ, 20 mM). Concentrations of test compound were determined from a dose-ranging assay in which the maximum tolerated concentration (MTC) was established. The main parameter used in this locomotor assessment was the mean total distance moved for each treatment group, based on a 60-min recording. As PTZ treatment was shown to induce a distinct series of movements resembling tonic-clonic seizures (Baraban et al. 2005), the aim of this study was to identify antiepileptic drugs, those that ameliorated the PTZ phenotype (Berghmans et al. 2007).

EVALUATION

When evaluating the adverse effects of compounds on zebrafish larvae, any significant increase or decrease in locomotor activity was determined by making comparisons with positive control, sham, and vehicle control larvae.

Compounds co-treated with PTZ were considered to have potential antiepileptic activity if treatment groups exhibited a statistically significant reduction in the total distance moved in comparison to PTZ-only control treatment groups. For the purpose of quality control, the PTZ treatment group had to show a significant increase in locomotion in comparison to the vehicle controls and no significant increase of locomotion had to occur for larvae treated with the test drug alone.

Data is typically analyzed by Student's *t*-test or one-way analysis of variance (ANOVA), followed by post-hoc comparisons between the experimental groups, such as using Tukey' test (significance $P = 0.05$).

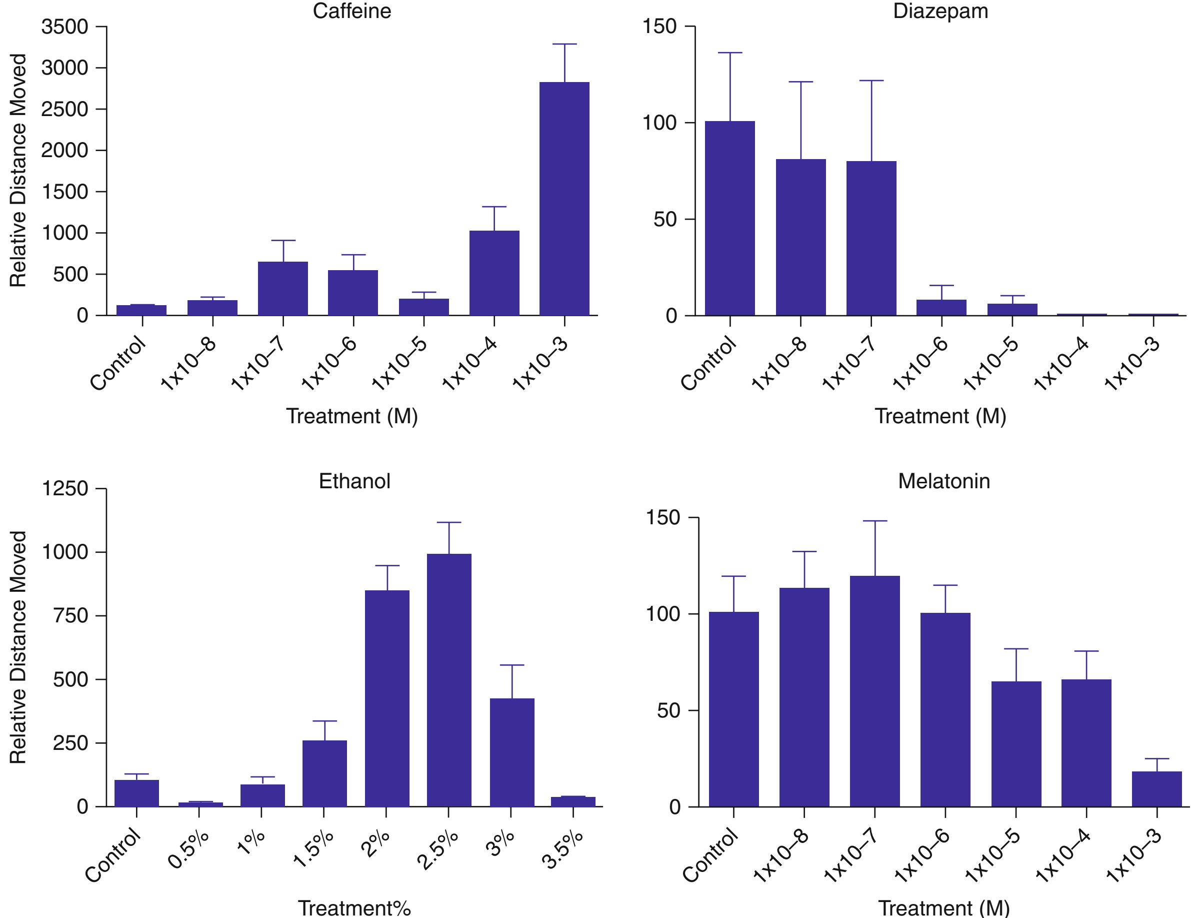

Fig. 20.2 Effect of stimulants and sedatives on zebrafish larvae at 7 dpf assessed via locomotor activity. Exposure to caffeine and ethanol causes increased movement (hyperactivity) whereas diazepam and melatonin induce a sedative effect. Concentrations of ethanol greater than 3% lead to toxicity

CRITICAL ASSESSMENT OF THE METHOD

During the early studies, problems were commonly associated with the software failing to identify the larvae. Cahill et al. (1998) reported that, in some cases, often when fish were inactive near the bottom of the well, a fish was not recognized because too few pixels crossed the given threshold. This therefore led to a possible underestimation for the locomotor activity as these instances were recorded as if the larva had not moved. They also noted that on occasion the software misinterpreted the background as an object or recorded two or more separate locations for the larvae, again due to subtle changes in pixel value. In contrast, as software became more advanced, new ways to identify and monitor the larvae were implemented, such as the use of different reference points on a larva including the eyes and swim bladder, to distinguish fish from other potential artifacts like air bubbles or shadows.

Nevertheless, the locomotor platform in various forms has successfully demonstrated that zebrafish larvae respond to certain compounds in a similar fashion as exhibited by man. For example, sedatives such as melatonin, diazepam, and pentobarbital have caused hypomotility (Fig. 20.2; Zhdanova et al. 2001) whereas stimulants including caffeine and low-medium doses of ethanol (Fig. 20.2; Lockwood et al. 2004) have caused hyperactivity. Although at high concentration (>3–4%), ethanol reduced locomotor activity, leading to toxicity and ultimately lethality. In addition, as noted previously, exposure to PTZ caused a dramatic increase in swimming speed in

combination with rapid circling and the induction of a series of postures and movements, culminating in generalized clonus-like seizures. This is a reproducible phenotype that has been used for large-scale screening for antiepileptic drugs which ameliorate the response (Berghmans et al. 2007; Bate et al. 2010). However, larvae have not always responded as expected after exposure to certain compounds. In fact, as a larval model for seizure liability assessment, this video-tracking method for identifying characteristic chemically induced changes in locomotion only achieved a predictivity of 72% in one study consisting of 25 blinded compounds, including the convulsants 4-aminopyridine, amoxapine, bemegride, maprotiline, picrotoxin, semicarbazide, and strychnine (Winter et al. 2008). As such, in the context of a high-throughput in vivo screen aimed at determining potential liability very early in the drug discovery process, this level of predictivity as a standalone assay may or may not be considered acceptable, and the future use of the assay may be dictated by how zebrafish respond to specific classes of compounds and whether these compounds are typically misclassified in vitro, in which case, the zebrafish assay could prove more advantageous. However, when applied in a cascade of assays alongside in vitro screens like brain (hippocampal) slice electrophysiology, the combined approach would be more valuable, offering increased specificity and sensitivity when compared to the outcome of each individual assay (Easter et al. 2009). This should therefore help prioritize candidate drugs before testing in the more expensive, yet more predictive, rodent behavioral seizure assays or the gold standard electroencephalogram (EEG).

MODIFICATION OF THE METHOD

As these methods are still evolving and are now predominantly commercialized with proprietary software and hardware, it is difficult to focus on specific modifications. On the whole, the key requirements that will enable this method to be widely accepted is the assessment of more validation compounds using a variety of parameters for analysis and a greater understanding and optimization of the protocol used to treat the larvae with compounds. Altered locomotion in response to subtle changes in concentration, confusion between a toxic and sedative response, and different results depending on the duration of compound exposure all need to be investigated further.

20.3.2 Behavioral Analysis: Cognitive Flexibility

PURPOSE AND RATIONALE

Some of the most complex and important CNS models involve the study and evaluation of behavior. Similar to established mammalian models, software has been developed to monitor the swimming behavior of fish in tanks as well more classical maze designs. To date, this has been attempted with both larval and adult zebrafish using a variety of platforms involving learning and memory tests, essential for determining the underlying molecular mechanisms of cognitive function.

Although more studies are required before the cognitive ability of zebrafish is fully understood, certain molecular factors have already been implicated (Pradel et al. 1999, 2000). Support for the use of fish cognition models is also available from other species. Goldfish for instance were one of the first fish to be studied and have been documented showing habituation to a fear response (Brookshire and Hognander 1968; Laming and Ennis 1982), short-term memory (Ohnishi 1997), and appetitive learning enhancement (Spieler et al. 1999). Toxicological studies were also used to demonstrate that compounds like atrazine can affect basic social behaviors such as grouping (Saglio and Trijasse 1998), fear responses can be altered by endorphins (Olson et al. 1978), and dizocilpine can impair escape learning (Xu and Davis 1992; Davis and Klinger 1994; Xu 1997).

Similarly, zebrafish have been observed responding to a manner of basic stimuli. In particular, early research utilized a defensive behavior linked to an antipredatory alarm response. For example, Hall and Suboski (1995) demonstrated that fish can be trained to react to harmless olfactory and visual stimuli in the form of an escape response if first presented to fish together with an alarm substance, a pheromone released under stress or injury. In contrast, in a later study, fish were trained within 3 weeks to swim to one side of the tank after an acoustic signal (tapping on the side of the tank) that represented the imminent delivery of food (Williams and Messer 1998). These kinds of investigations therefore set the scene for more complex learning paradigms.

PROCEDURE

In order to monitor several adult fish in a single assay, it may be necessary to permanently label them with a marker. In one example, zebrafish were anesthetized with MS-222 (84.5 mg/L) and subcutaneously injected with a fluorescent elastomer (Arthur and Levin 2001).

Depending on the hypothesis being tested, various designs of maze can be utilized. These can involve customized aquaria, such as a classic Y- or T-maze, or can be relatively simple apparatus consisting of static walls or moveable doorways intended to partition a standard tank. In the latter case, the most basic method is to separate the tank into two, thereby designating one half to be the "start" chamber and the other as an "escape" chamber (Fig. 20.3). Multiple partitions can then be added to provide alternative choices for escape, each with a differentiator (e.g. color, light/shade, chemical, etc.). Various stimuli can then be applied to test the immediate escape and/or avoidance response and repeated several times throughout each week to evaluate reinforcement of learning.

Threat avoidance: In the preliminary study by Arthur and Levin (2001), the aversive stimulus was in the form of a fishnet. After a period of acclimation, the net was lowered into the tank and a door was opened to an escape chamber. For one test group (fish tested individually), the net was then moved back and forth, whereas for a second group, the net remained stationary. The escape or avoidance latency was recorded over six repeat assays, after which the situation was reversed, so the fish used to the stationary net were observed how they responded to a moving net and vice versa.

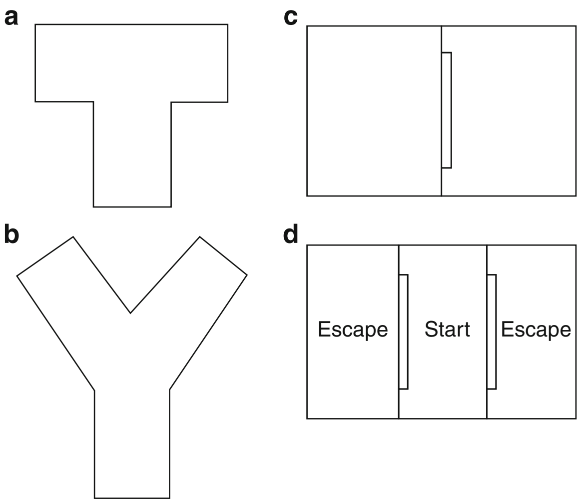

Fig. 20.3 Examples of classic maze designs for studying zebrafish behavior. (**a**) T-maze, (**b**) Y-maze, (**c**) two-compartment design with a single sliding door separating the chambers, and (**d**) three-compartment design with a central start chamber flanked either side by left and right escape chambers

Discrimination: Arthur and Levin (2001) continued to describe a similar assay, but in this study, they used a three-compartment maze with a central start chamber and two choices for an escape chamber (left and right): one predesignated as a "safe" chamber and the other as a "punishment" chamber (Fig. 20.3d). After a period of acclimation, the aversive stimulus was again lowered into the tank and moved back and forth. The net was removed if the fish entered the safe chamber, whereas those in the punishment chamber were subjected to further stimulation by the net. Two sets of fish were trained, one with the safe chamber on the left and the other on the right side of the tank. This exercise was repeated, 3 trials per session for 10 sessions. As performed previously, the assay was also repeated, but the punishment and safe chambers were reversed partway through the exercise (3 sessions prior to switching and 18 sessions afterwards).

EVALUATION

Zebrafish were scored for avoidance or escape learning depending on whether they reacted before (avoidance) or after (escape) the start of the stimulus. Latency was measured in seconds (mean ± SEM). The duration of the acclimation, stimulus, and punishment (where applicable) was strictly controlled, and no fish were touched with the net. The readouts from two sessions were averaged to assess performance.

CRITICAL ASSESSMENT OF THE METHOD

While the larval capacity for learning has been investigated via assessing altered responses and habituation to acoustic, touch, or visual stimuli (Best et al. 2008; Aizenberg and Schuman 2011), adult models are generally accepted to be more robust. This may be because the neural circuitry (Kastenhuber et al. 2010), endocrine systems (Kimmel et al. 1995), and neuromuscular systems (Dou et al. 2008) are not fully established at the earlier stages of development and thereby larvae may not always display the complex behavior of their adult counterparts, or may be attributable to certain screening parameters which can be used and optimized in such adult studies.

Due to the adaptability of the basic model that relies on assessing spatial and temporal tracking of the zebrafish, different test conditions and assay parameters can be applied to examine different hypotheses. The outcome of the initial threat avoidance study revealed that only fish regularly exposed to the stimulus (moving net) learned to escape the threat by swimming into the adjacent compartment, and when exposed to a stationary net, upon reversal of the test, these fish suppressed the escape response (Arthur and Levin 2001). The discrimination study demonstrated that fish could be trained within six sessions to avoid the punishment chamber and after the chambers were reversed, rapidly adapted. In addition, discrimination based on color was also demonstrated in another more complicated version of this study which used red and blue chambers to dictate which one was the punishment chamber. Once again, the fish learned to identify the safe chamber, even though it had to be determined from a visual versus a spatial cue (Arthur and Levin 2001).

In addition to conditioning the fish to display these behaviors when discrimination is related to a spatial or nonspatial, visual, or olfactory-based response, evidence of reversal and extinction have also been demonstrated when the assay parameters were changed, thereby indicating zebrafish possess cognitive flexibility.

MODIFICATION OF THE METHOD

Further modifications to these models have demonstrated that adults can respond to alternating feeding zones (Williams et al. 2002) or associating a food

reward with certain colors placed in the tank (Colwill et al. 2005) and reliably exhibit avoidance behavior when exposed to other adverse stimuli such electric shock (Xu et al. 2007). Also, as zebrafish have responded well when treated during development to compounds that enhance learning such as nicotine (Arthur and Levin 2001) or impede learning and cause memory deficits like lead and ethanol (Carvan et al. 2004), these studies add further support to the use of zebrafish in neurobehavioral screening.

Finally, a conditioned place preference (CPP) model can be used to evaluate the reward reinforcement properties of a test compound. In these studies, the zebrafish are allowed to choose a preferred location or compartment, after which a compound is added to the least preferred compartment and the zebrafish are observed to establish whether their preference in location changes, as demonstrated with cocaine and D-amphetamine (Darland and Dowling 2001; Ninkovic et al. 2006). In addition, as discontinuation of a nonanesthetic dose of cocaine leads to anxiety-like state consisting of hyperactive behavior and this increase in motility can be subsided by either treatment with diazepam or reinstatement of cocaine exposure, the adult zebrafish may also be a potential model for testing drug withdrawal (Lopez-Patino et al. 2008). These findings are supported by Cachat et al. (2010) who demonstrated that withdrawal of diazepam, ethanol, and morphine also produced anxiogenic-like behavioral responses as well as changes to the stress marker cortisol. Likewise, microarray analysis of ethanol- and nicotine-treated zebrafish, also showing the reward CPP response, confirmed that neuroadaptation pathways implicated in drug dependence were conserved between zebrafish and mammals (Kily et al. 2008). However, when performing assessments for anxiety-related phenotypes, the choice of zebrafish strain is important as certain mutants, including albino and leopard, have a higher baseline anxiety compared to wild-type strains and hence may be better suited for testing anxiolytics (Egan et al. 2009).

21.1 Introduction

In order to get an insight into the mechanisms of action, efficacy, the pharmacokinetics, side effects, and toxicity of a compound for clinical use, it is essential to perform studies in animal models. In preclinical studies, rodents such as rats and mice serve as an important tool for drug development. In addition, dogs, monkeys, pigs, and some other large animals are of great importance in preclinical safety evaluation. Safety pharmacology is an essential part of this process. This review will concentrate on published data within these groups of experimental animals under the special focus whether and to what extent biological rhythms are involved in studies using these animal models.

When going into detail concerning the published data, it is obvious that by far, the most data were obtained in rats and mice. Much less studies under a chronobiologic design were performed in large animals. This situation will be mirrored by composition of the review.

It is interesting to note that already in 1838, Kreutzer mentioned in his Handbook of Veterinary Medicine that daily variations exist in drug effects in animals (Kreutzer 1838).

21.2 The Biological Clock

Rhythmicity is the most ubiquitous feature of nature. Rhythms are found from unicellular to complex multicellular organisms both in plants, animals, and men. Living organisms are continuously influenced by external stimuli, many of which have rhythmic patterns. Environmental rhythms in daily and seasonal

patterns of light, food availability, temperature, etc., are predictable, and animals – including humans – have the ability to anticipate these environmental events with periodically and predictably changing internal conditions. These rhythmic patterns of anticipation have clear advantages and survival value (Strubbe and Woods 2004). The frequencies of rhythms in nature cover nearly every division of time. There are rhythms which oscillate once per second (e.g., in the electroencephalogram), once per several seconds (respiratory rhythm, heart rate), up to rhythms which oscillate once per year (circannual rhythm).

Table 21.1 Major hemodynamic parameters and duration of ECG intervals (mean ± SD) obtained by telemetry from freely moving beagle dogs and cynomolgus monkeys collected around 10–11 a.m. (adapted from Soloviev et al. (2007)), minipigs during daytime (adapted from Stubhan et al. (2008)), and CD(SD) rats collected around 9–11 a.m. (Adapted from Atterson P., WIL Research Laboratories - Historical control summary of hemodynamic values for male CD(SD) Rats (Body weight range: 239 – 453g), Personal communication 2011)

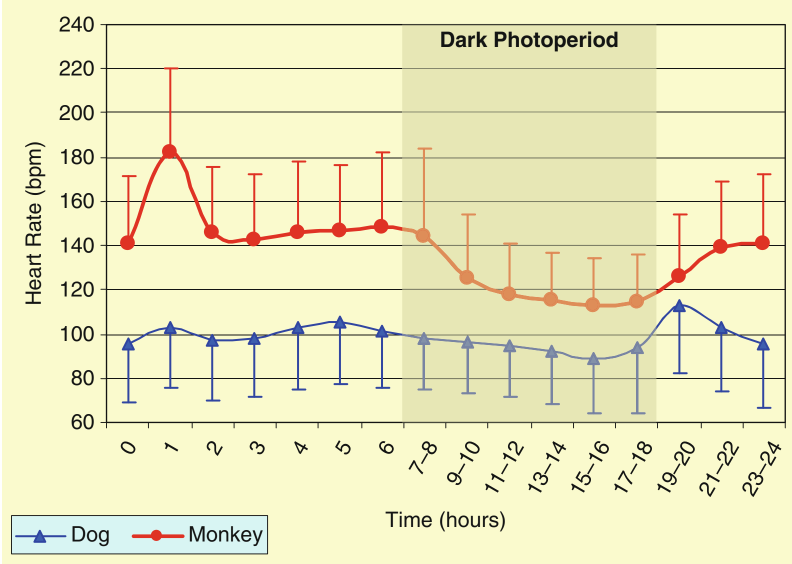

Fig. 21.3 Daily variations (mean ± SD) of the heart rate in dogs and monkeys (Adapted from (Soloviev et al. 2006c))

The most evident environmental change which results from the regular spin of the earth around its central axis and resulting in the alternation between day and night seems to have induced the predominant oscillation, the circadian rhythm (the about-24-h rhythm; circa = about, dies = day, as proposed by (Halberg 1959, 1969)). There is sound evidence that living systems including humans are not only organized in space but are also highly organized in time. One of the first observations on a rhythmic pattern in man was presented by the famous physiologist Sanctorius Sanctorius in 1664 when he described in a self-experiment daily variations in body weight due to transpiration, his famous experimental setting is shown in Fig. 21.1 Sanctorius (1644).

Circadian rhythms have been documented throughout the plant and animal kingdom at every level of eukaryotic organization. Circadian rhythms by definition are endogenous in nature, driven by oscillators or clocks (Aschoff 1954, 1963a, b, 1965), and persist under

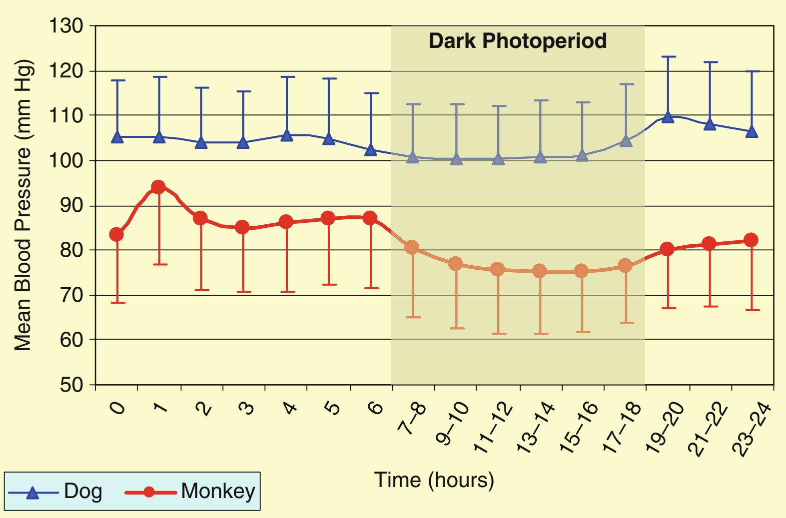

Fig. 21.4 Daily variations of the mean blood pressure (mean ± SD) in dogs and monkeys (Adapted from (Soloviev et al. 2006c))

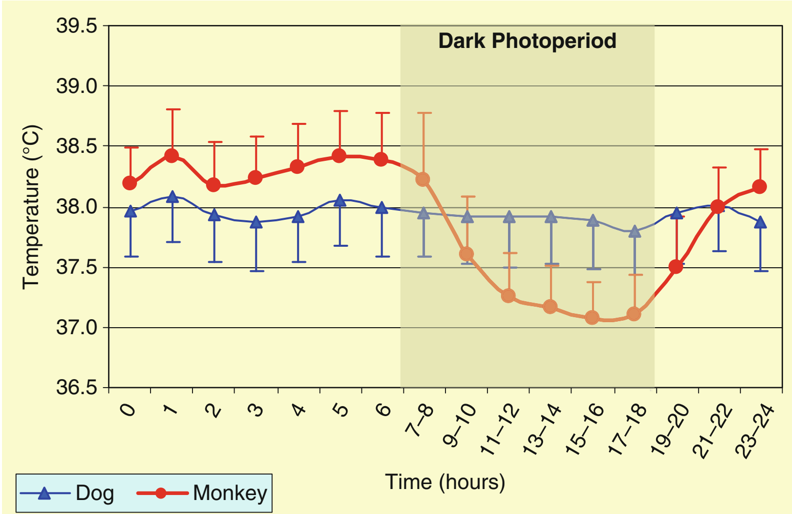

Fig. 21.5 Daily variations of the core body temperature (mean ± SD) in dogs and monkeys (Adapted from (Soloviev et al. 2006c))

free-running conditions. In various species (e.g., *Drosophila melanogaster, Neurospora,* mouse, golden hamster, rhesus macaque, man), the genes controlling circadian rhythms have been identified (genes: *per, frq, clock, tau, Rev-erb alpha*) (Hall 1998; Takahashi 1992; Sitzmann et al. 2008; Hastings 1998; Reppert 2000; Albrecht 2002). In 1971, Konopka and Benzer (1971) were able to identify on the X chromosome of *Drosophila* a region which controlled the period in the eclosion rhythm of three mutants (*per* clock gene). In 1984, Bargiello et al. demonstrated that a fragment of the *per* gene injected into embryos of an arrhythmic mutant of *Drosophila* could restore rhythmicity in eclosion (Bargiello et al. 1984). This data provided the first evidence that the biological clock is genetically determined and can even be transplanted from one animal into another, thereby inducing the rhythmicity of the donor into the recipient.

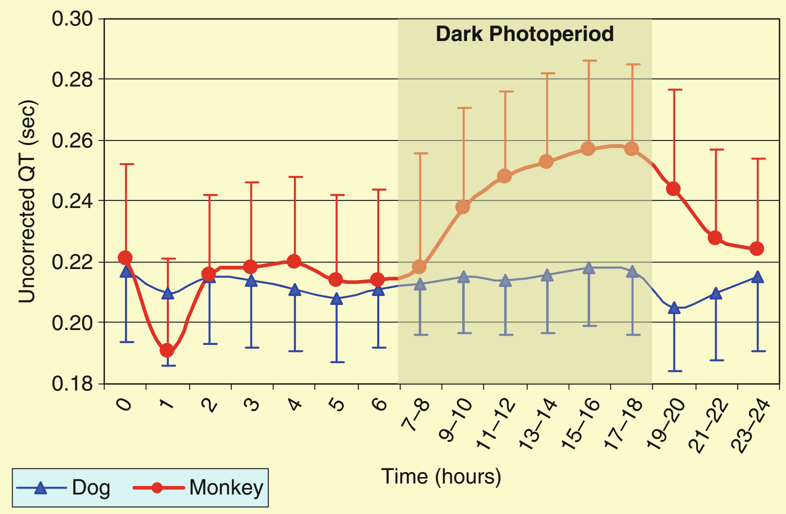

Fig. 21.6 Daily variations of the uncorrected QT interval (mean ± SD) in dogs and monkeys (Adapted from (Soloviev et al. 2006c))

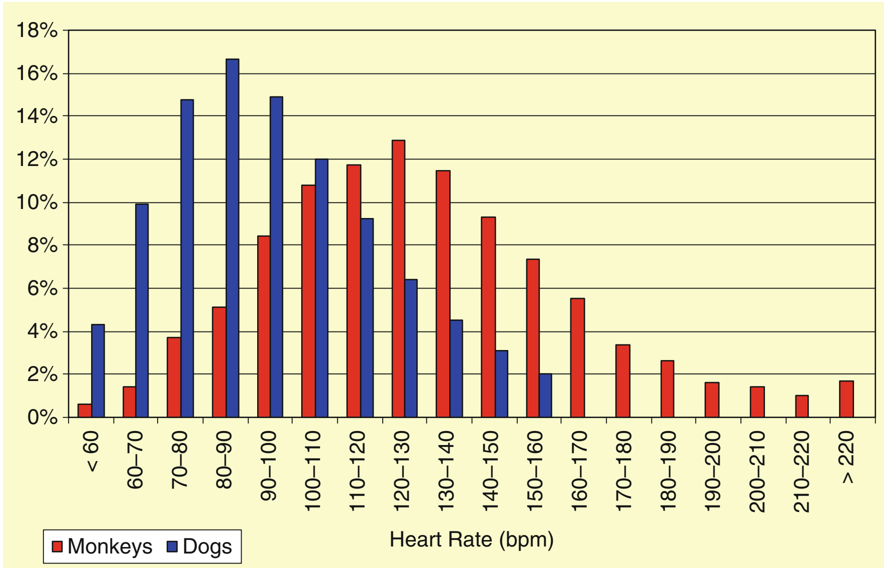

Fig. 21.7 Heart rate distribution in dogs and monkeys (Adapted from (Soloviev et al. 2007))

Circadian clocks are believed to have evolved in parallel with the geological history of the earth and have undergone selection pressures imposed by cyclic factors in the environment (Kyriacou et al. 2008). These clocks regulate a wide variety of behavioral and metabolic processes in many life forms (Hastings 1997; Edmunds 1997; Almon et al. 2008; Tsinkalovsky et al. 2007). They enhance the fitness of organisms by improving their ability to efficiently anticipate periodic events in their external environments, especially periodic changes in light, temperature, and humidity.

The mammalian circadian clocks, located in the neurons of suprachiasmatic nuclei (SCN) in the brain and in cells of peripheral tissues, are driven by a self-sustained molecular oscillator, which generates rhythmic gene expression with a periodicity of about 24 h (Reppert and Weaver 2002; Hastings and Herzog 2004). This molecular oscillator is composed of interacting positive

and negative transcription/translation feedback loops (Hastings 2003; Hardin 2004; Rensing 1997) in which the heterodimeric transcription activator CLOCK/Bmal1 promotes the transcription of E-box containing cryptochrome (Cry1 and Cry2) and period (Per1 and Per2) genes, as well as clock-controlled output genes. After being synthesized in the cytoplasm, CRY and PER proteins feedback in the nucleus to inhibit the transactivation mediated by positive regulators (Harms et al. 2004). The mPER2 protein acts at the interphase between positive and negative feedback loops by indirectly promoting the circadian transcription of the Bmal1 gene and by interacting with mCRY proteins (see Hardin 2004; Lowrey and Takahashi 2004).

It is interesting to note that clock genes have now been found in single cells of human skin

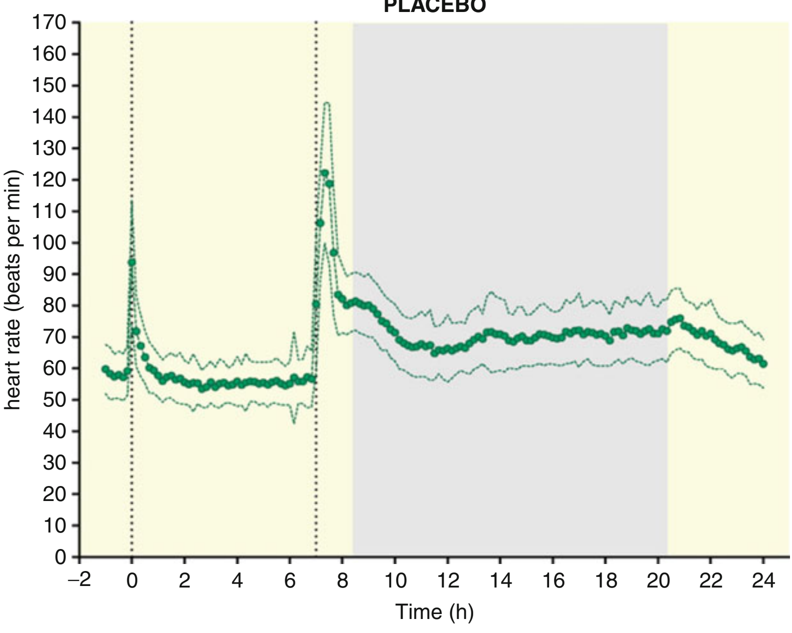

Fig. 21.9 Heart rate (mean ± SD) measured over a 24-h monitoring period by implantable telemetric device in freely moving Göttingen minipigs. The dotted line at 0 h indicates oral administration of placebo, whereas the dotted line at 7 h indicates feeding. The gray-shaded area represents the dark period (Adapted from Markert M (2011))

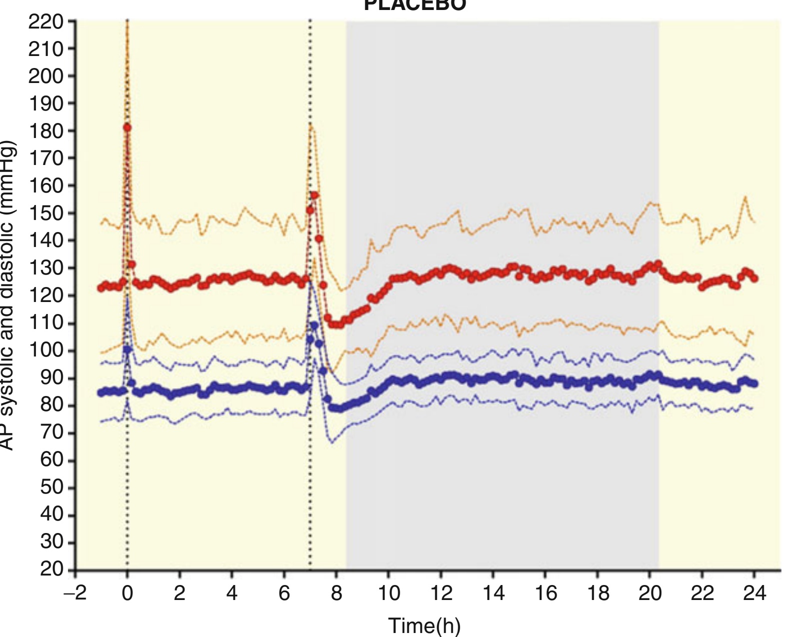

Fig. 21.10 Systolic and diastolic arterial blood pressures (mean ± SD) measured over a 24-h monitoring period by implantable telemetric device in freely moving Göttingen minipigs. and mucosa (Bjarnason et al. 2001); furthermore, it has been shown that about 8–10% of all genes are regulated in a circadian fashion (Storch et al. 2002).

In general, the human endogenous clock does not run at a frequency of exactly 24 h but somewhat slower. The rhythm in human body temperature which is timed by the biological clock has a period of

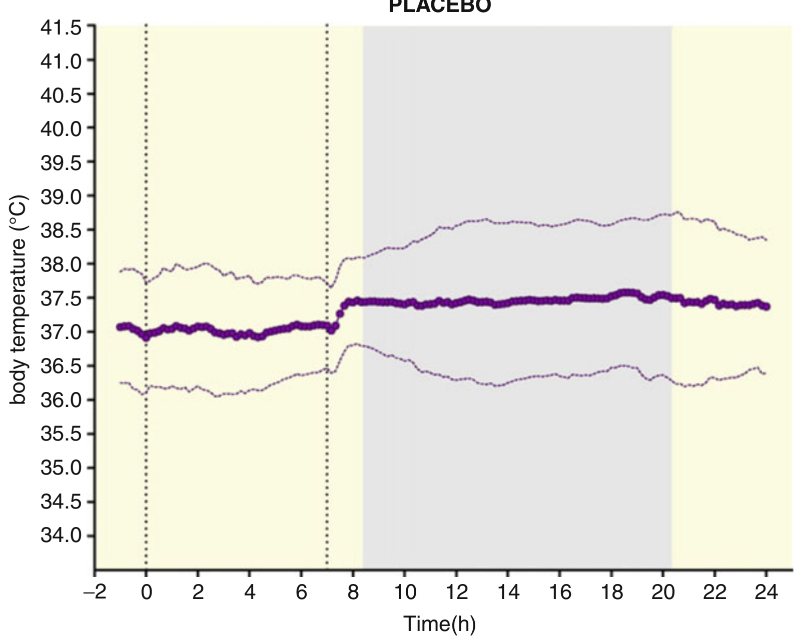

Fig. 21.11 Body temperature (mean ± SD) measured over a 24-h monitoring period by implantable telemetric device in freely moving Göttingen minipigs. The dotted line at 0 h indicates oral administration of placebo, whereas the dotted line at 7 h indicates feeding. The gray-shaded area represents the dark period (Adapted from Markert M (2011))

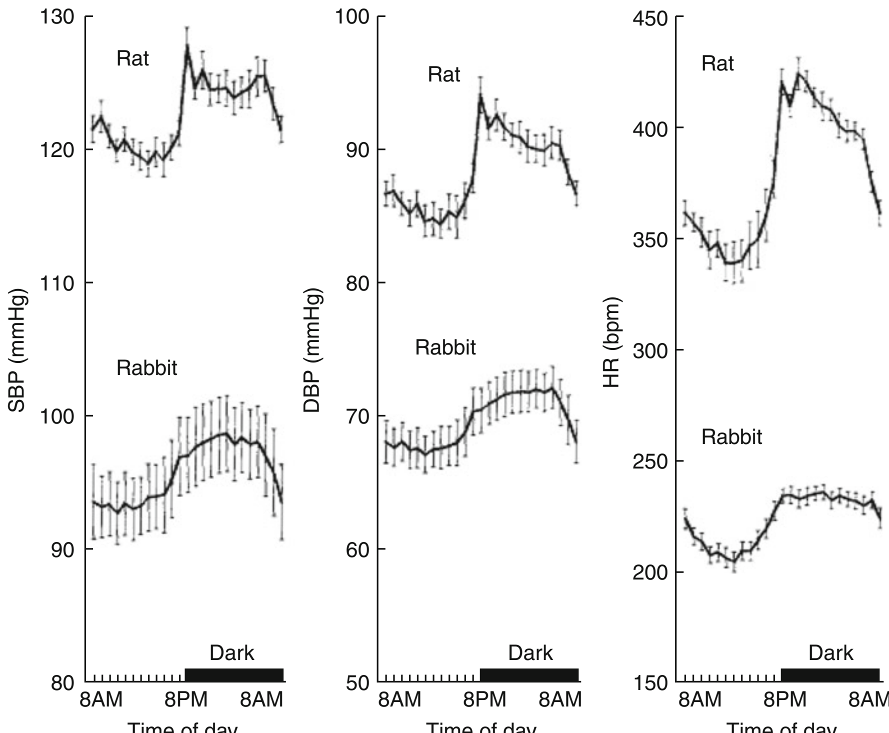

Fig. 21.12 Comparison of circadian rhythms of systolic blood pressure (SBP), diastolic blood pressure (DBP), and HR in rabbits (n = 17) and rats (n = 10). Hourly means are averages for 4 consecutive days (Adapted from Sato et al. (1995))

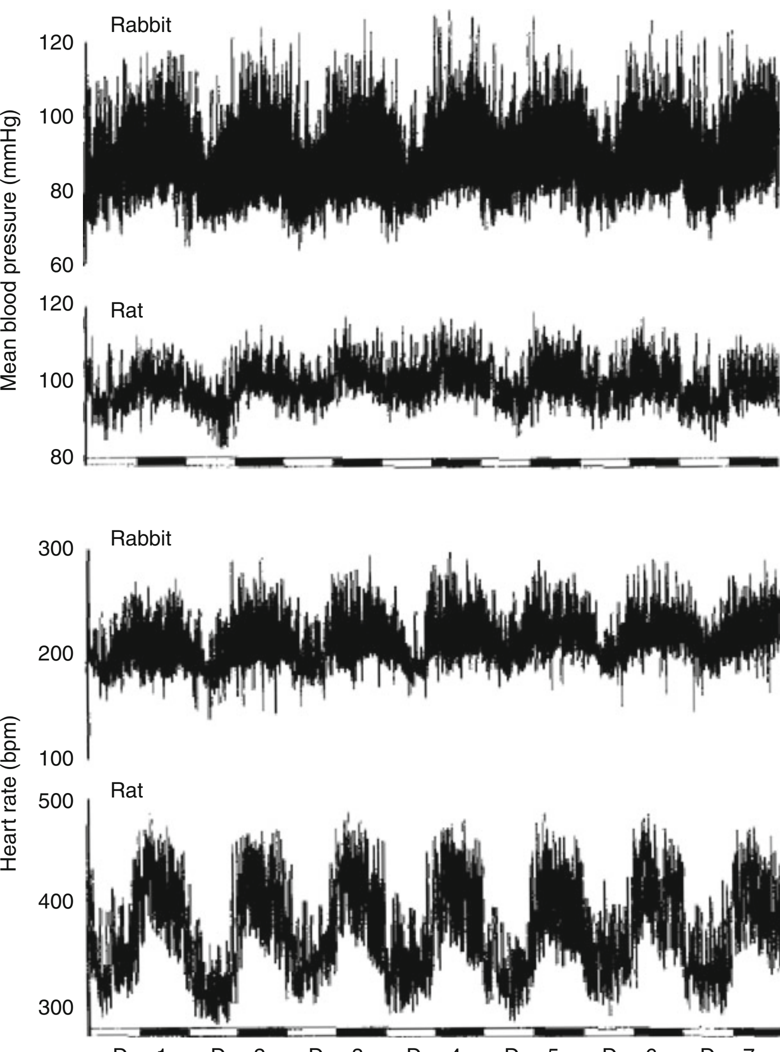

Fig. 21.13 Continuous recordings of mean blood pressure and heart rate plotted every 2 min for 7 days in one rabbit and one rat. Closed bar, dark phase; open bar, light phase (Adapted from Sato et al. (1995))

about 24.5 h under free-running conditions, i.e., without environmental time cues or zeitgebers (e.g., light, temperature) (Fig. 21.2).

The term "zeitgeber" introduced by Jürgen Aschoff (1954, 1965) is now part of the international scientific language. Mammals such as rodents or humans can entrain their activity to regular light cycles not shorter than 22 or longer than 26 h (Aschoff and Pöhl 1978). Zeitgebers entrain the circadian rhythm to a precise 24-h period. Zeitgebers are, therefore, necessary to entrain a living subject to a "normal" period of 24 h!

In experimental animals and in humans, however, most rhythmic fluctuations still cannot be studied under free-running conditions, leaving the answer open to what degree they are really "circadian." Purely exogenous rhythms are better termed as "24-h" or "daily" rhythms. Thus, an overt 24-h rhythm in a given parameter can be endogenous or predominately exogenous in nature. Within the published clinical literature, however, the term "circadian" is not always used in the above-mentioned correct sense (as used by chronobiologists); the broader term will be used here, too. Though seasonal rhythms in cardiovascular functions were also described, the present review will focus on circadian rhythms since much more data were accumulated over a 24-h scale and the underlying mechanisms studied.

21.3 Safety Pharmacology Assessments

A battery of safety pharmacology assessments (cardiovascular, respiratory, and CNS evaluation) is required by ICH S7A Guideline "Safety Pharmacology Studies for Human Pharmaceuticals" (Food and Drug Administration and H.H.S 2001) prior to first administration of a new chemical entity or biopharmaceutical to man. Major systems are evaluated in these assessments in order to identify any significant physiological effects around or above the intended clinical exposures. While respiratory and CNS studies can be conducted in rodents as well as in large nonrodent species, the lack of I_{kr} channels in rat and mice (Pond et al. 2000) dictates that cardiovascular evaluation be conducted in nonrodents. Use of modern telemetry systems with automated data collection from cardiovascular studies allows collection of information for a prolonged period of time – usually at least 24 h after dose administration (and in chronopharmacological research up to months, see below), thus covering the whole circadian cycle. Recent advances in technology allow the use of telemetry techniques on respiratory and CNS studies (Atterson et al. 2010; Authier et al. 2010; DeBoer and Friedrichs 2009; Pugsley et al. 2010), thus also making interpretation of those studies dependent on circadian rhythms. These safety pharmacology assessments are also used by toxicologists to increase confidence in safety and inform colleagues in clinical development, regulators, physicians, and ultimately patients about potential side effects of new drugs. All these require well-defined, robust assay systems that are well understood (Leishman et al. 2011).

21.3.1 Large Animals Used in Safety Pharmacology Studies

21.3.1.1 Most Common Large Species: Beagle Dogs and Cynomolgus Monkeys

Cardiovascular safety pharmacology studies in nonrodent species are usually conducted in nonhuman

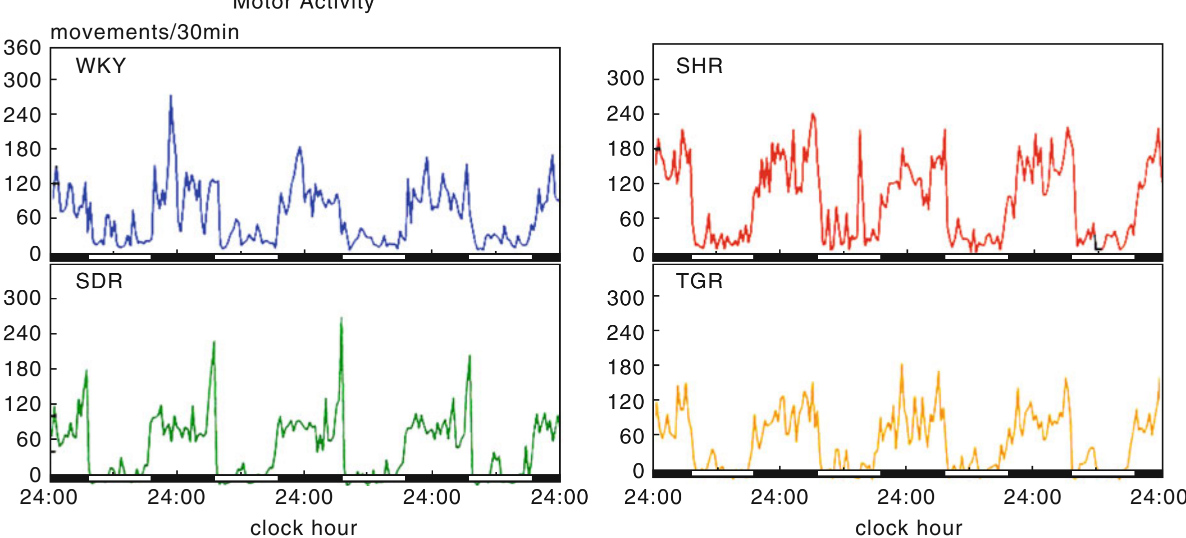

Fig. 21.17 Motor activity in four strains of rats as determined by radiotelemetry (Acc. Lemmer et al. (1993a))

primates and dogs (Bass et al. 2005; Davis 1998). In a 2003 survey of international pharmaceutical companies, 98% and 56% of responders used dogs and monkeys, respectively, in their assessment of QT interval prolongation (Friedrichs et al. 2005). Canine models are favored, though no model reliably correlates with human electrophysiologic results (Gralinski 2003). Small molecules are usually evaluated using a Latin square design, so each animal receives all dose levels including vehicle and serves as its own control. It is vital to recognize behavioral patterns of different species – their expected physiological reaction to the presence of technical personnel, dosing, bleeding, and other activities. Appreciation of the diurnal fluctuations in blood pressure (BP), heart rate (HR), core body temperature, and duration of ECG intervals that occur in animals is extremely important. Accounting for normal physiological reactions is crucial for accurate interpretation of study results and compliance with regulatory requirements. Section 3.1.3 "In vivo electrophysiology studies" of ICH S7B Guideline "Nonclinical Evaluation of the Potential for Delayed Ventricular Repolarization (QT Interval Prolongation) by Human Pharmaceuticals" (Food and Drug Administration H 2005) specifically requests the evaluation of the QT interval in an in vivo model. Several time-dependent factors may considerably alter results of the study, e.g., a remarkable difference in the duration of QT interval collected during the dark cycle versus the light cycle at the same HR has been documented in primates (Soloviev et al. 2006a). Although the reason is not fully understood, the hypothesis is that diurnal changes of vagal tone influence the duration of ECG intervals.

As mentioned above, dogs and monkeys are widely used to evaluate effects of new chemical entities on the hemodynamics and electrical activity (repolarization, conductivity, etc.) of the heart. Several publications with detailed description of dogs' (Soloviev et al. 2006a, b; Gauvin et al. 2006a, b) or monkeys' (Authier et al. 2007a, b) hemodynamic parameters obtained via radiotelemetry are available. There are significant differences in cardiovascular profile as well as physiological response to study-related activities in these two species. To illustrate this, a comparison of summarized data obtained during 2003–2006 after oral vehicle dosing from cardiovascular studies was conducted at a contract research organization (Soloviev et al. 2006c, 2007).

Data were collected from healthy animals: 22 male and 18 female cynomolgus monkeys and 41 male and 25 female beagle dogs. Overall, 64 monkey and 166 dog episodes of at least 25-h telemetry data collection in control group animals were summarized (Soloviev et al. 2007). Monkeys were between 2 and 5 years old. Body weight varied from 2.0 to 6.4 kg, with the majority between 2.5 and 4.5 kg. Dogs were between 6 and

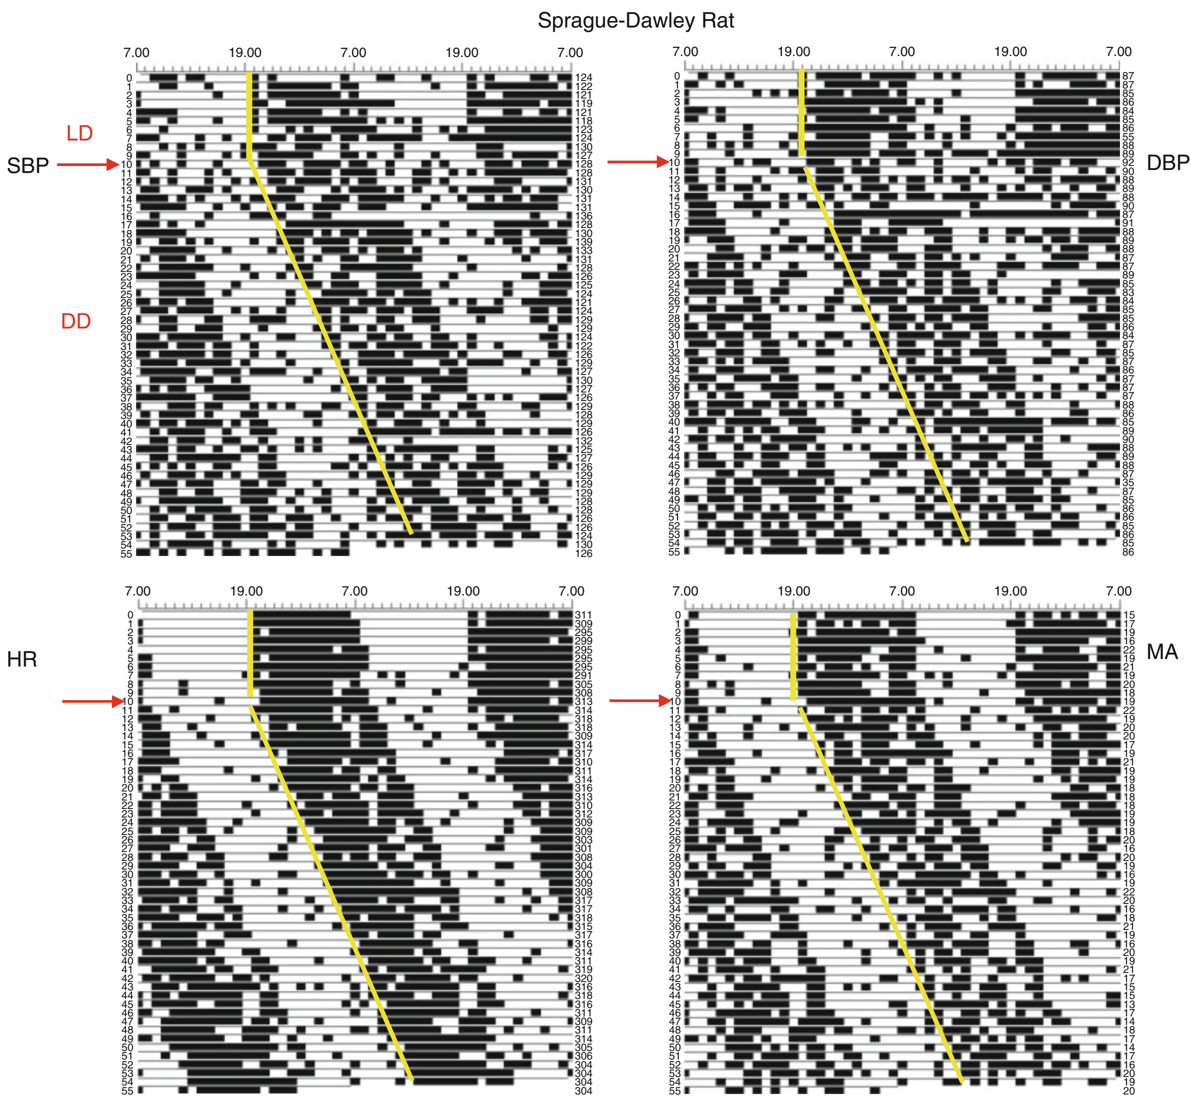

Fig. 21.18 Circadian rhythms in systolic blood pressure (SBP), diastolic blood pressure (DBP), heart rate (HR), and motor activity (MA) in a normotensive rat. Data are represented as double plots with values above the 24-h mean marked black. Experiments were performed under a 12:12 light–dark cycle as well as under free-run conditions in total darkness (DD). In: Lemmer (2011))

29 months old. Body weight varied from 6.3 to 14.8 kg, with the majority between 8 and 11 kg. Detailed physical examinations were performed prior to each data collection. Animals identified with abnormalities did not participate in the studies. The room temperature and humidity controls were set to maintain daily averages of 71 ± 5°F (22 ± 3°C) and 50 ± 20% relative humidity for CM and 68 ± 5°F (20 ± 3°C) and 50 ± 20% relative humidity for BD. Room temperature and relative humidity were monitored and recorded approximately hourly. A light–dark cycle of 12:12 h was used with lights on between 6:00 and 18:00. On the day of dosing, 1-h baseline recordings were obtained from all animals, starting approximately between 10:00 and 11:00 (at least 1 h after feeding). Dosing usually occurred between 11:00 and noon. After dosing, telemetry signals, which included ECG waveforms, were recorded for a 30-s interval

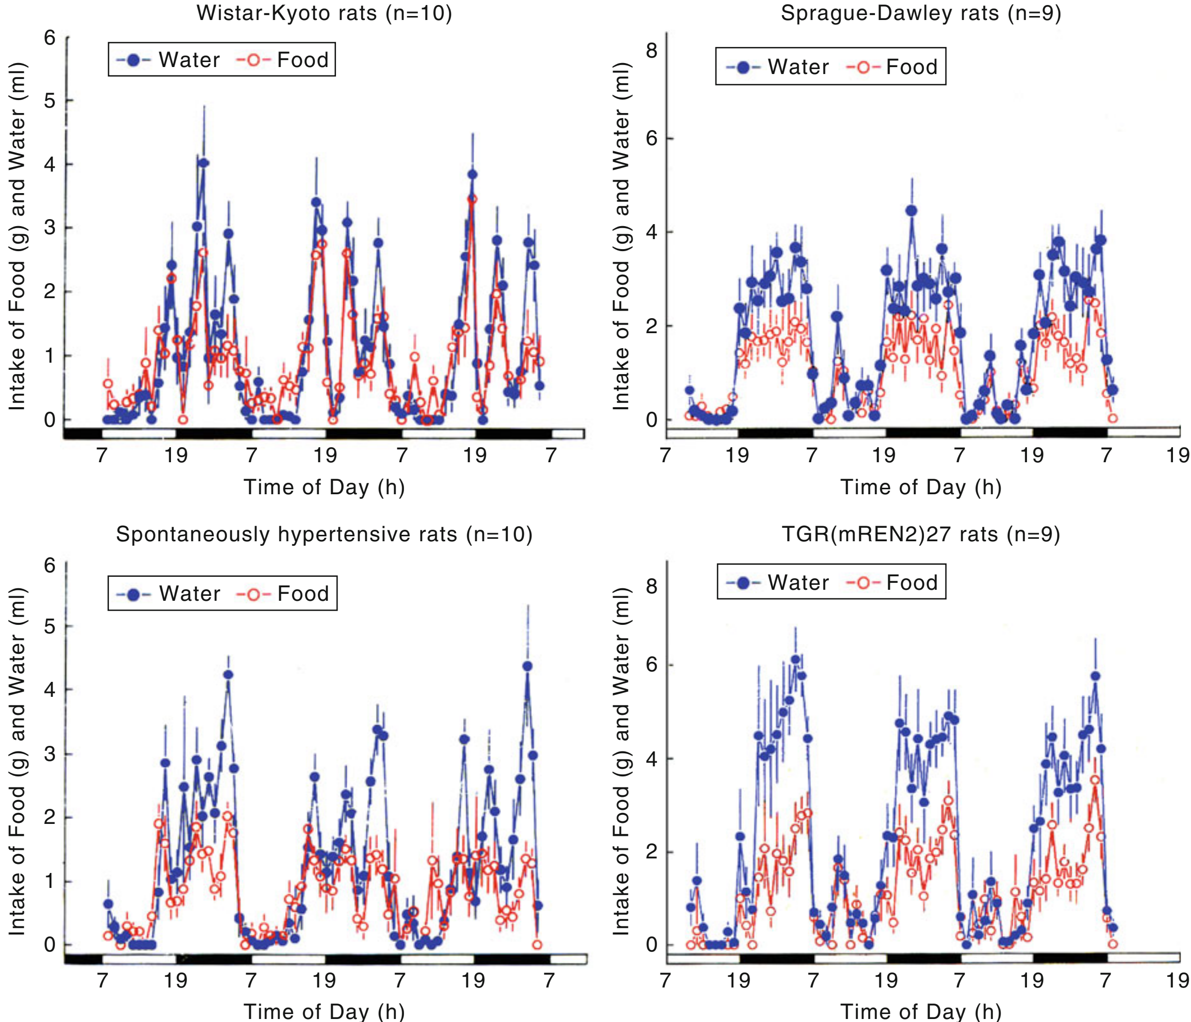

Fig. 21.19 Rhythms in drinking and feeding behavior in four strains of rats (Acc. Witte and Lemmer (1999) and unpublished)

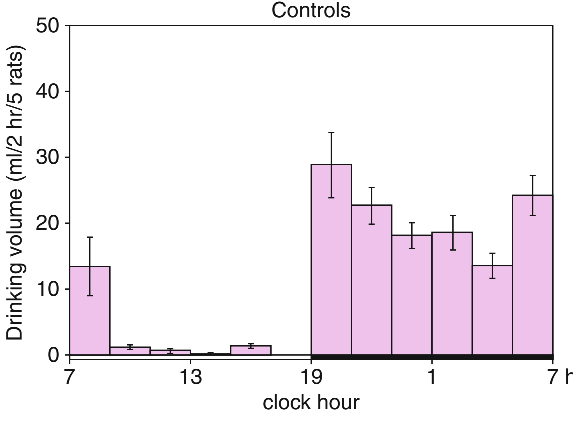
every 10 min for at least 24 h. DSI Physiostat ECG analysis software (version 4.0 and higher) summarized all ECG complexes recorded during an acquisition period (30 s) into the derived reference complex. The software then compared the derived reference complex based on statistical correlation to all actual complexes and identified and eliminated artifacts and/or abnormal complexes. Mean HR for each 30-s interval was used for QT correction to compensate for cardiac "memory phenomenon" (Pueyo et al. 2004). One-hour averages for hemodynamic parameters and ECG intervals were analyzed for the first 6 h after dosing and then 2-h averages were analyzed.

Major hemodynamic parameters and duration of ECG intervals for both species prior to dose administration (approximately between 10:00 and 11:00) are presented in the Table 21.1.

Cynomolgus monkeys had stronger hemodynamic response to dosing: the average HR for the hour following dosing increased 30% in monkeys versus 8% in dogs. The average mean BP for the same interval increased 12% in monkeys versus 1% in dogs. Monkeys had a pronounced diurnal pattern with night



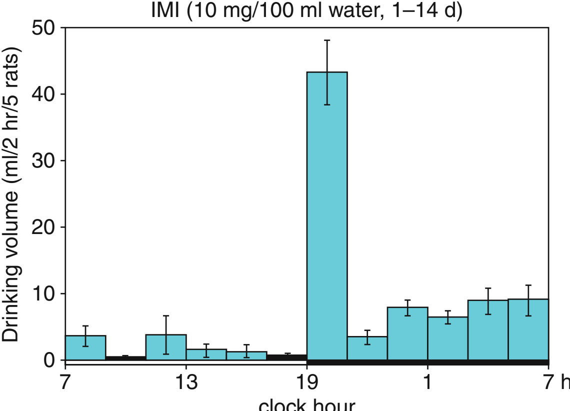


Fig. 21.20 Effect of imipramine on drinking behavior in rats (Acc. Lemmer and Holle (1991))

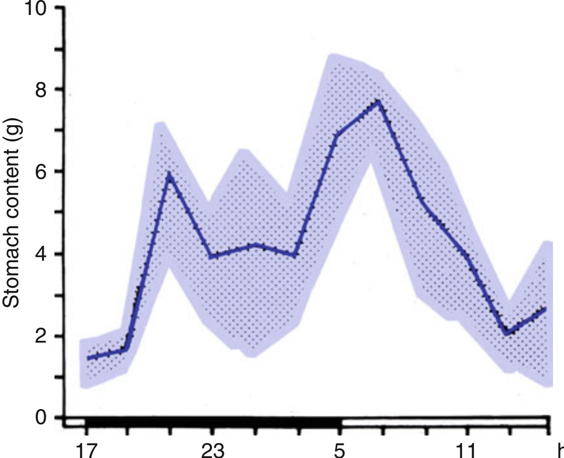

Fig. 21.21 Rhythm in gastric emptying in rats (Acc. Armstrong et al. (1978))

decreases in HR (20%), mean BP (10%), and core body temperature (1.1°C); in dogs, these changes were smaller – 10%, 4%, and 0.3°C, respectively. In both species, daily variations of the HR, mean BP, core body temperature, and uncorrected QT interval are presented on Figs. 21.3, 21.4, 21.5, and 21.6.

All recordings for both species (10,761 in monkeys; 24,882 in dogs) were arbitrarily divided into divisions ("bins"), each covering a range of 10 bpm, except for the first and the last bins (Fig. 21.7).

Ninety-five percent of all HR collected from monkeys were between 70 and 210 bpm, and 93% of all HR collected from dogs were between 60 and 160 bpm. The duration of the absolute QT interval depended upon the HR in both species, but different species required different QT correction formulas. Van de Water's correction formula (Van de Water et al. 1989) provides optimal results for evaluation of the QT interval duration in dogs, while Bazett's correction formula (Bazett 1920) provides optimal results in monkeys. QT interval duration measured during the light cycle (mostly active, awake) was compared to those collected during the dark cycle (sleeping) at the same HR (Fig. 21.8).

To avoid the influence of the transition period from the light cycle to the dark cycle and vice versa, only 8 h in the middle of the cycles were analyzed (2 h on each side of the cycle were not included in the analysis). In contrast to the dogs, monkeys demonstrated a remarkable difference – up to 32 ms prolongation (12.7%) of the QT interval measured during the dark cycle compared QT interval measured during the light cycle at the same HR (60–70 bpm). This difference became less prominent with the increase of the HR: QT was prolonged 27 ms (10.4%) at HR from 70 to 80 bpm and 20 ms (7.8%) at HR from 80 to 90 bpm. A less pronounced prolongation (4.2 ± 2.1%) of QT during the night at HR of 60 bpm was also described in healthy humans (Murakawa et al. 1992). A similar degree of nighttime QT prolongation (4.7%) was reported by Bexton et al. (Bexton et al. 1986). It is interesting that both of the aforementioned studies in addition to those conducted by (Ishida et al. 1997; Bilan et al. 2005) reported a decrease in the diurnal QT difference in diseased patients with sympathovagal balance shifted in the sympathetic direction. These results indicate that although

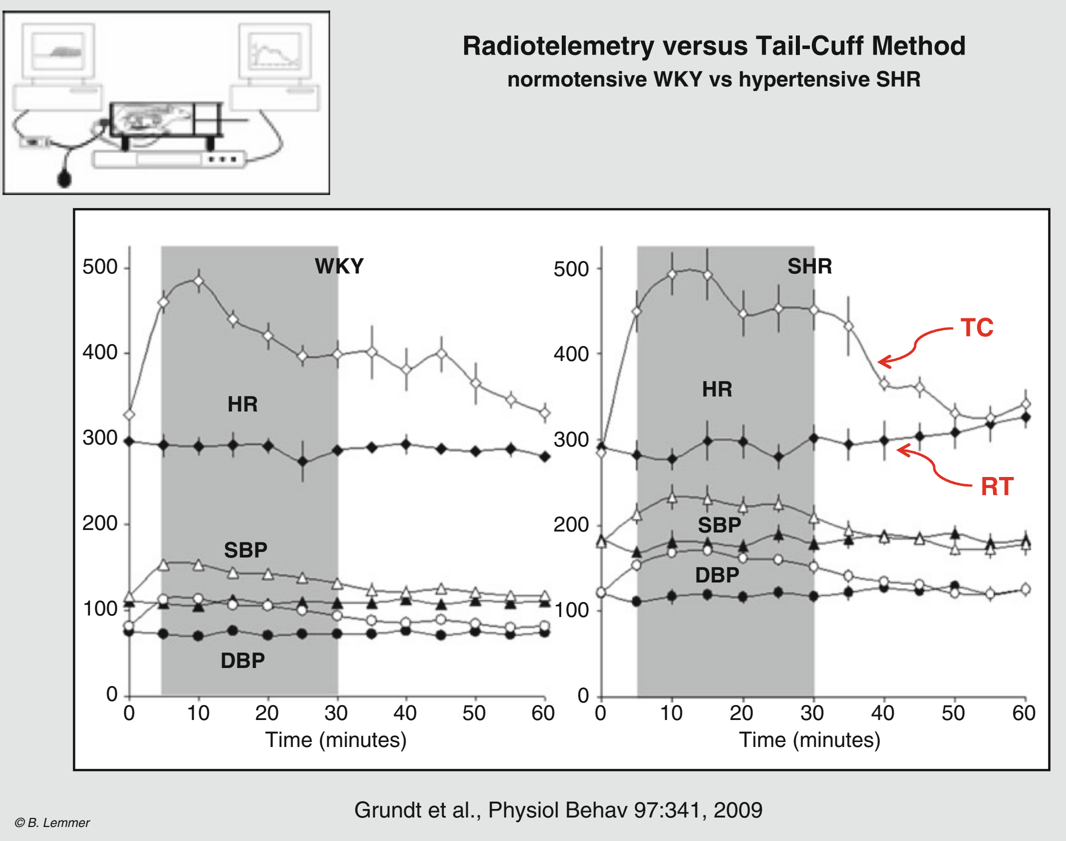

Fig. 21.22 Comparison of radiotelemetric data (RT) on systolic blood pressure (SBP), diastolic blood pressure (DBP), and heart rate (HR) with those obtained by the tail-cuff method (TC) in normotensive Wistar-Kyoto (WKY) and spontaneously hypertensive (SHR) rats, dark part represents time spend under tail-cuff (Acc. Grundt et al. (2009))

a change in sympathovagal balance was responsible for the diurnal variation in QT interval, the enhanced sympathetic activity in the day was a major determinant of this phenomenon. The absence of a similar effect on QT duration in dogs can be explained by their sleeping pattern – frequent "naps" during light cycle of the day (Takeuchi and Harada 2002).

It is of great interest that RR and QT intervals lengthen comparably at lower HR during the dark period (nonactive sleeping hours) in both monkeys and dogs, but the lengthening of QT in monkeys could not be attributed only – or even primarily – to lengthening of RR interval. That is, when QT was measured in monkeys at equivalent HR during daytime and nighttime, QT was longer at nighttime in monkeys but not longer in dogs. Thus, although lengthening of QT interval in dogs can be attributed to a reduction in HR, it cannot be attributed solely to the slowing of HR in monkeys. The changes in QT were attributable only to changes in ST-T interval because QRS did not manifest diurnal fluctuations (Gauvin et al. 2006b; Holzgrefe et al. 2007) and is known to be independent of HR. There are many determinants of the duration of ST-T interval, several of which are, themselves, interdependent. For example, it is well known that altering HR by changing autonomic efferent traffic to the sinoatrial node changes QT via the effects on I_{Ks}. However, drugs may both alter HR and still affect other channels important for ventricular repolarization (e.g., I_{Kr}, I_{Kto}, I_{Na}, I_{Ca}). In addition, there are other less investigated effects of ST-T interval. Among these nonautonomic effects are serum electrolyte

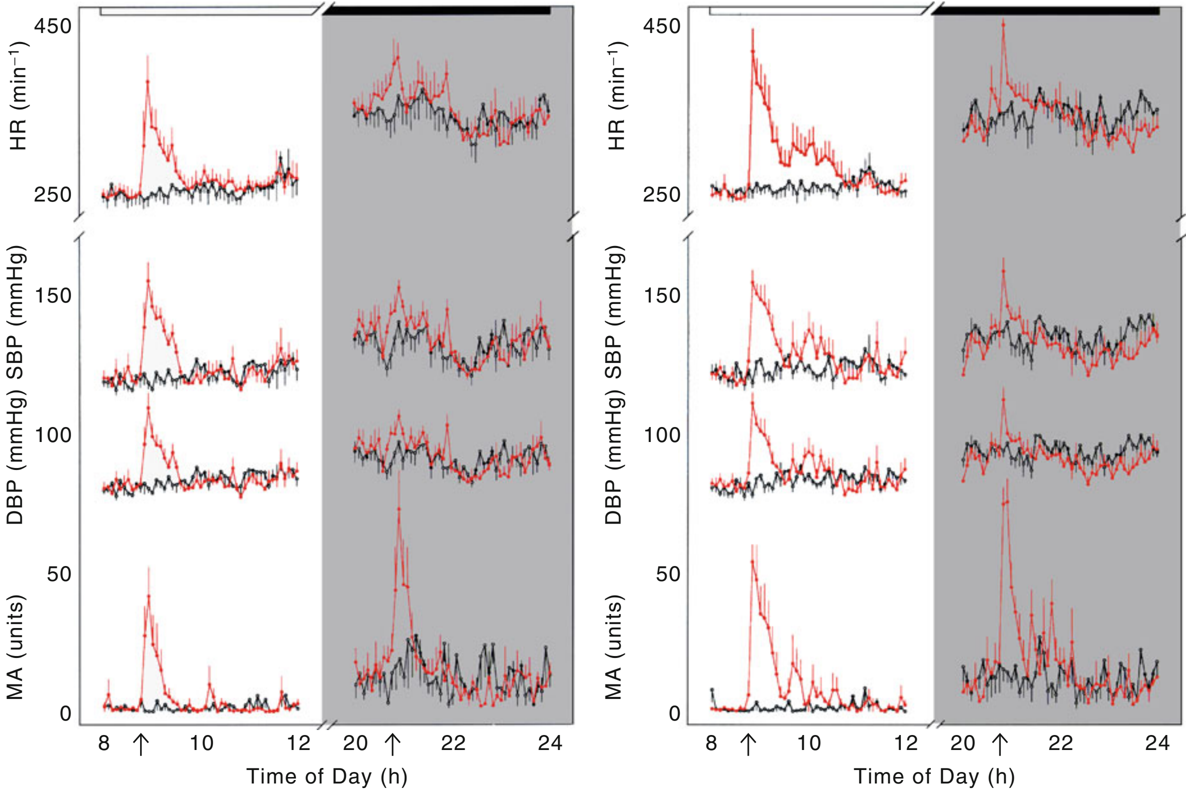

Fig. 21.23 Routine procedures on cardiovascular functions in rats. *Left*: i.p. injection of 0.5 ml NaCl solution. *Right*: clean cages and fresh bedding (Acc. Schnecko et al. (1996))

concentration (Lepeschkin 1951), neuroendocrine changes (Davey and Bateman 1999), gender (Bortolan et al. 2004; Nakagawa et al. 2005; Schulze-Bahr et al. 2005), aging (Bonnemeier et al. 2003), temperature (Mattu et al. 2002; van der Linde et al. 2008; Shellhammer et al. 2009), heart size, and heart failure (Bortolan et al. 2004).

In contrast to monkeys, who did not demonstrate differences in the duration of PR interval during light cycles, PR interval in dogs was slightly shortened during the night hours. The duration of the PR interval was prolonged at night by 3.3% in male dogs and 1.7% in female dogs despite the fact that HR was lower in both sexes during the dark cycle. HR usually slows at night because of an increase in parasympathetic (vagal) efferent activity and/or a decrease in sympathetic efferent activity to the sinus node. Because these factors also should decrease velocity of propagation across the atrioventricular conduction system, there should be a concomitant lengthening of the PR interval. However, the paradoxical abbreviation of the PR interval at night when HR is slower may be explained by the decreased rate at which the atrioventricular node is bombarded, which provides more time for the cells to complete their period of relative refractoriness. This implies that even at relatively slow HR during the day – but not as slow as at night – the atrioventricular node did not have sufficient time between inputs from the sinus node to completely recover from its relative refractoriness; thus, the PR interval was longer than in the nighttime when HR was still slower.

In addition to interspecies diversity, a possible reason for these dramatic differences in diurnal pattern as well as reaction to study-related activities may be due to autonomic regulation based on behavioral distinctions. While the beagle dog is a domesticated animal, the cynomolgus monkey is not. This fundamental behavioral difference may have implications for how

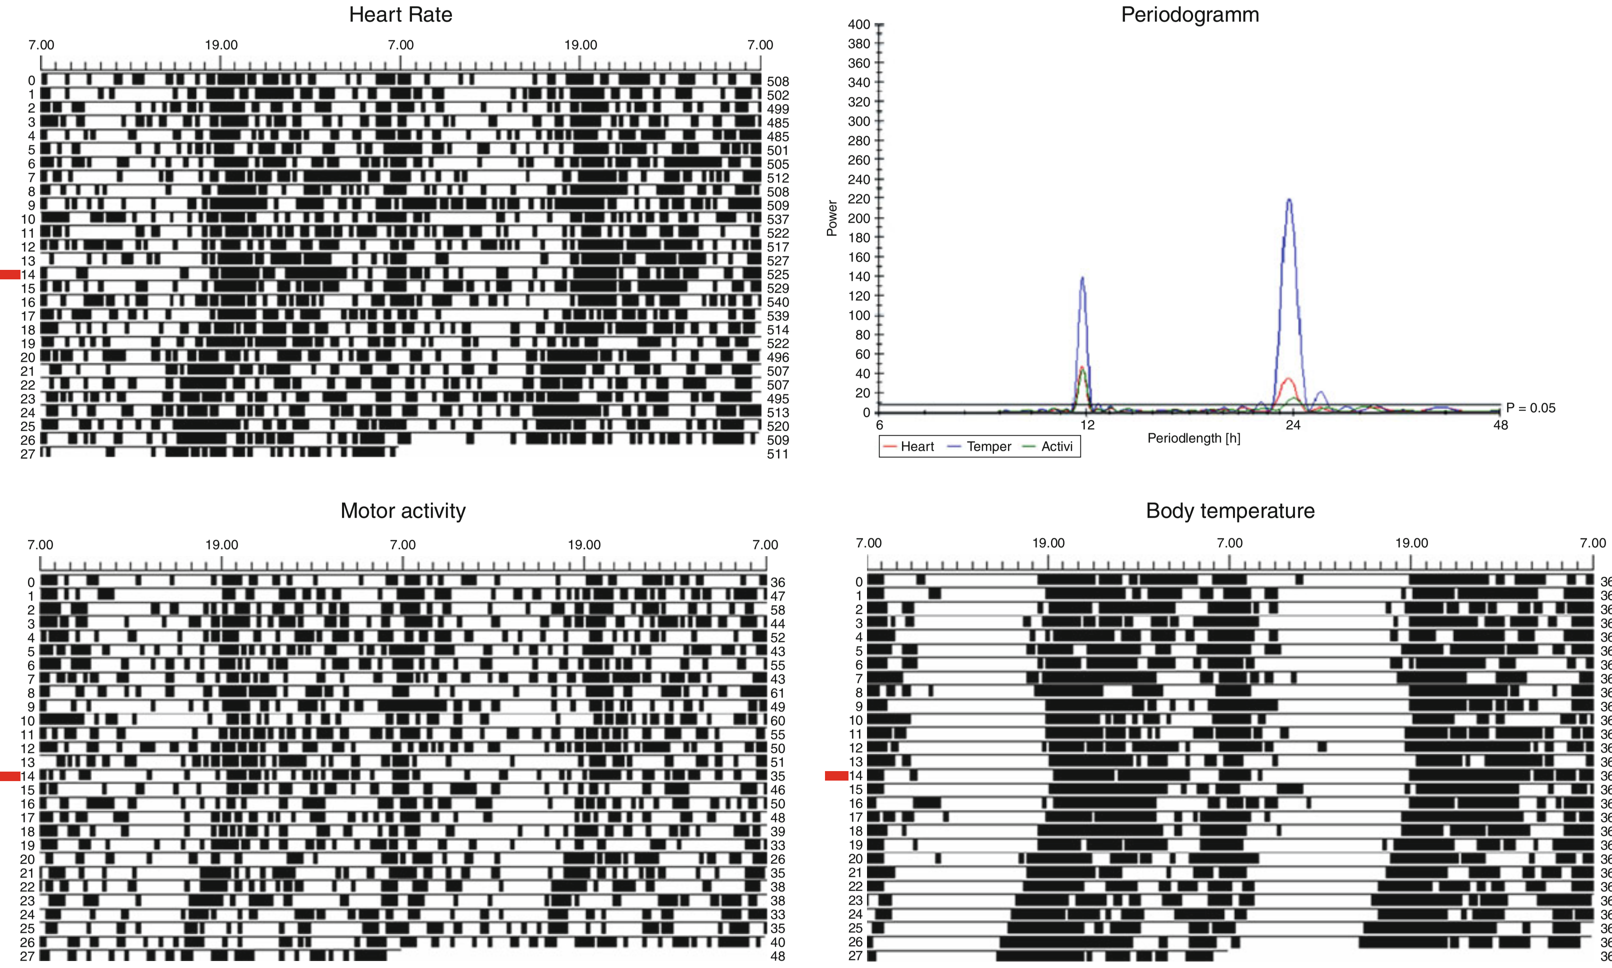

Fig. 21.24 Circadian rhythms in heart rate, motor activity, and body temperature in normotensive mice; under LD (day 0-13) and after free run in total darkness (DD) from day 14, a periodogram (Zuther and Lemmer 2004a) is shown for the data monitored (Acc. Arraj and Lemmer (2006))

the two species interact with their environment, particularly with regard to the presence of humans (response to dosing), and the corresponding changes in HR with changes in their respective environments. For example, in captivity, which is an ordinary condition to the domesticated animals, the dogs' HR is under parasympathetic control, whereas in captivity, the monkeys' HR is under strong sympathetic control.

Another important deliverable of cardiovascular studies is a determination of any qualitative ECG abnormalities. A thorough evaluation of qualitative ECG findings in dogs was done by (Cools et al. 2011). The authors analyzed ECG obtained by external telemetry for a 22-h period and concluded that a high percentage of clinically normal beagle dogs showed different types of arrhythmias: 49% of the animals had episodes of AV block second degree; 59%, single atrial premature complexes; 17.6%, junctional tachycardia; 13.7%, ventricular escape complexes; 21.6%, ventricular premature complexes; 3.9%, runs of ventricular complexes; and 3.9%, runs of ventricular escape complexes. The chronic implantation of a ventricular probe through the apex of the heart resulted in temporary (up to 8 weeks) higher incidences and frequencies of ventricular episodes. Interestingly, atrial and junctional arrhythmia incidence was higher during the night period, but the incidence of ventricular events during day and night was comparable. Similar work in primates is still to be done.

While circadian rhythms in animals have been elucidated in the literature, notably less information on seasonal variability of the hemodynamic parameters is available, and it remains controversial possibly because of the lack of thoroughly controlled environmental factors (Bícego-Nahas and Branco 1999; Dunlap et al. 2007; Martins et al. 2006). Table 21.2 gives data obtained from controlled environment of the experimental laboratory by analyzing cardiovascular studies conducted at different seasons of the year in the same facility in dogs of the same age (Soloviev et al. 2006b) (Table 21.2). To exclude the influence of circadian rhythms, the analyzed baseline data were collected approximately at the same time of the day. Seasons were defined by the study starting date (date on which the first telemetry data were collected) as follows: winter, December through February; spring, March through May; summer, June through August; and autumn, September through November. Although sufficient data for evaluation of females tested during the winter months were not available, both sexes demonstrated statistically significant higher HR and BP in spring when compared with other seasons. In males, the HR differed by 11–22 bpm (up to 23%) between the seasons. A smaller difference was noted in mean BP – 4–5 mmHg (~5%).

21.3.1.2 Minipigs

The minipig has gained an increased acceptance as an alternative for large animal toxicology and safety pharmacology assessments (van der Laan et al. 2010). ICH S7B Guideline (Food and Drug Administration H 2005) includes swine as a potential species for in vivo electrophysiology studies. The minipig becomes the species of choice for cardiovascular safety pharmacology studies when pivotal toxicology work is conducted in this species (Bode et al. 2010). Anatomical, physiological, and biochemical similarities between pigs and humans (Bollen and Ellegaard 1997; Douglas 1972; Hiebl et al. 2010; Hughes 1986) support the relevance of minipigs for regulatory safety pharmacology. Minor difference in ion channels, absence of 4-aminopyridine-sensitive transient outward K current I_{to1} (Li et al. 2003), and thus inability to identify QT-prolongation-specific I_{to1} blockade does not disqualify minipigs from cardiac safety pharmacology (Authier et al. 2011; Laursen et al. 2011; Pugsley et al. 2008). Today, several different minipig breeds are available and suitable for laboratory use. The Göttingen minipig is a special breed for medical research, the smallest of the minipig breeds available for research; it reaches a weight of only 20–35 kg when it is fully grown (Köhn et al. 2007).

Limited information on hemodynamic and ECG parameters in conscious minipigs is available, and below we present a brief summary of the most thorough studies available for us to date (Stubhan et al. 2008; Markert et al. 2009; Markert 2011). HR in freely moving minipigs during daylight hours averages about 56 bpm (Fig. 21.11). Kano et al. (2005a) reported values of 72–76 bpm in 17 kg, freely moving miniature pigs (but not Göttingen minipigs). The HR in resting miniature pigs was 80 ± 3.5 bpm (Kuwahara et al. 1999). Beglinger and Becker reported HR of 103 ± 14 bpm in sling-restrained Göttingen minipigs (~20 kg) (Beglinger et al. 1975a).

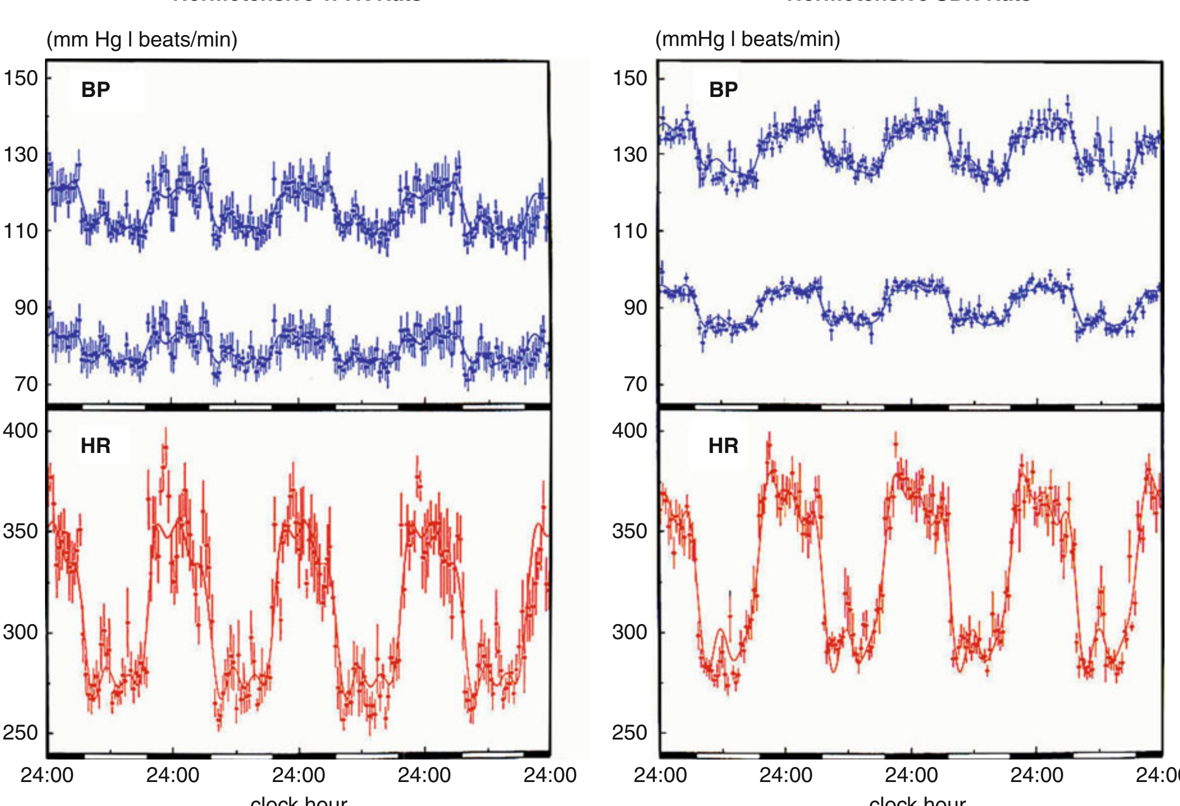

Fig. 21.25 Circadian rhythms in blood pressure (BP) and heart rate (HR) in two normotensive strains of rats (Acc. Lemmer et al. (1993a))

Comparing to the currently available data in minipigs obtained with invasive measurements, it may seem low. Markert (Stubhan et al. 2008; Markert et al. 2009; Markert 2011) attributed the very low HR to the low stress level achieved using well-trained animals in a laboratory environment where special measures have been taken to reduce unnecessary stress factors.

The diurnal rhythms of minipigs' HR have been investigated by Kuwahara et al. (1999). They found that HR in the daylight phase was higher than in the dark phase when the animals were housed singly, but minipigs housed in pairs had no diurnal variation. Another group (Kano et al. 2005b) reported no marked changes in HR between periods of daylight and darkness. Recent data from Market's group (Stubhan et al. 2008; Markert et al. 2009; Markert 2011) differ from earlier findings: they saw a significant increase in HR at night when the animals were fed shortly before the start of the dark phase (Fig. 21.9). Examination of videos taken at night indicated that the minipigs have been sleeping most of the time (main sleeping period 11 p.m.–5 a.m.), with only short periods of wandering but with no signs of excitement, and one would expect HR to decrease at night with an increase in parasympathetic activity. But when the study design was altered to eliminate feeding at 7 p.m., the HR at night was 51 bpm, being comparable to the daylight value. These findings indicate a dependency of the dark phase increase in HR on feeding. This phenomenon may be due to autonomic nervous fibers located in the wall of the digestive tract that react to the filling of the gastrointestinal tract. The pig is known to digest slowly, taking at least 24 h to empty the digestive tract after

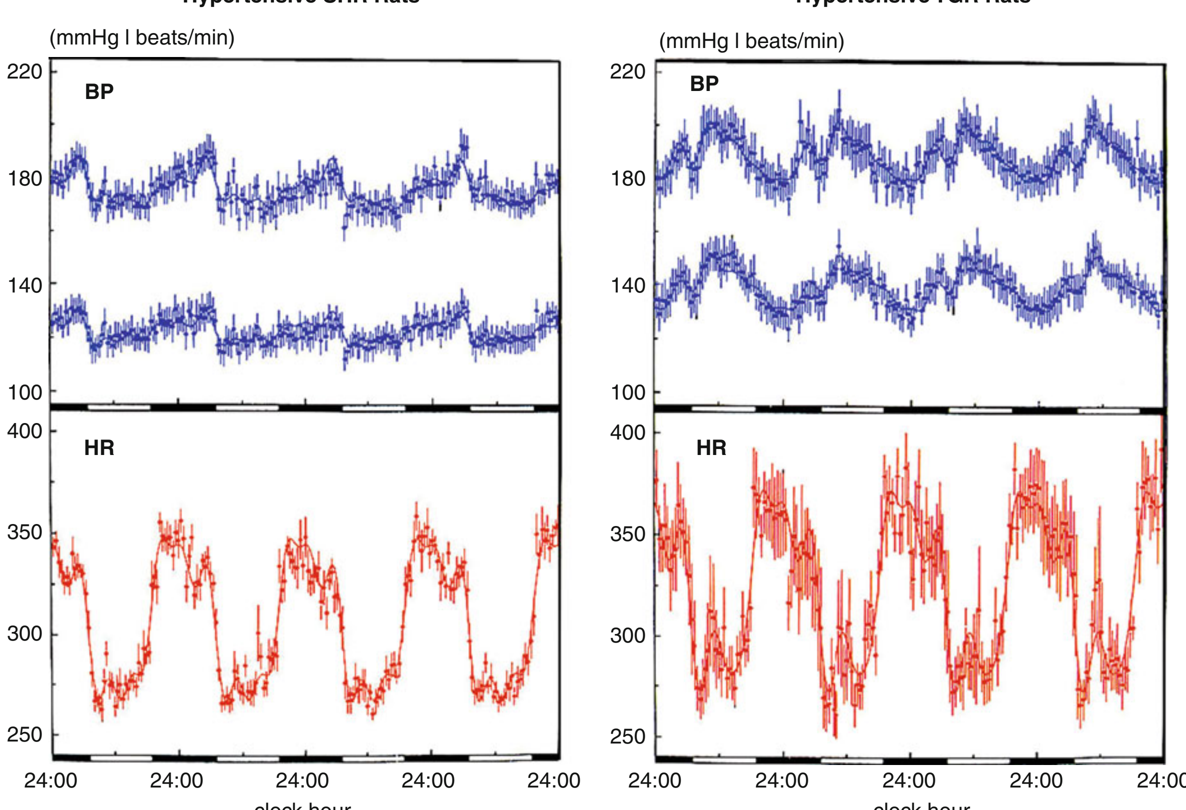

Fig. 21.26 Circadian rhythms in blood pressure (BP) and heart rate (HR) in two hypertensive strains of rats (Acc. Lemmer et al. (1993a))

a meal (Hossain et al. 1990). The point to consider is that the effect of feeding on HR can extend well beyond over 3 h and that this must be taken into account when designing studies involving Göttingen minipigs.

Systolic and diastolic BP over 24 h was remarkably stable with or without feeding (Fig. 21.10). Earlier reported values for arterial BP from minipigs ranged from 135 ± 12 to 160 ± 11 for systolic and 88 ± 4 to 96 ± 14 for diastolic (Beglinger et al. 1975b; Cimini and Zambraski 1985). However, nobody prior to Markert's group (Stubhan et al. 2008; Markert et al. 2009; Markert 2011) reported arterial BP data from freely moving minipigs (Markert et al. 2009). The slightly higher pressures reported previously may be attributable to the restraint used when taking the measurements. That restraint increases in BP and HR has recently nicely demonstrated – in accordance with the data in minipigs – in rats in which BP and HR were monitored both by telemetry as well as by the tail-cuff method (Grundt et al. 2009).

Markert's group (Stubhan et al. 2008; Markert et al. 2009; Markert 2011) also described fluctuation of the body temperature of the minipigs between daytime and nighttime (Fig. 21.11). During daytime (before feeding), body temperature was 37.0°C, whereas during the night, it increased to 37.5°C (Fig. 21.12). The body temperature cited in literature for miniature pigs ranged from 37–38°C (Bollen and Ellegaard 1997), 37.7 ± 0.2°C (Georgiev et al. 1972), to 38.2–39.9°C (Zambraski and Fuchs 1980). The increased HR during the night phase may contribute to the increase in body temperature. Nevertheless, temperature also increased in the experiment without feeding in which HR is not affected, indicating that factors other than elevated HR could be responsible. At least in rats and man, it is well

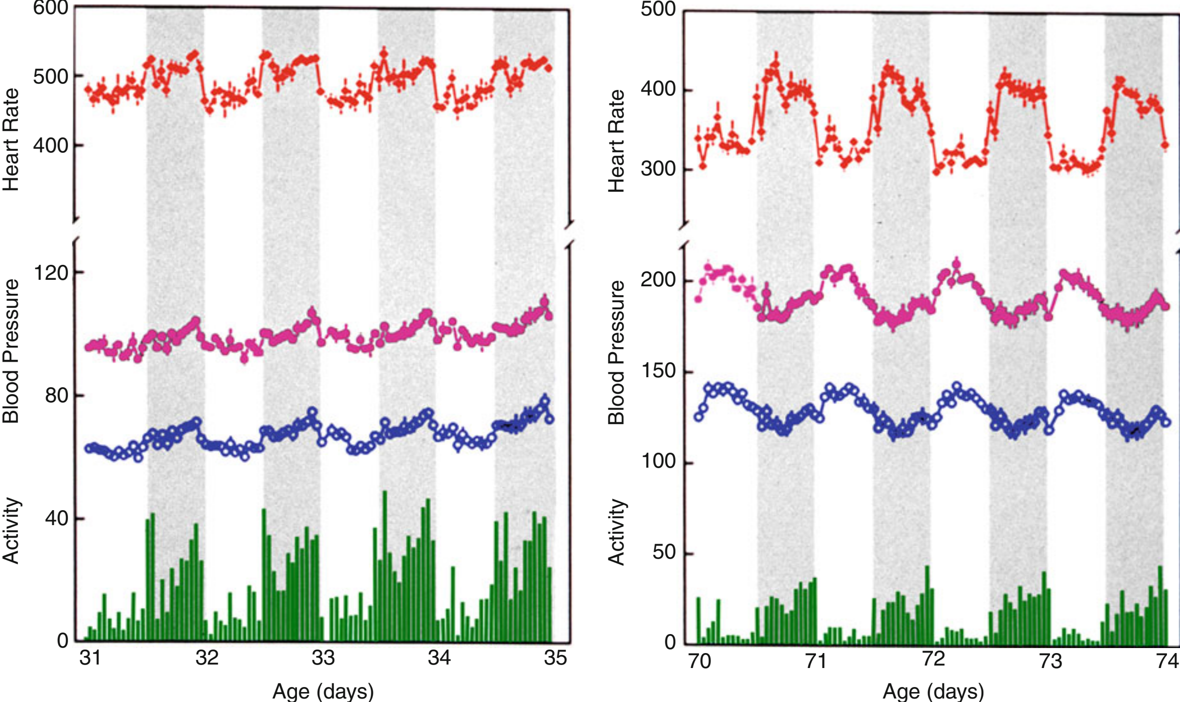

Fig. 21.27 Development of circadian rhythms with age in blood pressure, heart rate, and motility in transgenic hypertensive rats (TGR) (Acc. Witte and Lemmer (1999), Lemmer et al. (2003))

known that the body temperature is mainly governed by the internal clock, i.e., is really circadian (see below). However, such experiments have not been performed in minipigs.

ECG intervals reported from freely moving minipigs (Table 21.1) also range from earlier published data from nontelemetric studies. QT strongly correlated to the RR interval. The spontaneous changing of the T-wave polarity, which is not body-position-dependent, is thought to be due to the vegetative influences and may affect measurement of the QT interval. Markert's recommendation to use an individual correction of the QT interval for HR changes in swine is supported by observation from Harlan Laboratories (Jackson and Pohl 2010) and LAB Research (Authier et al. 2011), although the later two sources conclude that Fridericia correction (Fridericia 1920) can also be used.

However, in conclusion, it is important to note that the "circadian" (endogenous) character of rhythms in minipigs has not been investigated since no free-run data are available.

21.3.2 Small Animals

21.3.2.1 Rats and Rabbits

Limitations of the use of small animals in cardiovascular safety pharmacology studies are lack of I_{kr} channels in rat (no effects of ventricular repolarization can be studied) and nocturnal behavioral pattern of rats (see details in Sect. 4.1.3) and rabbits. With the advent of radiotelemetry (Brockway et al. 1991; Brockway and Brockway 1996; Mattes and Lemmer 1991; Lemmer et al. 1993a, see below), the circadian rhythms of hemodynamic data of rats and (later on) rabbits were investigated by numerous authors (Lemmer et al. 1993a; Akita et al. 2002; Eijzenbach et al. 1986; Hashimoto et al. 1999; Sato et al. 1995; Schnell and Wood 1993; Teelink and Clozel 1993; Kramer et al. 2000; Anigbogu et al. 2011; Kagohashi et al. 2008). Sato et al. (1995) collected by telemetry and compared BP and HR in conscious unrestrained rats and rabbits; unfortunately, a mixed set of both male and female animals was used. BP and HR in rabbits were lower than those in rats, but the circadian

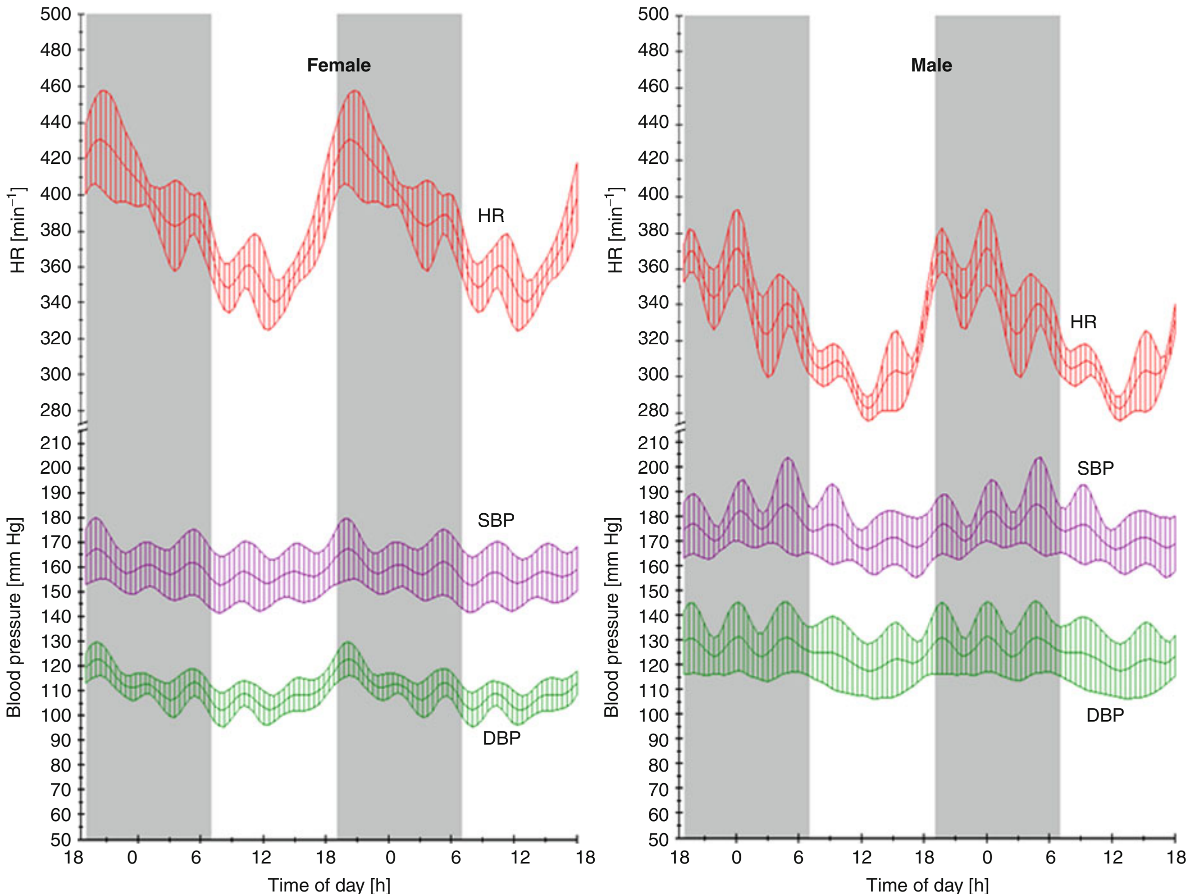

Fig. 21.28 Circadian rhythms in blood pressure and heart rate in female and male SHR rats (Acc. Grundt et al. (2006))

rhythms in rabbits showed nocturnal pattern similar to rats. In contrast, short-term variability in BP in rabbits was considerably larger than in rats. The hemodynamic data for 1-h intervals averaged over 4 days are shown in Fig. 21.12.

Data for any hour is the average of 120 points (30 points × 4 days). In each species, systolic BP, diastolic BP, and HR in the dark phase (08:00–20:00) tended to be higher than those in the light phase, showing nocturnal patterns. In rabbits, the line composed of hemodynamic data was almost flat in both the light and dark phases. The slope in each parameter during the transition period from the light phase to the dark phase (19:00–20:00) was gentle and obscure. In rats, values in the light phase were almost even, but those in the dark phase showed one peak in each parameter. The peaks appeared at 8 p.m. for systolic and diastolic BP and at 8–11 p.m. for HR. The slopes in each parameter during the switching period (19:00–20:00) were steep and obvious because of the presence of the peak in the dark phase, in contrast with the changes in rabbits.

Original recordings of mean BP and HR plotted every 2 min for 7 consecutive days in both species are presented in Fig. 21.13.

It clearly demonstrates not only the circadian rhythm but also short-term variability. It should be noted that the circadian rhythms of mean BP and HR in the rabbit showed nocturnal patterns, as already shown earlier for the rat (Brockway et al. 1991; Brockway and Brockway 1996; Mattes and Lemmer 1991; Lemmer et al. 1993a), and that the short-term variability in rabbits was appreciably larger than that in rats. The cause of short-term variability can be roughly

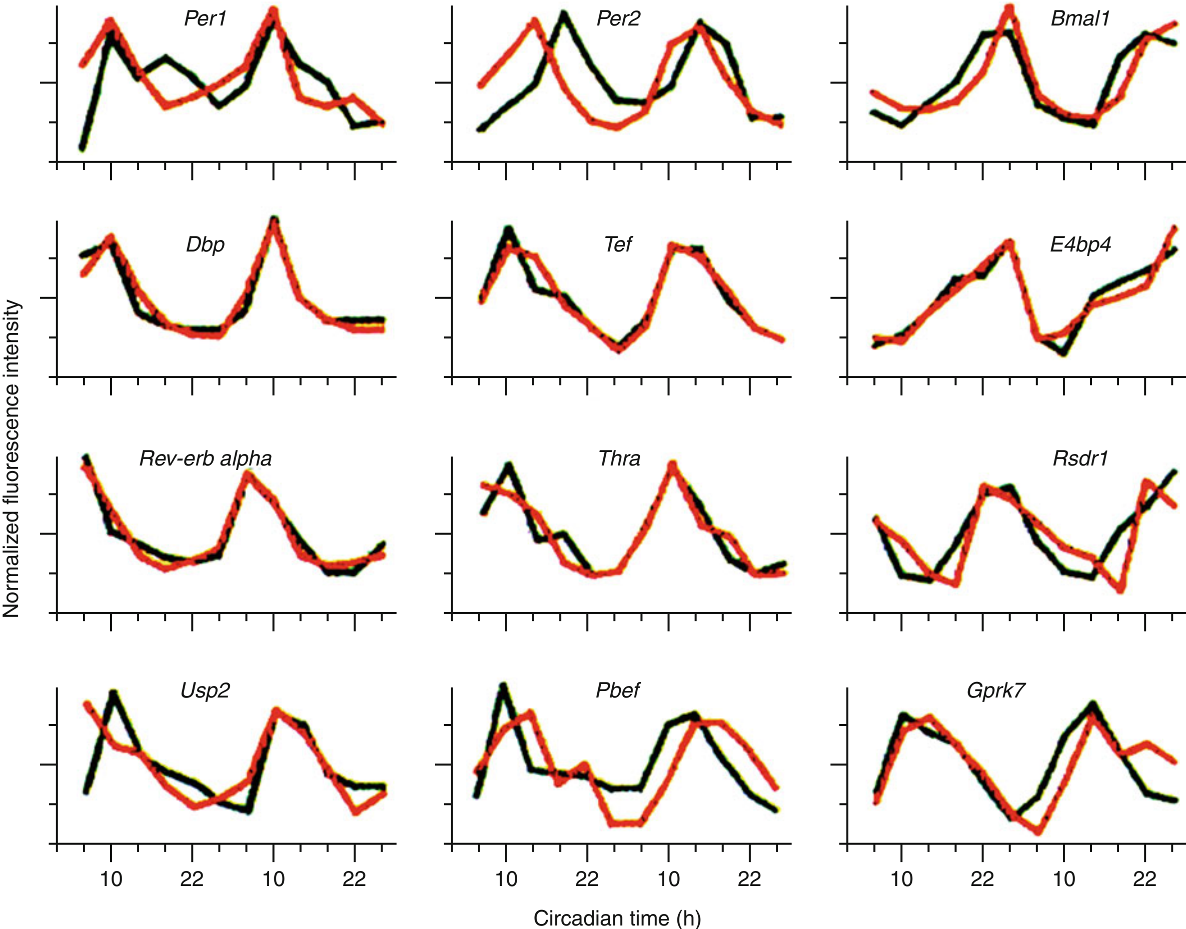

Fig. 21.29 Circadian gene expression profiles in mouse liver and heart; data for liver in black, those for heart in red color (Acc. Storch et al. (2002))

classified into two types: one is due to the routine behavioral changes including eating, drinking, and ambulating and the other is emotional or neural changes independent of body movement, which is considered to be more complex (Janssen et al. 2000). The effects of environmental conditions such as auditory stimuli also have to be taken into consideration. The analysis of the circadian rhythm of BP in rabbits is difficult to conduct, although it has been described that other physiologic functions in rabbits, including locomotor activity, food and water intake, urine and feces excretion, and body temperature, show clear nocturnal patterns in their circadian (Akita et al. 2002; Eijzenbach et al. 1986; Eisermann 1988; Varosi et al. 1990). The reason for the difficulty is considered to be primarily due to wide fluctuations in BP over short periods in rabbits. Another important condition for detecting the circadian rhythm in rabbits was considered to be reduction of stress. Since the swivel-tether system is stressful for the animals, some early studies failed to find the nocturnal pattern in rabbits even while evaluating HR (Hayashi 1981), which showed a clearer rhythm than BP in this study.

The data published by Sato et al. (1995) clearly indicate the complexity of biologic systems, their dependency on the internal clock and receptiveness to numerous signals. Knowledge of the test system's specific biological rhythms, awareness of animal models' responsiveness to internal and external

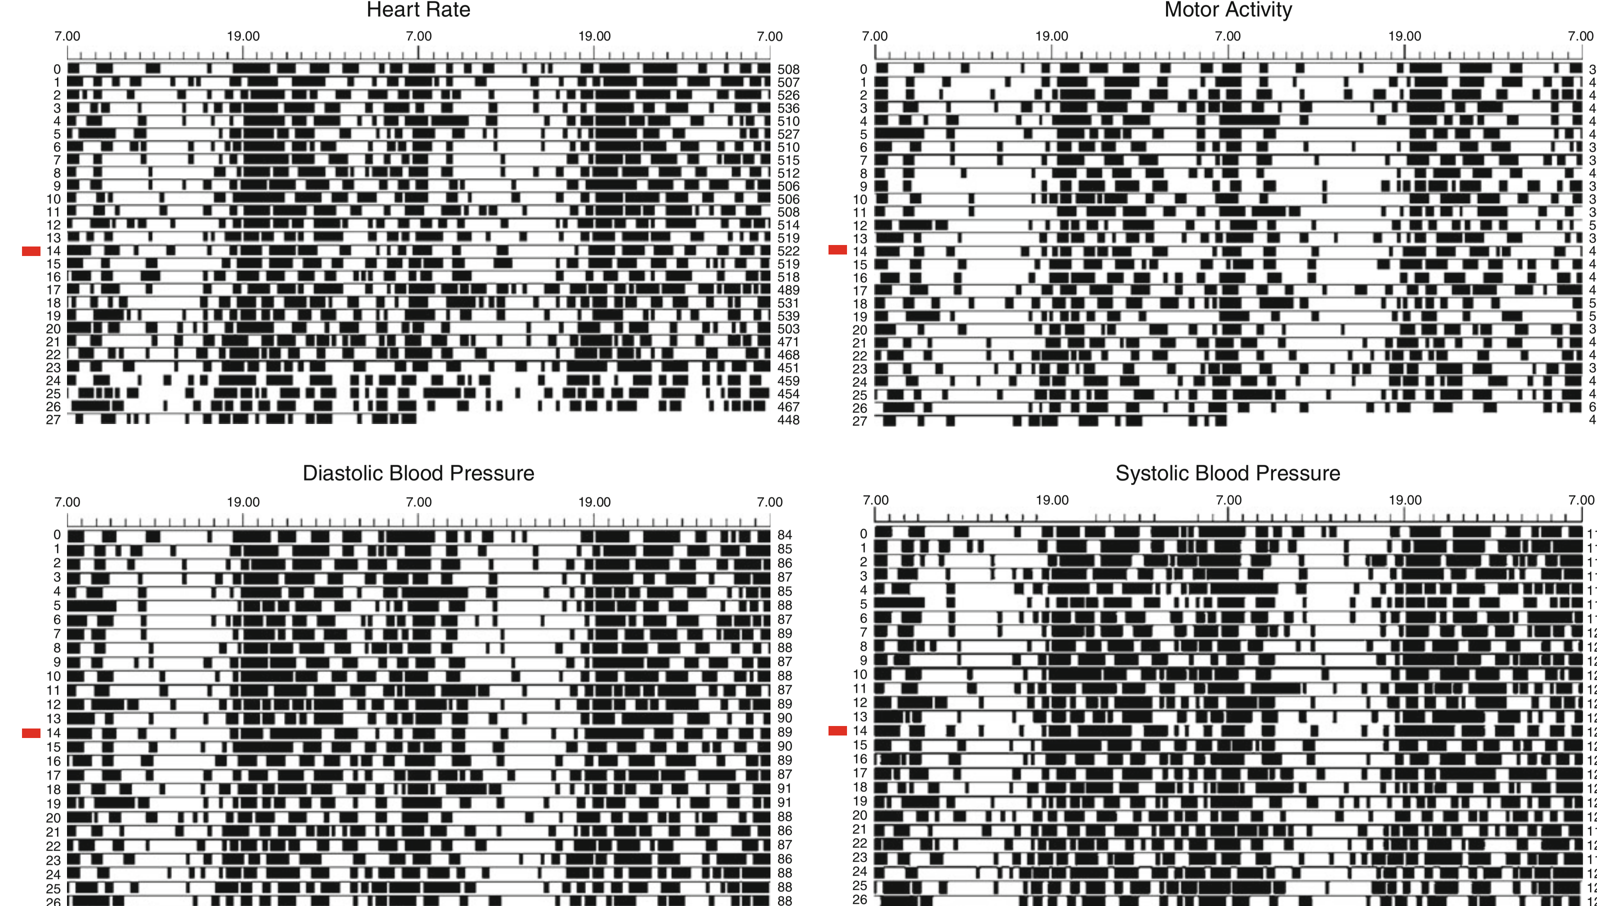

Fig. 21.30 Circadian rhythms in heart rate, blood pressure, and motility under synchronized conditions of LD 12:12 h light–dark and after free run in total darkness DD (Acc. Arraj and Lemmer (2007))

stimuli, and the extreme sensitivity of modern implantable telemetry should be taken into account for data analysis and interpretation.

21.4 Biological Clock and Chronopharmacology in Animal Models

21.4.1 Small Animals: Rats and Mice

Rodents such as mice and rats are widely used in testing drug toxicity and drug effects. In both species several strains were bred to study the influence of genetics on drug effects. Within the last century, several models of transgenic rats gained a lot of interest; however, rats are not suitable for developing knock-out animals. This can be much more efficiently done in mice; thus, new knock-out mice appear even daily on the market. In order to gain stable knock-outs, one needs to breed them for several generations, which, however, has not always been done.

21.4.1.1 Drug Toxicity

Already in the 1950s, toxicity of drugs was studied in rats and mice in relation to time-of-day. In 1951, Halberg et al. (1951) reported on daily variations in the blood eosinophil levels in mice. In rats, these authors showed, in addition, daily variations in tissue mitosis and rectal temperature (Halberg et al. 1954).

It is not possible to mention in detail all the data obtained on the circadian rhythm in drug toxicity in mice and rats; the interested reader will find such data in reviews (e.g., (Lemmer 1989; Reinberg and Smolensky 1983; Haus and Halberg 1959; Reinberg and Halberg 1971; Redfern and Lemmer 1997; Koukkari and Sothern 2006; Dunlop et al. 2004)).

Some examples may demonstrate circadian-phase-dependency in toxicity.

In 1976, Heinz von Mayersbach (1976) clearly demonstrated that the mortality of several compounds in mice can vary between 0% and 100% depending on the time of day of drug application (Fig. 21.14), a finding which has been a shock to many researchers. That LD_{50} values without looking at the time of day of drug application may be without any value of information is also seen in data on LD_{50} of procainamide (Fig. 21.15) and diazepam (Fig. 21.16) in mice (Ross et al. 1981; Bruguerolle 1984).

21.4.1.2 Behavioral Aspects

Activity is clearly circadian-phase-dependent in rodents which are night-active animals. Many studies have shown that both in rats and mice, motor activity predominates in the activity period during darkness. This is documented in telemetric studies (Figs. 21.17 and 21.18) and should be taken into account when testing drugs, which might influence motor activity.

In rats and mice, feeding and drinking behavior (Fig. 21.19) occur mainly during the activity period (Witte and Lemmer 1999). A rhythm in water intake and urine excretion could also be demonstrated in spontaneously hypertensive rats (SHR) using metabolic cages (Abu-Taha and Lemmer 2006). It is self-understanding that these rhythms must have implications for drug application. As a result, drugs given in either the drinking water or in the food pellets will *not* results neither in constant drug supply nor constant drug levels in these animals! This has been shown, e.g., after oral application of imipramine in the drinking water in rats (Fig. 21.20) (Lemmer and Holle 1991).

Food intake is rhythmic and persists also under free-run conditions in LL (light-light) (Rosenwasser et al. 1981), indicating that it is run by the internal clock.

Similarly, gastric emptying (Armstrong et al. 1978) (Fig. 21.21) and cytological liver organization (Müller 1971) are also not independent from circadian time. This indicates that even feeding the animals with drugs by a stomach tube will not result in constant drug absorption over time.

21.4.1.3 Cardiovascular System

It is generally accepted that multiple endogenous systems/mediators (sympathetic nervous system and catecholamines, renin-angiotensin-aldosterone system, endothelin, nitric oxide, vasoactive peptides, the hypothalamic-pituitary-adrenal axis, etc.) contribute to the regulation of BP. However, the regulation of the rhythmicity of BP and its disease-induced disturbances are not fully understood (Lemmer et al. 2005a, 2003).

There is some debate on whether and to what degree human rhythms in BP and HR are endogenous in nature (Kerkhof et al. 1998; Krauchi et al. 2002; Lemmer 1996). Therefore, animal models of primary and secondary hypertension can contribute to a better understanding of the mechanisms involved. We used different strains of normotensive, hypertensives, and

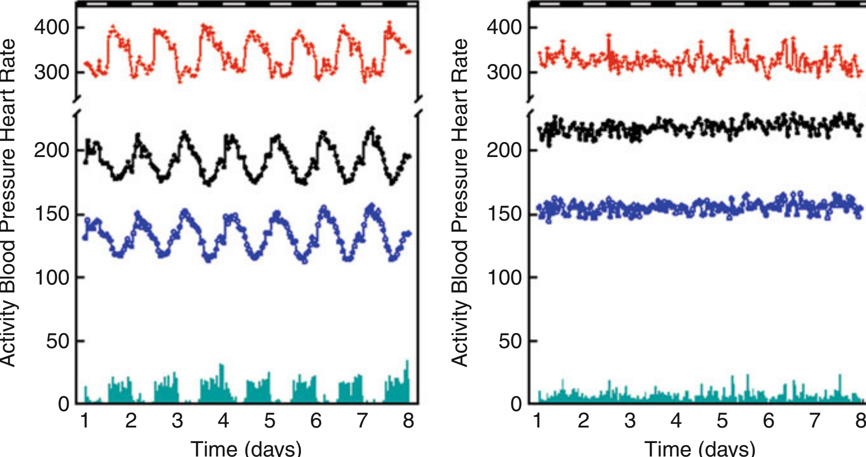

Fig. 21.31 Effect of SCN lesion (SCN-x) in transgenic-hypertensive rats (TGR) on blood pressure, heart rate, and activity (Acc. Witte et al. (1998c))

transgenic rats as well as wild-type and knock-out mice to address this question with the help of radiotelemetry.

21.4.1.4 Radiotelemetry

The availability of implantable radiotelemetric devices made it possible to study respiratory (Brockway and Brockway 1996) and various cardiovascular functions in freely moving, unrestrained animals (Brockway and Brockway 1996; Lemmer et al. 1993a; Kramer et al. 2000; Lange et al. 1991). There is a clear-cut advantage of radiotelemetry over the conventional tail-cuff method since radiotelemetry does not induce stress reactions in experimental animals, and furthermore, they can be monitored over several months. This was shown recently when comparing in the same animal radiotelemetry with tail cuff (Fig. 21.22). The procedure of tail cuff significantly increased BP and HR due to stress (Grundt et al. 2009).

We have shown that handling the animals and supplying food and water or cage change can increase BP and HR (Schnecko et al. 1996) (Fig. 21.23) as well as increase plasma concentrations of norepinephrine (NE) and angiotensin II (Schiffer et al. 2000, 2001). We have used these devices (Dataquest IV system, Data Sciences Inc., St. Paul, MN) in rats and mice either to measure simultaneously systolic and diastolic BP, HR, and activity by implanting the BP transmitter into the abdominal aorta (rats) (Lemmer et al. 1993a) or into the carotid artery (mice) (Lemmer et al. 2004a; Meier et al. 2004; Arraj et al. 2004), or an ECG-transmitter was used (Arraj and Lemmer 2006) (Fig. 21.24) to allow continuous monitoring of the HR as well as temperature and activity in mice.

Moreover, radiotelemetry can be applied to chronopharmacological studies in rodents, having the advantage that each single animal can be its own control, and dose–response studies can be performed at any circadian time after adequate wash-out periods (Meier et al. 2004; Lemmer et al. 1992; 1994; Schnecko et al. 1995; Witte et al. 1998a, 2001; Lemmer 2000; Pummer and Lemmer 2000; Janssen et al. 1998, 1993), these studies will not be further discussed here.

For data analysis, the Chronos-Fit program (Zuther and Lemmer 2004b) was used which fits partial Fourier series to the data (algorithm presented in (Zuther et al. 1996)) and allows presentation of a rhythmic pattern for single and grouped animals as well as transforming data into actograms (data marked black above the 24-h mean) to better demonstrate its rhythmicity.

21.4.1.5 Circadian Rhythm in Blood Pressure and Heart Rate in Rodents

Aside from normotensive control rats (models of human normotension: Sprague–Dawley: SPD, Wistar-Kyoto: WKY), spontaneously hypertensive rats (SHR) (Lemmer et al. 1993a) were used as a model of human primary hypertension, and transgenic TGR(mRen2)27 rats (TGR), as a model for human secondary hypertension (Lemmer et al. 1993a, b, 2003, 2005a) (Figs. 21.25 and 21.26). Experiments

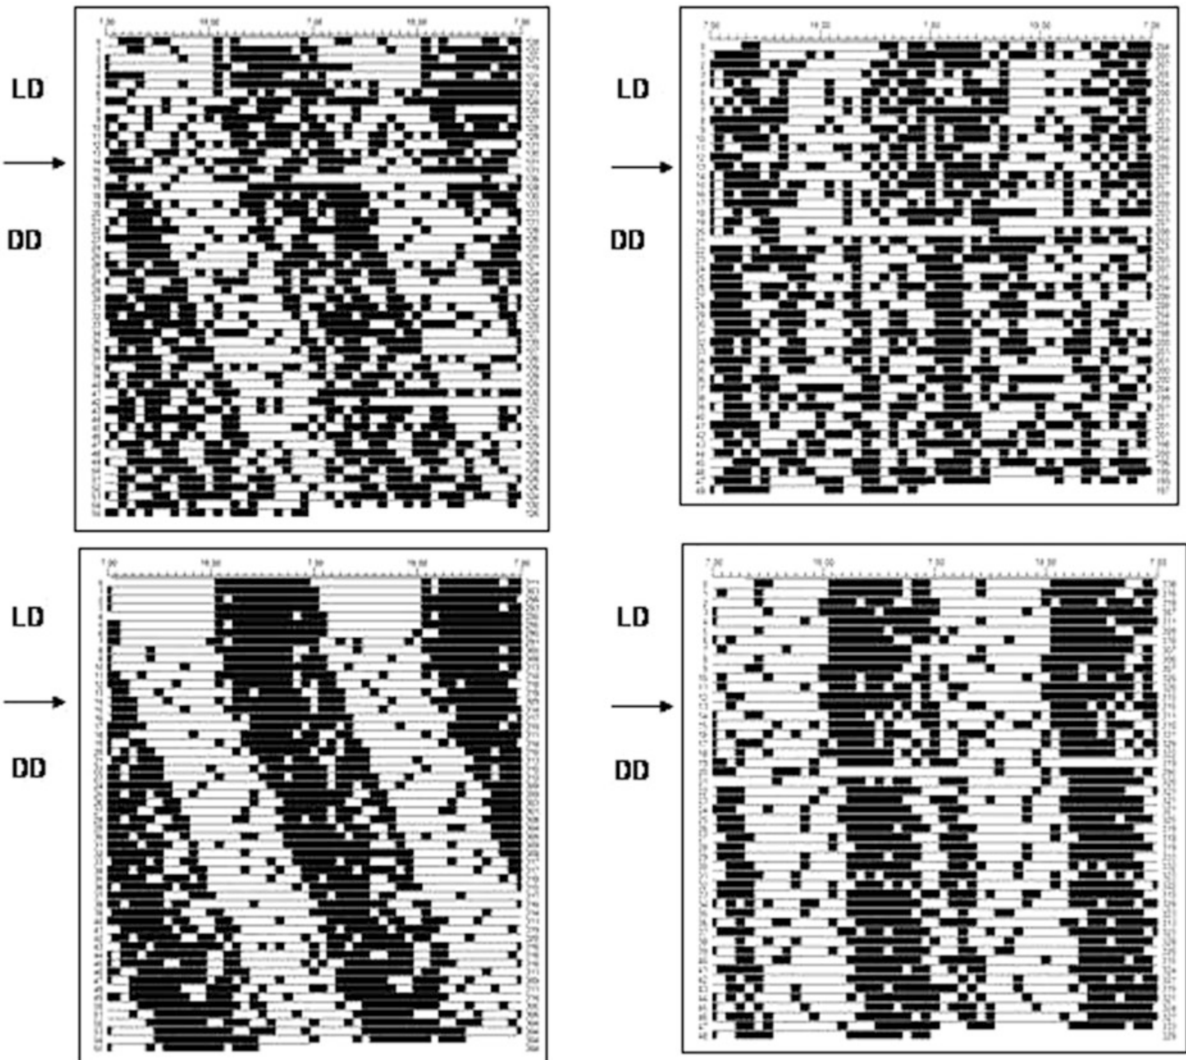

Fig. 21.32 Effects of LD (12:12 h) or DD (total darkness) on circadian rhythms in systolic blood pressure (SBP) and heart rate (HR) in normotensive and hypertensive TGR rats (Acc. Lemmer (2006))

were also performed in wild-type (C57) mice (Lemmer et al. 2004b, 2005b); several strains of transgenic (Witte et al. 2004) or knock-out mice are under investigation.

TGR(mREN2)27 rats develop a severe hypertension through the introduction of an additional mouse renin gene into the rat genome (Mullins et al. 1990). This is accompanied by an increase in the plasma concentrations of angiotensin II (Schiffer et al. 2000, 2001; Tokita et al. 1994), renin, aldosterone, and corticosterone (Lemmer et al. 2000a), all, with the exception of renin, exhibiting pronounced circadian rhythms.

In telemetric studies, not only was the severe hypertension confirmed but surprisingly an inverse circadian BP pattern with peak values in the resting phase of the rats, i.e., during the light phase, was found in this rat strain, whereas the rhythm in HR and activity were not disturbed with peak values in the dark phase (Lemmer et al. 1993a, b) (Figs. 21.27 and 21.28). Thus, there was an internal desynchronization between BP and HR in TGR, obviously induced by the transgene.

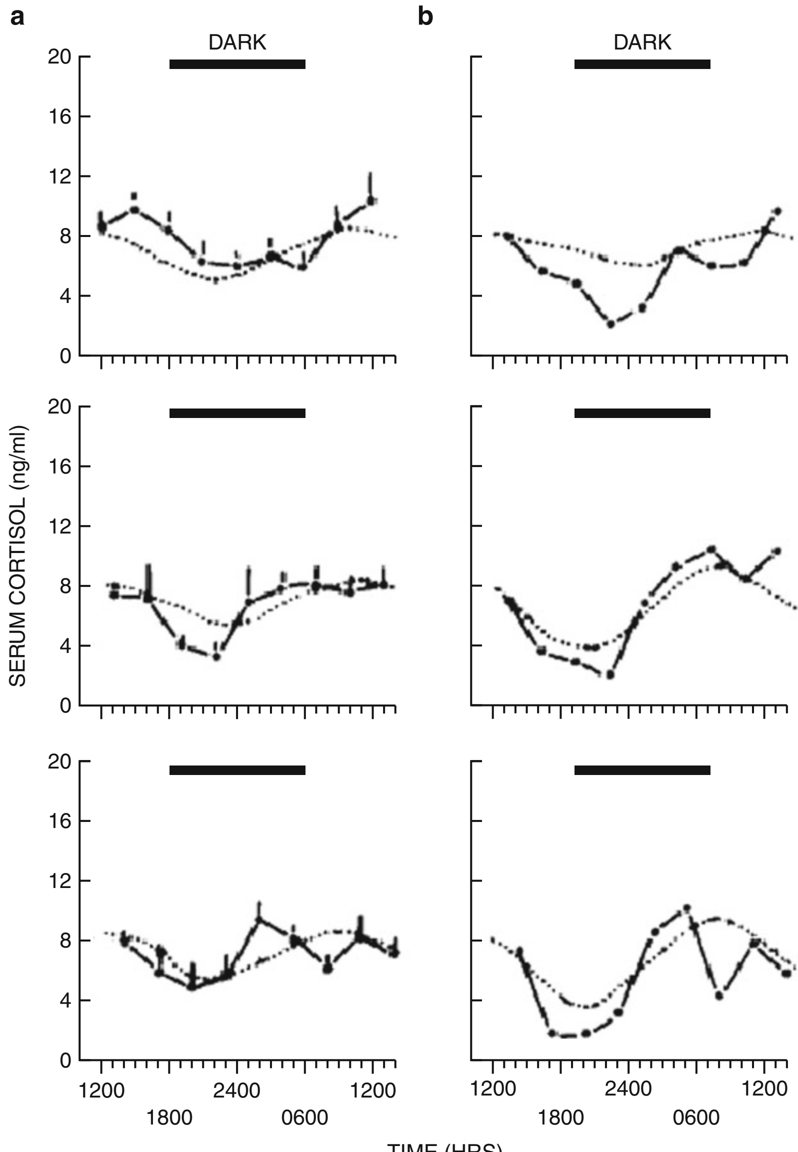

Fig. 21.33 Serum cortisol in female beagle dogs (Acc. Palazzolo and Quadri (1987))

Due to the nondipping behavior of BP during the rest phase, we proposed TGR as an animal model of human secondary hypertension (Lemmer et al. 1993a, b). Transgenic rats are normotensive up to about 7 weeks after birth and also display a normal circadian profile in BP, HR, and activity with peak values in the activity period during darkness (Witte and Lemmer 1999; Lemmer et al. 2003, 2005a; Witte et al. 1998b). Thereafter, TGR develop hypertension simultaneously with an about 12-h shift of the peak in BP from the dark into the light/rest phase (Witte and Lemmer 1999; Lemmer et al. 2003) (Fig. 21.29). This seems due to an ontogenic regulation of the mouse renin gene (Zhao et al. 1993). These data underline the need to monitor *before* drug testing whether a circadian rhythm in the parameter investigated is normal or possibly disturbed in relation to the age of the animal.

The circadian rhythms in BP and HR of WKY, SDR, and SHR – but not of TGR(mRen-2)27 – mirrored their

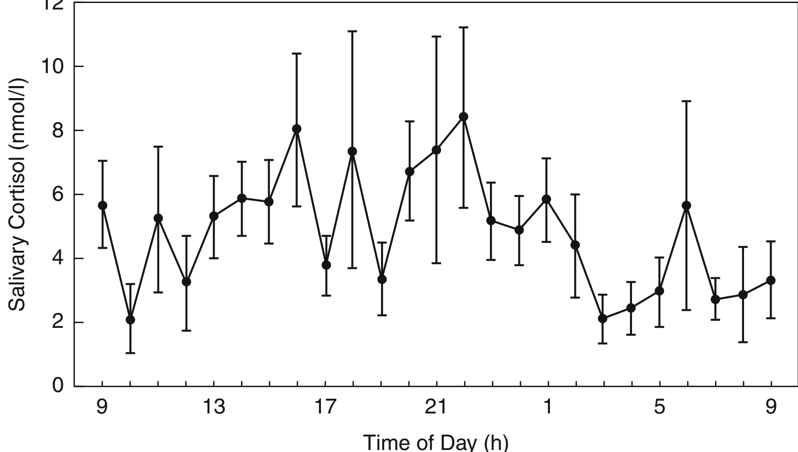

Fig. 21.34 Salivary serum cortisol in dogs (Acc. Koyama et al. (2003))

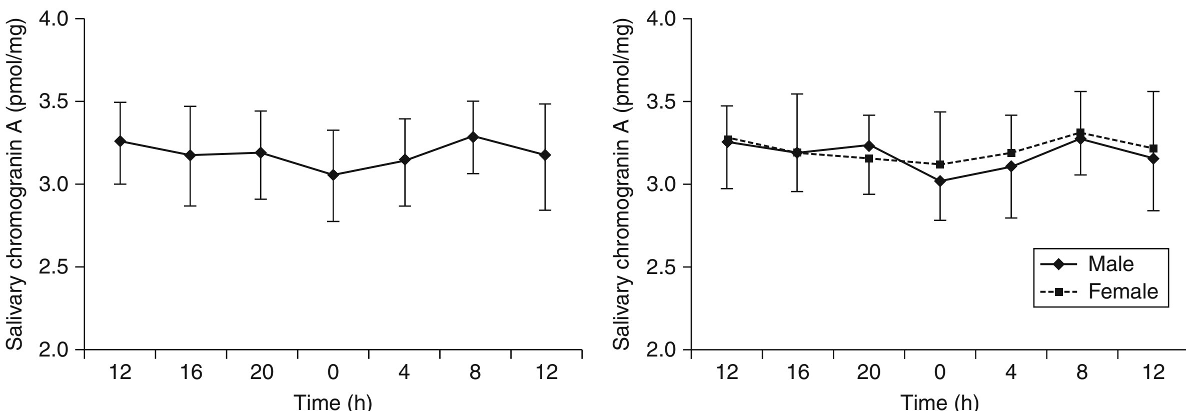

Fig. 21.35 Daily variations in salivary chromogranin in dogs (Acc. Kanai et al. (2008))

activity patterns in that peak values were observed in the rats' activity phase (Lemmer et al. 1993a). The circadian patterns in BP and HR of WKY, SDR, and SHR are similar to patterns observed in normotensive and primary hypertensive humans with the BP dipping in the rats' resting phase.

Radiotelemetric studies in male and female SHR also gave evidence for a gender-dependent rhythm in BP and HR, BP being lower and HR being higher in female than male rats (Fig. 21.28) (Grundt et al. 2006).

Interestingly, hypertensive TGR have a normal circadian pattern in kidney function, including renal plasma flow (Pons et al. 1996), and in the cerebral blood flow (Wauschkuhn et al. 2005), both peaking in the dark span. Thus, in TGR, renal and cerebral blood flow are internally desynchronized from the systemic flood flow, the underlying mechanisms are under investigation.

These data clearly show that studies on cardiovascular active drugs in rodents cannot be performed without taking the circadian rhythms and/or their internal desynchronization in cardiovascular functions into account.

Although BP is significantly elevated in TGR, we, however, found that plasma catecholamine

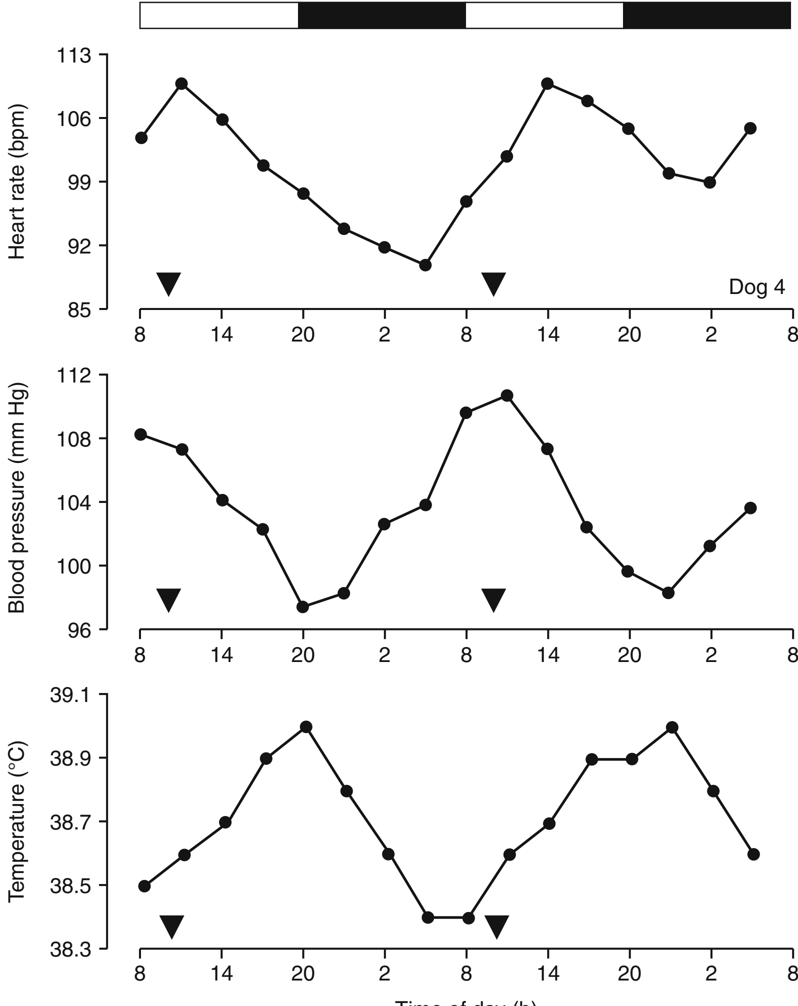

Fig. 21.36 Cardiovascular rhythms in fed and fasted dogs; there is an effect of feeding (triangle) (Acc. Piccione et al. (2005))

concentrations were reduced rather than increased in TGR; however, the rhythmic pattern and nocturnal peak were unaltered (Schiffer et al. 2000, 2001). Thus, the reduction in peripheral NE could be the result of different pathophysiological changes, such as an increased turnover of catecholamines, which is not detectable by measurement of plasma catecholamines, or an exhausted adrenergic system due to chronic stimulation by the renin-angiotensin-system, possibly with influence on the synthesizing enzyme tyrosine hydroxylase.

In a recent study, we were able to demonstrate by RT-PCR/Western blot in both nonhypertensive (4 weeks of age) and hypertensive (10 weeks) TGR lower NE concentrations and a reduced expression of the tyrosine-hydroxylase in cardiac tissue and adrenal glands. In the hypothalamus, NE concentrations were not different between the strains; however, tyrosine hydroxylase mRNA was significantly higher in TGR than SPD (Lemmer et al. 2003, 2005a). The turnover of NE was also reduced in hypertensive TGR in heart tissue and increased in the hypothalamus, both in the light and the dark phase. In adrenal glands of TGR, the mRNA of NE reuptake$_1$ transporter was also reduced, which could not be detected in hypothalamus (Lemmer et al. 2005a). These data indicate that the transgene in TGR leads to an increased central stimulation of the sympathetic nervous system and a consequent downregulation in the peripheral organs.

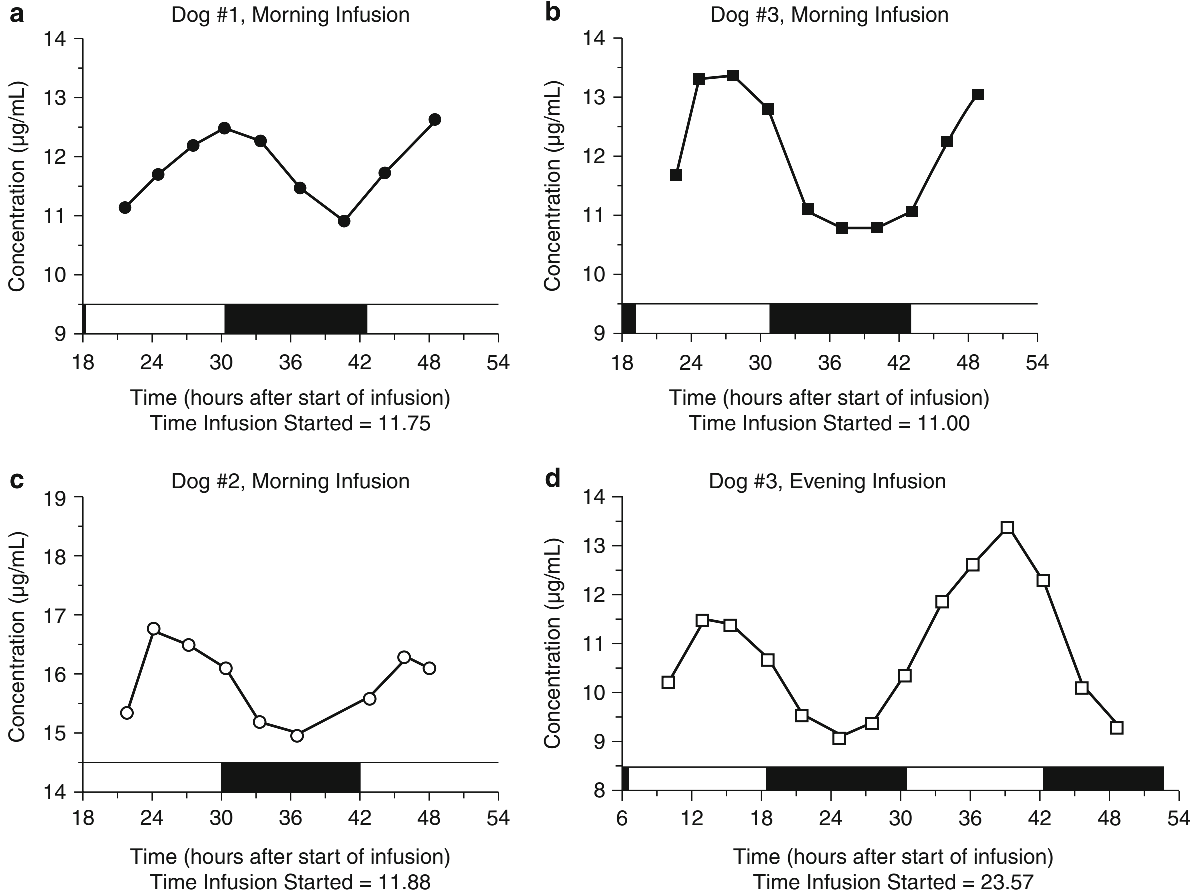

Fig. 21.37 Rhythm in serum theophylline concentration after constant infusion for 48 h in dogs (Acc. Rackley et al. (1988))

The data give evidence that the circadian pattern in cardiovascular functions can also be traced down to the molecular level. This observation also implies that studies on the genetics of, e.g., hypertension must be time-specified. Already in 2002, Storch could give evidence that the gene expression in mouse liver and heart follows a reproducible circadian rhythm (Fig. 21.29) (Storch et al. 2002).

In wild-type mice, a circadian rhythm in HR and BP similar to that found in rats was found by telemetry (Lemmer et al. 2004c, 2005b; Witte et al. 2004) with evidence for being endogenous since the rhythms persisted under total darkness under free-run conditions in DD (Fig. 21.30). This observation was confirmed by radiotelemetric ECG registration in mice (Lemmer et al. 2005b) (Fig. 21.24).

21.4.1.6 Cardiovascular Rhythms Driven by a Biological Clock?

Most behavioral and physiological parameters in mammals display at least some evidence of a 24-h temporal structure, reflecting an innate temporal program provided by biological clocks. The suprachiasmatic nucleus (SCN) of the hypothalamus serves as the main zeitgeber for such circadian rhythms. Light induction of clock genes might be a general factor through which the body clock is brought into synchronization with the external environment (Albrecht et al. 1997; Shigeyoshi et al. 1997; Spoelstra et al. 2004; Albrecht 2004). In rodents, light-induced phase shifts of behavioral rhythms are known to be positively correlated with the induction of the transcription factor Fos in the SCN, and it has been suggested that Fos itself mediates these light-induced

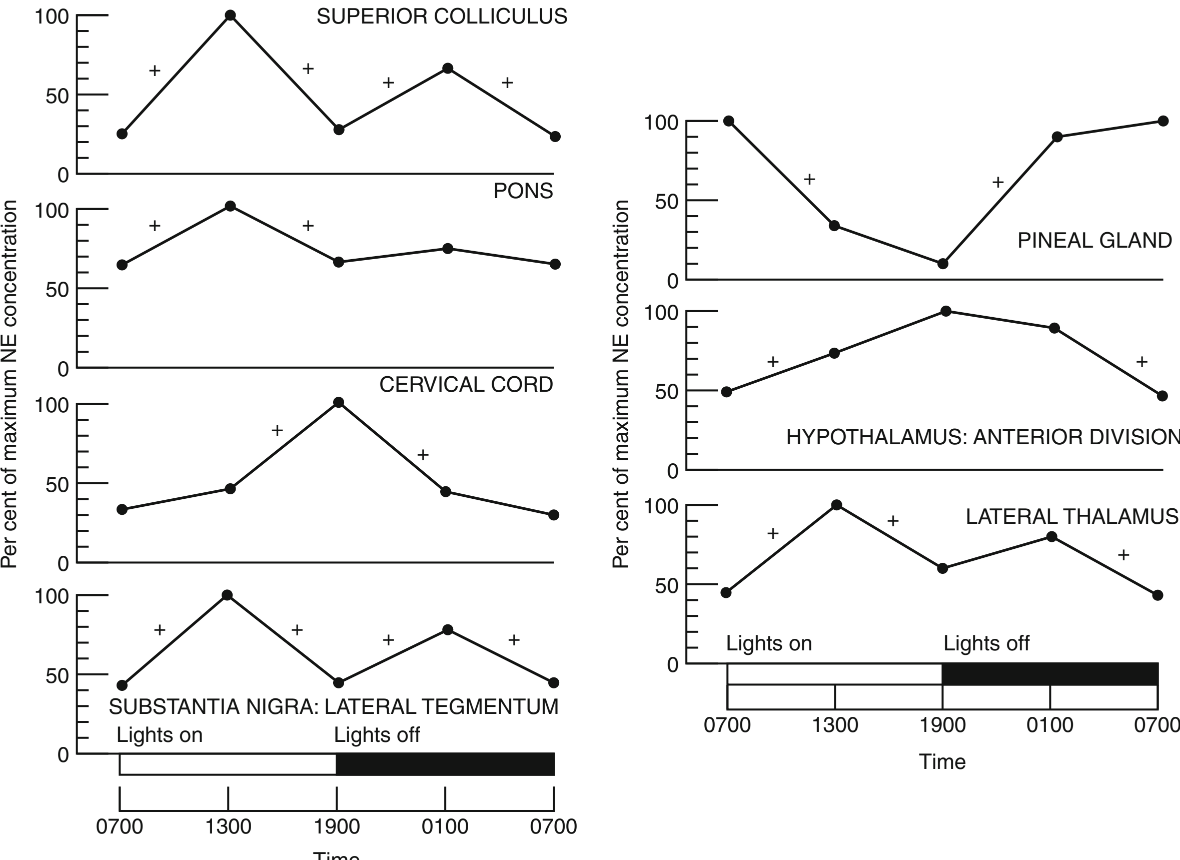

Fig. 21.38 Circadian rhythm in norepinephrine concentration in cat brain (Reis et al. 1968)

phase shifts (Kornhauser et al. 1996; Shimomura et al. 1998; Rusak et al. 1992; Sutin and Kilduff 1992; Lemmer et al. 2000b). As described above, alterations of endogenous rhythms, including severe changes in the rhythmic pattern of BP have been detected in TGR (mRen2)27 rats (Lemmer et al. 1993a, 2003, 2005a). Both in normotensive rats and in TGR, ablation of the suprachiasmatic nucleus eliminates 24-h BP variability (Janssen et al. 1994) and abolishes the rhythm in activity as well as in HR and BP (Witte et al. 1998c) (Fig. 21.31). This observation gives evidence that – at least in the rat – cardiovascular rhythms must also be under the control of the central clock(s) located in the SCN.

Another important feature of circadian rhythms is that they free run under constant environmental conditions, i.e., during constant darkness, indicating that they are really governed by an internal clock. Both in rats (Witte and Lemmer 1995) and mice (Lemmer et al. 2005b), we were able to demonstrate that the rhythms in cardiovascular functions (BP, HR) persisted under free run with a period deviating from 24 h. In normotensive rats, an increase (Figs. 21.18 and 21.31), and in normotensive mice, a shortening (Fig. 21.30) of the periods was found. Interestingly, BP and HR in TGR did not free run under DD (Fig. 21.32) (Lemmer 2006), indicating that light perception must be disturbed in this transgenic rat strain (Witte and Lemmer 1995).

In conclusion, the data obtained in various strains of rodents can help to better understand the rhythmic regulation of BP and HR and the underlying mechanisms involved. These data convincingly demonstrate that preclinical drug testing on cardiovascular functions and studies on safety pharmacology in rats and mice cannot be performed without taking the circadian rhythmic organization of these animals into account. Of additional importance are the observations

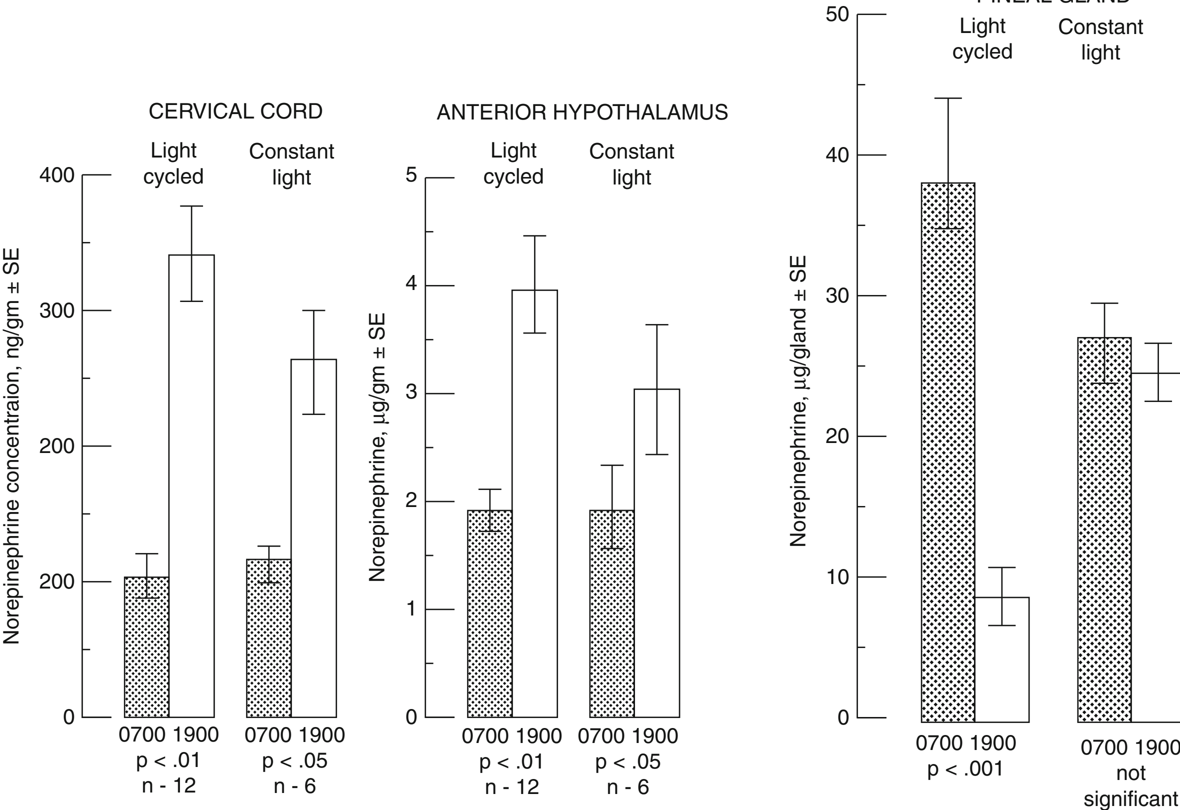

Fig. 21.39 Day-night differences in norepinephrine concentration in different areas of cat brain, either during a light–dark cycle or during continuous light (Acc. Reis et al. (1968))

that strain, gender, and age-dependent differences can occur in these rhythmic patterns. Finally, it is evident that radiotelemetry is the gold standard to study cardiovascular function in unrestrained, freely moving rodents. It should be mentioned that tissue pieces taken from brain, kidney, or liver even exhibit circadian rhythms during in vitro incubation (Reppert and Weaver 2002), clearly indicating the wonderful circadian organization of living material.

21.4.2 Other Experimental Animals

As already mentioned above, chronobiological investigations were rarely performed in other animal species used in preclinical studies and in safety pharmacology. Some examples are outlined below. With the exception in monkeys, experiments were generally not performed under free-run conditions to test for the endogenous component of a rhythmic pattern.

21.4.2.1 Dogs

In female beagle dogs, the rhythm in serum cortisol (radioimmunoassay) was studied at three different ages (Palazzolo and Quadri 1987). Blood samples were sampled every 3 h for three 24-h periods. In adult animals (3.3 years), a circadian rhythm could be detected, but not in puppies (8.4 weeks) and in older dogs (12.1 years). The authors concluded that the circadian rhythm was disrupted in old animals while not yet developed in puppies (Palazzolo and Quadri 1987) (Fig. 21.33).

More or less in line with the findings mentioned above are data on salivary cortisol (enzyme-linked immunosorbent assay) in adult beagle dogs in which no significant circadian rhythm was detected (Koyama et al. 2003) (Fig. 21.34).

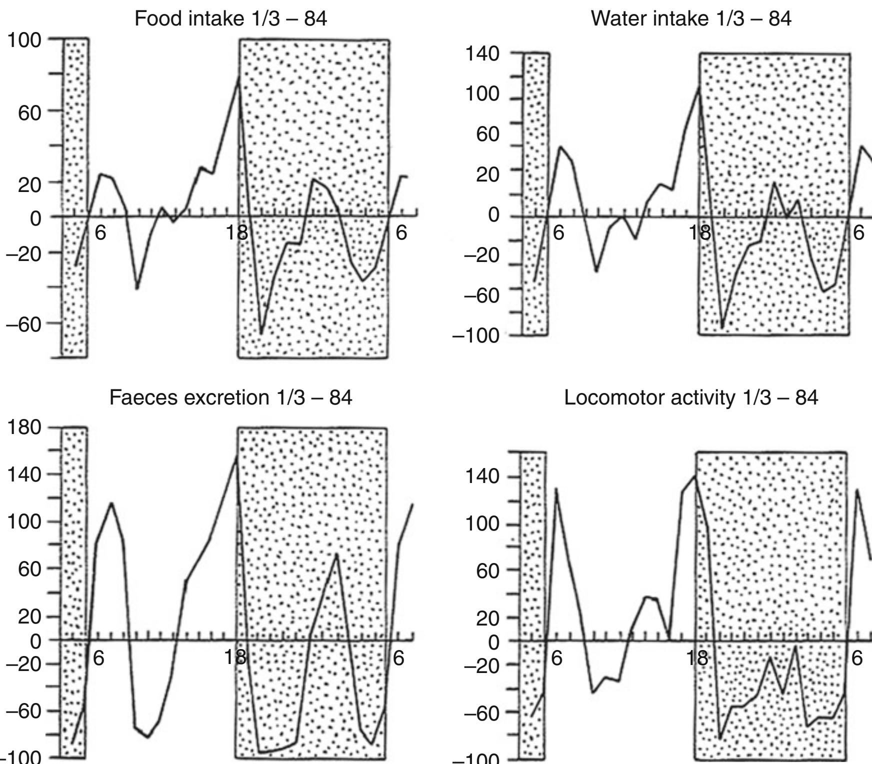

Fig. 21.40 Behavioral rhythms in guinea pigs (Acc. Jilge (1985))

There was also no circadian rhythm in salivary chromogranin in 16 beagle dogs (Kanai et al. 2008) (Fig. 21.35). Chromogranin exists in chromaffin granules of the adrenal medulla and is co-released with epinephrine or NE.

As discussed already earlier, with the use of telemetry, body temperature in female beagle dogs, in which the rectal temperature was determined by an electronic thermometer for 7 days, however, seems to be really circadian rhythmic (Refinetti and Piccione 2003). The authors speculate that the small robustness and a not-very-stable environmental condition may be responsible that, in the past, a significant rhythm was not detected.

The same group also reported on significant circadian rhythms on HR, BP, and temperature in 1-year-old beagle dogs which were not (??) altered by feeding (Piccione et al. 2005) (Fig. 21.36); this cannot be definitely concluded since no data are available under free-run conditions.

In eight unrestrained mongrel dogs, telemetry also gave evidence for circadian rhythms in the 24-h patterns of circulation as shown for HR, BP, peripheral resistance, and cardiac workload (Ashkar 1979).

In three mongrel dogs, the disposition of a theophylline infusion at a constant rate over 48 h was studied (Rackley et al. 1988). A characteristic 24-h rhythm was observed which was attributed to theophylline disposition with a draught around the night and a peak around the end of the light phase (Fig. 21.37).

In conclusion, the chronobiological studies in dogs give evidence for a 24-h rhythm in the cardiovascular system, which, however, was not verified under free-run conditions. It is possible that the daily routine and the feeding pattern of dogs may act as a prominent zeitgeber for these rhythms. It is of interest that the cortisol rhythm was not constantly rhythmic as found under entrained as well as free-run conditions in rats, man, and monkeys.

21.4.2.2 Cats

In mongrel adult cats, daily variations in NE concentration were reported in different areas of the brain (Fig. 21.38) (Reis et al. 1968).

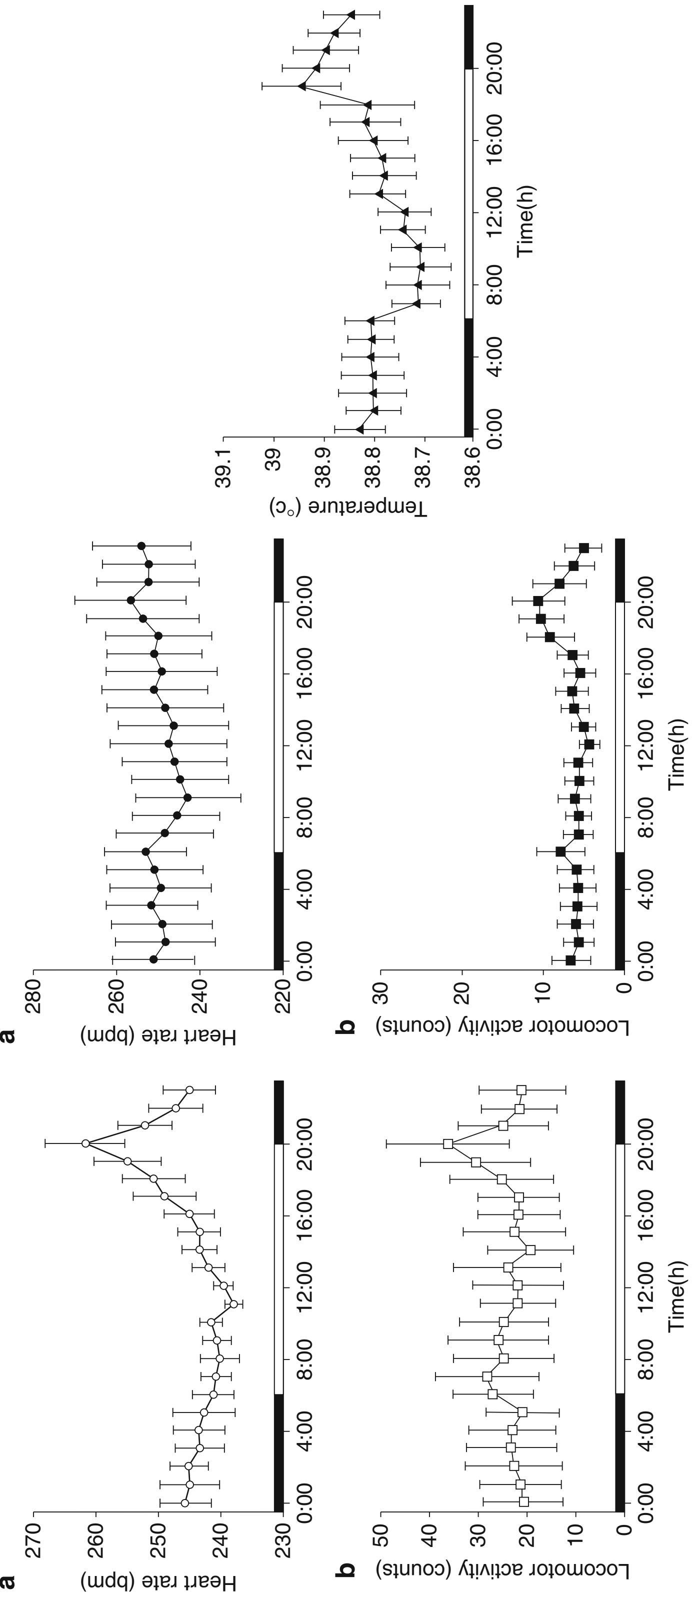

Fig. 21.41 Daily patterns in heart rate, body temperature, and activity in guinea pigs (Acc. Akita et al. (2001))

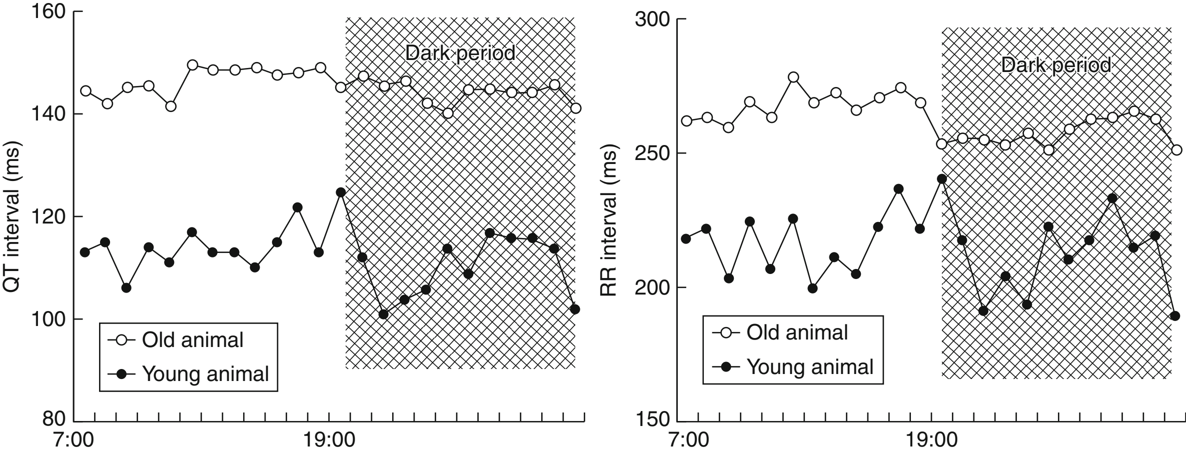

Fig. 21.42 Rhythm- and age-related changes in guinea pigs (6 weeks; 23 months) (Acc. Shiotani et al. (2008))

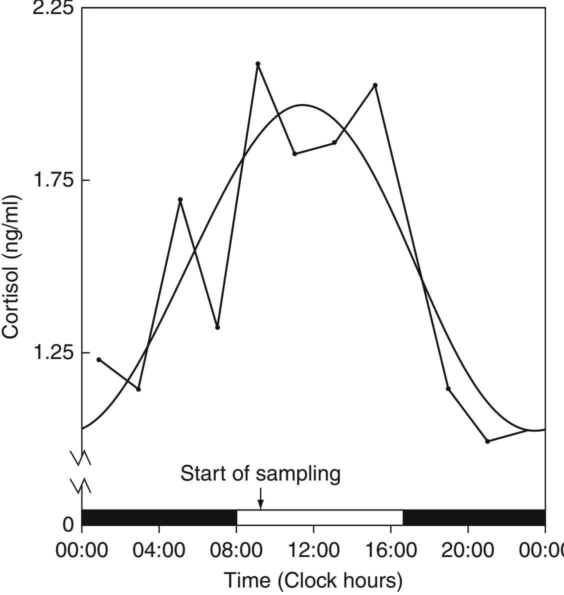

Fig. 21.43 Circadian rhythm in salivary cortisol in pigs (Acc. Ekkel et al. (1996))

Whereas in the pineal gland this rhythm did not persist under constant light, constant light did not abolish the rhythm in the cervical cord and anterior hypothalamus, giving evidence for the endogenous nature of this rhythm (Reis et al. 1968) (Fig. 21.39).

In conclusion, there are too few chronobiological data in cats. However, some 24-h rhythms were described and have to be taken into account in experiments when performed in cats.

21.4.2.3 Guinea Pigs

In guinea pigs, only very few data were reported. Jilge showed (Jilge 1985) that behavioral aspects such as food intake, water intake, feces secretion, and locomotor activity displayed 24-h rhythms (Fig. 21.40). However, the rhythm in locomotor activity as well as in HR and body temperature were only observed in some animals (Akita et al. 2001) by radiotelemetry (Fig. 21.41) which is the best method available. The authors underline that guinea pigs should not be used in chronobiomedical research.

In addition, cardiovascular data on QT and RR intervals showed some rhythm in young guinea pigs, but not in elderly ones (Fig. 21.42) (Shiotani et al. 2008).

In conclusion, the documentation of chronobiological data in guinea pigs is small.

21.4.2.4 Pigs

Data on minipigs were presented above. Additional chronobiological data were published in other pig strains. Salivary cortisol displays a significant circadian rhythm with a peak at the onset of the light period (Ekkel et al. 1996) (Fig. 21.43).

Similar data were reported for peripheral levels of melatonin (Fig. 21.44) (Bubenik et al. 2000). Heat production seems to be also circadian-phase-dependent both under feeding and during starvation and refeeding (Fig. 21.45) (Chwalibog et al. 2004).

In domestic pigs, a circadian rhythm exists also in the rhythm of body temperature (Fig. 21.46) with an

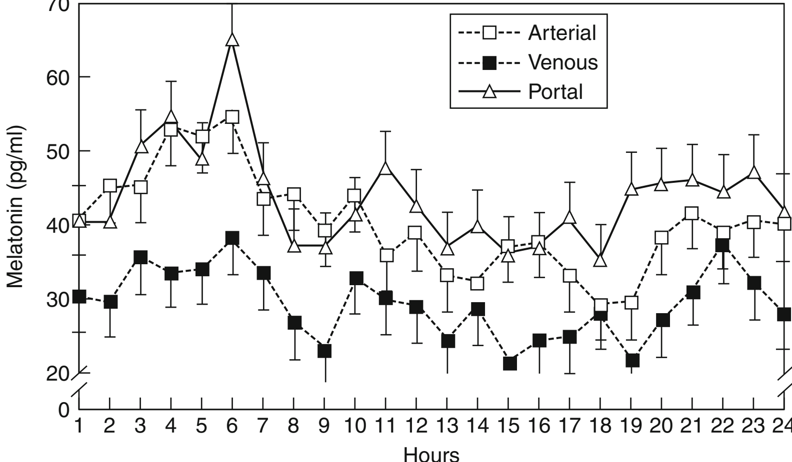

Fig. 21.44 Daily variation in peripheral melatonin in ten pigs (Acc. Bubenik et al. (2000))

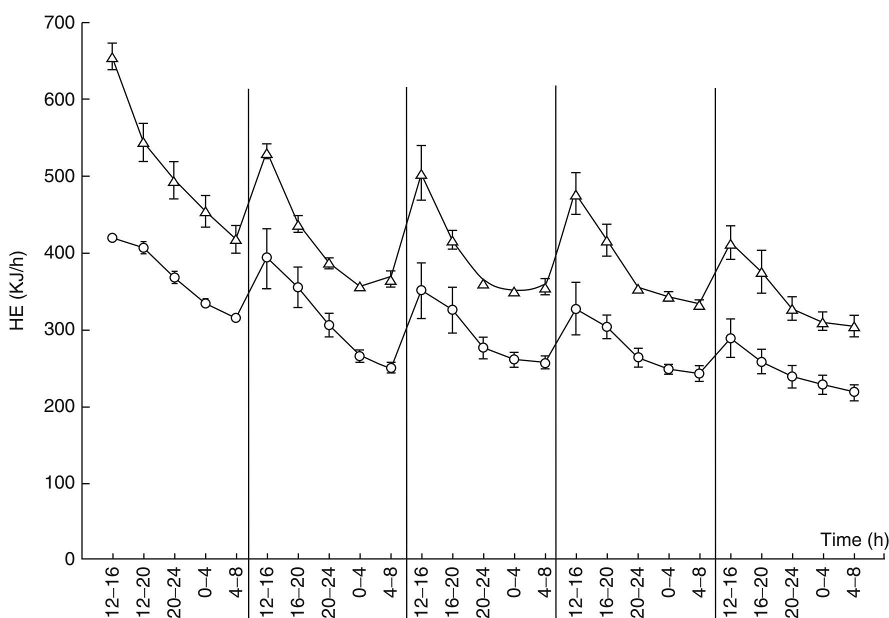

Fig. 21.45 Rhythm in heat production in pigs (Acc. Chwalibog et al. (2004))

acrophase at the end of the light phase (Hanneman et al. 2005).

21.4.2.5 Monkeys

Much more chronobiological data were obtained in monkeys. The temperature rhythm – which in man is really governed by the internal clock – displays pronounced circadian variations in cynomolgus monkeys with peak values in the activity period during the light phase as discussed earlier and shown in Fig. 21.47 (Almirall et al. 2001).

Circadian rhythms were also described for melatonin and ultradian rhythms in NE concentrations in rhesus (Fig. 21.48) and in Japanese monkeys (Levin et al. 1978; Nozaki et al. 1990).

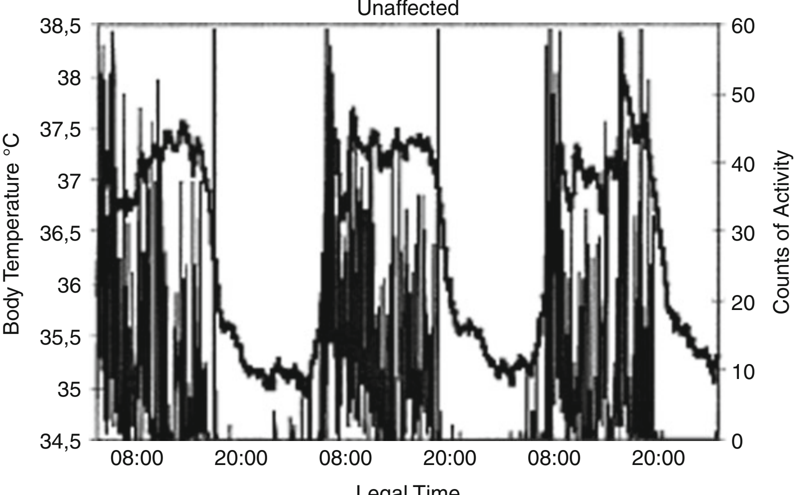

Fig. 21.47 Rhythms in body temperature and activity in cynomolgus monkeys (Acc. Almirall et al. (2001))

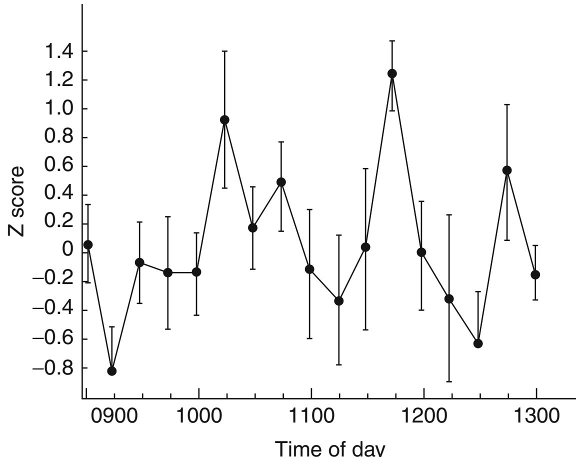

Fig. 21.48 Ultradian plasma norepinephrine concentration rhythm in rhesus monkey (Acc. Levin et al. (1978); Nozaki et al. (1990))

In capuchin and squirrel monkeys, circadian rhythms were documented, in activity, temperature, ACTH, cortisol (Torres-Farfan et al. 2008), and in temperature and activity (Boulos et al. 1996) (Fig. 21.49), as well as in pig-tailed macaques (Weed and Hienz 2006).

Most interestingly, the rhythm in temperature in squirrel monkeys persisted under free-run condition during total lightness (Fig. 21.50), clearly indicating the endogenous nature of this rhythm (Fuller and Edgar 1986).

Quite recently, it has been shown that the sleep rhythm in the primate Macaca mulatta persisted under constant dim light (CDL) – which again indicates the involvement of the biological clock in rhythm generation – and was reduced age-dependently (Zhdanova et al. 2011) (Fig. 21.51).

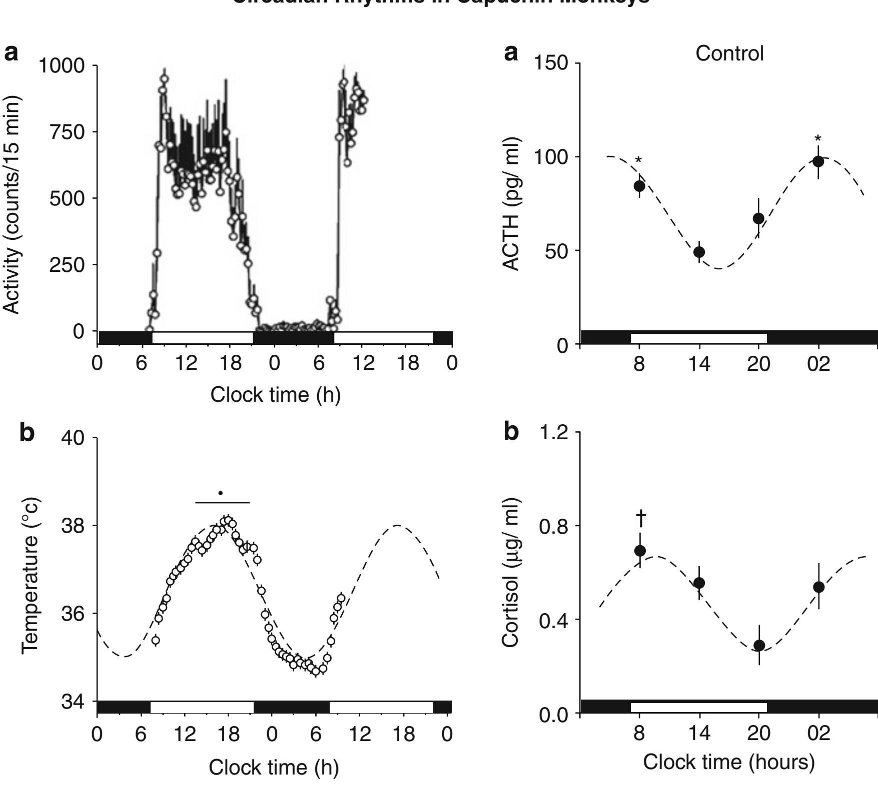

Fig. 21.49 Circadian rhythms in capuchin monkeys (Acc. Torres-Farfan et al. (2008))

21.5 Conclusion

In conclusion, monkeys convincingly display circadian rhythms in various body functions which must be considered in safety pharmacology studies. In this respect, monkeys seem to be very similar to humans in which many functions were nicely documented to be circadian-phase-dependent.

In this chapter, we have tried to document that circadian rhythms in bodily functions do exist in many animal species. There is no doubt that safety pharmacology experiments as well as other preclinical studies MUST take into account the rhythmic organization in planning and performing drug studies.

I would like to underline the importance of radiotelemetry for chronobiology, chronopharmacology, and safety pharmacology. When about 20 years ago, we received a cardiovascular telemetric device from Brian Brockway – the inventor and founder of DataSciences – and when our group (B.L.) and his were the first to publish telemetric data from rats ((Brockway et al. 1991; Brockway and Brockway 1996; Mattes and Lemmer 1991; Lemmer et al. 1993a)), we were already fully convinced that radiotelemetry in freely moving, unrestrained, unstressed animals would become the gold standard of cardiovascular research in the future. This has turned out to be true as we can demonstrate in this chapter. However, we have to admit that the concept of chronobiology/chronopharmacology should be more intensively incorporated in safety pharmacology as well as in other preclinical studies. The biological clock which is present in all living creatures must be looked at as a keystone in animal research in order to get a better understanding of bodily functions and in order to obtain a sound and reliable evaluation of a drug's kinetics and effects/side effects!

Acknowledgment The research of B.L. was supported by several grants from the Deutsche Forschungsgemeinschaft and from PROCOP program of the European Community.

22.1 Introduction

The use of biomaterials to enable and enhance life-saving therapies in medicine has its documented roots in the 1600s. Historically, drugs were administered systemically for acute emergency situations. As injectable drug technologies developed, it was soon observed that drug administration would often be more effective if given in sustained-release or tailored-release profiles. However, the potential safety risks of drugs administered by these novel devices and biomaterials were also quickly realized. This chapter will examine the documented evolution of the delivery of such compounds, the challenges encountered, and the solutions developed to address the need for safe delivery of drugs, proteins, and cells for human use. Each biomaterial-based drug delivery system is unique to the drug, peptide, or protein employed in the system. Therefore, this chapter will focus on the safety considerations along with the therapeutic efficacy offered by this evolving and developing area of therapeutics.

22.1.1 Biomaterial Beginnings

The first documented scientific drug delivery studies may be traced to 1655, when Dr. Richard Lower in England successfully transfused blood. His initial transfusion experiments kept an exsanguinated dog alive by using a sharpened quill to connect a donor dog to the carotid artery of (Blundell 1829) the second animal (Lower 1932).

Lower's work was followed by attempts to conduct animal-to-human transfusions by various investigators

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_25, © Springer-Verlag Berlin Heidelberg 2013

in Europe in the late 1600s. These experiments quickly revealed the toxicity and the immunologic differences between animal and human blood. Consequently, the Paris Society of Physicians quickly outlawed animal-to-human transfusions in 1678 because of numerous adverse reactions, many resulting in death (Learoyd 2006). These observations represented some of the first documented potential toxicities of biologic compounds administered from one organism to another as early advances in biomaterials allowed transfusions to take place.

In 1817, Dr. John Leacock at Edinburgh Medical School described experimental transfusions between dogs and cats using an ox ureter connected with two crow's quills (Leacock 1817). In 1825, James Blundell, a British obstetrician, performed the first successful transfusion of human blood to a patient for the treatment of postpartum hemorrhage based on Dr. Leacock's studies (Schmidt and Leacock 2002), (Blundell 1829). He extracted a small amount of blood from a husband's arm, and he successfully transfused the man's wife. Between 1825 and 1830, he performed ten documented transfusions, five of which proved beneficial to his patients and five failures due to blood type incompatibility, and published these results (Blundell 1829). It was not until Karl Landsteiner developed the ABO blood-typing system in 1900 did safe human blood transfusions became feasible to avoid immunological differences among humans (Landsteiner 1900).

22.1.2 Development of the Hypodermic Needle

Dr. Francis Rynd described the invention of the hollow needle in 1844 in order to replace the quills derived from bird feathers (Rynd 1845). In 1853, Charles Pravaz is credited with the development of the first practical metal syringe made entirely from silver (Dippenaar 2007). The trocar and cannula were made of gold or platinum (Schorr 1966). Later in the same year, Alexander Wood experimented with the use of a hollow needle and syringe for the more effective subcutaneous administration of morphine in the treatment of neuralgia (Wood 1855). Injections of drugs such as morphine were initially targeted at treating local pain among individuals. It soon became apparent that there was systemic absorption of these drugs as ailments far removed from the site of injection also benefited. Ultimately, this observation would become the basis of all injection therapies. Virtually all therapeutic protein drugs are administered in aqueous solutions using needles and syringes.

22.1.3 Disinfection of Surgical and Drug Administration Devices

All of these instruments used for injection were of course subject to bacterial contamination. John Erichsen lectured through the 1860s that surgery was traditionally conducted without any attempts to avoid infection (Erichsen 1974). His student, Joseph Lister, experimented with the use of phenol to disinfect wounds and found a significant reduction of gangrene among surgical patients (Lister 1867).

22.2 Establishment of Standards and Regulatory Guidance for Biomaterials and Drug Combinations

These early attempts to develop syringes, needles, biomaterials, and drugs foretold the same basic challenges confronting the delivery of drugs today using advanced biomaterials:

(a) The drug–biomaterial stability and compatibility
(b) The immunologic consequences of drugs interacting with the recipient
(c) The need for sterile injectables (Siegel et al. 2007)

Each country's regulatory bodies have established the safety standards for the combination of biomaterials and drugs. The United States' Food and Drug Administration (FDA) and the European Commission set their standards independently. Each regulatory agency also takes guidance from the nongovernmental "International Organization for Standardization" (ISO) whose headquarters are in Geneva, Switzerland (Biological Evaluation of Medical Devices 2007). The biological evaluation of medical devices is outlined in ISO 10993.

The ISO guidelines apply to biomaterials that are either:

(a) Solid and nonbiodegradable
(b) Degradable and/or resorbable
(c) Nonsolid, such as porous materials, liquids, pastes, and particulates

There are 19 sections of the ISO standards covering tests for genotoxicity, carcinogenicity, and reproductive toxicity; tests for interactions with blood; tests for in vitro cytotoxicity; tests for local effects after implantation, identification, and quantification of potential degradation products; tests for irritation and skin sensitization; tests for systemic toxicity, toxicokinetic study design for degradation products and leachables; and principles and methods for immunotoxicology testing of medical devices (International Organization for Standardization 2010).

Drug and delivery device combinations for the FDA are defined in 21 CFR § 3.2(e) of the Code of Federal Regulations as (Code of Federal Regulations, Title 21 2005):

1. A product comprised of two or more regulated components, i.e., drug/device, biologic/device, drug/biologic, or drug/device/biologic, that are physically, chemically, or otherwise combined or mixed and produced as a single entity
2. Two or more separate products packaged together in a single package or as a unit and comprised of drug and device products, device and biological products, or biological and drug products
3. A drug, device, or biological product packaged separately that according to its investigational plan or proposed labeling is intended for use only with an approved individually specified drug, device, or biological product where both are required to achieve the intended use, indication, or effect and where upon approval of the proposed product the labeling of the approved product would need to be changed, e.g., to reflect a change in intended use, dosage form, strength, route of administration, or significant change in dose
4. Any investigational drug, device, or biological product packaged separately that according to its proposed labeling is for use only with another individually specified investigational drug, device, or biological product where both are required to achieve the intended use, indication, or effect

Additionally, the FDA has issued a draft Guidance for Industry and Staff entitled "Classification of Products as Drugs and Devices" with the goal of providing direction of the process to obtain a formal determination of whether a product is classified as a drug, device, biological product, or combination product (Office of Combination Products Food and Drug Administration 2011). Biomaterials that release low-molecular-weight drugs and proteins are considered combination products.

The complexity of the drug approval process can potentially result in products that meet the drug definition or both the drug and device definitions and that also meet the definition of biological product, might be classified as biological products, rather than as devices or drugs, and be subject to licensure under the PHS Act (Office of Combination Products Food and Drug Administration 2011).

22.3 Immunogenicity of Proteins and Biomaterials

The interaction of recombinant proteins and biomaterials (Meade and Silver 1990) can result in immunogenic reactions as a result of exposing the body to foreign compounds (Kessler et al. 2006; European Medicines Agency 2006) (Swanson). Any variables that may cause a change in protein structure, i.e., pH, temperature, interactions with packaging materials, storage conditions, etc., may potentially elicit the production of antibodies. Production of antibodies in preclinical studies can affect the regulatory path of the protein. Serious side effects may be observed in humans. For example, antierythropoietin antibody formation and pure red-cell aplasia has been observed in patients treated with recombinant human erythropoietin (Casadevall et al. 2002).

Therefore, antibody monitoring with appropriate assays is required to ascertain the safety and efficacy of therapeutic proteins. The combination of biomaterials and therapeutic proteins may accelerate protein unfolding and structure change. Preclinical immunogenicity assessment is important to determine toxicology and antibody neutralization potential. In general, initial responses to new compounds are IgM with low affinity and of low concentration. High-affinity mature IgG class antibodies are more likely to neutralize therapeutic proteins. These studies take at least 6–12 months to determine both binding and neutralizing antibodies to the protein or biomaterial. In patients, clinically relevant antibodies (Ab) include (a) the clearing Ab, (b) the sustaining Ab, (c) the neutralizing Ab, (d) allergic reactions, and (e) cross-reactions with endogenous proteins. Immunoassays are developed to detect antibodies using ELISA, RIA, surface plasmon resonance (BIAcore), or electrochemiluminescence.

22.4 Biotechnology Needs for Drug Delivery

The modern biotechnology revolution began in 1974 with the first expression of a foreign gene implanted in bacteria using recombinant DNA methods (Morrow et al. 1974; Berg et al. 1974). The need to administer most of these therapeutic protein compounds by injection is compounded by their short half-lives, and therefore, there is a need to inject these drugs frequently (Duckworth et al. 1998). There are over 70 self-administered injectable drugs approved for marketing in the United States with the goal of encouraging better therapy through improved patient compliance (Indepdence Blue Cross 2010). The vast majority of these compounds are therapeutic proteins. Therapeutic protein drugs such as insulin, interferon, and growth hormone are now dispensed from injector pens (Fischer et al. 2008). The therapeutic advantages, device safety, ease of use, accuracy of dose, and small needle size of injector pens are helping to increase patient compliance and positive outcome among those who self-administer therapeutic proteins. From a regulatory viewpoint, the drug stability in these prefilled self-contained delivery systems must be assessed to the same degree as a new chemical entity. Table 22.1 is a representative summary of biomaterials and drugs that have been combined to enable delivery of a variety of pharmaceuticals for therapeutic benefit to the patient.

22.5 Drug Delivery Technologies to Alter Drug Pharmacokinetics

The short pharmacodynamic half-lives of these biotechnology compounds have stimulated much research to deliver these drugs by the oral route, by the nasal route, by inhalation, or in a sustained-release fashion. Unfortunately, only a small subset of peptide-based therapeutics has been marketed through noninvasive routes (e.g., cyclosporine, insulin, calcitonin, desmopressin). This is primarily a function of their low molecular weights and small dosing requirements (Brown 2005).

22.5.1 Chemical Excipients to Alter Pharmacokinetics of Proteins

The most successful approaches for increasing the biological and pharmacodynamic half-lives of therapeutic proteins have been the use of chemical excipients. The use of ionic complex formation, covalent pegylation or glycosylation, and amino acid alterations of proteins has resulted in several successful FDA-approved products. Chemical excipient biomaterials that are used to enhance the half-life of therapeutic compounds include both naturally occurring and synthetic compounds.

22.5.1.1 Ion Complex Formation

Many significant advances in protein drug delivery systems have been accomplished using insulin as a model. This is a consequence of insulin being the first pure protein therapeutic molecule discovered and that diabetes affects an increasing percentage of the world's population. Therefore, the discovery of insulin by Frederick Banting and Charles Best in 1922 is naturally associated with the beginning of research aimed at finding optimal means to administer this exogenous protein to patients (Banting and Best 1922) and altering its delivery profile.

Insulin complexes came into use 15 years after its discovery. Hagedorn showed that insulin combined with the basic protein protamine derived from salmon sperm resulted in continuous insulin action for 3–12 h (Hagedorn et al. 1936). Protamines are small arginine-rich peptides that are positively charged. When combined with insulin, they shift the isoelectric point of insulin to physiologic pH. This lowers its solubility, forming a subcutaneous depot after injection and significantly extends its half-life. Hallas-Moller showed an unique interaction of proteins with metal ions in 1952 when he developed the Lente insulin form by adding zinc to insulin in an acetate buffer which also effectively decreased insulin's solubility (Hallas-Moller et al. 1952). The primary chemical and amino acid structure of insulin remains unaltered in both these examples of ion complex formation.

22.5.1.2 Pegylation

There are several FDA-approved therapeutic proteins whose pharmacokinetic properties improved and

Table 22.1 Biomaterial–drug combinations

Biomaterial/drug attachment	Drug	Purpose	Benefits/adverse reactions	Reference
PLGA/physical	Leuprolide, goserelin	Prostate cancer	Increased patient compliance/lower dose, injection site pain	Knobil (1990), Okada (1997)
PLGA/physical	Octreotide (Sandostatin)	Acromegaly	Increased patient compliance/injection site pain	Scarpignato and Pelonsini (2001), Anthony and Freda (2009)
PLGA/physical	Exenatide	Type II diabetes	Increased patient compliance/injection site pain, pancreatitis, gastrointestinal pain, hypoglycemia	Bunck et al. (2009), Bydureon
PLGA/physical	hGH	Pediatric growth hormone deficiency	Increased patient compliance/injection site pain, nodules, erythema, bruising, itching	Nutropin Depot Package Insert (1999)
Protamine/ionic	Insulin	Diabetes	Extended-release basal insulin/hypoglycemia	Hagedorn et al. (1936)
Zinc/ionic	Insulin	Diabetes	Extended-release basal insulin/hypoglycemia	Hallas-Moller et al. (1952)
Polyethylene glycol (PEG)/covalent	Enzyme adenosine deaminase	Severe combined immunodeficiency disease	Better efficacy, longer half-life/allergies, bleeding, dizziness	Adagen® Package Insert, Enzon Pharmaceuticals (2008)
Polyethylene glycol (PEG)/covalent	Interferon	Hepatitis C, cirrhosis, bridging fibrosis	Better efficacy, longer half-life/immune reaction	Avramis and Panosyan (2005)
Polyethylene glycol (PEG)/covalent	hGH	Acromegaly	Better efficacy, longer half-life/immune reaction	Schreiber et al. (2007)
Polyethylene glycol (PEG)/covalent	Filgrastim	Febrile neutropenia infection	Better efficacy, longer half-life/immune reaction, bone ache, bleeding, injection site redness	Neulasta® Package Insert, Amgen, Inc. (2002)
Glycosylation/covalent	Erythropoietin	Anemia	Better efficacy, longer half-life/immune reaction, cardiovascular problems	Macdougall et al. (2007)
Fatty acid/covalent	GLP-1 receptor agonist	Type II diabetes	Increased patient compliance/injection site pain, pancreatitis, gastrointestinal pain, hypoglycemia	Watson et al. (2010)
Fatty acid/covalent	Insulin	Diabetes	Sustained release/injection site redness, hypoglycemia, allergic reaction	(Levemir® Insulin Detemir (rDNA) Injection, Package Insert Novo Nordisk)
Amino acid substitutions/ covalent	Insulin	Diabetes	Faster onset or longer half-life/injection site redness, hypoglycemia, allergic reaction	DeFelippis et al. (1988), Home et al. (1999), Dailey et al. (2004), Gillies et al. (2000), Luzio et al. (2003)
Drug-eluting stents, stainless steel, cobalt-chromium-nickel-molybdenum alloy, tantalum, nitinol, EVAc, PBMA/physical	Paclitaxel, sirolimus (rapamycin), zotarolimus, everolimus	Prevention of restenosis following angioplasty	Longer interval between coronary blockage/bleeding, allergic reaction, myocardial infarction, stent thrombosis	Morice et al. (2007)
EVA copolymer, PVA/physical	Ganciclovir	Cytomegalovirus retinitis	Extended half-life of drug/visual acuity loss, hemorrhage, retinal detachment, cataracts	Vitrasert Package Insert, Bausch and Lomb (2003)
Silicone, PVA/physical	Fluocinolone acetonide	Posterior uveitis	Extended half-life of drug/increase intraocular pressure, glaucoma, optic nerve damage, visual acuity field defects, cataract formation, infection	Retisert Package Insert, Bausch and Lomb (2009)

extended by formation of covalent polyethylene glycol (PEG) conjugates with the drug (Alconcel et al. 2011; Mehvar 2000). The most common chemical approach has been to activate the PEG with functional groups suitable for reaction with lysine and N-terminal amino groups (Kozlowski and Harris 2001). Pegylation of a protein generally masks the protein's surface. This effectively increases the protein's molecular size, reduces renal ultrafiltration, inhibits antibodies or antigen processing cells, and reduces degradation by proteolytic enzymes. In vivo circulation lifetimes are increased, but the specific activity of the compounds may be compromised. Thus, the protein's distribution is significantly altered. From a chemistry viewpoint, pegylating a protein can result in variations in the number of PEG chains bound to the protein. The protein may then have increased polydispersity with regard to the molecular weight of the newly formed molecule. There may also be difficulties in determining the exact sites of conjugation in polypeptides (Veronese 2001; Overbay and Manley 2002).

There are many approved pegylated proteins currently in clinical use (Brown 2005). The first FDA-approved pegylated product was Enzon's Adagen®. It is a PEG-modified version of the bovine enzyme adenosine deaminase (ADA). It is used to treat ADA, commonly known as the "bubble boy disease." Another Enzon product called Oncaspar® is a PEG-modified version of the enzyme L-asparaginase used as a chemotherapeutic agent for acute lymphoblastic leukemia (Avramis and Panosyan 2005; Mehvar 2000).

Clinical studies examined the efficacy and safety of Genentech's Pegasys® peginterferon-**α**2a in patients with hepatitis C-related cirrhosis or bridging fibrosis. The studies showed that 180 μg of peginterferon-**α**2a administered once weekly was significantly more effective than 3 million units of standard interferon-**α**2a administered three times weekly (Heathcote et al. 2000; Heathcote et al. 2000). Merck's PEG-Intron®, peginterferon-**α**2b, is also indicated for the treatment of chronic hepatitis C. Pfizer's pegvisomant (Somavert®) is a pegylated hGH receptor antagonist used in the treatment of acromegaly (Schreiber et al. 2007). Amgen's pegfilgrastim (Neulasta®) is used to decrease the incidence of infection, manifested by febrile neutropenia.

22.5.1.3 Glycosylation

Darbepoetin-α (Aranesp®) is an erythropoiesis-stimulating protein similar to recombinant human erythropoietin. It is for the treatment of chronic renal disease-induced anemia or in patients with anemia caused by chemotherapy (Overbay and Manley 2002). It is produced in Chinese hamster ovary cells by recombinant DNA technology. It differs from human erythropoietin by the addition of two N-linked oligosaccharide chains. These two additional sites result from amino acid substitutions in the peptide backbone, which do not interfere with receptor binding. Darbepoetin-α has also has 22 sialic acid residues compared to 14 sialic acid residues in human erythropoietin. The carbohydrate chains increase the molecular weight of this glycoprotein from approximately 30,000 Da for human erythropoietin to 37,000 Da for darbepoetin-α. It has a threefold longer terminal half-life in humans than erythropoietin, leading to a decrease in frequency of administration and greater patient compliance (Macdougall et al. 2007).

22.5.1.4 Covalent Attachment of Long-Chain Fatty Acids

Liraglutide is an analogue of human GLP-1 that acts as a GLP-1 receptor agonist to stimulate insulin release from pancreatic beta cells. As a result, it is injected once daily for the treatment of type II diabetes (Watson et al. 2010). Clinical studies have confirmed reductions in HbA1c, low risk of hypoglycemia, and reductions in body weight and systolic blood pressure. Liraglutide differs from native GLP-1 by replacing $arginine_{34}$ with a lysine residue. In addition, a C-16 fatty acid (palmitic acid) is covalently attached with a glutamic acid spacer on the lysine residue at position 26 of the peptide. This structural alteration increases the drug's half-life from 1.5 min to 13 h resulting in a once-daily injectable formulation for this 3,751-Da peptide.

Insulin detemir is a long-acting analogue of human insulin. This formulation has a covalently attached fatty acid to the molecule in order to increase its biological half-life. Insulin detemir (Levemir®) differs from human insulin in that the B-chain amino acid threonine in position B30 has been removed and C14-myristic fatty acid chain has been attached to the lysine at amino acid position B29 (Levemir® Insulin Detemir (rDNA) Injection, Package Insert Novo Nordisk). The 24-h prolonged action of this insulin

analogue is mediated by the slow systemic absorption of insulin detemir molecules from the injection site. The slow absorption is due to strong self-association of the drug molecules and albumin binding. Insulin detemir is distributed more slowly to peripheral target tissues since insulin detemir in the bloodstream is highly bound to albumin.

22.5.1.5 Amino Acid Substitutions

Several novel insulin formulations have been developed that dramatically affect insulin's pharmacokinetic properties. This has been accomplished by substituting amino acids in the primary structure of the protein in a manner that does not change the biological activity of the molecule. These amino acid substitutions can increase or decrease insulin pharmacokinetics.

22.5.1.6 Rapid-Onset Insulins

Insulin is composed of two polypeptide chains: A and B. Chain A consists of 21 amino acids and chain B consists of 30 amino acids. In human insulin, amino acids 28 and 29 on the B-chain are $proline_{28}$ and $lysine_{29}$, respectively. Eli Lilly's Lyspro Humalog® insulin decreases the onset of action of insulin by a factor of 2 compared with insulin's native structure. In this insulin formulation, two amino acids have been reversed from native human insulin so that lysine appears in position 28 and proline is found at position 29 (DeFelippis et al. 1988; Home et al. 1999). This form of insulin favors the more soluble monomeric structure, and hence, it diffuses from the injection site more rapidly to control postprandial glucose compared with regular human insulin. Novo Nordisk's Novolog insulin-aspart analogue accomplishes the same rapid onset-of-action effect as the $proline_{28}$ $lysine_{29}$-insulin by simply substituting the $proline_{28}$ with aspartic acid in the same position of the B-chain (Home et al. 1999). Sanofi-Aventis' Apidra insulin glulisine is another rapid-acting human insulin analogue produced by recombinant DNA technology utilizing a nonpathogenic laboratory strain of *Escherichia coli* (K12) (Dailey et al. 2004). Insulin glulisine differs from human insulin in that the B-chain amino acids $asparagine_3$ is replaced by lysine and the $lysine_{29}$ on position B29 is replaced by glutamic acid.

Each of these rapid-acting insulins is designed to benefit diabetic patient care by helping to maintain postprandial blood glucose close to the normal.

22.5.1.7 Slow-Release Insulin

Other insulin primary structure substitutions are designed to increase the biological half-life of insulin. Sanofi-Aventis' Lantus insulin glargine is a 24-h, long-acting recombinant insulin analogue. Structurally, the A-chain $asparagine_{21}$ amino acid is replaced with a glycine and two arginine amino acids are added to the C-terminus of the B-chain (Gillies et al. 2000). This insulin analogue is injected in aqueous solution at pH 4. On subcutaneous injection, the insulin glargine precipitates at physiological pH and forms a slow-dissolving depot of hexameric insulin. Studies have shown a relatively constant 24-h concentration profile, with no pronounced insulin peak (Luzio et al. 2003). This profile effectively mimics physiological basal insulin release.

Thus, chemical alterations of existing proteins have resulted in dosage forms with significantly altered pharmacokinetics compared with their native molecules. These methods are not panaceas, for pegylation and amino acid substitutions can alter the biological activity of the molecules, their toxicities, or their bioavailabilities.

22.6 Biodegradable Sustained-Release Delivery Systems

Poly-lactide-glycolide (PLGA) is a biodegradable copolymer that has been used by most companies and investigators as a matrix for the sustained release of drugs. The rationale for its safe use is based on decades of extensive experience using the polymer in bioerodible sutures and studies showing its biocompatibility (Bourges et al. 2006). PLGA hydrolyzes to degrade into lactic acid and glycolic acid. Lactic acid is then oxidized to pyruvic acid and is fully metabolized by the tricarboxylic acid cycle. Lactate can also be converted to glucose in the liver. Glycolic acid is metabolized by glycolic acid dehydrogenase in the liver to oxalic acid (Fry and Richardson 1979). Thus, the degradation products of this polymer are readily metabolized as natural products and eliminated by the organism.

A key consideration for all polymer matrix-based delivery systems is the selection of compounds with wide therapeutic indices. This is a direct result of the difficulty in producing commercially viable, injectable

delivery systems that do not result in an initial "burst" of drug release within the first few hours after administration (Brown et al. 1986). Therefore, drugs must be effective at very low doses and with minimal side effects at very high doses.

The maintenance of the peptide or protein drug's chemical stability while releasing at physiological temperature and pH is a major concern in order to bring stable, reliable, and reproducible products to market.

22.6.1 LHRH Sustained-Release Matrices

The first marketed sustained-release products incorporated with luteinizing hormone-releasing hormone (LHRH) agonists into PLGA implants or microspheres were for the treatment of prostate cancer. LHRH is also known as gonadotropin-releasing hormone (GnRH). LHRH is a relatively low-molecular-weight 10-amino-acid-length peptide of approximately 1,100 Da. LHRH is normally secreted in pulses; however, sustained release of LHRH has been shown to inhibit the secretion of steroid hormones (Knobil 1990). Prostate cancer is a steroid-dependent tumor; therefore, blocking the release of testosterone results in shrinkage of the prostate tumor. Initially, 1 mg daily injections were used to deliver this peptide to shrink prostate tumors. The first PLGA product was a relatively large 1.5-mm subcutaneous implant containing an LHRH analogue called goserelin (Zoladex®) which released the drug for 1 month. The drug–device combination is delivered subcutaneously through a 14-gauge or 16-gauge needle. Pain occurring at the injection site has been associated with this relatively large needle used to inject the implant (R&D Directorate Report No. 54 1996). PLGA microspheres that were injectable through 20-gauge or smaller-bore needles were developed containing the leuprolide analogue of LHRH (Lupron Depot®) (Okada 1997). From a safety viewpoint, it is important to note that sustained release of LHRH agonists is a classic example of how total drug administered may be markedly reduced compared to daily injection. As described previously, 1 mg was originally administered in the daily dosage form. Sustained-release dosage forms of this peptide reduced the leuprolide dose four- to eightfold. Thus, the patient is exposed to significantly less systemic drug by virtue of the depot form compared to the daily injectable form. LHRH and its analogues have a very wide therapeutic index. They are effective in inhibiting steroid release at relatively small doses, and a toxic upper dose limit has never been identified. Thus, these LHRH compounds are ideally suited to sustained-release dosing from a safety and therapeutic perspective.

22.6.2 Octreotide

Another PLGA peptide sustained-release delivery system is Sandostatin LAR (long-acting release) (Novartis Pharmaceuticals) for the treatment of acromegaly. This delivery system releases octreotide acetate from a PLGA microsphere depot. Octreotide acetate is a long-acting peptide with pharmacological actions mimicking those of the somatostatin. Octreotide LAR is administered by injection into the gluteal muscle every 28 days. Local side effects of octreotide include pain, stinging, or burning at the injection site and occur in approximately 28% patients treated with octreotide LAR (Lancranjan et al. 1996).

These small therapeutic peptides all lack the three-dimensional structure of larger proteins. Therefore, these peptides are not very susceptible to denaturation and chemical degradation and are therefore less likely to induce an immunogenic response. These peptides also have fairly wide therapeutic indices (Anthony and Freda 2009). They have low toxicity potential even during the initial burst of drug release after drug administration (Scarpignato and Pelonsini 2001; Warner et al. 1983). These safety considerations plus their therapeutic benefit in treating conditions such as prostate cancer support their widespread use as a sustained-release biomaterial–drug combination.

22.6.3 Exenatide

Exenatide is a 39-amino-acid peptide possessing glucoregulatory activity. Presently, it is injected twice daily for the treatment of type II diabetes (Bunck et al. 2009). This 4,187-Da synthetic hormone was discovered in the saliva of the Gila monster. The incretin GLP-1 hormone stimulates insulin secretion from the beta cells of the islets of Langerhans in the pancreas. A PLGA-based microsphere has been developed and has recently been granted marketing authorization by the European Commission under the name

Bydureon (exenatide once weekly) for the treatment of type II diabetes. FDA approval in the United States had been delayed due to undisclosed cardiac safety, but was approved in 2012.

Therefore, from an extended-release drug delivery point of view, we see that the polymeric-based sustained-release technology has generally been limited to low-molecular-weight peptides rather than large therapeutic protein molecules.

22.6.4 Human Growth Hormone

A notable exception to the restriction of PLGA sustained-release delivery systems for small peptides was the Nutropin Depot® product developed by Alkermes and Genentech. This PLGA-based microsphere product provided sustained release of human growth hormone over a 2- or 4-week period from a single injection (Nutropin Depot®, Genentech, Inc. 2002). Human growth hormone (hGH) is a 191-amino-acid protein with a molecular weight of 22,125 Da. The depot product was approved in 1999 by the US FDA as a treatment for growth hormone deficiency in pediatric patients. In June 2004, Genentech and Alkermes announced their decision to discontinue commercialization of Nutropin Depot. The companies stated that their decision was based on the significant resources required by both companies to continue manufacturing and commercializing the product. The adverse event profile of the Nutropin Depot product showed several potential side effects when administering the PLGA dosage form to children. In studies involving 138 pediatric patients treated with Nutropin Depot, the most frequent adverse reactions were injection-site reactions, which occurred in nearly all patients (Nutropin Depot®, Genentech, Inc. 2002). On average, two to three injection-site adverse reactions were reported per injection. These site of injection reactions included nodules (61% of injections), erythema (53%), pain postinjection (47%), pain during injection (43%), bruising (20%), itching (13%), lipoatrophy (13%), and swelling or puffiness (8%). The intensity of these reactions was generally rated mild to moderate, with pain during injection occasionally rated as severe (7%). The discontinuation of this novel product is further evidence of the complexity of developing viable sustained-release delivery systems for high-molecular-weight protein molecules.

The Nutropin Depot was also plagued with a dosage form that used a comparatively large 21-gauge needle for injecting pediatric patients and had a volume of injection that could be as large as 1.2 mL. This competed with a relatively pain-free daily dosage form that uses a very small 30-gauge needle. Thus, PLGA-based systems for protein-based therapeutics still remain limited and suboptimal. A single sustained-release delivery platform for all proteins remains elusive despite many attempts.

22.7 Site-Directed Local Delivery of Drugs from Medical Devices

All the previous examples describe systemic distribution of a drug from chemically altered compounds, PLGA implants, and microspheres. There are also conditions where the maintenance of local high concentrations of drug is necessary. In these cases, the goal is to obtain the appropriate local therapeutic affect without exposing the patient to high concentrations of drugs systemically. This section reviews three examples of local delivery: drug-eluting coronary stents, intravitreal delivery of ophthalmic medications, and the cell-targeting challenges of nucleic acids.

22.7.1 Drug-Eluting Stents

Drug-eluting stents represent one of the most intensely studied biomaterial drug delivery system. Coronary balloon angioplasty often results in occlusion and restenosis of the artery. Stainless steel bare metal stents were then inserted to act as an intravascular mechanical support to prevent occlusion of the coronary artery following balloon angioplasty (Sigwart et al. 1987). Several trials in the 1990s showed the superiority of stent placement over balloon angioplasty. Initially, restenosis was reduced because the stent acted as a scaffold to hold open the dilated segment of artery. Unfortunately, over time, coronary stents remained vulnerable to restenosis. Restenosis was usually caused by neointimal tissue growth. Investigators attempted to inject drugs at the time of the stent insertion. Unfortunately, the local concentration of these drugs could not be maintained within the coronary artery and restenosis occurred. Hwang et al. showed in 2001 that the continuous release of drugs from

a coated stent could achieve local high concentrations (Hwang et al. 2001). Drugs like rapamycin were shown to inhibit neointimal growth within the artery. As a result, rapamycin was coated onto stainless steel stents in an ethylene vinyl acetate copolymer and poly *n*-butyl methacrylate matrix. Drugs such as paclitaxel were also introduced onto coronary stents for clinical use. These drug-eluting stents were shown to be superior to bare metal stents 5 years after implantation (Morice et al. 2007). There are now new concerns that after extended time periods within the artery, fully released stents again put patients at risk for the formation of a clot within the stent. Therefore, new drug-eluting biodegradable stents fabricated from polylactic acid are currently under development to address stent thrombosis (Tsuji et al. 2003).

The evolving complexity of drug-eluting stents requires numerous tests to account for assessment of the composition, dimensions, and functional attributes of the stents. A series of tests are recommended to characterize the drug delivery properties of the stents (Center for Devices and Radiological Health 2010). The FDA has therefore issued guidance describing the nonclinical engineering tests and recommended labeling for intravascular stents and associated delivery systems (Center for Devices and Radiological Health 2010).

22.7.2 Intravitreal Drug Delivery Devices

Topical eyedrops are the most common mode of ophthalmic drug delivery. However, this route severely limits the dose, the class of drug, and the molecular weight of the drug that can be administered to treat posterior eye disease such as age-related macular degeneration (AMD). New protein-based drugs such as Lucentis (ranibizumab) and EYLEA (aflibercept ophthalmic solution) require intravitreal injection (Fung et al. 2007). These drugs target and bind vascular endothelial growth factor (VEGF) that is involved in stimulating abnormal blood vessel growth in those affected by AMD. These drugs must be injected monthly or bimonthly, respectively. There are practical limits to the number of intravitreal injections that can be administered through the eye. In general, a 27–30-gauge needle is used for intravitreal injections. Therefore, there are numerous efforts underway to develop sustained-release systems such as implants or microspheres to extend the half-life of for these ophthalmic drugs.

Biocompatibility of either nonerodible or degradable systems require that all components be chemically inert, noncarcinogenic, hypoallergenic, and mechanically stable at the implantation site (Choonara et al. 2010). Several intravitreal sustained-release implants have been approved for the delivery of drugs such as fluocinolone acetonide over a 2.5-year period to treat uveitis (Retisert Package Insert, Bausch and Lomb 2009) and ganciclovir (Vitrasert Package Insert, Bausch and Lomb 2003) for the treatment of cytomegalovirus retinitis. These products require surgical implantation into the eye. There are several untoward side effects associated with these implants including retinal detachment, glaucoma, and the need for cataract surgery (Bourges et al. 2006; Choonara et al. 2010). This has limited their use to ophthalmic applications with no alternative therapies.

22.7.3 Nucleic Acids

The discovery of small interfering RNA (siRNA) opened the possibility of specifically downregulating excess protein expression involved in various diseases (Fire et al. 1998). The delivery of nucleic acid therapeutics presents several unique technological and safety hurdles for the pharmaceutical industry. Diseases such as hypercholesterolemia, liver cancer, respiratory syncytial virus infection, kidney injury, age-related macular degeneration, and Duchenne muscular dystrophy have been targeted by numerous companies and research groups. The challenge for delivering nucleic acids is that these molecules must be delivered into the cell rather than interacting with receptors on the cell surface. It is chemically and physically challenging to target specific cells and deliver 13,300-Da-sized double-stranded nucleotides into a cell (Zabner et al. 1995).

Cationic lipids have been used to form ionic complexes with siRNA and antisense oligonucleotide therapeutics in order to facilitate delivery across cell walls (Lv et al. 2006). There is little to no effect on organ function or tissue architecture at low doses. However, acute inflammation and significant tissue damage often occurs at higher doses. Intravenous

administration tends to cause more severe adverse effects and can be lethal at higher doses of the complex (Yew and Scheule 2005). Therefore, at present, most leading candidate siRNA drugs are focused on targets such as kidney and liver diseases where systemic clearance naturally concentrates the drug in those organs.

22.7.4 Tissue Engineering of Cell-Based Structures

The combinations of natural and synthetic scaffolding to allow the growth of new tissue for body structure and functional implants are an important and exciting new field of combination biomaterials. An early experimental example of tissue engineering demonstrated the growth of chondrocyte cells on a human ear-shaped PLGA polymer template (Yilin et al. 1997). This implant was successfully implanted on the dorsa of athymic mice. It is important to note that in these tissue engineering procedures, autologous cells are harvested from the subject. Then the patient's own cells are seeded and grown on a sterile template in vitro. Then after several days time such that enough cell proliferation has occurred on the scaffold, the tissue-engineered implant is implanted into the patient.

Elle-Behnke has demonstrated the ability to restore sight in an animal model using a novel peptide-based nanofiber hydrogel scaffold (Ellis-Behnke et al. 2006). The scaffold consisted of a self-assembling beta-sheet nanofibril approximately 10 nm in diameter that contains 99% water (Zhang 2003). Elle-Behnke showed that the treatment with synthetic biological materials solution enabled reconnection of brain tissue after acute injury in hamsters.

Early laboratory successes with this technology have prompted several notable clinical applications. Myelomeningocele is a birth defect in which the backbone and spinal canal do not close before birth. High pressure or poorly compliant bladders are a common complication of this birth defect. A study in 2006 showed that bladder repair and reconstruction was possible by conducting a biopsy to collect urothelial and muscle cells from these patients. These cells were then grown in tissue culture and seeded onto a collagen and PLGA bladder-shaped scaffold. These autologous cell-based artificial bladders were then implanted into the patients. Four-year postsurgery follow-up showed improved bladder function in all patients who received these tissue-engineered bladder tissues (Atala et al. 2006).

Recently, a report from the Karolinska University Hospital in Sweden described the implantation of a synthetic trachea into a patient stricken with tracheal cancer (Naik 2011). A scaffold formed from the biodegradable PLGA polymer was impregnated with the patient's own stem cells over a 2-day period. The synthetic trachea was surgically implanted into the patient with the stem cells directed to differentiate as normal trachea cells. About 48 h after the transplant, imaging and other studies showed cells in the process of populating the artificial windpipe, which had begun to function like a natural windpipe. There was no rejection by the patient's immune system, because the cells used to seed the artificial windpipe came from the patient's own body. The patient no longer has cancer and is expected to have a normal life expectancy. Previously, this laboratory at the Karolinska University hospital had conducted this procedure using cadaver tracheas.

22.8 Conclusions

This chapter has presented the interface of biomaterials with the delivery of biotechnology-based drugs to man. This is an ever-evolving field that remains very dependent on the role of the original needle and syringe first developed by investigators and physicians in the 1800s. Today, injection needles and devices are designed to be minimally invasive, sterile, and disposable. Thus, they are insuring the safe pharmacological delivery of these new drugs to man. The use of biodegradable polymers such as PLGA for delivery of proteins and peptides is very limited by the inherent biological properties of individual drugs and the nature of the diseases that they are treating. Therefore, these important developments cannot yet be termed "platform technologies" applicable to every drug, peptide, protein, or nucleic acid. Each compound must be developed and tested on its own as if the drug–biomaterial combination was itself a new chemical entity. The recent advances in tissue engineering are among the most exciting developments in the field of biomaterials. However, at present, it is clear that each tissue engineering procedure will be highly individualized.

23.1 Introduction

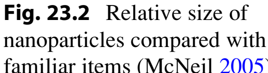
The advent of nanotechnology is considered to be the biggest engineering innovation since the Industrial Revolution. Proponents of this new technology promise to reengineer the man-made world, molecule by molecule, sparking a wave of novel revolutionary commercial products from machines to medicine This "industrial revolution" in molecular manufacturing will alter the relationship of materials so profoundly that this change may produce both positive and negative effects on health and the environment. The worldwide market for products produced using nanotechnology is estimated to reach US $1 trillion by 2015 (Gwinn and Vallyathan 2006a).

Study in nanotechnology began in the 1900s, expanded slowly, then reached extensive growth in the later twentieth and early twenty-first centuries. Nanotechnology has expanded into many fields including, but not limited to, physics, chemistry, energy, agriculture, electronics, and medicine (Wikipedia 2011a). Figure 23.1 shows some products already impacted by nanotechnology (Whiteley and Hawxhurst 2006). A list of the numerous consumer products impacted by nanotechnology is maintained by The Project on Emerging Nanotechnologies (www.nanotechproject.org/inventories/consumer/). However, this list should not be considered complete because of the rapid growth of the industry and the evolving nature of the commercial definition of "nano."

Because of the many facets of nanotechnology, there are several definitions that are application dependent. A common definition is the deliberate manipulation of matter in the structural size range of 1–100 nm. A nanometer is one-billionth of a meter or 1/100,000th of a millimeter (National Health Laboratory Services 2011; National Nanotechnology Initiative 2011; US Centers for Disease control (CDC) 2009a). Figures 23.2 and 23.3 provide some comparative perspective on nanomaterials (McNeil 2005; Yokel and MacPhail 2011).

A full review of the complex and growing topic of nanotechnology and its implications is beyond the scope of this chapter. This discussion will be limited to an overview of engineered (deliberately created) nanotechnology used in medical devices and diagnostics and medications intended for human use, and their implications for drug safety, pharmacovigilance, and risk management. The discussion would not be complete without some comment on the environmental impacts of these products and an overview of their regulation. Because of the rapid growth of nanotechnology, it is strongly suggested that readers thoroughly research their specific areas of interest using the information in this chapter as a starting point (see Sect. 23.12 listed at the end of the chapter).

Fig. 23.1 Illustration of some products impacted by nanotechnology (Whiteley and Hawxhurst 2006)



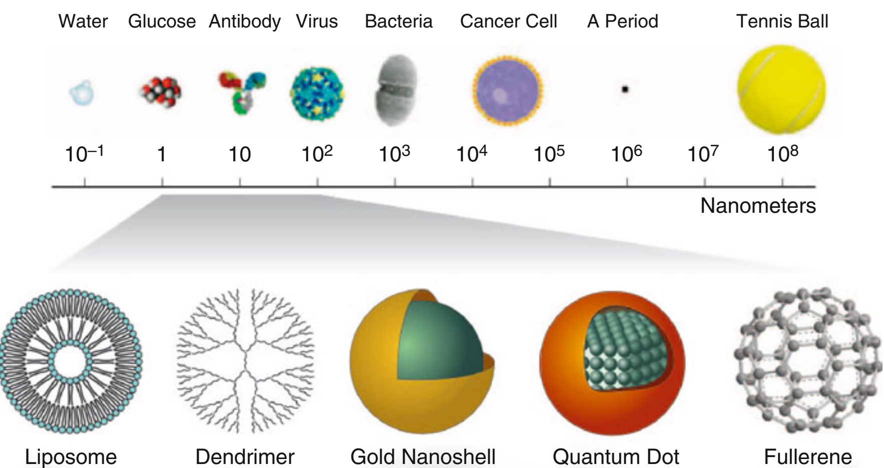


Fig. 23.2 Relative size of nanoparticles compared with familiar items (McNeil 2005)

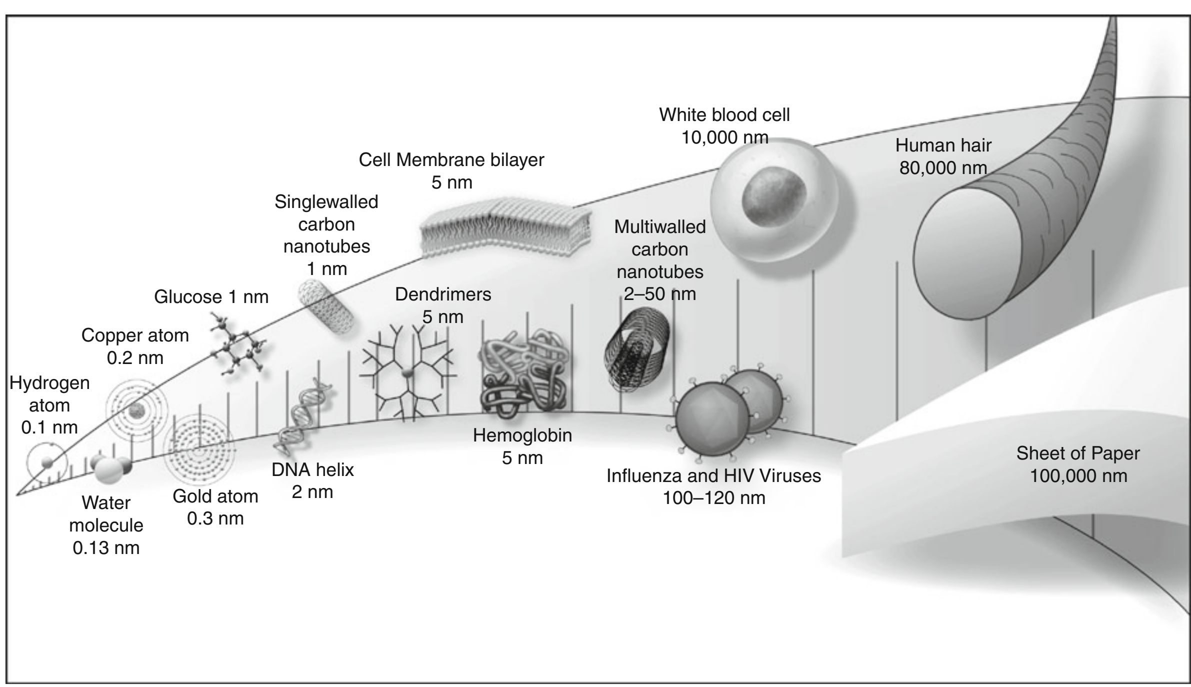

Fig. 23.3 The sizes and shapes of some nanomaterials as compared to more familiar materials. Shown for comparison are materials that are below, within, and above the nanoscale range, to put nanomaterial size in perspective (Yokel and MacPhail 2011)

23.2 Unique Properties of Nanomaterials

Because of their diminutive size, nanomaterials have an increased surface area; their physical, chemical, and biologic properties can unpredictably change and be different from their bulk counterparts. There are no product class distinctions with nanomaterials as of this writing. A 10 nm particle may have properties different from a 20 nm particle of the same material (Pautler and Brenner 2010a). For example, nanogold is being studied for cancer, antibiotic use, and its other unique nanoproperties (Fig. 23.4). Above 60 nm in particle size, gold retains its known properties. However, below this size

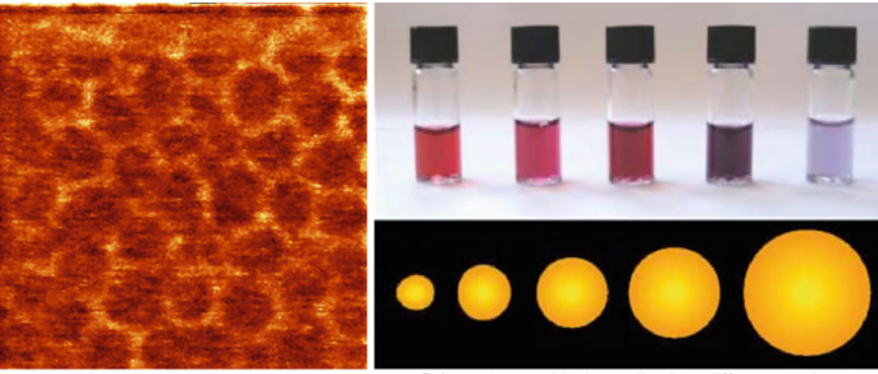

Fig. 23.4 Illustration of physical characteristics of nanogold (SRI International 2005)

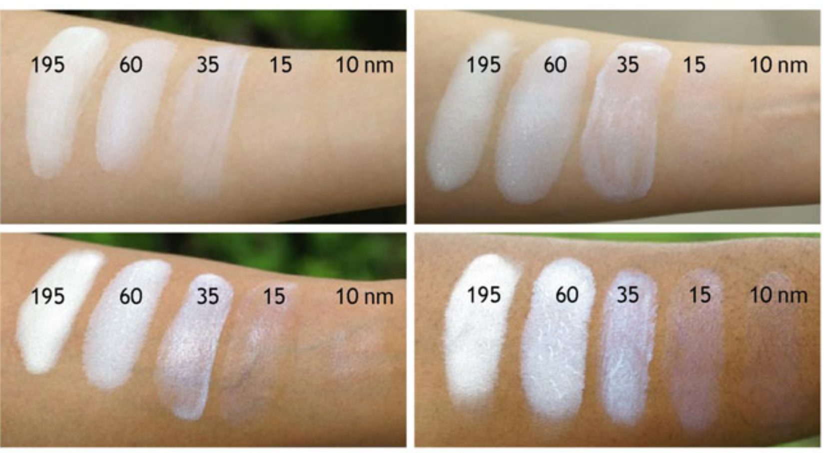

Fig. 23.5 Topical appearance of nano-titanium dioxide dispersions on different skin types (Schlossman et al. 2011)

nanogold's color changes from gold to red; its melting point and its reactive properties also change (Alanazi et al. 2010). As particle size decreases, optical properties of nanomaterials change. Titanium dioxide, a common ingredient in sun protection products, is opaque (white) in its macro form, becomes more transparent as particle size decreases, and ultimately becomes clear in appearance. Figures 23.5 and 23.6 illustrate some of these properties (Tzeng 2011; SRI International 2005; Schlossman et al. 2011). For drug delivery, engineered nanoparticles may be used as carriers; however, the drug itself may be formulated on a nanoscale and then function as its own carrier (DeJong and Borm 2008a).

23.3 Lack of Standardization for Toxicology

As of this writing, there are several dilemmas that confound the safety evaluations of nanomaterials, in addition to the differences in chemical identity and behavior among varying sizes of a specific nanomaterial mentioned above. A nanomaterial may have a variety of uses: the nanomaterial itself may be used as a medical treatment, as a carrier for a pharmacologic, biologic or diagnostic agent, or as a carrier for genetic material, in humans or in other species. Additionally, the same nanomaterial may be used in the manufacture of tires,

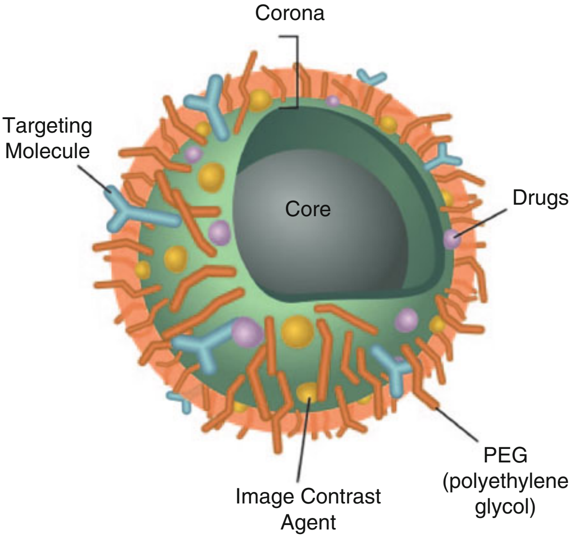

Fig. 23.6 Multifunctional nanoparticle. A nanoparticle's "corona" can be functionalized with hydrophilic polymers, targeting molecules, therapeutic drugs, and image contrast agents. The interior core can be solid (e.g., quantum dots) or liquid (e.g., liposomes). Molecules are not shown to scale. *PEG* polyethylene glycol (Harper et al. 2011)

paint, or automobile wax. It may have other applications in agriculture, electronics, or sporting equipment. Additionally, nanomaterial may not be used as an entity unto itself; it may be combined with other agents, for example, surface-active agents, that facilitate dispersal in solution. Targeting molecules may be added to the nanomaterial to facilitate biologic or chemical activity (Fig. 23.6). Figure 23.7 highlights some physical and chemical factors that can influence the biological effects of nanomaterials.

To compound the above, a lack of standardization of nanomaterials creates ambiguity in their safety assessment. Table 23.1 lists some of the issues that surround the standardization of nanotoxicology reported by Broverhof and David in 2007 (Broverhof and David 2010). In a review of nanomaterial standardization (or the lack thereof) as related to informatics, Thomas DG, et al. list the needs for standardization (Table 23.2) and report on the activities of several organizations devoted to the topic (Thomas et al. 2011). In an effort to demonstrate the importance of standardization in the bioevaluation of

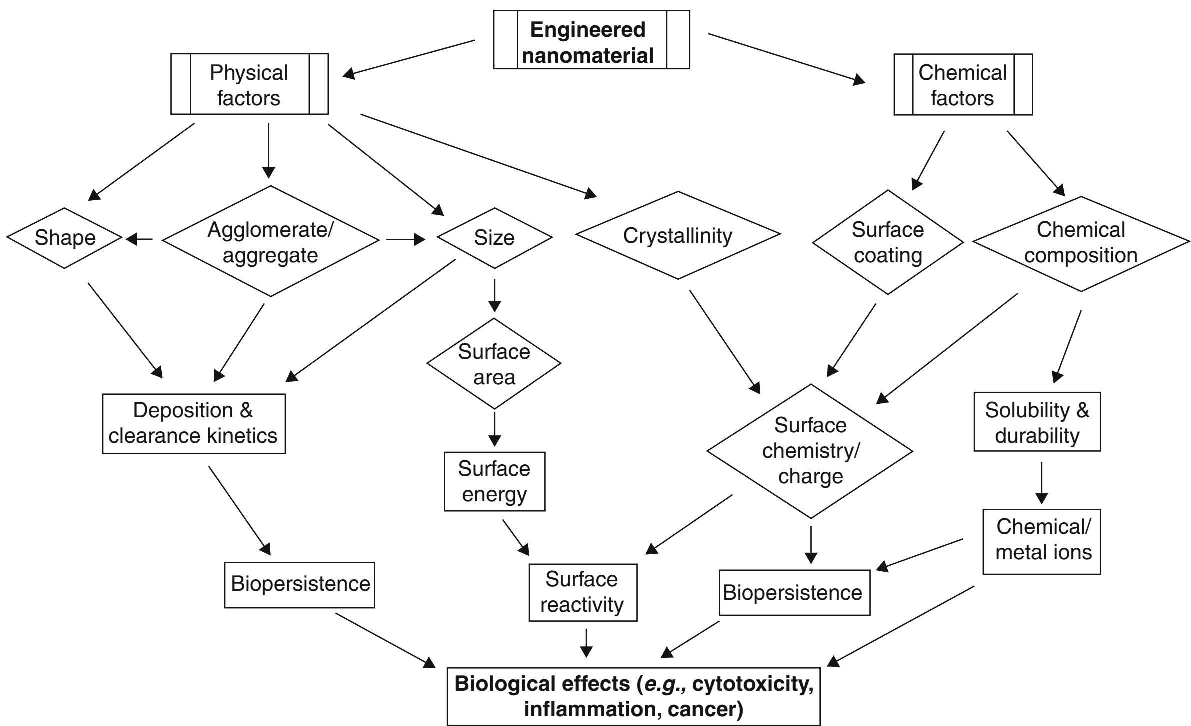

Fig. 23.7 Some physical and chemical factors that can influence the biological effects of nanomaterials (Lai 2011)

Table 23.1 Issues in nanotechnology characterization (Broverhof and David 2010; Lai 2011)

Engineered nanomaterials have unique characteristics than their macro counterparts
May or may not be water soluble
May behave differently (e.g., agglomeration) in a biologic medium (e.g., ionic buffers, protein, serum)
Existing testing strategies for chemicals do not always apply to nanomaterials
Nanoparticles consist of more than one molecule
Dissolution in aqueous medium may be poor
Crystalline structure, water insolubility, and slow dissolution can impact biologic systems differently
Composition, shape, and dimensions may play a role in toxicity assessments
May require new specific toxicology assessments to be developed
Traditional methods (e.g., sonication) may alter the nanomaterial structure and affect subsequent assessments
Dose (e.g., mg/kg) may not be the most appropriate metric for assessment
Dose assessments may be based on surface area, particle number, or other measure (e.g., hemolytic potential)
Laboratory to laboratory variation in culture medium preparation
Lack of characterization may lead to conflicting results
Surface coatings of nanomaterials may influence assessments
Nanomaterials may vary in their impact on different cell lines
Varying structure-activity relationships due to lack of characterization
Broad characterization may be impracticable, even overwhelming
Paucity of nanoparticle reference standards
Minimal knowledge of how known reference standards influence toxicologic techniques

Table 23.2 Rationale for standardization (Thomas et al. 2011)

Enable collaboration
Data sharing
Unambiguous representation and interpretation of data
Semantic (meaningful) search
Integration of data
Ensuring quality data
Reliability
Reproducibility
Nonstandardized data does not lend itself to computerized analysis or data mining
Nonstandardized information may confound protocol development

nanomaterials, Harper et al. exposed zebra fish embryos to nanogold particles of different sizes and varying charges. While uncharged nanogold particles appeared to have no detrimental effects, positively charged particles caused mortality and negatively charged nanogold induced malformations. Rigorous controls demonstrated that only the change in charge produced deleterious effects. Large differences in biologic response can occur as a result of small changes in nanomaterial properties (Harper et al. 2011). These concepts were underscored in a 2010 presentation by Geertsma who stated that because of the lack of standardization, nanomaterials must be evaluated on a case-by-case basis (Geertsma 2010). Toxicologists must be aware of all of the nuances of nanotechnology evaluations to deliver meaningful results.

In an effort to address much of the above, Lai proposed a paradigm in toxicologic testing of nanomaterials for moving forward into the future. He states that use of a “one size fits all” approach to testing nanoparticles ignores the complexity of the toxicity and mechanism of nanoscale materials. The proposed paradigm for testing and evaluating the health hazards of various classes/subclasses of nanomaterials uses reference materials, short-term in vivo studies in conjunction with high-throughput screenings, and class-specific low-throughput in vitro assays (Fig. 23.8).

23.4 Pharmacokinetics

Figure 23.9 illustrates various exposure types and biosystems that may be affected by nanoparticles and provides an excellent starting point for the pharmacokinetic discussion. Pharmacokinetic study is complicated by the issues that face the toxicology outlined above and the complexities of combining a therapeutic agent with a nanoproduct. Pharmacokinetic study in humans should include the therapeutic agent and the nanoproduct used and consider the issues raised by dose, metabolism, populations, ethnicity, other therapies, diet, disease states, and adverse events. Protein binding and tissue accumulations are other important pharmacokinetic factors. However, nano-pharmacokinetics is a discipline that is in its infancy. This section provides a starting point for researchers interested in the pharmacokinetics of nanomaterials. The pharmacokinetic

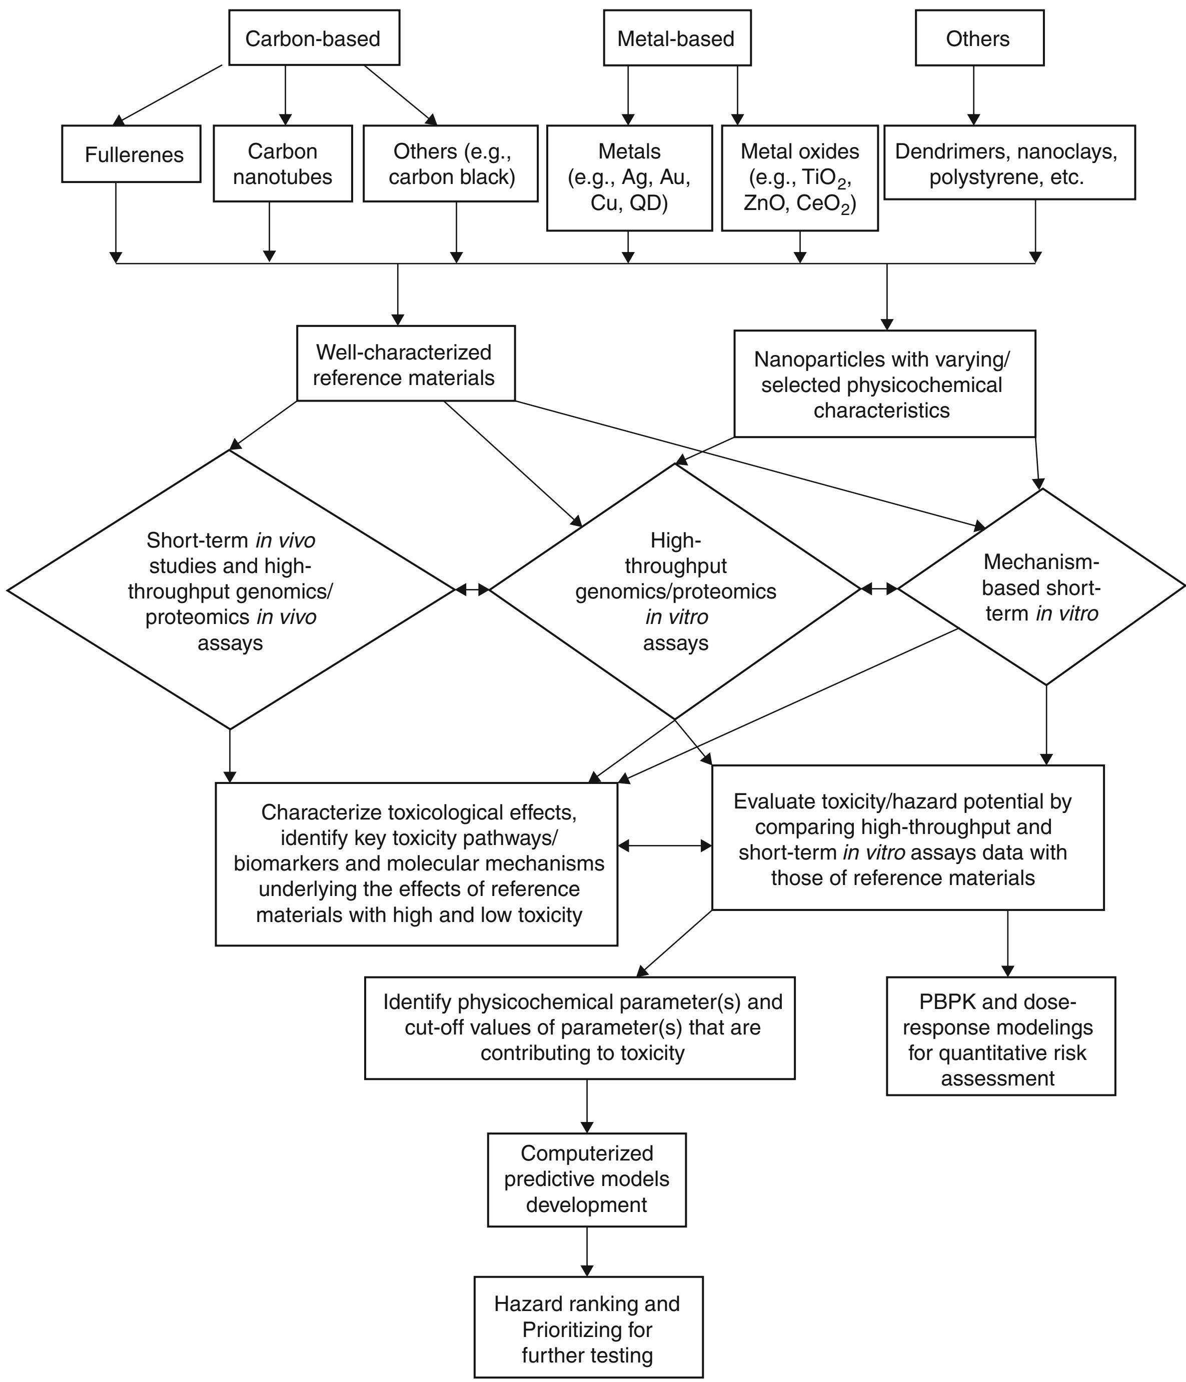

Fig. 23.8 Proposed paradigm for the toxicity testing of nanomaterials (Lai 2011)

principles of adsorption, distribution, metabolism, and elimination (ADME) are illustrated in Fig. 23.10. Riviere reported the pharmacokinetics of carbon nanotubes, fullerenes, and quantum dots following parenteral administration in rats. He reported that the pharmacokinetics of nanomaterials studied differ from those of traditional drug molecules. Decay in blood concentration may be related to the (nano)compound movement into tissues where further excretion does not occur (e.g., trapped in the

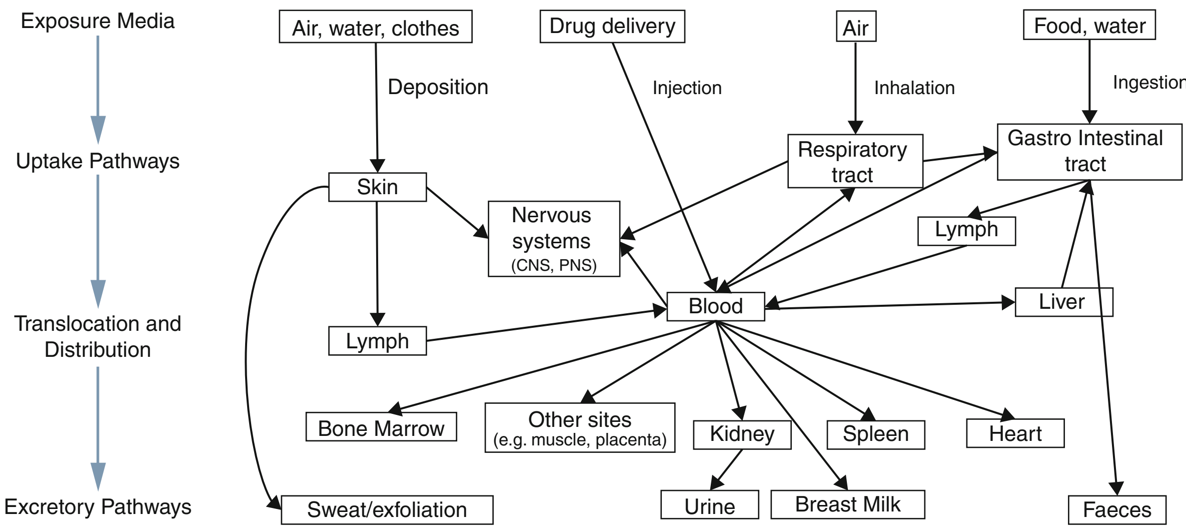

Fig. 23.9 Nanoparticle routes of exposure and affected bio systems (Rouhiainen et al. 2010)

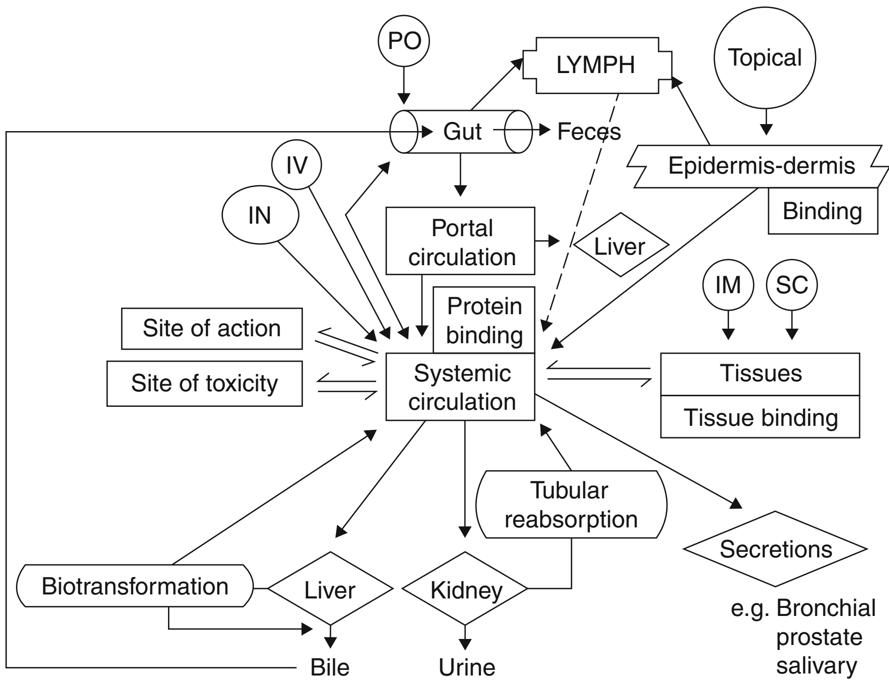

Fig. 23.10 Pharmacokinetic stages involved in adsorption, distribution, and elimination (ADME) (Riviere 2009)

reticuloendothelial (RE) system, bound to tissue proteins, post distributional aggregation). In these instances, blood half-life may be relatively short despite prolonged body persistence. "Nanomaterials may also be transported in the body via the lymphatic system, a phenomenon which complicates their pharmacokinetic analysis based on blood sampling and also exposes lymphoid tissue to higher concentrations than would be seen secondary to distribution from blood. These idiosyncrasies of nanomaterials compared to most drugs or small molecule xenobiotics require caution in using classic interpretations of the meaning of basic ADME parameters." From his literature review, he reported that pharmacokinetic analysis of fullerenes can be complicated by the lack of nanomaterial controls, attached ligands (e.g.,

antiviral, anticancer drugs), different vehicles, and tracking labels. Carbon nanotube studies were complicated by the lack of sensitive radiolabel analysis, small numbers of study animals, and lack of control in carbon nanotube length. Despite these limitations, carbon nanotube studies showed a pattern of distribution of larger material to tissues of the RE system, liver, spleen, lymph nodes, and bone marrow. The pharmacokinetics of quantum dots was influenced by coating with polyethylene glycol (to escape detection by the RE tissues, so-called stealth mode), size, charge, and periodicity. Renal excretion of particles 5–6 nm in size was reported; however, larger particles with specific surface characteristics (e.g., negative charge) may interact with the RE system or become protein bound and may not be eliminated from the body. Biodegradable nanomaterials found in marketed products can be described by standard pharmacokinetic approaches. Manufactured nanomaterials are not biodegradable and may accumulate in certain tissues. The unique surface chemistry of these manufactured materials may further alter their disposition of bioactivity. The preferential uptake of some nanomaterials by the lymphatic system coupled with the tendency of some nanomaterials to react with the RE system was also discussed. Nanomaterial clearance from the blood does not necessarily correlate to clearance from the body (Riviere 2009).

Li and Huang reviewed pharmacokinetic parameters focusing on chemotherapy and their pharmacokinetic nuances in the delivery of anticancer agents. In addition to many of the concepts mentioned above, they reviewed concepts at enhancing cargo drug delivery including targeting tissue-specific microvasculature, caveolae-mediated transcytosis and tumor micro-vessel clotting (Li and Huang 2008).

Longmire reported the concepts of nanoparticle flexibility may be important in the application of dendrimeres in imaging. Imaging tissue uptake and subsequent renal clearance was enhanced by dendrimeres exhibiting enhanced flexibility. Additionally, dendrimeres with long PEGylated tails underwent rapid renal clearance as opposed to those with shorter PEG tails (Fig.23.11). They proposed that their nontraditional models may have use in other therapeutic applications (Longmire et al. 2011).

For a thorough review of how nanomaterials (1–100 nm and >100 nm) behave in the blood and other organs with correlation to pharmacokinetics, see Moghimi et al. summarized in Table 23.3. This group also addressed future issues in nanomaterial pharmacokinetics presented in Table 23.4 Moghimi et al. 2012).

In addition to an excellent discussion of nanomaterial ADME, Li et al., proposed use of physiologically based pharmacokinetic modeling (PBPK) as a method to provide consistent pharmacokinetic information. However, PBPK may be limited because it requires large amounts of information, consistency in study designs, and consistent cross-discipline teamwork. Another limitation to PBPK modeling is that "tissues need to be harvested from animals in cohorts at each time point of study, resulting in a large number of animals needed for each study. A fairly large number of tissues and organs from each animal are required for PBPK modeling, further amplifying the number of samples to analyze. These limitations result in experimental designs being very time and cost consuming. Noninvasive measurement of nanoparticle bio-distribution, such as imaging, could greatly reduce this difficulty" (Li et al. 2010).

Overt and subtle manipulations of nanomaterials can greatly affect their pharmacokinetics.

23.5 Safety Issues

Nanomaterials by their nature have safety and environmental issues involved in their manufacture and laboratory use. Nanomaterials that escape the laboratory or manufacturing site can enter the environment where they may deteriorate or are free to interact unpredictably with anything and potentially create unknown environmental hazards. Because of the limited knowledge about them, organ toxicity, tumor development, and immune responses are possible concerns with exposures through the routes described below (Hoet et al. 2009; Gwinn and Vallyathan 2006b).

23.5.1 Inhalation Route

Inhaled nanomaterials can aggregate in the alveoli where their increased surface area places a burden on mucociliary and macrophage clearance. While in the lung, nanomaterials may translocate to the systemic circulation. Inhaled nanoparticles can also gain access to the CNS via olfactory nerves.

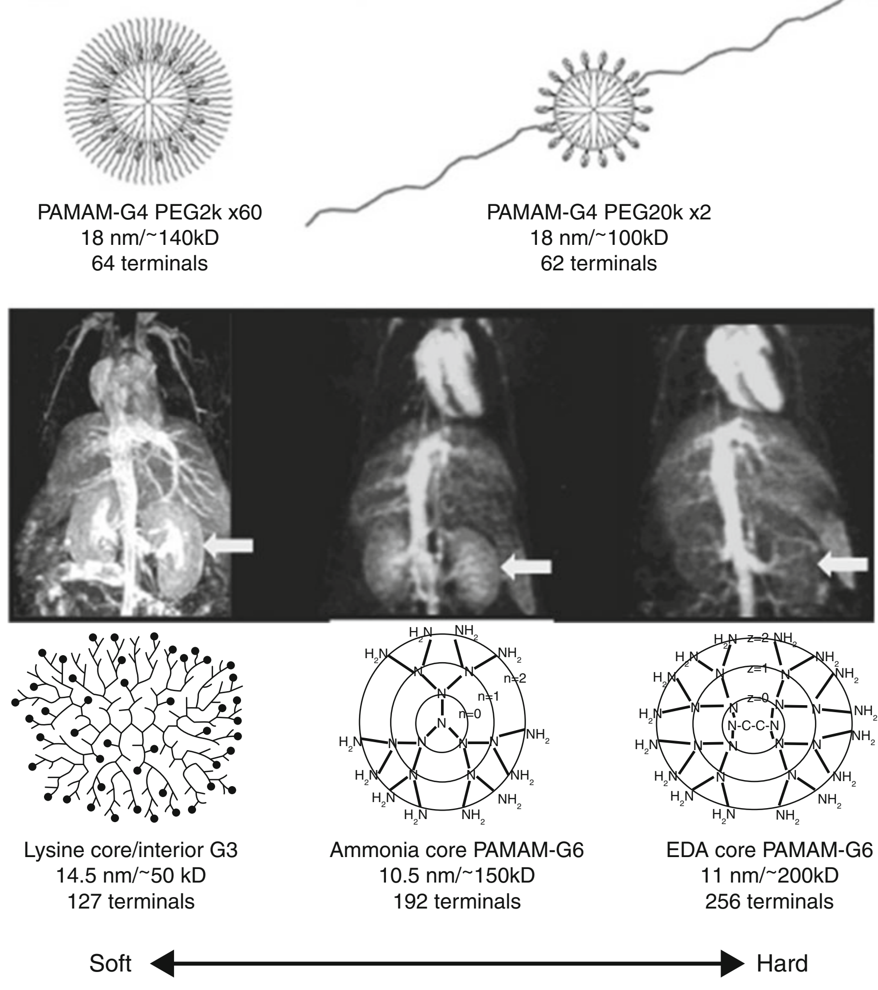

Fig. 23.11 PEGylated dendrimers and enhanced renal excretion of "softer" nanomaterials (Longmire et al. 2011)

Table 23.3 Summary points: factors controlling nanoparticle pharmacokinetics – an integrated analysis and perspective (Li et al. 2010)

1. Intravenously injected nanoparticulate drug carriers provide a wide range of unique opportunities for site-specific targeting of therapeutic agents to many areas within the vasculature and beyond. Cancer nanomedicines have shown the success of this approach. This progress continues in other therapeutic areas such as inflammatory conditions
2. PK and biodistribution of nanocarriers are controlled by a complex array of interrelated core and interfacial physicochemical and biological factors. Size, morphology, and surface characteristics of nanocarriers can be tuned to afford controlled PK and biological targeting according to the type, developmental stage, and location of the disease
3. The plasma protein coat remains a key determinant in controlling nanocarrier PK and secondary responses, but not all deposited proteins play a role. The composition of the plasma protein coat is expected to differ considerably among nanoparticles in amount and heterogeneity, and in a time-dependent manner, on the basis of the physicochemical properties of the nanoparticles as well as the pathological state and the dosing regimen
4. Geometric parameters play a significant role in nanoparticle PK – in flow properties (margination dynamics), vascular adhesion, cellular internalization, and escape routes from vasculature – but the bulk of current data is available for spherical nanoparticles
5. As a result of altered PK, stealth systems with encapsulated therapeutic agents may induce new toxicity profiles

Table 23.4 Future issues: factors controlling nanoparticle pharmacokinetics – an integrated analysis and perspective (Li et al. 2010)

1. Breaching the biological barriers may induce diseases. Should we breach biological barriers with nanoparticles? Alternatively, should we concentrate on exploiting biological opportunities offered by the disease states for rational nanocarrier engineering and targeted drug delivery?
2. Sophistication in design and nanoengineering techniques may result in the generation of more heterogeneous populations of nanoparticles. These developments may cause more difficulties in interpretation of biological events following their administration. Can we develop technologies that yield more homogeneous populations of complex nanocarriers in terms of surface chemistry, architecture, and morphology?
3. Can we generate definitive maps that establish the interdependency of size, shape, and surface characteristics of nanoparticles in relation to biodistribution, controlled drug release, excretion, and adverse effects?
4. To what extent is the composition/conformational state of the outer surface proteins regulated by the type and the mode of deposition of the primary protein scaffold? Can appropriate methodologies be developed to control these factors?
5. Can carbon nanotubes, quantum dots, and many other nonbiodegradable nanoparticles/nanomedicines reach their clinical targets? Or should future efforts concentrate on the refinement of proven biodegradable nanocarriers?
6. How important are the physical and mechanical properties of nanoparticles and nanoassemblies with respect to target binding and therapeutic performance?
7. A detailed understanding of dynamic behavior and interactive forces between therapeutic agents (and particularly macromolecular cargo) and nanocarriers is still required and remains central for optimization strategies

23.5.2 Dermal Exposure

Nanosized particles may penetrate more deeply into the skin than their larger counterparts. It has been hypothesized that nanoparticles of titanium dioxide (5–20 nm) can penetrate the skin and enter the immune system or the systemic circulation. Quantum dots have been shown to penetrate porcine skin within 8 h of application.

23.5.3 Oral Route

Uptake of nanoparticles after oral exposure depends on particle size and surface chemistry (certain nanoparticles are combined with other materials). In rats, 50 nm to 3 μm particles were detected in the liver, spleen, blood, and bone marrow after oral exposure. Particles >100 nm did not reach the bone marrow and particles >300 nm did not reach the blood, suggesting that nanoparticles less than these sizes have been detected in bone marrow and blood. Nanomaterials can be used to enhance the GI absorption of a pharmacologically active compound.

23.5.4 Genotoxicity and Carcinogenicity

Nanomaterials can enter the cell and in some cases the nucleus where it is possible for them to interact with internuclear processes where DNA damage may occur. While useful in concept to cancer treatments, the genotoxic effects on normal cells must be considered. Carbon nanotubes (CNTs) administered to mice demonstrated genotoxic results that were similar to those of asbestos.

23.5.5 Development

Nanomaterials have been shown to cross the placenta in rats suggesting a risk to the developing fetus. Carbon nanotubes (CNTs) have shown to induce changes, in vitro, in cell proliferation and other cellular activities suggesting in vivo consequences in development.

23.5.6 Immunological Responses

Nanomaterials have demonstrated both positive and negative effects on the immune system that differ for inorganic and organic nanotypes. These effects may be desirable or undesirable. Therefore nanomedicine testing should exclude undesirable immunological responses. In general, positively charged (cationic) particles are more likely to induce acute inflammatory reactions (innate reaction) than negatively charged (anionic) particles. Two parameters – size and surface charge – play a central role in these responses. The phagocytic activity of macrophages in the lung has also been linked to particle size; although micrometer-sized particles stimulate phagocytosis, smaller, nanometer-sized materials often do not, or even reduce the capacity of the macrophages (Hoet et al. 2009).

Table 23.5 Classes of nanomaterials for use in medicine (Surendiran et al. 2009)

Type of nanomaterial/basic description	Potential medical use	Disease state
Liposomes Spherical nanoparticle, lipid bilayer membrane, hollow interior	Drug delivery system	Cancer
Nanopores 20 nM pores	Permits nutrients but limits immune penetrations	Transplanted tissue, genetics
Fullerenes, "soccer ball" framework	Encapsulates radioactive material; transports antibiotic, antiviral, and anticancer products	Imaging procedures, antibiotic with light stimulation, infection, HIV, cancer
Nanotubes 1–25 nm tubes with and without "caps"	Drug delivery, Amphoteracin B, DNA transport, increasing immune response	Can penetrate the cell wall, fungal, cancer therapy, vaccines
Quantum dots 2–10 nm nanocrystal	Drug delivery by conjugation	Diagnosis and treatments, prostate cancer, melanoma, breast cancer
Nanoshells Silica core and thin metallic shell	Immunologic manipulation	Cancer, immunoglobulin determinations
Nanobubbles Nanoscaled bubble	Drug transport, combined with heat or ultrasound	Cancer, increased uptake by target cells. Vascular clearing
Paramagnetic nanoparticles (e.?g., iron)	Diagnostics, imaging, rapid cell uptake	MRI imaging, cancer
Nanosomes Silica coated iron oxide nanoparticles with targeted antibody and contrast elements	Targeted diagnosis and treatment, combined with laser	Brain cancer
Dendrimers Nanomolecule with branching structures	Drug transportation within the branch "cavities"	Gene therapy, anti-retroviral, type 1 diabetes, potential for intranuclear cancer applications
Respirocytes Nano device hypothetical RBC	Deliver up to 236x more oxygen than RBC	Cardiac arrest

With nanoparticles, the smaller they are, the greater their surface area to volume ratio and the higher their chemical reactivity and biological activity. Greater chemical reactivity of nanomaterials can result in increased production of reactive oxygen species (ROS), including free radicals. ROS production has been found in a diverse range of nanomaterials including carbon fullerenes, carbon nanotubes and nanoparticle metal oxides. ROS and free radical production is one of the primary mechanisms of nanoparticle toxicity; it may result in oxidative stress, inflammation, and consequent damage to proteins, membranes, and DNA. Size is not the only variable influencing the safety of a nanomaterial, chemical composition, shape, surface structure, surface charge, aggregation and solubility, and the presence or absence of functional groups of other chemicals can also contribute (Fig. 23.6) (Nel et al. 2006).

23.5.7 Products in Use Today

Nanotechnology and nanomedicines are in use today. Many cosmetics and sunscreens use nanosized ingredients (e.g., nanotitanium dioxide, nanozinc oxide) (Friends of the Earth (FOTH) 2006; Nano Patents and Innovations 2009). Currently, there are nano-enabled drugs that have been approved by the FDA for the treatment of cancer, such as Abraxane®, which is used to treat breast cancer, and Doxil® for ovarian cancer (Table 23.5) (Surendiran et al. 2009).

23.5.8 Safety Challenges

Laboratory and manufacturer's workers may be at risk for accidental exposures through dermal, nasal, ophthalmic, and oral routes. Topically applied sunscreens and cosmetics that contain nanomaterials when washed off enter water ecology with possible unknown repercussions. Nanomedications and nanomaterials may confound the safety evaluation of bio/pharma agents to which they are combined. Nanomedications and bio/pharma products combined with nanodelivery systems may present unique safety issues. The preliminary evaluation of many products

is performed in normal animals and humans. However, sick individuals can be prone to unforeseen toxicities. Studies need to focus on therapeutic effects as well as nanoparticle disposition (Gwinn and Vallyathan 2006b; DeJong and Borm 2008b).

Nanomedications need to be evaluated for their effects on clinical laboratory tests, drug interactions, dose, hepatic and renal impairment, special populations (e.g., pediatrics, elderly), interactions with other existing pathologies, and interactions with foods and over-the-counter products. To the chagrin of consumer advocacy groups, at this time the FDA, EMEA, and MHRA do not believe that additional regulations are required for managing the licensure of nanomaterials/medications (Hoet et al. 2009; Friends of the Earth (FOTH) 2006; Nano Patents and Innovations 2009; Pautler and Brenner 2010b; DeJong and Borm 2008b). While unrelated to the clinical safety evaluation of nanomedicine, insurance providers may consider expensive nano treatments as "experimental" or environmental hazards and outside the scope of coverage of certain health insurance policies (Fink 2010).

23.5.9 Safety Summary

The current safety track record for nanomedicines is without clinical problems so far; however, because of rapid expansion in the area, much remains to be elucidated. Nanomaterials' bio/pharma properties are different from their macro counterparts, and there are at present no class distinctions. The use of nanomaterials in the laboratory and manufacturing process may require "nanoproof" protective equipment to prevent inadvertent exposures. Environmental implications regarding nanomaterials need to be reviewed and updated, especially wastewater testing standards. The environmental impact of nanomaterials and metabolites is largely unknown.

The implications for drug safety, pharmacovigilance and risk management are as limitless as the possible applications of the technology. Nanomaterials and nanomedicines will require specific safety evaluation on a case-by-case basis for their use in humans. Clinical research will need to focus not only on therapeutic safety and effectiveness but also on nanomaterial impact and disposition. Pharmacokinetics for active moieties, nanomaterials, and metabolism of both will need to be studied. Present concepts of risk detection may not apply to nanomedications especially in long-term exposures and effects or use in individuals with impaired health (DeJong and Borm 2008b).

Current regulations may or may not be adequate in managing nanomaterials' licensing process for commercial use. Current US labeling requirements do not stipulate that nanomaterials are used in a product (Hoet et al. 2009; Pautler and Brenner 2010b; CDC 2009b; CDC 2009c).

However, health authorities should always be notified early in the development process when nanotechnology is involved in a medical treatment. Regulators do not want to see nanomaterials turn into the twenty-first century's "asbestos" (Gwinn and Vallyathan 2006b).

The USEPA is taking a new path forward on regulation of manufactured nanomaterials under the Toxic Substances Control Act ("TSCA"). Revised regulations are expected in the near future (US Environmental Protection Agency 2011).

Nanotechnology, nanomaterials, and nanomedicines currently under development represent a revolution in the visualization, diagnosis, and treatment of many disease states. While current medical applications of nanotechnology appear to be "safe," in this rapidly growing promising area, much remains to be revealed regarding their environmental and clinical safety profiles.

23.6 Nanotechnology and Medical Devices

Appendix 2 lists some of the medical devices that may utilize nanotechnology in some form. It is beyond the scope of this section to address all of these topics, some of which have already been addressed while others are not germane to the discussion. Because of the variation in nanotechnology vernacular, some authors list nanoparticles that may carry therapeutic or diagnostic payloads also as "nano devices." These types of compounds have been addressed in earlier sections. This section will highlight technology that would be considered "hardware," but on a nanoscale. In this realm, nanoscale may refer to beyond the 1–100 nm scale. Research in this area also lacks standardization and is performed on a case-by-case basis. Many of these devices and techniques are in the early stages of development. Information changes rapidly; therefore researchers are again encouraged to review their specific area of interest for the most current information relevant to their topic.

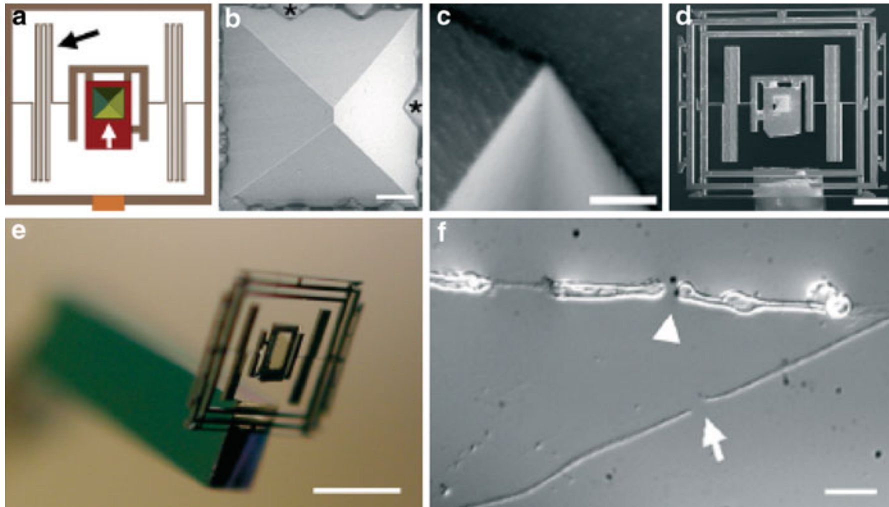

Fig. 23.12 Nanoknife (Chang et al. 2010). Nanoknife for microscale axon cutting. (**a**) Schematic planar view of microsuspension and cutting shell microassembled into a nanoknife. *Black arrow*, serpentine flexures acting as compliant microsuspension. *White arrow*, 1-μm thick silicon nitride cutting shell. Footprint of entire structure is 1 mm^2. (**b**) Scanning electron microscope (SEM) view of pyramidal-shaped cutting shell with apex serving as cutting edge (scale = 20 μm), (**c**) SEM showing cutting edge with an ~20 nm radius of curvature (scale = 100 nm), (**d**) Image of assembled nanoknife (scale = 200 μm). (**e**) Nanoknife mounted at an angle to a rod and held by a micromanipulator (not in view). For axon cutting in vitro, the nanoknife is positioned and angled, so that its planar footprint is parallel to the cell culture dish. The cutting stroke is executed as a downward movement delivered via the micromanipulator (scale = 500 μm). (**f**) Examples of cuts made by a nanoknife in an unmyelinated axon (*arrow*) and a myelinated axon (*arrowhead*) (scale = 25 μm)

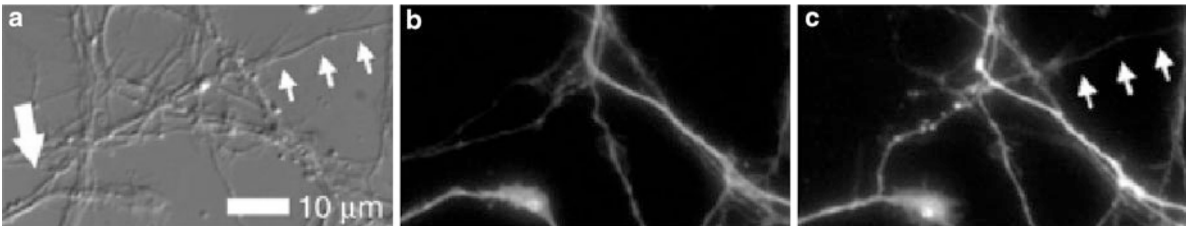

Fig. 23.13 Mouse axon electrofusion (Chang et al. 2010). Axon microelectrofusion demonstrated by the passage of soluble cytoplasmic green fluorescent protein (GFP) from one axon fusion partner into another. (**a**) Bright field image showing hippocampal axons in culture. *Single arrow* points to location where microelectrofusion was induced. (**b**) Perfusion image of the same field as in "a" showing axons containing soluble cytoplasmic fluorescent GFP. (**c**) After microelectrofusion, GFP passed from the axon at the *bottom left* into an axon fusion partner that did not originally have GFP, indicating successful fusion of the two axonal compartments

23.6.1 Nanoknife and Axon Refusion

Chang et al. discussed the nuances of neuronal damage and repair via a variety of techniques. They used a nanoknife with a cutting edge of 20 nm (Fig. 23.12) to sever mouse axons that were later rejoined by microelectrofusion (Fig. 23.13). While admittedly cumbersome and time consuming, the process demonstrated success, principally via the use of soluble cytoplasmic green fluorescent protein (GFP).

23.6.2 Nanoburrs

Nanoburrs (Fig. 23.14) are a relatively new development in nanotechnology and demonstrate its

multifunctionality. Nanoburrs reported were "60-nm core-shell hybrid NPs consisting of a polymeric core, a lipid interface, and a poly(ethylene glycol) (PEG) corona. For temporal control, we achieved the capacity for slow drug elution over 2 weeks using poly(lactic acid) (PLA) conjugates of paclitaxel as a model therapeutic agent, made by a modified drug-alkoxideringopening strategy." Nanoburrs were reportedly successful in repairing vascular damage and as a vehicle for an anti-angiogenics used to inhibit cell division and prevent growth of scar tissue that can clog arteries. Paclitaxel was control released over a period of 10–12 days. Nanoburrs reportedly can be used in conjunction with or instead of traditional arterial stents. An advantage of nanoburrs is that they can be injected intravenously protecting patients from more invasive procedures (Fig. 23.15). This technology could have broad applications across other important diseases, including cancer and inflammatory diseases where vascular permeability or vascular damage is commonly observed (Langer 2010; Chan et al. 2010; Rajiv et al. 2011).

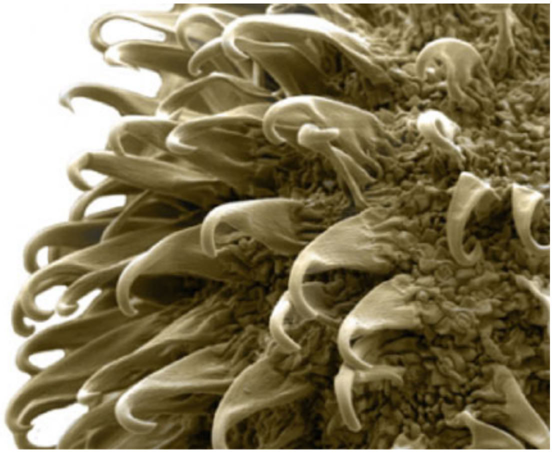

Fig. 23.14 Nanoburr (Langer 2010)

23.6.3 Nanoneedles

Demuth et al. reported the use of nanoneedles (Fig. 23.16) as an alternative delivery system for needle-based therapies (e.g., vaccines and drugs). Therapeutic materials are coated on nanoneedles on thin film arrays and administered through the stratum corneum (SC), promoting efficient and pain-free transcutaneous delivery. Their findings suggested the potential delivery of DNA vaccines, gene therapy as the administration of degradable polymer nanoparticles for controlled release of cargos in vivo (DeMuth et al. 2010).

23.6.4 Nanoscaffolds

In addition to tissue repair, nanotechnology holds promise in the area of tissue regeneration. This involves seeding tissue on a "scaffold" that can be constructed

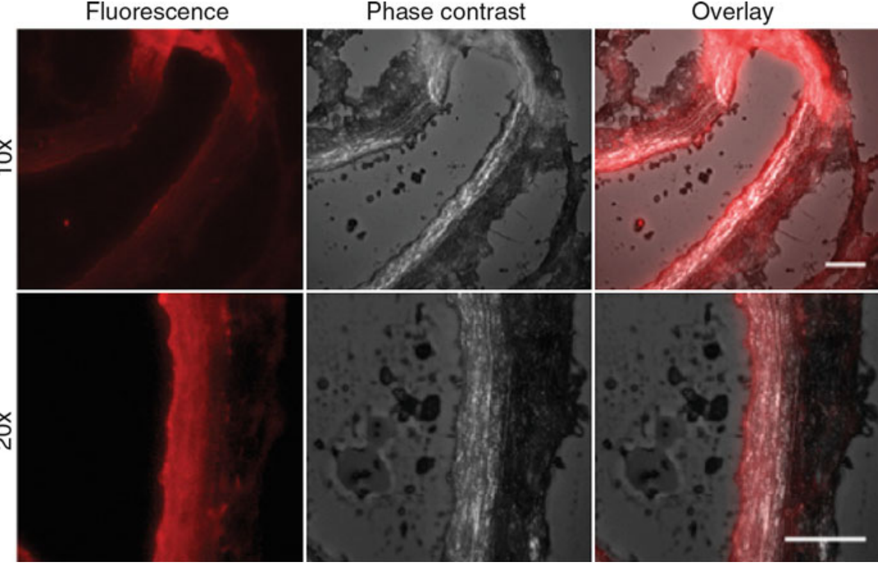

Fig. 23.15 Nanoburrs binding in vivo (Langer 2010). Representative images of nanoburr binding in vivo by i.v. delivery to angioplastied left common carotids. (*Left* to *right*) fluorescence, phase contrast and overlay images of angioplastied left common carotid arteries incubated with nanoburrs at 10× and 20× magnification (scale bar, 100 μm). Images were obtained with a DeltaVision deconvolution microscope using the 10× and 20× objective

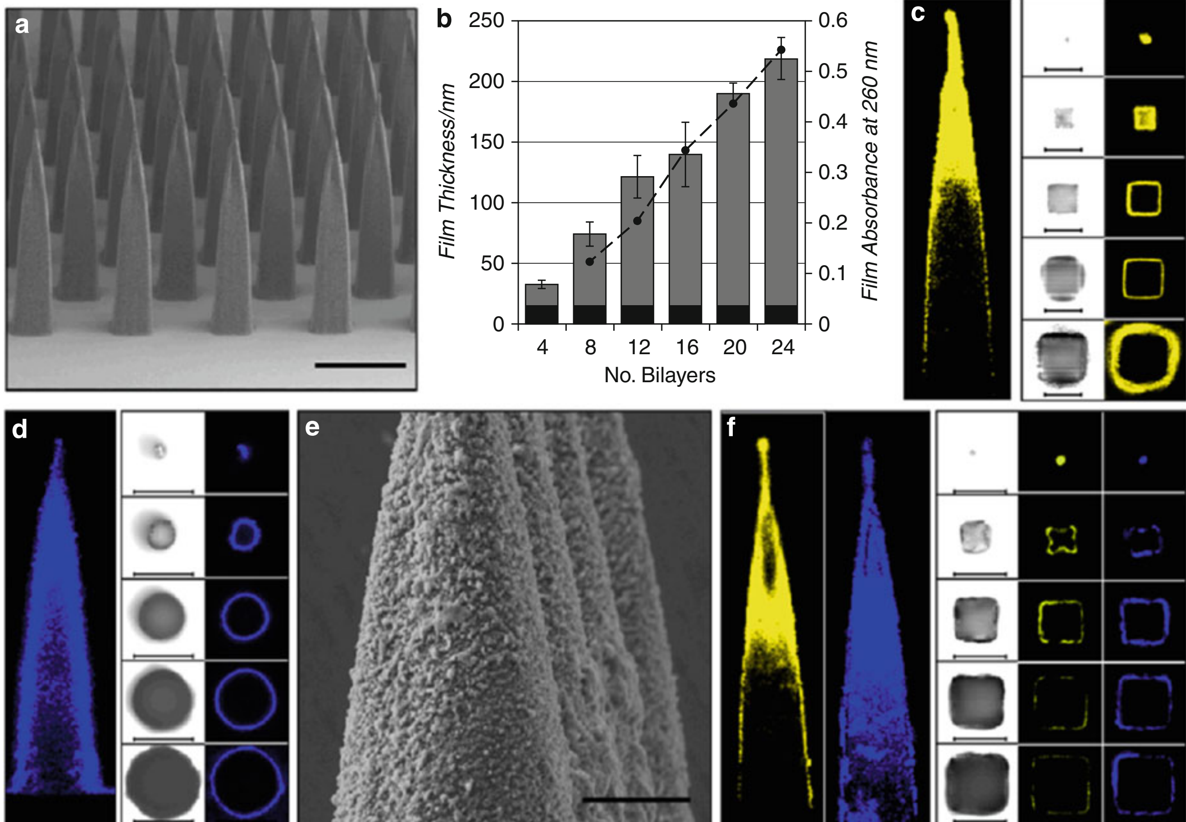

Fig. 23.16 Nanoneedles (DeMuth et al. 2010). (**a**) SEM micrograph of uncoated PLGA rnicroneedle arrays of pyramidal geometry (scale – 500 μm). (**b**) Film growth (*left* axis) and absorbance (*right* axis) for (Poly-1/pLLC)$_n$ multilayers assembled on silicon/quartz substrates bearing a (PS/SPS)$_{20}$ initiating layer (*black bar* – (PS/SPS)$_{20}$, *grey bar* – (Poly-l/pLUC)$_n$, *dashed line* – Ab-260 nm). (**c**, **d**) Representative confocal micrographs showing (C) (PS/SPS)$_{20}$-(Poly-1/Cy3-pLUC)$_{24}$-coated microneedle and (**d**) (PS/SPS)$_{20}$-(Poly-1/DiI-PLGA NP)$_4$-coated microneedle (*left* – transverse section, *right* – lateral sections, 200 μm intervals, scale – 200 μm). (**e**) SEM micrograph showing a (PS/SPS)$_{20}$-(Poly-l/PLGA NP)$_4$-coated microneedle array (scale – 50 μm). (**f**) Representative confocal micrographs showing a (PS/SPS)$_{20}$-(Poly-l/Cy3-pLUC)$_{24}$-(Poly-l/DiD-PLGA NP)$_4$ co-coated microneedle (transverse and lateral sections, *left* – Cy3-pLUC, *right* – DiD-PLGA NP, 200 μm intervals, scale – 200 μm)

from a variety of nanomaterials (Figs. 23.17, 23.18). Tissues under study include bone, cartilage, vascular, neural, and bladder tissues. Additional tissues under study include muscle, skin, kidney, liver pancreas, and immune system. Zhang and Webster's review provides an excellent starting point for those interested (Zhang and Webster 2009).

23.6.5 Nanobots (Nanorobots)

Nanobots remain an intriguing aspect of nanotechnology that has yet to be realized.

An excellent description of nanorobotics can be found at numerous websites including Wikipedia (Wikipedia 2011b). In brief, these are nano devices capable of performing any number of medical applications including cell repair, identification and destruction of cancer cells, diagnostics, and others. Such devices would require the ability to be navigated, non-replicating as well as being safe and effective. Figures 23.19–23.21 show some artistic renditions of futuristic nanobots. Mavroidis provides a comprehensive overview (Mavriodis 2011). Interested researchers should review the literature for updates in their specific field of interest.

A report published in *Nature* (Davis et al. 2010) received a lot of attention in the lay press as the first successful implementation of a "nanobot"

Fig. 23.17 Nanoscaffolds (Zhang and Webster 2009). (**a**) Scanning electron microscopy (SEM) image of poly(L-lactic acid) (PLLA) nanofibrous scaffold with interconnected spherical macropores created by a phase-separation technique. (**b**) Electrospun polycaprolactone/hydroxyapatite/gelatin (PCL/HA/gelatin, 1:1:2) nanofibers which significantly improved osteoblast functions for bone tissue engineering applications. (**c**) Densely aligned single wall carbon nanotube (SWCNT) forest grown with novel water-assisted chemical vapor deposition in 10 min. (**d**) Transmission electron microscopy (TEM) image of monodispersed magnetic Fe_3O_4 nanoparticles (6 nm) deposited from their hexane dispersion and dried at room temperature. Scale: A = 500 nm, B =10 nm, C = 1 μm (inset = 5 nm), D = 20 nm

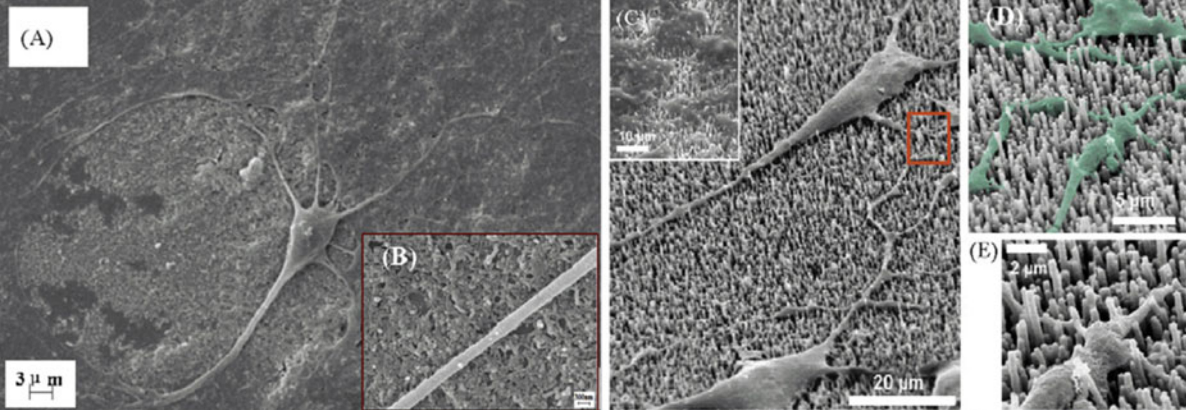

Fig. 23.18 Neural cells grown on nanoscaffolds (Zhang and Webster 2009). SEM images of neural cell adhesion on carbon nanotube/fiber substrates. (**a**) Neonatal hippocampal neurons adherent on purified MWCNT glass substrates with extended neurites after 8 days; *inset* image (**b**) shows a single neurite in close contact to CNTs (Images are adapted from). (**c**–**e**) PC12 neural cells grown freestanding on vertically aligned CNFs coated with polypyrrole at different magnifications. Scale: A = 3 μm, B = 300 nm, C = 20 μm (insert 10 nm), D = 5 μm, E = 2 μm

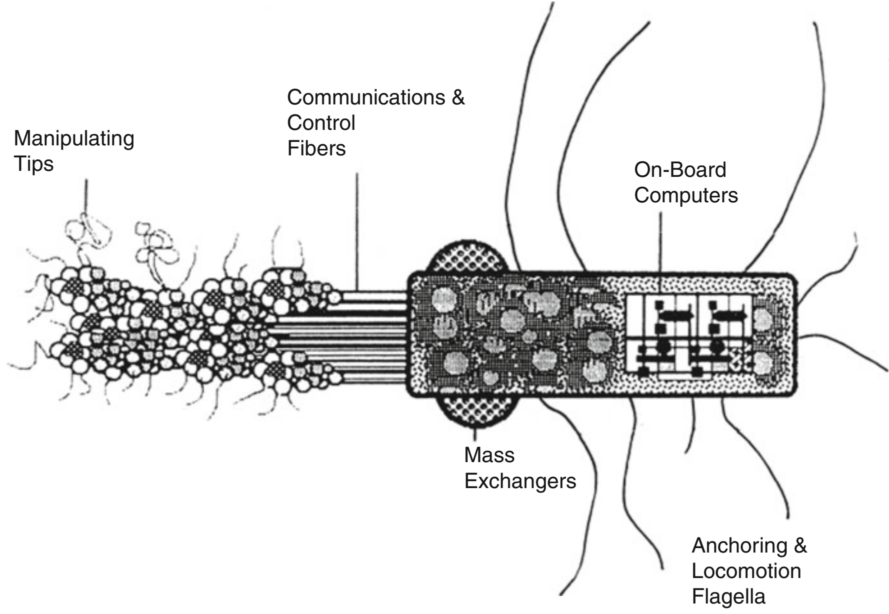

Fig. 23.19 Nanobot, fictionalized cell repair machine VI. http://www.foresight.org/Nanomedicine/Gallery/Captions/

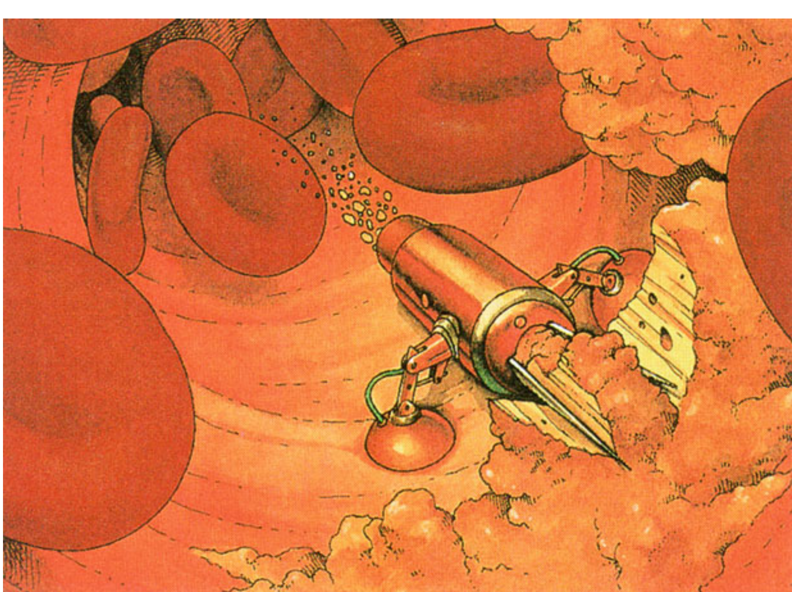

Fig. 23.20 Fictionalized nanobot manipulating cholesterol. http://www.foresight.org/Nanomedicine/Gallery/Captions/

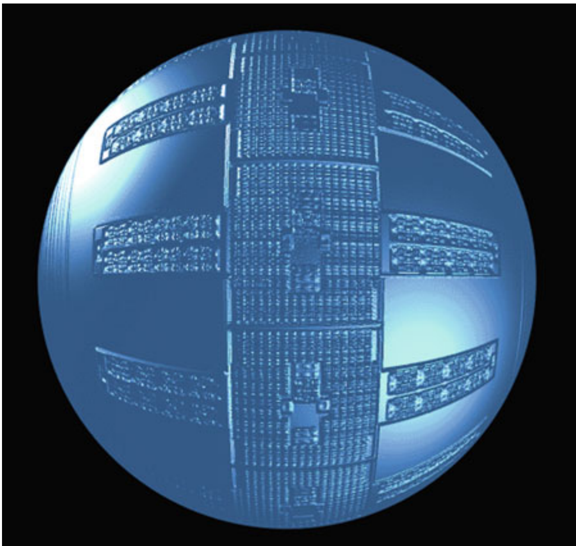
(Figs. 23.22, 23.23). However, close inspection reveals that the group used a targeted nanoparticle administered intravenously and not a piece of "hardware" as described earlier in this section. It is a demonstration of the potential of nanotechnology that can deliver genetic therapy to targeted cancer cells. Results in humans of this clinical trial have yet to be reported. This study could also be used to demonstrate the ambiguity of nanotechnology vernacular.

Al-Fandi et al. (Al-Fandi et al. 2011) reported using flagellated *Escherichia coli* as potential nanobots, using biochemical gradients as a navigation system.

Another report (Muscat et al. 2011) described a programmable and autonomous "molecular robot"



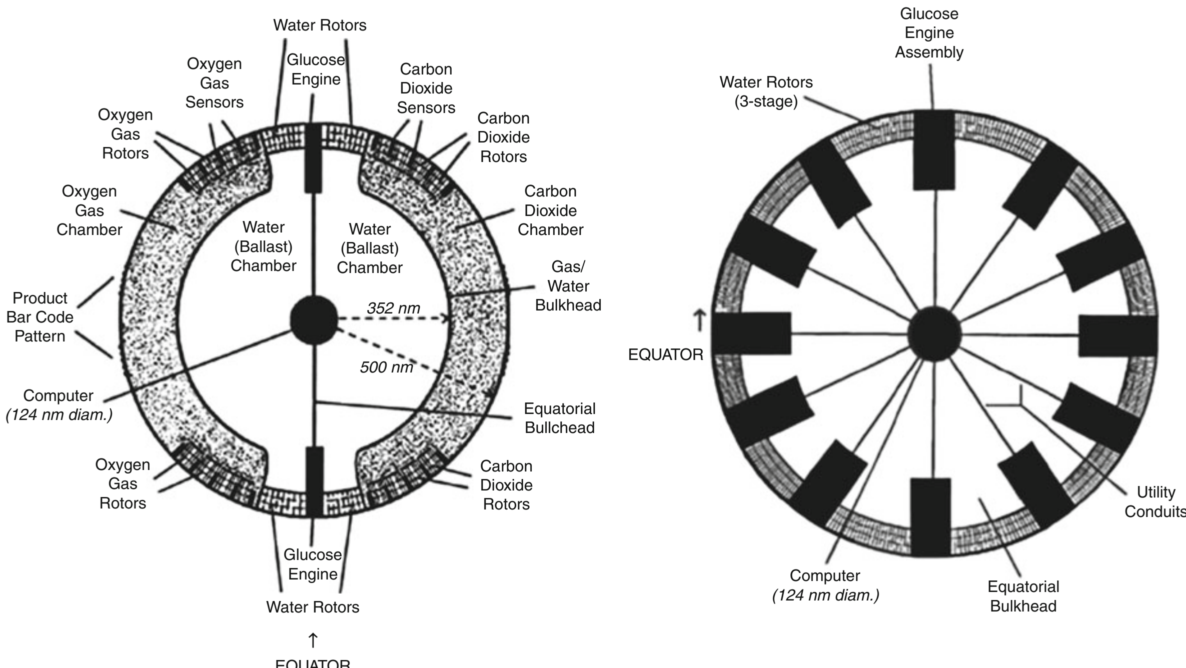


Fig. 23.21 Fictionalized respirocyte. http://www.foresight.org/Nanomedicine/Gallery/Captions/

whose motion was fueled by DNA hybridization and allowed precise control of genetic cargo delivery, not really a demonstration of a nanobot but another example of where research is headed.

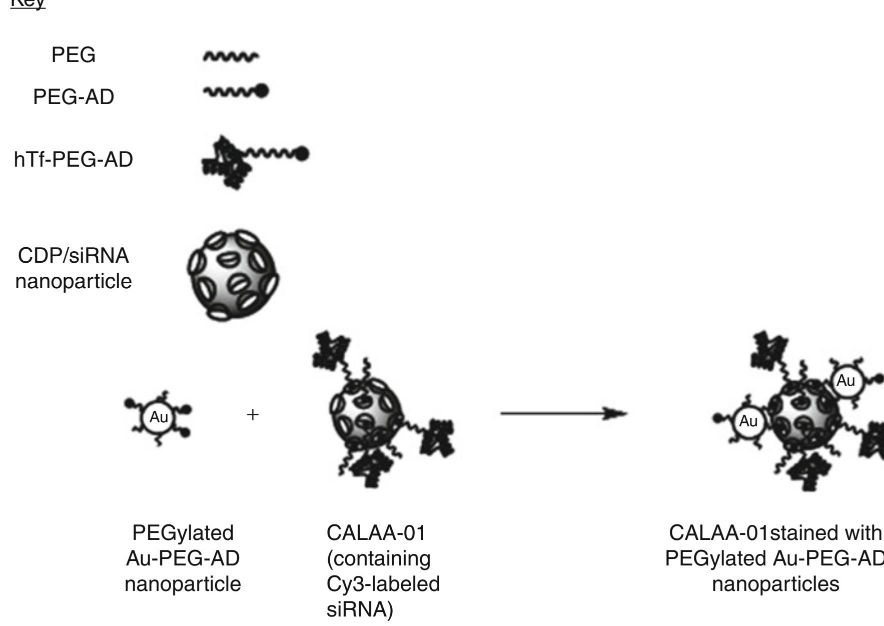
Much maligned in science fiction (e.g., *Prey* – Michael Crichton 2002), nanobots promise significant impacts in medicine, surgery, drug delivery, and diagnostics in the future.

23.7 Nanodiagnostics

The capability of nanomaterials for specific targeting, payload transport, and elimination of payload and carrier makes them ideal for specific diagnostic applications. As in the previous sections, progress in this area has been in volume and this section is

Part II: Principle of staining

A schematic representation of the interactions between the Au-PEG-AD particles and CALAA-01 is shown in Schematic SI 2.



Scheme SI 2: Representation of the staining process of CALAA-01 by Au-PEG-AD Particles.

Fig. 23.22 Targeted nanoparticle "nanobot" (Davis et al. 2010)

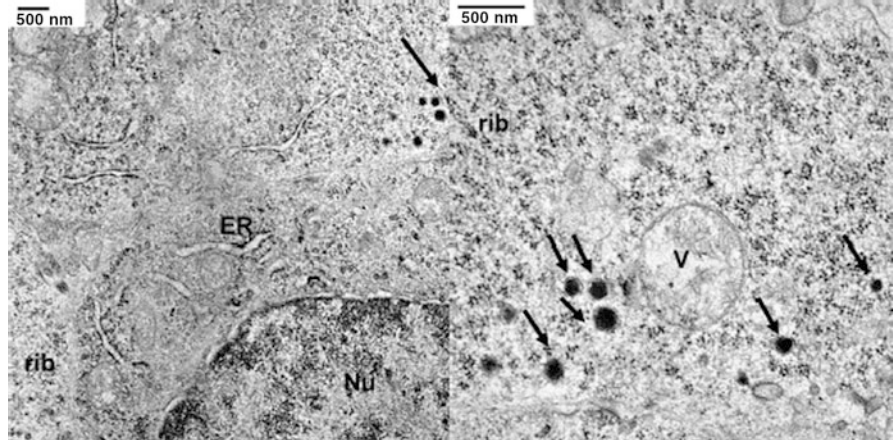


Fig. 23.23 Nanoparticle "nanobot" in tumor (Davis et al. 2010). Transmission electron microscopy confirms the existence of siRNA containing, targeted nanoparticles inside a mouse subcutaneous tumor. Figure S2: Transmission election micrographs snowed intracellular localization of siRNA- containing, cyclodextrin-based, targeted nanoparticles (*dark round objects* – the siRNA within the nanoparticle is stained by the presence of the uranyl ions that bind to the nucleic acid) inside N2A cells of the tumor subcutaneously implanted in mice (same tumor tissue used for confocal fluorescence imaging in Fig. 23.1). *Left:* The proximity of targeted nanoparticles to the nucleus shows their intracellular localization. *Right*: Expanded view of nanoparticles shown in *left panel* (Scale bar = 500 nm). *Solid arrows* point to the nanoparticles. Labeling is as follows, *Nu* nucleus, *rib* ribosome, *ER* endoplasmic reticulum, *V* vesicle

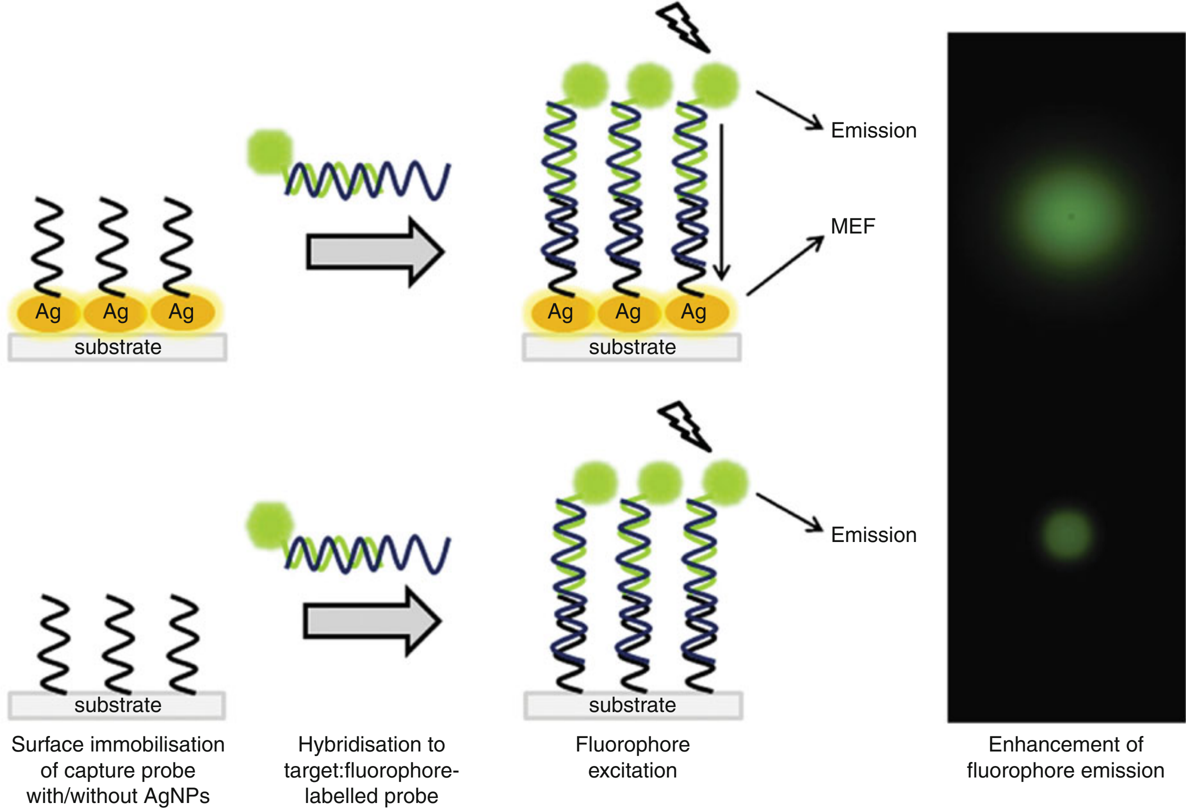

Fig. 23.24 Enhanced fluorescence using gold nanoparticles (Larguinho and Baptista 2011). Schematic configuration for a metal-enhanced fluorescence (MEF) system. Fluorescence signal enhancement may be achieved by deposition of AgNPs onto a surface, before probe immobilization. Upon hybridization with fluorophore-labeled probe, the intensity of fluorescence emission is potentiated by the AgNPs (MEF)

intended only to highlight some of these complex applications. Nanodiagnostics must be safe and effective for use in humans. Researchers should review their specific areas of interest for the most current information.

23.8 Examples of Nanomaterials Used in Diagnostics

23.8.1 Gold and Silver Nanoparticles

In a report of theoretical use of gold and silver nanoparticles in imaging techniques for proteomic and genomic detection, Larguinho and Babtista reviewed their use in a variety of settings. These nanoparticles have found application in diverse strategies, such as electrochemistry, luminescence, target labeling, and SPR-based biosensors, and may further be combined in different assembly structures to promote synergistic conditions with concomitant increase in sensitivity and versatility. They focused on the development of nanoscale devices and platforms that can be used for single molecule characterization of nucleic acid, DNA or RNA, and protein at an increased rate when compared to traditional techniques. Also, several advances were reported on DNA analysis in real time, at both high resolution and very high throughputs, suitable for biomedical diagnostics. While still in the developmental phase, their findings suggest higher sensitivities (Fig. 23.24), economy, and early diagnosis in genomic screenings for cancer, hepatitis, and diabetes (Larguinho and Baptista 2011).

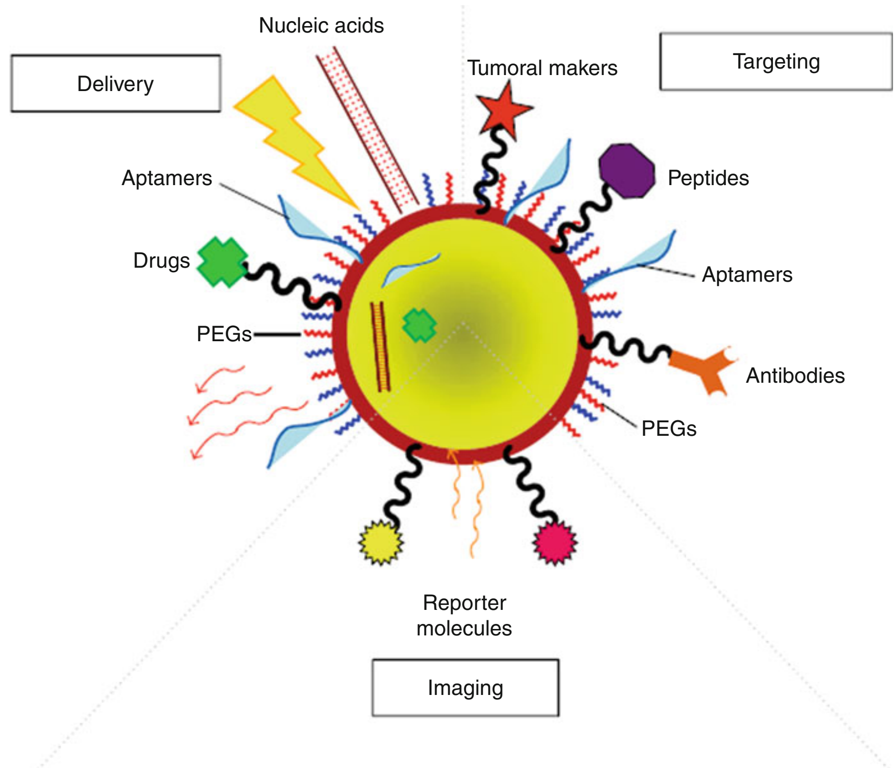

Fig. 23.25 Multipurpose noble metal nanoparticle (Conde et al. 2012). Multifunctional KP-based systems for tumor targeting, delivery, and imaging. These innovative NPs comprise nucleic acids, aptamers, and anticancer drug molecules for delivery to the target tissue. Depending on the targeting mechanism, they can be on the surface or inside the NPs. Responsive NPs/molecules can also trigger reaction upon external stimuli through the functionality of valuable tumor markers, peptides, polymers, and antibodies that can used to improve NP circulation, effectiveness, and selectivity. Multifunctional systems can carry reporter molecules tethered to the particle surface and employed as tracking and/or contrast agents

Conde et al. reviewed noble metals (primarily nanogold and nanosilver) used in the proposed treatment and diagnosis of cancer including their short- and long-term toxicities. They reported: "light absorption from biologic tissue components is minimized at near infrared (NIR) wavelengths, most noble metal NPs for in vivo imaging and therapy have been designed to strongly absorb in the NIR so as to be used as effective contrast agents. However, noble metal nanomaterials, such as nanoparticles, nanoshells, nanoclusters, nanocages, and nanorods, have showed widespread application as contrast agents for in vivo cancer imaging: those presenting a significant absorbance and scattering in the NIR region or surface-enhanced Raman scattering (SERS), or as contrast agents for computed tomography (CT), magnetic resonance imaging (MRI), optical coherence tomography (OCT), and photoacoustic imaging (PAI). Moreover, most noble metal nanomaterials are capable of combining multiple imaging modalities that can yield complementary information and offer synergistic advantages over any single imaging technique" (Figs. 23.25, 23.26). Enhanced imaging via computerized tomography (CT), magnetic resonance imaging (MRI), optical coherence tomography (OCT), photoacoustic imaging (PAI), photoacoustic tomography and surfaced-enhanced Raman scattering was reported (Conde et al. 2012).

23.8.2 Quantum Dots (QDs), Plasmonic Nanoparticles, Magnetic Nanoparticles, Nanotubes, and Nanowires

Chi et al. reviewed nanobiotechnology and a variety of materials as nanoprobes for bioanalysis for in vitro bioanalysis and diagnosis (Table 23.6). Major classes of nanoprobes include quantum dots (QDs), plasmonic nanoparticles, magnetic nanoparticles, nanotubes, nanowires, and multifunctional nanomaterials. With the advantages of high volume/surface ratio, surface tailorability, multifunctionality, and intrinsic properties, nanoprobes have tremendous applications in the areas of biomarker discovery, diagnostics of infectious diseases, and cancer detection. They highlight the distinguishing features of nanoprobes for in vitro use,

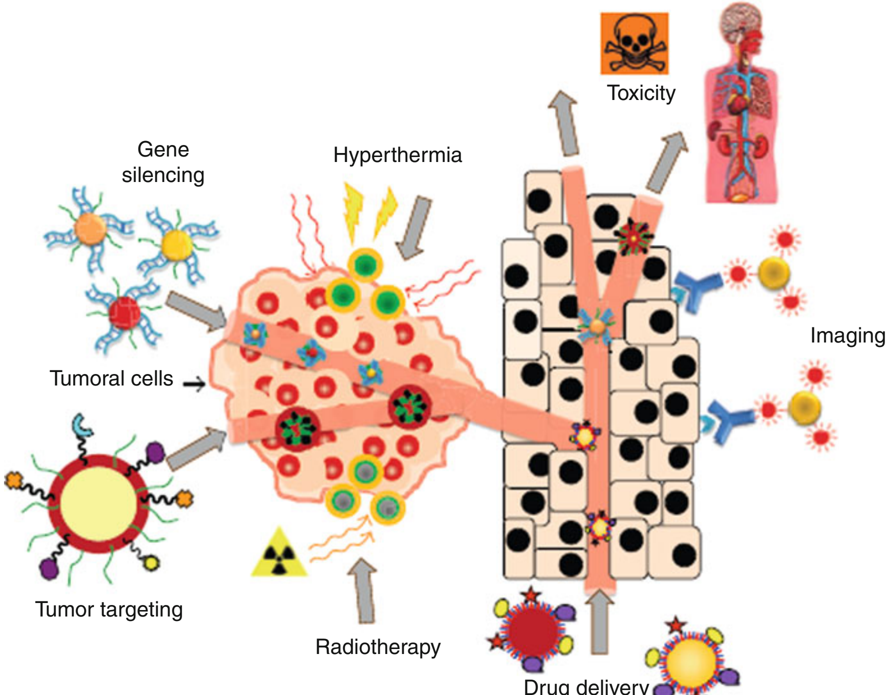

Fig. 23.26 Noble metal nanoparticles for cancer treatment (Conde et al. 2012). Noble metal NPs for cancer therapy. Once the tumor is directly connected to the main blood circulation system, NPs can exploit several characteristics of the newly formed vasculature and efficiently target tumors. Tumor cells are supplied by blood capillaries that perfuse the cells of the tissue where NPs can (1) passively accumulate or (2) anchor through targeting moieties to biomarkers overexpressed by tumor cells. NPs can act simultaneously as therapeutic agents, inducing hyperthermia, enhancing radiotherapy, silencing genes, and/or delivering drugs to induce tumor cell death, and as imaging enhancers or contrast agents, to help track the therapeutic effects in real time

such as safety, ultrasensitivity, multiplicity, and point-of-care use, which will bring a bright future in in vitro nanodiagnosis (Chi et al. 2012a).

23.8.3 Quantum Dots and Carbon Nanotubes

Tan et al. reported that "quantum dots (QDs) can be used to image cancer cells as they display superior fluorescent properties compared with conventional chromophores and contrast agents. In addition, carbon nanotubes (CNTs) have emerged as viable candidates for novel chemotherapeutic drug delivery-platforms. The unique photothermal properties of CNTs also allow them to be used in conjunction with near-infrared radiation and lasers to thermally ablate cancer cells. Furthermore, mounting evidence indicates that it is possible to conjugate QDs to CNTs, making it possible to exploit their novel attributes in the realm of cancer theranostics (diagnostics and therapy)" (Tan et al. 2011).

23.8.4 Iron Oxide

In the context of MRI imaging using superparamagnetic iron oxide nanoparticles (SPIONs), Rosen et al. discuss both passive and active uptakes of contrast media to enhance visualization (Fig. 23.28). Active techniques using iron nanoparticles combined with transferrin, RGD peptides, monoclonal antibodies, aptamers, and other targeting molecules were reviewed in a variety of oncological contexts (Table 23.10). While the pharmacokinetics and safety of many of these moieties have yet to be determined,

Table 23.6 Overview of selected nanoprobes and their potential applications of in vitro diagnostics (Chi et al. 2012a)

Nanoprobes	Physical properties	Analytical methods	Potential applications
QDs	Unique fluorescence	FRET based	Detection of DNAs, proteins, and enzymes
		BRET based	Detection of disease-related protease
Metal nanoparticles	Collective electronic excitations	Surface plasmon coupling	Single-molecule detection and the related disease diagnosis
		LSPR based	Detection of disease-related biomarkers
		SERS based	Detection and identification of biomolecules
Magnetic nanoparticles	Superparamagnetism	Magnetic capture	Bacterial detection
		Diagnostic magnetic resonance	Detection of infectious agents including bacteria, viruses, fungi, and parasites; as well as a variety of other biological targets, such as nucleic acids, proteins, antibodies, viruses, stem cells, and circulating tumor cells
		Giant magnetoresistive sensor	Multiplex detection of protein
CNTs	Resonant Raman scattering	Raman imaging	Detection and differentiation of cancer cells, detection of biomarkers
Si nanowires	Electrical properties	Field-effect device	Detection and measurement of various biological species and their interactions, including proteins, DNAs, and viruses
Multifunctional nanomaterials	Optical, fluorescent, magnetic, and/or electrical properties	Multiplexed methods	Detection and tracking of biomolecules and cells, multiplexed assay, and multimodal imaging

Table 23.7 Nanoparticles for contrast imaging of cardiovascular disease (CVD) (Godin et al. 2010)

Category	Agent (examples)	Imaging techniques
Fluorescent	Quantum dots	Fluorescence tomography
Radioactive	^{18}F CLIO, ^{111}In nanoparticles	PET, SPECT
Paramagnetic	Gd-DTPA	MRI
Superparamagnetic	Iron oxide nanoparticles	MRI
Electron dense	Gold or I-based nanoparticles	CT
Light scattering	Gold nanoshells	Optical coherent tomograpy
Photoacoustic	Colloidal nanobeacons	Photoacoustic tomography
Multimodal	Copper-CLIO	PET, MRI, NIRF
	Perfluorocarbon nanoparticles	MRI, molecular imaging

they believe that these techniques could lead to the next generation of cancer diagnostics and treatments (Rosen et al. 2011).

Diagnostic applications of nanomaterials include but are not limited to:

- In vivo near-infrared fluorescence (NIRF) imaging
- Magnetic resonance imaging (MRI)
- Positron emission tomography (PET)
- Computed tomography (CT)
- Ultrasound (US), photoacoustic imaging (PAI)
- Cancer theranostics (the combination of diagnostic and treatments) (Table 23.10)
- HIV, pathogen detection, infectious disease
- Cardiovascular disease, demonstrating the versatility of nanomaterials (Tables 23.7–23.9, Fig. 23.27)
- Heart, lung, and blood diseases
- Alzheimer's disease
- Crossing the blood-brain barrier
- Thrombosis
- Endoscopy (Hahn et al. 2011; Pan et al. 2010; Sharma et al. 2011; Shinde et al. 2011; Chi et al. 2012b; Godin et al. 2010; Buxton 2007; Brambilla et al. 2011; Bhaskar et al. 2010; McCarthy and Jaffer 2011; Niu et al. 2011)

Table 23.8 Examples of nanocarriers for cardiovascular disease therapy (Godin et al. 2010)

Nanocarrier	Example of agent	Experimental model	Outcomes
Neutral liposomes	Bisphosphonates (clodronate, alendronate, etc.)	Injured rat carotid artery	Macrophage depletion, reduced inflammation
Cationic liposomes	Chloramphenicol acetyl transferase (CAT) encoding gene (Pautler and Brenner 2010b)	Balloon injured Yorkshire pig artery, local delivery	Increased CAT expression
	Vascular endothelial growth factor (VEGF) encoding viral vector	Clinical trial, patients with 60–99% stenosis in major arteries, local delivery through catheter	Significant improvement in myocardial perfusion
Hemaglutin virus of Japan (HVJ) liposomes	Tissue factor pathway inhibitor gene	Iliac artery of hyperlipidemic rabbit following angioplasty. Local delivery through catheter.	Reduction of intimal hyperplasia
Perfluorocarbon nanoparticles	Surface bound streptokinase, $\alpha 3\beta$ integrins, others	Human plasma clots, hyperlipidemic animals	In vitro fibrinolysis, theranostic in vivo
Polyelectrolyte nanoparticles (RNA or polyvinyl sulfate with polyethylene imine/DNA complex)	Gene encoding for urokinase plasminogen activator	Rat carotid artery	High transfection efficiency
Polymeric (PLA or PLGA)	AG-1295 and AGL-2043	Balloon injured rat carotid artery	Inhibition of restenosis

Table 23.9 Nanotechnology based in-vivo cardiovascular disease sensors (Godin et al. 2010)

Sensor targets	Technology	Applications
K^+, H^+ ions	Field effect transistor (FET)	Myocardial ischemia
Na^+ ions	Fluorescent nanosensors	QT syndrome, Heart failure
Ca^{2+} ions	Boron-doped silicon nanowires (SiNWs)	Multiple CVD
Nitric oxide	Single-walled carbon nanotube (SWNT)	Hypertension
oxLDL	Phorphyrinic nanosensor	Ischemia/reperfusion
Cholesterol	In_2O_3 nanowire-based FET	Acute heart attack
Blood pressure	Piezoelectric-BioMEMS	Pressure monitoring
	Chip embedded flexible packaging (CEFP)	Myocardial infarction stenosis in heart bypass
Blood flow	Piezoelectric-BioMEMS	Grafts

23.9 Nanomaterials and Cosmetics

No discussion of nanomaterials would be complete without the mention of their application in the cosmetic industry. Nanomaterials can be found in many cosmetic products including moisturizers, hair care products, makeup, and sunscreens. Their use began in 1986. In 2006, the European Union estimated that 5% of cosmetic products contained nanoparticles.

Nanomaterials used in cosmetics include but are not limited to:

- Titanium dioxide and zinc oxide (sunscreens, cosmetics)
- Organic sunscreens
- Liposomes and niosomes (delivery vehicles, shampoo, minoxidil scalp lotion)
- Solid lipid nanoparticles
- Nanostructured lipid carriers
- Nanocrystals
- Nanoemulsions
- Cubosomes
- Dendrimeres

As before, the application of nanomaterials in cosmetics could fill a textbook. Therefore only brief highlights will be presented here. Readers are encouraged to review the literature and other sources for their specific applications. An excellent starting point

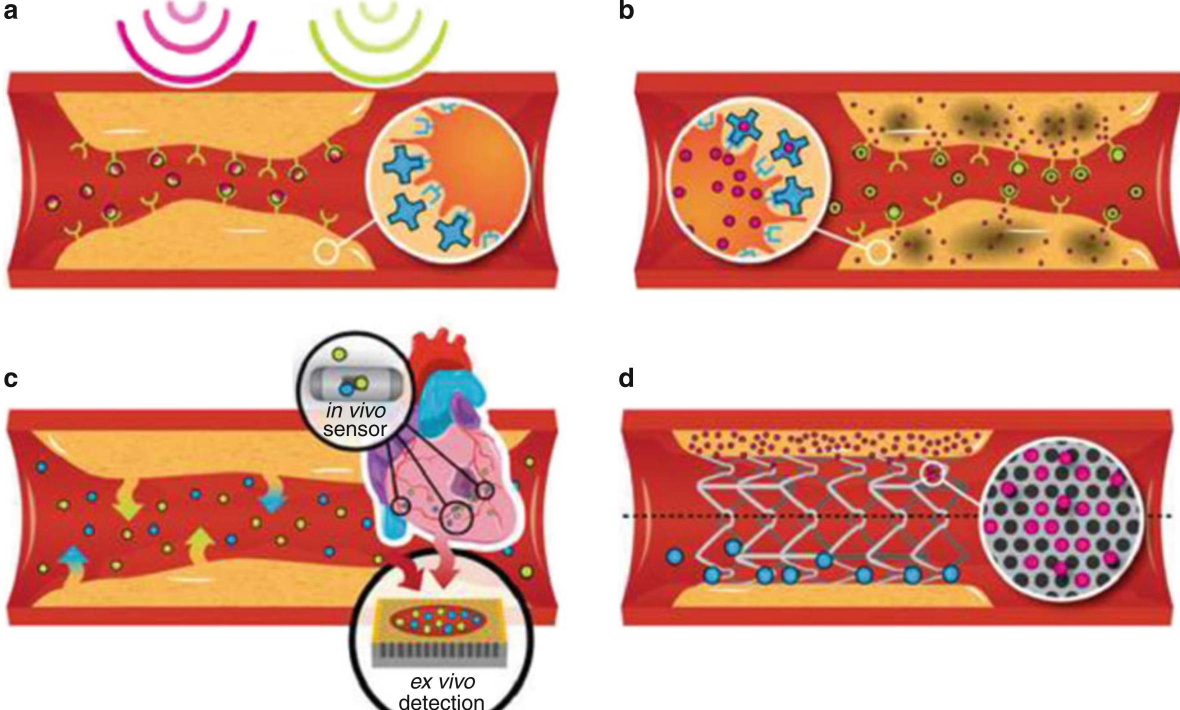

Fig. 23.27 Application of nanotechnology in the diagnosis and treatment of cardiovascular disease (Godin et al. 2010). Schematic presentation of various nanotechnological approaches for advanced CVD diagnosis and therapy: Nanoparticles for (**a**) multimodal image contrast and (**b**) improved treatment of CVD can be targeted to immune cells or the specific ligands presented on the inflamed endothelium of the atherosclerotic plaque; (**c**) in vivo sensors implanted in the pericardial region or on one of the main blood vessels and techniques for ex vivo biomarker detection; (**d**) nanostructured drug/nanoparticles eluting stents

can be found at The Institute of Nanotechnology, (www.observatorynano.eu) (http://www.observatorynano.eu/project/filesystem/files/Cosmetics%20report-April%2009.pdf) (Institute of Nanotechnology 2012). Hair follicles have been considered as reservoirs and entry points for nanomaterials. Somewhat to the chagrin of the lay press and consumer groups nanomaterials used in cosmetics appear to have a good track record to date (Morganti 2010). However, a primary concern is that there is no labeling stipulation for "nano" materials giving rise to suspicions of lack of labeling transparency. Use of nanomaterials in cosmetics suffers from toxicology limitations previously mentioned (Tables 23.1 and 23.2).

Additional confusion arises when lay and consumer reporters highlight research from one area and apply it to another; an example is from Trouiller et al., a report that received a lot of lay attention. The group found genetic anomalies in mice that were fed titanium dioxide in water (Trouiller et al. 2009). No dermal work was reported. However, they mentioned that titanium dioxide nanoparticles are used in a variety of materials from paint to cosmetics. Reference to cosmetics by others citing this work was inaccurate and confusing.

Nonetheless, consumers are entitled to transparency in labeling of any product that they use. Regulators cite the enormous volume of nanomaterial information, a reasonably safe track record, and lack of funding and resources as responses to consumer and press advocates for enhanced safety precautions.

23.10 Future Prospects

23.10.1 Handheld Diagnostic Devices

Using magnetic nanotechnology platforms, there is the promise of specific, economical, and rapid medical diagnosis either in the office or field environments. Training

Table 23.10 Cancer types and cell lines (human) used with active targeting methods directed against a variety of surface receptors (Rosen)

Targeting agent	Cell lines used for in vitro studies with this targeting agent	Cell lines used for in vivo studies with this targeting agent	Cancers that this method has been shown to be able to target
Monoclonal antibodies	LX-1, TE8, L-2981[a], C-3347[a], M-2669[a], NCI-125[a], H2981[a], H3347[a], LNCaP, WiDr, MCF-7, AU-565	LX-1, TE8, WiDr	Small cell lung carcinoma, squamous-cell carcinoma of the esophagus, lung adenocarcinoma, colon carcinoma, melanoma, non-small cell lung carcinoma, prostate cancer, mammary adenocarcinoma, breast adenocarcinoma
Nanobodies	LS174T[a], SW2[a], A431[a], HeLa[a]	LS174T[a], SW2[a], SK-OV-3[a], A431[a]	Colon carcinoma, small cell lung carcinoma, ovarian adenocarcinoma, epidermoid squamous-cell carcinoma
Affibodies	SKOV-3[a], SKBR-3[a], Capan-1[a]		Ovarian adenocarcinoma, breast adenocarcinoma, pancreatic adenocarcinoma
Aptamers	LNCaP CCRF-CEM, Ramos, Toledo, Sup-T1[a], Jurkat[a], Molt-4[a], SUP-B15[a], U266[a], Mo2058, NB-4[a], K562[a], BNL 1ME A.7R.1[a], H23[a], A549[a], HLAMP[a], NCI-H460[a], NCI-H299[a], NCI-H520[a], NCI-H157[a], NCI-H446[a], HepG2[a], Huh7[a]	BNL 1ME 1.7R.1[a]	Prostate cancer, acute lymphoblastic leukemia, B-cell lymphoma, diffuse large-cell lymphoma, T-cell acute lymphoblastic leukemia, mantle cell lymphoma, acute promyelocytic leukemia, Burkitt's lymphoma, chronic myelogenous leukemia, non-small cell lung cancer non-small cell lung cancer (adenocarcinoma), non-small cell lung cancer (large cell lung cancer), non-small cell lung cancer (large cell carcinoma), non-small cell lung cancer (squamous cell carcinoma) Small cell lung cancer, liver cancer

[a]Cell lines not tested directly with SPIONs

to operate these battery-powered systems could be minimal, enabling their use in developing countries with minimal user training (Gaster et al. 2011).

23.10.2 Personalized Medicine

The multiple utility of nanomaterials has given rise to the concepts of "nanobiotechnology" and "theradiagnostics," where targeted particles carry diagnostics and treatments combined designed for application in specific patients.

Personalized medicine is defined as the prescription of specific treatments best suited for an individual taking into consideration both genetic and other factors that influence the response to therapy. Personalized medicine is the best approach to integrate new biotechnologies into medicine in order to improve understanding of the pathomechanism of diseases, molecular diagnosis and integration with therapeutics. Nanomedicine is defined as the application of nanobiotechnology to medicine. Nanobiotechnology also makes important contributions to personalized medicine through refinement of various technologies used for diagnostics and therapeutics as well as interactions among these (Fig. 23.29).

Innovative diagnostic technologies that are increasingly utilized in personalizing treatment include novel polymerase chain reaction (PCR), direct molecular analysis without amplification, DNA sequencing, biochips/microarrays, and nanobiotechnologies. Technologies for detection of copy number variations, single nucleotide polymorphisms, and cytogenetic alterations provide basic information for personalized medicine. Molecular diagnostic technologies are used for the detection of biomarkers, which may form the common basis of diagnostics and therapeutics.

Nanobiotechnology techniques provide an analysis of DNA and protein and could dramatically improve speed, accuracy and sensitivity compared to conventional molecular diagnostic methods. Nanobiotechnology based approaches can provide more precise measurements and insight into nanoscale inherent functional components of living cells. Nanobiotechnology facilitates point-of-care diagnosis and the integration of diagnostics with therapeutics, thus advancing the development of personalized medicine (Jain 2011; Jain 2010).

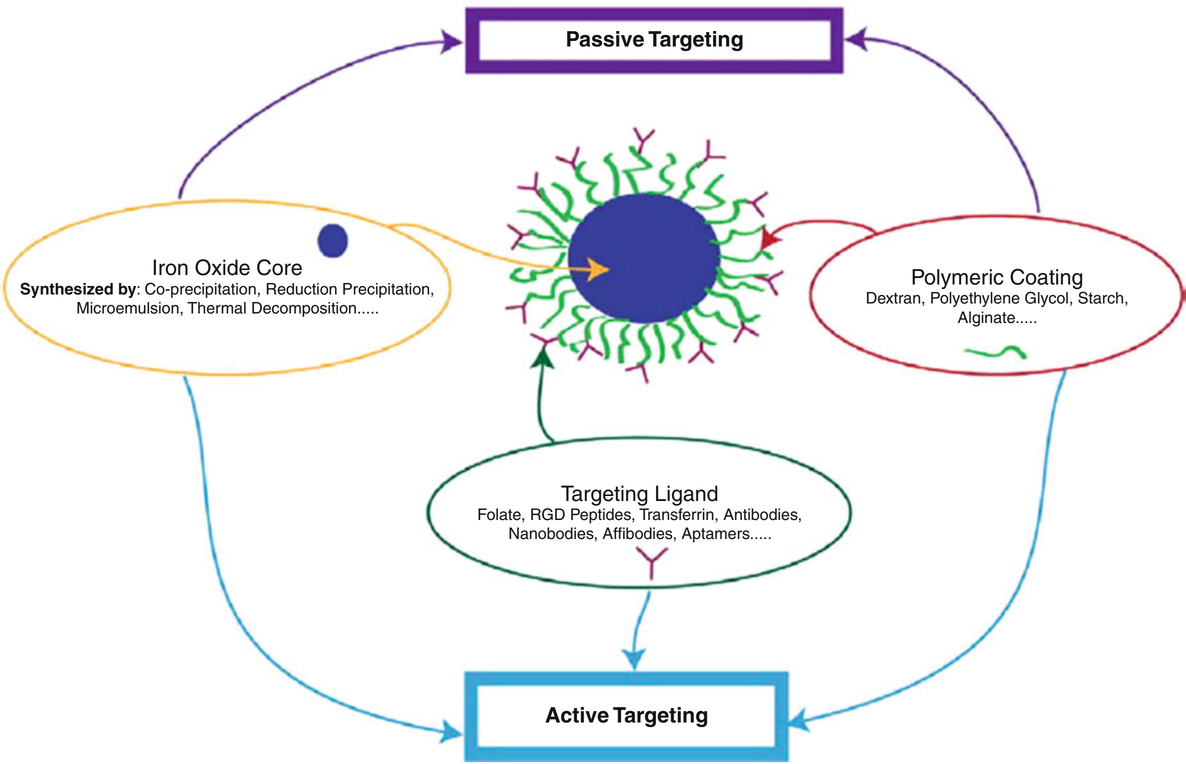

Fig. 23.28 Image showing the various components that make up active targeting–based and passive targeting–based SPIONs (Rosen et al. 2011)

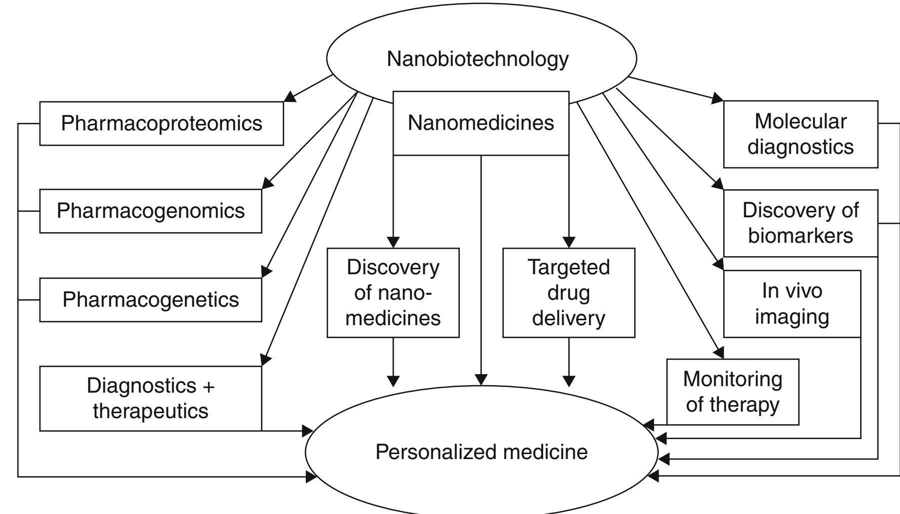

Fig. 23.29 Relationship of nanobiotechnology and personalized medicine (Jain 2010, 2011)

The Invention issue of *Time* magazine (Grossman 2011) provides some final insights on where nanotechnology will be taking direction. Fig. 23.30 shows the development of a drone hummingbird capable of all hummingbird flight motions (11 mph, right, left, forward, backward, up, down, hovering, "perching") and equipped with a camera. Drone insects are reportedly under development (Watson 2011). While still

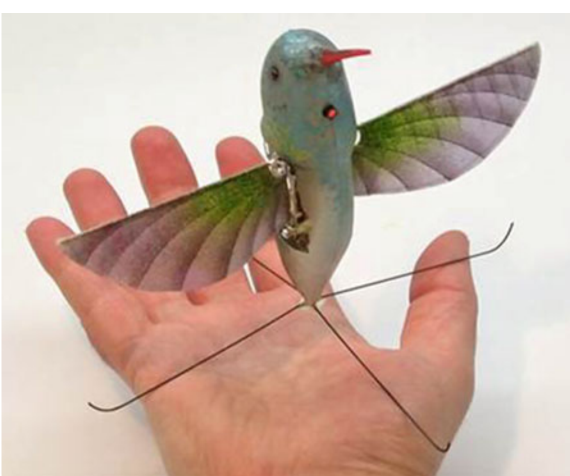

Fig. 23.30 Drone hummingbird (Grossman 2011; Watson 2011). This life-size hummingbird-like unmanned aircraft, named Nano Hummingbird, was developed by AeroVironment Inc., for the Defense Advanced Research Projects Agency. The prototype has a wingspan of 6.5 in., can fly up to 11 mph, and weighs just two-thirds of an ounce

"macrotechnology," these developments beg the question: Just how distant is the development of a true nanobot? A 22 nm, 3D TriGate transistor that will increase the performance and efficiency of computing could lend itself toward developing small, user friendly, nano diagnostic devices.

Finally, the development of a double-stranded-RNA-activated caspase oligomerizer (DRACO) molecule that is <10 nm in size. A DRACO is a genetically engineered molecule designed to trigger suicide in cells that have been invaded by a virus yet does not affect uninfected cells. It is reportedly effective against 15 viruses including rhinovirus (common cold), H1N1 influenza, and dengue fever (Rider et al. 2011).

23.11 Concluding Remarks

The purpose of this chapter was to introduce the reader to nanotechnology and its implications in a number of environments. Readers are encouraged to use these passages and references as a starting point in their own work in this rapidly expanding area. Nanotechnology represents the next technological revolution that will impact most areas of commercial application. In the 20 years prior to 2011, research in nanotechnology has grown rapidly because of predicted immense markets. Nanomaterials used in consumer products are a rapidly expanding area. Because nanomaterials have a multifunctional capability, there is a strong interest to apply them in the clinical environment as diagnostics, treatments, and in/as medical devices. Nanomaterials' variable reactivity is their great strength *and* weakness. Their application for benefit is only limited to the imagination; however, minute changes in a nanomaterial or product used in conjunction with a nanomaterial can have dramatic impact on patient safety.

Because of their variability, there is little product class information for nanomaterials. The clinical science of nanomaterials can sometimes yield variable or conflicting results because of a lack of standards and standardized testing. This has given rise to studying nanomaterials on a case-by-case basis. Progress in nano-research may become increasingly sluggish because of the lack of research standards and informatics.

Despite the current shortcomings, research in medical applications continues to expand and offers the promise of personalized diagnostics and treatments for a large variety of conditions that currently have high mortality and morbidity (e.g., cancer, heart disease, Alzheimer's). Once safe clinical use of nanomaterials has been achieved, it is ironic to consider the enormous healthcare impacts that will arise from the smallest of applications.

Appendices

Appendix 1

Nanotechnology – Nomenclature

Nanosciences and nanotechnologies mean, in their concept, new approaches to the understanding and utilization of properties of the mass that critically depend on sizes, which are at the nanometer scale.

Nanoscience is the study of phenomena and manipulation of materials at atomic, molecular, and macromolecular scales, where properties significantly differ from those at larger scale.

Nanotechnologies are the design, characterization, production, and application of structures, devices, and systems controlling shape and size at the nanometer scale.

The presented definitions were formulated within the preparation of the British study "Nanoscience and Nanotechnologies: Opportunities and Uncertainties" in 2004 (An excellent reference document, however, published in 2004). It is important to define this interdisciplinary area of science and technology in order to make it different from classic disciplines of science and technology. That is the reason why the words with the prefix of "nano," like, for example, nanomaterials, nanomedicine, nanobiotechnology, nanoanalytics, nanoelectronics, and a number of others, but also nanochemistry and nanophysics, are often used, even if that can be sometimes misleading. On the other hand, many authors, institutions and companies do not use, in their fields of work done within the nanometer sizes, the prefix "nano" and that makes the identification of their activities more difficult and may even lead to not precise results of conducted research.

Nanotechnologies – Nomenclature (as of 2004 Which Includes but is Not Limited to Its Contents)

1. *Nanomaterials*
   (a) Nanopowder materials, nanoparticles, quantum dots, and nanofibers
   (b) Composite materials containing nanoparticles
   (c) Materials with carbon nanotubes or fullerenes
   (d) Thin layers, nanolayers, and nanocoatings
   (e) Nanostructural metals and alloys
   (f) Nanoceramics
   (g) Polymer nanocomposites and polymer nanomaterials
2. *Nanotechnology for the storage and transmission of information, micro- and nanoelectronics*
   (a) Nanoelectronics, materials, and equipment
   (b) Photonics
   (c) Optic materials, structures, and equipment
   (d) Magnetic materials and equipment, spintronics
   (e) Organic photonics and bioelectronics
   (f) MEMS, NEMS
3. *Nanobiotechnology and nanomedicine*
   (a) Encapsulating of drugs
   (b) Targeted transport of medicine (including genetic material)
   (c) Tissue engineering
   (d) Biocompatible and bio-analogical materials and layers
   (e) Molecular analysis and DNA analysis
   (f) Biological-inorganic interface and hybrids
   (g) Diagnostics and molecular recognition
4. *Nanotechnology for applications in sensors*
   (a) Sensors utilizing nanomaterials
   (b) Biomolecular sensors
5. *Nanotechnology in the (electric) chemical processing technologies*
   (a) Filtration, membranes, molecular sieves, and zeolites
   (b) Catalysis or electrodes with nanostructural surfaces

   (c) Chemical synthesis, supramolecular chemistry
6. *Long-term research with the wide spectrum of applications*
   (a) Self-assembly
   (b) Quantum physics, quantum phenomena in nanosizes, and nanophysics
   (c) Nano- and mesoscopic systems
   (d) Chemical materials and processes – nanochemistry
   (e) Ultraprecise engineering
7. *Instruments and facilities, research, and applications of technologies*
   (a) Analytical instruments, methods, techniques, and research
   (b) Manufacture (preparation) of nanopowders (nanoparticles) and their processing
   (c) Facilities and methods for the creation of layers and coatings
   (d) Facilities and methods for the creation of objects (patterning, ECAP, fiber fabrication, etc.)
   (e) Ultraprecise machining and nanometrology
8. *Health, ecological, ethical, social, and other aspects of nanotechnologies*
   (a) Toxicity of nanoparticles
   (b) Environmental aspects
   (c) Social and ethical aspects (including regulatory issues)
   (d) Standardization
   (e) Patenting
   (f) Roadmaps and foresight
   (g) Popularization of nanotechnologies
   (h) Trade in nanoproducts

Appendix 2. Uses of Nanotechnology in Medical Devices

Technology is shrinking at a rather rapid rate. As a result, more and more advancements are taking place at the cellular, molecular, and atomic levels – at the nanoscale. With scientific understanding growing, it is becoming possible to engineer the smallest devices and applications to help in a variety of fields. One of the fields that is likely to benefit greatly from nanotechnology is medicine.

Nanotechnology is especially important to medicine because the medical field deals with things on the smallest of levels. Additionally, the small nano devices that are being developed right now can enter the body and look around in ways that large humans can only dream of. Here are 25 ways that nanotechnology is revolutionizing medicine:

1. *Nanobots*: These devices have great potential for medical uses. These smallest of robots could be used to perform a number of functions inside the body, and out. They could even be programmed to build other nanobots, increasing cost efficiency.
2. *Nanocomputers*: In order to direct nanobots in their work, special computers will need to be built. Efforts to create nanocomputers, as well as the movement toward quantum computing, are likely to continue to provide new processes and possibilities for the science of medicine.
3. *Cell repair*: Damage to the cells of the body can be very difficult to repair. Cells are so incredibly small. But nanotechnology could provide a way to get around this. Small nanobots or other devices could be used to manipulate molecules and atoms on an individual level, repairing cells.
4. *Cancer treatment*: There are hopes that the use of nanotechnology could help in cancer treatment. This is because the small, specialized functions of some nano devices could be directed more precisely at cancer cells. Current technology damages the healthy cells surrounding cancer cells, as well as destroying the undesirables. With nanotechnology, it is possible that cancer cells could be targeted and destroyed with almost no damage to surrounding healthy tissue.
5. *Aging*: Nano devices could be used to erase some of the signs of aging. Already, laser technology can reduce the appearance of age lines, spots, and wrinkles. With the help of powerful nanotechnology, it is possible that these signs could be done away with completely.
6. *Heart disease*: There is a possibility that nanobots could perform a number of heart-related functions in the body. The repair of damaged heart tissue is only one possibility. Another option is to use

nano devices to clean out arteries, helping unclog those that have buildup due to cholesterol and other problems.

7. *Implanting devices*: Instead of implanting devices as we have seen in some cases, it might be possible to send a nanobot to build the necessary structures inside the body.
8. *Virtual reality*: Doctors could explore the body more readily with the help of a nanobot injection. Creating a virtual reality that would help medical professionals and others learn could help make some operations more "real" and provide practice ahead of time.
9. *Gene therapy*: Nanotechnology would be small enough to enter the body and even redesign the genome. This would be a way to alter a number of conditions and diseases. However, the human genome would need to be understood a little better for truly advanced gene therapy. However, nanobots would be qualified for swapping abnormal genes with normal genes and performing other functions.
10. *Drug delivery*: Systems that automate drug delivery can help increase the consistency associated with providing medication to those who need it. Drug delivery systems can be regulated using nanotechnology to ensure that certain types of medications are released at the proper time, and without the human error that comes with forgetting to take something.
11. *Nanotweezers*: These devices are designed to manipulate nanostructures. These can be used to move nano devices around in the body, or position them prior to insertion. Nanotweezers are usually constructed using nanotubes.
12. *Stem cells*: Nanotechnology can actually help adult stem cells morph into the types of cells that are actually needed. Studies showing how nanotubes can help adult stem cells turn into function neurons in brain-damaged rats.
13. *Bone repair*: It is possible to accelerate bone repair using nanotechnology. Nanoparticles mad up of different chemical compositions can help knit bones back together, and can even help in some cases of spinal cord injury.
14. *Imaging*: Nanotechnology can provide advancements in medical imaging by allowing a very specific and intimate peek into the body. Nano devices result in molecular imaging that can lead to better diagnosis of a variety of diseases and conditions.
15. *Diabetes*: Instead of having to draw blood to test blood sugar level, nanotechnology is providing a way for diabetics to use lenses to check their blood sugar. These nanocomposite contact lenses actually change color to indicate blood sugar level.
16. *Surgery*: We already have robotic surgeons in some cases, but nanosurgery is possible using some lasers as well as nano devices that can be programmed to perform some surgical functions. Being able to perform surgery at the smallest level can have a number of benefits for long-term medicine.
17. *Seizures*: There are nanochips being developed to help control seizures. These chips are meant to analyze brain signals and then do what is needed to adjust the brain so that epilepsy could be better controlled.
18. *Sensory feedback*: For those who have lost feeling in their body, it is possible to use nanotechnology to increase sensory feedback. Nanochips provide the opportunity for electrical impulses to be intercepted and interpreted.
19. *Limb control*: Prosthetics continue to advance, and nanotechnology is likely to help revolutionize the way paralysis is handled. There are some attempts to use nanochips that can help those who have lost limb control use their minds to send signals to provide a certain amount of motion.
20. *Medical monitoring*: You might be able to increase your ability to monitor your own body systems with the help of nanotechnology. Small nanochips implanted in your body could monitor your health and systems, and then send feedback to your computer or other device.
21. *Medical records*: In addition to monitoring your own body systems, nanotechnology can be used to send information to your health care providers and increase the efficiency of electronic medical records.
22. *Disease prevention*: Having a nano device in your body could actually help prevent diseases. With proper programming, it should be possible to help you avoid some diseases, repairing problems before they become serious issues. It may even be able to help prevent chronic diseases.

23. *Prenatal*: There are a number of ways that nanotechnology can help in terms of prenatal diagnosis. Being able to get inside the uterus and even inside the fetus without causing trauma can be beneficial to prenatal health, and nanotechnology can also help potentially repair problems in the womb.
24. *Individual medicine*: Nanotechnology is moving toward making medicine more personal. Being able to accurately work up your genome can help health providers more precisely pinpoint the proper treatments and tweak a treatment plan according to your individual needs and responses.
25. *Research*: Nanotechnology is advancing medical research, providing the tools that can help us learn more about the body and how it functions, as well as providing insight into chemistry and physics, which provide the building blocks for the body.

24.1 Introduction

Regulation (EC) No 1907/2006 on Registration, Evaluation, Authorization and Restriction of Chemicals (REACH) initiated a significant change in the way industrial chemicals are regulated in the European Economic Area (EEA). It harmonizes the control of chemicals placed on the European market and replaces a large number of European and national regulations with a single legal framework. One of the major changes established by the REACH regulation is that the burden of proof on chemical safety is shifted from government to industry. EU manufacturers and importers are responsible for gathering information on the properties of their chemical substances, which will allow their safe handling, and to register the information in a central database run by the REACH regulator, the European Chemicals Agency (ECHA), based in Helsinki. The agency manages the databases necessary to operate the system, coordinates the in-depth evaluation of potentially hazardous chemicals, and is building a public database in which consumers and professionals can find hazard information.

A striking difference from the old regime is the requirement to provide safety information for *all* existing chemicals placed on the EU market at annual volumes above 1 tonne per annum (t/a). Prior to REACH, all chemicals first placed on the EU market before 1981 were grandfathered; that is, they could continue to be used without providing any data on intrinsic toxicological properties. These existing chemicals accounted for approximately 100,000 substances are listed in the *E*uropean *IN*ventory of *E*xisting *C*ommercial chemical *S*ubstances (EINECS). Since 1981, approximately 2,700 new substances have

ENVIRON Germany GmbH, Germany

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_28, © Springer-Verlag Berlin Heidelberg 2013

been introduced to the market and thus subject to a substantial hazard and risk assessment. Of the 2,700 new substances, 70% have been found to be "dangerous" as defined by EU Directive 67/548, because of corrosive, flammable, mutagenic, carcinogenic, developmentally or otherwise toxic, irritating, or sensitizing properties (Strategy for a Future Chemicals Policy—White Paper. COM (2001) 88 final, 27 February 2001). Companies now face the challenge to demonstrate chemical safety for approximately 30,000 grandfathered chemicals marketed in annual volumes above 1 t/a on which toxicological data is limited or does not exist. To complete this task, REACH requirements will be phased in over about a decade, first addressing high production volume chemicals produced or imported at volumes above 1,000 t/a as well as the most dangerous chemicals (i.e., classified as carcinogens, mutagens, or reproductive toxins or toxins with long-term aquatic toxicity). The registration deadline for these substances was December 2010. Chemicals produced or imported at volumes between 100 and 1,000 t/a will need to be registered by May 2013, and registration of chemicals produced or imported at volumes between 1 and 100 t/a is required by May 2018. As a result, all chemicals placed on the EU market in volumes above 1 t/a will be assessed within 10 years after REACH came into effect on January 1, 2008. In comparison, under the old regime, only 141 substances were prioritized for comprehensive risk assessment under the Existing Substances Regulation (Regulation (EEC) 793/93), and in the first decade after adoption, draft risk assessments were finalized for less than half of them.

24.2 REACH: Basic Principles

REACH is an acronym for Registration, Evaluation, Authorisation and Restriction of Chemicals. The registration is initiated jointly by all companies manufacturing or importing the same substance in annual volumes of 1 t or more. The main objective of the registration is to identify and manage risks linked to manufacturing and importing of chemicals. The REACH registration dossier consists of all available data on a substance, including proof of unambiguous substance identity, data on physicochemical properties, toxicological and ecotoxicological hazards, and environmental fate and behavior. In contrast to the old chemical legislation, REACH does not regulate chemicals based on their hazard profile alone but also on potential exposure to humans and the environment as well. Consequently, the registrant needs to evaluate if specific exposure scenarios are considered to be safe, or if a potential user needs to establish specific measures to ensure a safe use. The result of this consideration is documented by means of a Chemical Safety Report (CSR) which is part of the REACH registration dossier that is subsequently submitted to the European Chemicals Agency (ECHA). The amount of information that is needed for a valid registration depends on the annual tonnage. There are four tonnage bands requiring various types of hazard evaluation data—1–10 t/a, 10–100 t/a, 100–1,000 t/a, and above 1,000 t/a—and four corresponding annexes (VII–X) specifying the information requirements. The annual volume not only defines the amount of information that needs to be gathered but also the deadline for registration, that is, 2010, 2013, and 2018 (Box 24.1). It is important to note that these transition periods only apply to substances that have been preregistered with ECHA in accordance with Article 23 before December 1, 2008.

The second phase of the REACH process is the evaluation of dossiers performed by ECHA. The agency runs different types of evaluation ranging from a basic technical completeness check of a registration dossier to a thorough assessment of all submitted data and the validity of the ultimate risk assessments. The latter will be performed on at least 5% of all dossiers received by the agency for each tonnage band (Article 41). Evaluation may lead to the conclusion that action should be taken under the restriction or authorization procedures or that risk management action should be considered in the framework of other appropriate legislation. The ECHA reported that dossier evaluations of the 2010 registrations showed that the quality of many of the chemical safety assessments was of concern and needed to be improved by the registrant (Evaluation under REACH Progress Report 2010: (http://echa.europa.eu)). Hence, reviewing only 5% of the dossiers may potentially be a significant limitation in the REACH system.

The last phase of the REACH process is the restriction and authorization of chemicals. The aim of the authorization process is to assure that the risks from substances of very high concern (SVHC) are properly controlled and that these substances are progressively

Table 24.1 Entry for DEHP in Annex XIV to the REACH regulation

Entry Nr	Substance	Intrinsic property(ies) referred to in Article 57	Transitional arrangements		Exempted (categories of) uses
			Latest application date	Sunset date	
4.	Bis(2-ethylhexyl) phthalate (*DEHP*) EC No: 204-211-0 CAS No: 117-81-7	Toxic for reproduction (category 1B)	August 21, 2013	February 21, 2015	Uses in the immediate packaging of medicinal products covered under Regulation (EC) No 726/2004, Directive 2001/82/EC, and/or Directive 2001/83/EC

Table 24.2 Entry for phthalates in Annex XVII to the REACH regulation

Column 1	Column 2
Designation of the substance, of the group of substances, or of the mixture	Conditions of restriction
51. The following phthalates (or other CAS and EC numbers covering the substance): (a) Bis (2-ethylhexyl) phthalate (DEHP) CAS No 117-81-7 EC No 204-211-0 (b) Dibutyl phthalate (DBP) CAS No 84-74-2 EC No 201-557-4 (c) Benzyl butyl phthalate (BBP) CAS No 85-68-7 EC No 201-622-7	1. Shall not be used as substances, or in mixtures, in concentrations greater than 0.1% by weight of the plasticized material, in toys and childcare articles 2. Toys and childcare articles containing these phthalates in a concentration greater than 0.1% by weight of the plasticized material shall not be placed on the market 3. The commission shall reevaluate, by January 16, 2010, the measures provided for in relation to this entry in the light of new scientific information on such substances and their substitutes, and if justified, these measures shall be modified accordingly 4. For the purpose of this entry, "childcare article" shall mean any product intended to facilitate sleep, relaxation, hygiene, the feeding of children, or sucking on the part of children

replaced by suitable alternatives where economically and technically viable. SVHCs are substances that meet one or more of the following criteria:

- Carcinogenic, mutagenic, or toxic to reproduction (CMR), meeting the criteria for classification in category 1a or 1b according to the CLP-Regulation (EC) No 1272/2008
- Persistent, bioaccumulative, and toxic (PBT) or very persistent and very bioaccumulative (vPvB) according to the criteria in Annex XIII of the REACH regulation
- Identified, on a case-by-case basis, from scientific evidence as giving rise to an equivalent level of concern as those above (e.g., endocrine disrupters or neurotoxicants)

As described by the agency, the initial steps of the authorization process are the identification of SVHCs and their inclusion in the candidate list, and the subsequent prioritization of those substances for inclusion in the authorization list (Annex XIV to the REACH regulation). Proposals for inclusion in the candidate list are prepared by a member state or by ECHA on request of the commission. Each substance included on the authorization list is assigned a specific phase out date (Table 24.1). After this "sunset date," substances may be placed on the market only if an authorization has been granted for a specific use or the use has been exempted from authorization. The application for authorization has to be done by each individual member of the supply chain (manufacturer, importer, only representative (OR), or downstream user) and authorization will in general be granted per use and per individual user. However, if an authorization is granted within a supply chain, all members downstream from the applicant are covered by this single authorization.

The European Commission has authority for decisions regarding authorizations. The EU white paper estimates that about 1,400 substances are considered to be SVHC (Strategy for a Future Chemicals Policy–White Paper. COM (2001) 88 final, 27

February 2001). Some of these substances are likely to be banned altogether. REACH explicitly invokes the precautionary principle—that when scientific evidence suggests a substance may harm human health or the environment but the type or magnitude of harm is not yet known, the burden of proof for the safety of the substances falls on the manufacturers and importers, and interim risk management measures need to be implemented until a final assessment is achievable.

In addition to the authorization, EU authorities may impose restrictions on the manufacture, use, or placing on the market of substances causing unacceptable risks to human health or the environment. This restriction process is implemented as a "safety net" to manage risks that are not addressed by other REACH processes and if it is demonstrated that risks need to be addressed on a community-wide basis. The restriction process is initiated by member states competent authorities or the agency on request from the commission by preparing an Annex XV dossier. These restriction dossiers need to justify that the proposed restriction is the most appropriate risk management measure. All agreed restrictions will be published in Annex XVII to the REACH regulation. Any subsequent manufacture, placing on the market, or use of the substance must comply with the conditions of the restrictions. An example of an entry in Annex XVII is given below (Table 24.2). In contrast to the registration, both authorization and restriction are independent form the volume. They apply to substances manufactured or placed on the market, irrespective of quantity.

Box 24.1 REACH: Timeline.

1998	The European Commission (EC) began developing REACH
2001	EC adopted a white paper, "Strategy for a Future Chemicals Policy," detailing the proposed system
June 1, 2007	REACH came into force
June 1, 2008	Preregistration for existing ("phase-in") substances and registration for new ("non-phase-in") substances starts
October 28, 2008	ECHA publishes first candidate list (SVHC)
December 1, 2008	Preregistration for "phase-in" substances ends and registration for existing substances (that have not been preregistered) starts
January 1, 2009	ECHA publishes first list of preregistered substances
December 1, 2010	Phase 1: By this date, preregistered "phase-in" substances should have been registered when supplied at: $>$1,000 t/a $>$100 t/a and classified as very toxic to aquatic organisms $>$1 t/a and classified as Cat 1a or 1b (CLP) carcinogens, mutagens, or reproductive toxicants
January 3, 2011	Notification of substances to ECHA's Classification and Labeling (C&L) Inventory
February 17, 2011	ECHA publishes first Annex XIV (authorization list)
June 1, 2011	Notification of SVHC in articles if present at $>$0.1% (w/w) and exceeding annual volume of 1 t/a
June 1, 2013	Phase 2: By this date, preregistered "phase-in" substances should have been registered when supplied at $\geq$100 t/a
June 1, 2018	Phase 3: By this date, preregistered "phase-in" substances should have been registered when supplied at $\geq$1 t/a

24.3 The Scope of REACH

The REACH regulation covers most chemical substances that are manufactured in or imported into the EU and applies to substances used alone and in mixtures, as well as in articles, if the substance is intended for release during normal and reasonably foreseeable conditions of use. The scope of REACH is defined in Article 2 of the regulation. Substances for which risks associated with manufacture and use are sufficiently covered by other legislations may be totally exempted from the requirements of REACH. Substances which fall into the following categories are fully exempt from REACH: radioactive substances within the scope of Council Directive 96/29/Euratom, substances which are subject to customs supervision, nonisolated intermediates, the carriage of dangerous substances, and waste as defined in Directive 2006/12/EC. Other substances are partially exempt from certain aspects of REACH because they fall under the scope of more specific legislation. These include substances in medicinal products, cosmetic products, medical devices, or food and feeding stuffs. In addition, some substances are specifically exempted in Annex IV, as sufficient information is known about their intrinsic properties and they are considered to cause minimum

risk, or in Annex V, because registration is deemed inappropriate or unnecessary for these substances.

Although polymers are not subject to registration and evaluation, the monomers or other substances within the polymer require registration. Moreover, there are partial exemptions of substances for specific uses such as for scientific or product- and process-oriented research and development.

Scientific research and development (R&D) under REACH means any scientific experimentation, analysis, or chemical research carried out under controlled conditions in a volume below 1 t/a. Substances in those low quantities are not subject to registration by default. But in contrast to regular substances that are subject to authorization and restriction when imported or manufactured in quantities below 1 t/a, substances used in R&D are exempted from these obligations.

In order to encourage innovation, substances used in product- and process-oriented research and development (PPORD) are exempted from the obligation to register for a period of up to 10 years if they are notified to the agency for this use. Hence, chemicals used for drug development and clinical trials may be exempted from REACH requirements. A prerequisite for using this exemption is that the substances are only to be used by a number of listed customers included in the notification and that the risks to human health and the environment are adequately controlled in accordance with the requirements of legislation for the protection of workers and the environment. The agency could decide to impose conditions to ensure that a substance will be handled only by staff of listed customers in reasonably controlled conditions and will not be made available to the general public and that remaining quantities will be recollected for disposal after the exemption period. In contrast to scientific R&D, substances used in PPORD are subject to authorization and restrictions, unless an exemption is explicitly specified in Annex XIV and XVII.

24.4 Pharmaceuticals Under REACH

Medicinal products for human or veterinary use are partially exempted from REACH. This applies to the registration, evaluation, and authorization but does not affect the obligation to communicate along the supply chain or comply with restrictions as defined in Annex XVII. Importantly, substances (active ingredients and excipients) are exempted only to the extent that they are used in medicinal products in accordance with Regulation (EC) No 726/2004, Directive 2001/82/EC, and Directive 2001/83/EC. The exemption is not applicable to quantities of substances used for other nonmedical applications like cosmetics, fermentation, or other industrial applications. It is also not applicable to chemicals in pharmaceutical production that do not end up in the finished product like starting materials, intermediates, and process chemicals.

25.1 Introduction

The International Conference on Harmonisation (ICH) S7A guideline for safety pharmacology studies was adopted in 2000. The ICH S7A guidelines describe a core battery of studies that are to be conducted prior to first administration in humans. These studies are conducted to assess potential effects on the respiratory, cardiovascular, and central nervous systems. Due to the safety implications of results from these studies, it is recommended that such studies be conducted according to good laboratory practices (GLP).

Importantly, safety pharmacology studies are not limited to the core battery studies that are described in the ICH S7A (Guth and Siegl 2007). Pharmaceutical companies are putting additional effort into understanding potential effects on the respiratory, cardiovascular, and central nervous systems earlier in the discovery process. These studies are not conducted GLP, and they often use smaller animals or in vitro systems. The study design of these early studies varies significantly from company to company and usually do not meet the ICH requirements. Study designs depend on the company's internal data and willingness to take business risks when deciding to move compounds forward in the development process. Because of the wide variety of study designs utilized by companies early in discovery, this chapter will not attempt to characterize those studies. In contrast, as companies move into the safety pharmacology studies required by ICH guidelines, less variability is observed across companies. This chapter will specifically discuss studies required by the ICH S7A guidelines and factors that should be considered when they are being designed. Although, there is a fair amount of consistency across the core

DOI 10.1007/978-3-642-25240-2_29, © Springer-Verlag Berlin Heidelberg 2013

battery of studies, there are also decisions that must be made depending on the properties and the intended use of the drug being developed. The components of study design that must be considered are model selection, sample size, route of administration, dose selection, and data analysis.

25.2 Respiratory System

The ICH S7A guidelines state, "Effects of the test substance on the respiratory system should be assessed appropriately. Respiratory rate and other measures of respiratory function (e.g., tidal volume or hemoglobin oxygen saturation) should be evaluated. Clinical observation of animals is generally not adequate to assess respiratory function, and thus these parameters should be quantified using appropriate methodologies."

25.2.1 Model Selection

The rat is the preferred species in most drug development programs, and plethysmography is the preferred technique to measure respiratory function. In addition to the measurement of respiratory rate, most companies assess tidal/minute volume as their other measure of respiratory function (Lindgren et al. 2008). The most accurate plethysmographs are designed to directly monitor lung volume changes or airflows generated by thoracic movements. This is accomplished by isolating openings to the upper airways from the thorax and is referred to as "head-out" or "head-enclosed" chambers. The primary advantage of this technique is that the pressure changes in these chambers are a direct measure of lung airflow and accurately measure both duration and volume of each breath (Murphy 2005). In addition, this technology can be utilized for commonly used non-rodent species such as dogs and monkeys. The primary disadvantage of this technology is that restraint of the animals is required. Restraint of animals could potentially effect baseline parameters and impact the response to drugs (Ewart et al. 2010).

Whole body (barometric) plethysmography is also used to monitor ventilatory patterns. Using this method, the volume of each breath is determined indirectly from relatively minor increases in chamber pressure resulting from the expansion of inhaled gases due to a decrease in intrapulmonary pressure and to increases in intrapulmonary temperature and humidity (DeLorme and Moss 2002; Murphy 2005). The primary advantage of the technology is that animals are not restrained and are allowed to roam freely. The primary disadvantage is that it is an indirect measurement of respiratory function and has been shown to give different responses to drugs when compared to direct measurement. For example, whole body plethysmography measures an increase in tidal volume and a decrease in respiratory rate in response to inhaled methacholine. In contrast, direct measurement demonstrates only a decrease in respiratory rate (Delorme and Moss 2002). Despite the potential downside of utilizing an indirect measurement, whole body plethysmography remains a common technique used in the pharmaceutical industry to measure respiratory function because of the ability to make measurements without restraining the animals.

All of the techniques that are available for respiratory assessment in rodents are also available in the non-rodent species commonly used in drug safety assessment (dogs and monkeys) (Iizuka et al. 2010; Murphy et al. 2010). Despite their availability, large animals are not used as often as the rodent models. In general, most companies will conduct initial respiratory assessment in rats. Studies are conducted in large animals when driven by a scientific rationale. For example, effects observed in non-rodent toxicology studies could require follow-up studies further investigating respiratory effects or species differences in pharmacokinetic studies could drive a company to conduct respiratory studies in non-rodent species.

In addition to respiratory rate and minute volume, some scientists have also suggested that pulmonary resistance should be measured as part of the respiratory assessment prior to first administration to man (Murphy 2005; Murphy et al. 2001). Total pulmonary resistance defines the change in pleural, airway, or transpulmonary pressure (ΔP) required to produce a defined change in lung airflow (ΔF) and is calculated as $\Delta P/\Delta F$. In addition to the measurement of airflow described earlier, this procedure requires a pressure catheter for the measurement of pleural, airway, or transpulmonary pressure. The primary disadvantage of the technique is that the placement of a pressure catheter requires that the studies be conducted in either anesthetized animals or surgically implanted animals. A recent industry survey revealed that most

pharmaceutical companies are not including pulmonary resistance in their core battery of measurements (Lindgren et al. 2008). This is probably because compounds that are known to cause increased pulmonary resistance usually cause changes in respiratory rate, respiratory volume, or minute volume (Authier et al. 2009; Ewart et al. 2010). Although there is the potential for a drug to actually cause increased resistance (bronchoconstriction) without changes in rate or volume, published data on the frequency or severity of this are lacking. Therefore, it is considered low risk that a compound will cause adverse effects due to increased pulmonary resistance without also causing monitorable changes in respiratory rate or volume. In addition, the ability to get consistent and reliable resistance measurements in conscious animals remains difficult (Ewart et al. 2010).

25.2.1.1 Sample Size

When rodents are utilized, separate groups of animals are usually used for each dose group. The common dose group size for rodent respiratory studies is 8–10 (Authier et al. 2009; Legaspi et al. 2010). Three to four dose groups are used, allowing the assessment of a dose response. Since vehicles have been shown to impact respiration and environmental changes (i.e., noise) can also impact respiration, a vehicle control group should always be run on the same day as other dose groups.

25.3 Central Nervous System (CNS)

The ICH S7A guidelines state, “Effects of test substance on the central nervous system should be assessed appropriately. Motor activity, behavioral changes, coordination, sensory/motor reflex responses and body temperature should be evaluated. For example, a functional observation battery (FOB), modified Irwin’s, or other appropriate test can be used.”

25.3.1 Model Selection

Historically, most companies have assessed potential CNS effects of drugs by systematically documenting alterations in behavior of rodents. The standard method for assessing these changes has been the Irwin test (Irwin 1968) or the functional observational battery (FOB) (Moser 1989). The Irwin test was introduced to the pharmaceutical industry as a rapid psychomotor screening procedure that was commonly used in early discovery screening (Redfern et al. 2005). The FOB was first introduced as a component of neurotoxicity screening for the agrichemical industries and then adopted for use in the testing of pharmaceuticals (Trabace et al. 2000). Both assays have proven effective in assessing potential CNS effects of chemicals. The primary disadvantage is that they both require highly trained personnel to conduct the assays. Maintaining the training of personnel running these studies can be resource intensive (Mattson et al. 1996; Ross et al. 1998). In addition, the results and interpretation of these studies can be subjective (Markgraf et al. 2010).

Although the conduct of these CNS studies is most common in rodents, neurobehavioral test batteries have been developed for use in dogs (Gad and Gad 2003; Moscardo et al. 2009) and monkeys (Gauvin and Baird 2008; O’Keeffe and Liftshitz 1989). Investigators may choose to utilize a non-rodent species if the metabolism is similar to what is expected in man or if the non-rodent species is more pharmacologically relevant (e.g., monoclonal antibodies). In addition, nonhuman primates possess more similarities to man when compared to rodents, in terms of the nervous system anatomy, morphology, and functional process (Moscardo et al. 2010). Recent studies have concluded that neurologic toxicities observed in monkeys and dogs translated clinical findings better than other species (Igarashi et al. 1995; Olson et al. 2000).

Attempts have also been made to make the CNS measurements more automated thus reducing the training required for individuals running the studies and reducing subjective interpretation of the results. For example, automated assessment of motor activity by quantifying interruptions of infrared beams has been available for over a quarter century (Lynch et al. 2011; Menniti and Baum 1981). In addition, body temperature is commonly measured as part of cardiovascular telemetry studies (Lynch et al. 2008). A more recently commercialized, automated behavior analysis system that includes a locomotor activity component is the LABORAS (Lynch et al. 2011; Van de Weerd et al. 2001). Instead of using infrared photocells, LABORAS measures weight displacement and mechanical vibrations produced by the rodent and

translates the vibrations into electrical signals that the software converts into motor activity. The LABORAS system also converts the vibration patterns into additional behavioral parameters such as grooming, drinking, and feeding. At the present time, the LABORAS system is not commonly used within a regulatory environment in the pharmaceutical industry.

25.3.1.1 Sample Size

When rodents are utilized, separate groups of animals are usually used for each dose group. The common dose group size for rodent CNS studies is 6–10 (Lindgren et al. 2008). Three to four dose groups are used, allowing the assessment of a dose response. Since vehicles have been shown to impact behavior and environmental changes (i.e., noise) can also impact CNS parameters, a vehicle control group should always be run on the same day as other dose groups.

25.4 Cardiovascular System

The ICH S7A guidelines state, “Effects of the test substance on the cardiovascular system should be assessed appropriately. Blood pressure, heart rate, and the electrocardiogram should be evaluated. In vivo, in vitro and or ex vivo evaluations, including methods for repolarization and conductance abnormalities should also be considered.”

The ICH S7B guidelines state, “The ionic mechanism of repolarization in adult rats and mice differ from larger species, including humans (the primary ion currents controlling repolarization in adult rats and mice is I_{to}); therefore, use of these species is not considered appropriate. The most appropriate in vivo test systems and species should be selected and justified.”

25.4.1 Model Selection

The ICH guidelines clearly state that cardiovascular studies should not be run in rodents because of the differences in cardiovascular electrophysiology when compared to humans. The most common species used for cardiovascular assessment is dog. In a survey by Lindgren et al. (2008), 100% of the companies that responded utilized dogs to assess cardiovascular effects. There is no clear difference in clinical relevance when comparing dog and nonhuman primate cardiovascular studies. The primary advantage of dogs is that primate studies cost more and many companies have more experience running dog studies. Most companies will move to monkeys for scientific reasons. For example, if a drug causes emesis in dogs and appropriate systemic exposures cannot be achieved, monkeys may be an alternative. Similarly, if metabolism of the drug by nonhuman primates is most like human metabolism, monkeys may be used.

The ICH guidelines include swine as a potential species for the assessment of cardiovascular drug effects. However, the pharmaceutical industry utilizes the minipig less than dogs and monkeys for assessment of cardiovascular safety (Lindgren et al. 2008). The reason for this is probably not scientific, since minipigs have similar cardiovascular electrophysiology to humans (Laursen et al. 2011). In addition, hERG blockers (moxifloxacin, haloperidol, sotalol), β-adrenergic antagonists (propranolol, sotalol, esmolol), α_2-adrenergic agonists (medetomidine), opioid agonists (remifentamil), and dopamine induce clinically relevant cardiovascular effects in minipigs (Authier et al. 2011). The primary reason minipigs are not utilized is that most pharmaceutical companies have a larger historical data base on preclinical safety in dogs and monkeys. Therefore, companies tend to default to models where they have the most experience.

In addition to species selection, the ICH S7A guidelines state that it is preferable to use unanesthetized animals to assess the cardiovascular effects. This is due to the fact that cardiovascular effects due to neurohumoral responses that would be present in conscious animals can be blunted by anesthesia (Cox 1972). Since 1965, the technology to remotely monitor blood pressure and pulse rate by telemetry in conscious animals has been available (Sarazan and Schweitz 2009; Van Citters and Franklin 1966). The utilization of this technology shifted from academic laboratories to pharmaceutical safety assessment in the 1990s (Sarazan et al. 2011) and is presently the technology that is most utilized to conduct conscious animal studies.

In addition to telemetry, chronically instrumented dogs that are conditioned to the laboratory setting can be utilized for cardiovascular assessment. Dogs sitting quietly in a sling allow for easy intravenous dosing and blood sampling. If the dogs are appropriately trained to the sling and laboratory environment, resting heart

rates of 50–60 beats/min are common (Fossa 2008). This resting heart rate is actually lower than most resting heart rates reported in telemetry studies. The disadvantages of using animals conditioned to the laboratory environment are the time and resources required to train the animals, the time in the sling may be limited (less than 8 h of data), and nonhuman primates cannot be conditioned like dogs. Due to the practical limitations of sling trained dogs, telemetry studies will probably remain the most common method for conducting conscious animal studies.

25.4.1.1 Study Sensitivity

A significant amount of discussion has occurred in recent years around the appropriate sensitivity of nonclinical cardiovascular safety studies (Sarazan et al. 2011). The studies probably do not need to be highly sensitive if their main purpose is to protect phase 1 human volunteers from potentially life-threatening effects. This is because large effects, which would be considered life threatening, can be observed in studies with lower sensitivity. However, if the scientist wants to reduce the risk of advancing a molecule with any degree of cardiovascular liability, the sensitivity must be increased. For example, a clinical thorough QTc study is designed to have the sensitivity to detect very small changes in QTc (~5 ms). Therefore, some scientists would argue that the nonclinical studies should have a similar statistical sensitivity. Factors that impact sensitivity include, study design, number of animals, and data variability. Although extensive discussion has taken place regarding the sensitivity of cardiovascular studies, minimal discussion has taken place about the sensitivity of CNS and respiratory assays.

25.4.1.2 Study Design

The Latin square crossover design is commonly used in nonclinical cardiovascular studies testing small molecules in conscious animals (Sarazan et al. 2011). The most basic design utilizes four animals and four treatment groups (vehicle, low dose, mid-dose, high dose) administered on four different days. Daily treatments are assigned in a balanced fashion, such that each treatment group is represented on a given day and all four animals receive all treatments, none in the same order. An appropriate washout period is allowed between doses so that drug exposures return to baseline levels before the next dose. An example of a Latin square 4×4 design is shown in Table 25.1. One of the primary advantages of a Latin square design is that each animal provides information for each treatment group; thus, the number of animals required to detect the change of a specific magnitude is reduced. When using the Latin square design, there can be no treatment carryover effect that would influence responses to subsequent treatments. Carryover effects could be due to slow elimination, the presence of an active metabolite or desensitization of the receptor targeted by the drug. Drugs that have a carryover effect would not be good candidates for this study design.

Table 25.1 Example of a Latin square 4×4 design

Animal ID	Dose day 1	Dose day 2	Dose day 3	Dose day 4
No. 1	Low dose	High dose	Vehicle	Mid-dose
No. 2	High dose	Mid-dose	Low dose	Vehicle
No. 3	Vehicle	Low dose	Mid-dose	High dose
No. 4	Mid-dose	Vehicle	High dose	Low dose

In an escalating dose design, all animals receive all doses (Sarazan et al. 2011). Unlike the Latin square design, all animals receive the treatments in the same order, starting with the vehicle. The big advantage of this design is that it allows for dose modification as the study evolves, making it preferable when there is minimal preliminary pharmacokinetic, pharmacology, and toxicology data available. One concern with this design is the possibility of initial doses causing desensitization of the pharmacological effect, leading to a smaller effect in the high-dose animals. Also of concern is if the study environment is different on separate days of dosing. For example, increased noise in the facility on a dosing day could lead to higher heart rate and blood pressure. It would be difficult to separate the environmental effect from a potential drug effect, and one could conclude that a drug had a cardiovascular effect when the effect was actually due to environmental differences.

The parallel design is seldom used for stand-alone large animal cardiovascular studies. In this design, a group of animals is separately assigned to only one-dose group (Sarazan et al. 2011). The advantage of this design is that data accumulation and analysis can continue for as long as desired after or during treatment. This advantage allows the parallel design to be used for compounds such as biologics that may have extended biological effects or this design can be used when investigating the repeat-dose effects of a compound.

One disadvantage is that the number of animals required to run this type of study is much higher. If you assume that four to eight animals will be required per dosing group and if the study design includes four dosing groups, a large study of 16–32 animals will be required. The second, disadvantage for this study is that each animal no longer serves as its own control. Therefore, this design is less sensitive (Chiang et al. 2004).

25.4.1.3 Data Variability

One of the most important factors impacting the statistical sensitivity of a study is the background variability in the data. In addition to inter-animal variability that can be controlled by study design (i.e., Latin square design), there is also the reproducibility within each animal from day to day (intra-animal variability) (Chaves et al. 2006). Intra-animal variability can be reduced in animals by the quality of the surgical telemetry implants and the environment that the animals are housed (Chaves et al. 2006; Klumpp et al. 2006). It is very important to acclimate animals to the setting in which they will be tested. Not only will testing animals under a familiar setting reduce variability but it can also reduce resting cardiovascular parameters, increasing the probability of detecting drug-induced cardiovascular changes.

25.4.1.4 Animal Numbers

The most common group size across the industry is four to eight animals per dose when conducting cardiovascular telemetry studies (Lindgren et al. 2008). When designing cardiovascular studies, it is important to assess the assay sensitivity at a specific laboratory (Sarazan et al. 2011). The statistical sensitivity should be calculated based on experimental design and established variability (based on a historical database). Information about the assay sensitivity should be used prospectively by the sponsor to modify study design when indicated. Periodic recalculation of statistical power should be routinely conducted as a means to monitor drift in experimental procedures. If increases in variability (reduced statistical power) are observed, it may mean that procedures or the environment of the facility have changed over time. Assessment of those procedures may allow the investigators to reduce variability. If variability cannot be reduced, the number of animals required per dose group may have to be increased.

25.5 Route of Administration

The ICH S7A document states, “the expected clinical route of administration should be used when feasible. Regardless of the route of administration, exposure to the parent substance and its major metabolites should be similar to or greater than that achieved in humans when such information is available. Assessment of effects by more than one route may be appropriate if the test substance is intended for clinical use by more than one route of administration (e.g., oral and parenteral), or where there are observed or anticipated significant qualitative and quantitative differences in systemic or local exposure.”

Since most safety pharmacology packages are designed to support first in human studies, they should use the route of administration that will be used in the phase I clinical trials. If the route of administration changes in the clinic, the safety pharmacology studies may need to be repeated. However, if an argument can be made that exposures are similar with the new route of administration, additional safety pharmacology studies may not be required. For example, if the initial safety pharmacology package was conducted with oral dosing, additional safety pharmacology studies may not be required if the clinical route changes to intravenous infusions as long as the Cmax in the clinic does not increase substantially.

25.6 Dose Selection

Prior to the ICH guidelines on safety pharmacology, most laboratories that conducted safety pharmacology studies for pharmaceutical companies were located within the discovery organization of their companies (Kinter et al. 1993). Discovery based groups tended to select the doses for safety pharmacology studies based on multiples of the efficacious dose. The primary change brought about by the ICH S7A guidelines was the recommendation that the highest dose should produce moderate adverse effects. The guidelines also state that some acute toxicities (e.g., tremors or fasciculation during ECG recording) may interfere with the ability to monitor functional changes, and these types of adverse effects need to be avoided. One option for dose selection is to use the same doses for the safety pharmacology and 28-day

toxicology studies. The reason for this is that the high dose in a 28-day toxicology study will usually cause an adverse effect after multiple days of dosing. However, the effect cannot cause a severe acute toxicity that will limit the number of days the animal can be dosed. The lack of severe acute toxicity allows the functional assessment of the CNS, respiratory system, and cardiovascular systems without interference from effects that may confound the interpretation of the results.

25.7 Summary

With the acceptance of the ICH guidelines on safety pharmacology, specific recommendations were outlined for the safety pharmacology package that is submitted to worldwide regulatory agencies. Despite the fairly detailed regulation, there are a number of important decisions that must be made based on the properties of each individual drug. The purpose of this chapter was to discuss the components of the study design that must be considered. In all cases, practical aspects (i.e., technology available may favor use of rodents) versus scientific aspects (i.e., monkeys may have similar metabolism to humans) must be taken into consideration and balanced. At the end of the day, each of these decisions must be defensible to both scientific and regulatory communities.

Conflict of Interest
The author of this chapter is currently employed at Abbott Laboratories, Abbott Park, IL, USA.

Pharmacokinetics

26 Safety Pharmacokinetics: Introduction

Jochen Maas

As already stated in the introduction of the first edition, no toxicology or safety pharmacology assays are conceivable without a pharmacokinetic evaluation. If we talk about safety, we urgently need to know the exposure either of the animals used for safety studies or of the patients in clinical studies. It is common to talk about PK/PD, describing the relationship between Pharmacokinetics and pharmacodynamic efficacy, but in fact PK/Safety, describing the relationship between Pharmacokinetics and Safety, is at least as important. It is becoming ever more important since there is a clear tendency at the Regulatory Agencies to focus more and more on safety aspects—and those must always be linked to data about the individual exposures.

Pharmacokinetics per se is a relatively young and dynamic science. The basic principles—absorption, distribution, metabolism and elimination—are described in this section in detail, together with the technologies to generate data in all these aspects. Modifications in these areas together with progress in technology required an update and/or amendment to the respective chapters of the first edition. But besides these basic principles, which have already been well described, some new tendencies can be observed which have become more and more important for both scientific and regulatory reasons. One of these new approaches involves studies to evaluate the transporters which influence the pharmacokinetics of a drug and its metabolites in the body.

Until recent years few were aware of the influence of transporters, but now after only a short time, regulatory agencies are asking for details about the transporter contribution to drug disposition. For this reason, the chapters in these "cutting-edge-areas" have been completely adapted to give the most up to date information to the reader.

27.1 Introduction

In the pharmaceutical industry, we observed a change in paradigm during the 1990s: project teams focused their search for potent compounds not exclusively on potency and specificity—they added pharmaceutical, biopharmaceutical, pharmacokinetic, metabolic, and toxicological characteristics for the most interesting compounds as well. The motivation to characterize compounds for a set of pharmacokinetic and toxicological parameters was driven not only by economic reasons. The number of hits from combinatorial and other chemical libraries raised the necessity to increase quality of nominated drug candidates to reduce the attrition rate in preclinical and clinical stages of project development. Nearly all pharmaceutical companies introduced an expanded assessment for drugability and developability of compounds at the stage of lead selection and lead optimization (Borchardt et al. 1998).

The integration of pharmaceutical, pharmacokinetic, and toxicological criteria into discovery and development of compounds at the stage of compound lead nomination resulted in a higher percentage of successful clinical drug candidates. Most important criteria for developability and drugability of a compound include pharmacokinetic parameters like permeability, efflux potential, metabolic stability, metabolic profiling, protein binding, metabolic finger printing, inhibition and induction of major metabolizing enzymes, and safety aspects like Ames, HERG interaction potential, Irwin screening, Micronucleus tests, IC_{50} determination with important cells, and others.

This chapter will focus on one part of early ADME (adsorption, distribution, metabolism, excretion) strategy: the absorption and efflux screening.

Since many projects focus on the most accepted route of administration—the oral one—assessment of oral bioavailability potential for a compound is a very important part in early ADME screening.

In vivo different factors play a crucial role during absorption processes: disintegration of the dosage form, dissolution of the compound in different parts of the gastrointestinal tract (GI), metabolism in the GI tract and in the liver (so-called first-pass), permeation across the intestinal mucosa, and clearance. There is no integrative in vitro model being able to cover all aspects if in vivo absorption. Therefore, an approach to divide the aspects into different test systems has been used: HTS methods for solubility testing, drug partitioning into membranes between aqueous and lipid phases, metabolic stability, permeability, CYP-inhibition and induction, efflux, protein binding, and of course in silico methods and Lipinskis rule of 5 are used prior first animal experiments in pharmacokinetics. Due to the in vivo complexicity, an in vitro prediction of absorption is only possible taking all factors of in vitro experiments together into account.

27.1.1 Absorption in the Gastrointestinal Tract

Absorption of compounds in the gastrointestinal tract occurs mainly in the small intestine with three different regions (duodenum, jejunum, and ileum) and in the large intestine (colon). In the small intestine, the uptake surface is increased by folds (3 times), villi (30 times), and microvilli (600 times). In the colon, folds and villi are absent (Daugherty and Mrsny 1999a, b).

The major physiological role of the GI—to provide a protection against pathogens and allow at the same time the permeation of nutrients and vitamins—is supported by the brush border structure of microvilli and glycocalyx. They form an enzymatic and physiological barrier. Mucus secreted by goblet cells and subepithelial glands interacts with compounds and can bind compounds (Larhed et al. 1998). During the passage through the GI, a compound passes regions with different pH: from slight acidic to slight basic impacting solubility and stability. The protection against pathogens in the GI is provided by lymphoid cells producing antibodies and forming a part of the immune system called the gut-associated lymphoid tissue (GALT, Mestecky and Mc Gee 1987). In the small intestine, lymphoid cells form structures called Peyers patches.

Peyers patches are covered by epithelial cells which can differentiate into M cells. M cells play an important role in the immunologic surveillance of the gut and are involved in specific functions like transport of particles, antigens, and macromolecules. M cells seem to be involved in the absorption of intact proteins (Walker and Sanderson 1992). Peyers patches have been studied for uptake of macromolecules. Their proximal vicinity to immunocompetent cells is another hurdle for industrial use as a preferred uptake route (Daugherty and Mrsny 1999a, b; Neutra 1998). M cells have been used to study uptake of lectins (for overview, see Daugherty and Mrsny 1999). However both cell types—Peyers patches and M cells—clearly are limited in their use as a preferred uptake route due to a small surface area they are covering and the limited capacity of absorbed molecules.

Epithelial cells covering the Peyers patches form the barrier in the intestine.

27.1.2 Mechanisms of Control and Barrier Function of Epithelial Cells

The main functions of the GI—digestion and absorption of nutrients, vitamins, and cofactors as well as movements of ions and water—need a precise mechanism of biochemical and physiological control to maintain barrier functions. The cells in the intestine are characterized by high enzymatic activity (lumen and wall), low permeability and typical resistance (between cells, tight junctions are formed characterizing the very tight barriers in the organism), efflux pathways back into the gut lumen, and first-pass metabolism. The barrier function of the gut is a crucial prerequisite for a normal function of intestine. Impairments lead to diarrhea and other serious consequences.

Epithelial cells in the intestine form tight monolayers with tight junctions between polarized cells. Tight junctions of epithelial intestinal cells are studied extensively and contain among others ZO-1, occludin, claudin-1, and claudin-2. Tight junctions and complexes of adherence junctions in the membrane are closely connected to cytoskeleton. Studies with CACO-2 cells showed that localization of ZO-1 in

the zonula occludens of tight junctions depends on Ca^{++} and Mg^{++} concentrations in the medium (Anderson et al. 1989). CACO-2 cells cultured in serum-free medium did not differ from cells cultured in serum-containing medium concerning brush border enzymatic activity, but the transepithelial electrical resistance (TEER) was significantly lower in cells grown without serum reflecting an impairment of tight junctions (Hashimoto and Shimizu 1993; Jumarie and Malo 1991). Cells grown without serum show also a decreased transport of glucose, alanine, and Gly-Gly (Hashimoto and Shimizu 1993). This might be related to incomplete differentiation and different expression of receptors and transporters without serum.

Biochemical part of the barrier contains alkaline phosphatase, γ-glutamytranspeptidase, dipeptidyl-peptidase IV, aminopeptidase *N*, endopeptidase 24-11 and disaccharidases, saccharidase, isomaltase, and lactase. Among metabolizing enzymes, phase I enzymes CYP 1A1 and 3A4 and phase II enzymes glutathione-S-transferase, sulfotransferase, and glucuronidase are present.

Uptake and efflux transporters complete the equipment of brush border membrane cells in performing controlled permeation of compounds.

27.1.3 Routes of Permeation Across Intestinal Cells

Compounds can cross intestinal cells by different routes (Fig. 27.1):

Transcellular passive diffusion (drug absorbed from GI tract mainly in unionized form)

Paracellular diffusion (size and charge dependent)

Transcellular diffusion by endocytosis

Transcellular diffusion using lipid particles

Paracellular passive diffusion modulating tight junctions

Carrier-mediated diffusion and active transport

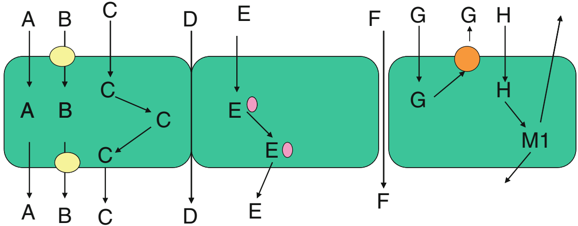

Fig. 27.1 Drug permeation across intestinal cells. A-transcellular passive diffusion. B-carrier-mediated transport. C-transcellular diffusion by endocytosis. D-paracellular passive diffusion. E-transcellular diffusion by lipid particles. F-paracellular passive diffusion via modulation of T.J. G-efflux. H-metabolism

The surface area of brush border membranes is 1,000-fold larger than paracellular surface area (Pappenheimer and Reiss 1987). Therefore, the probability for transcellular permeability is much higher than for paracellular permeability. Indeed, lipophilic drugs with rapid and complete absorption have a high probability for passive transcellular route. Hydrophilic drugs tend to pass cellular membranes via water-filled pores in the paracellular pathway (for review, see Lee et al. 1991). However, there is also a part of hydrophilic molecules passing membranes by transcellular route (Nellans 1991). The paracellular pathway is used by some positively charged compounds whereas transcellular pathway is preferred with unionized compounds.

Regulation of tight junctions seems to be an attractive way of increasing bioavailability. There have been attempts to induce a transient damage of the intestinal mucosa and to enhance drug uptake. Surfactants, detergents, unsaturated cyclic ureas, fatty acids, bile acids, and chelating agents were used with more or less serious consequences of transient entry of pathogens and lack of control concerning repair mechanism in the gut. None of the agents used so far resulted in an approval by the FDA for drug absorption support due to the risk of local epithelial trauma (Daugherty and Mrsny 1999).

Other interesting approaches to enhance drug absorption used cyclodextrins. They act as solubilizers of drugs or alter the physical structure of administered proteins.

Transcytosis through epithelial cells is of limited capacity.

Several processes limit the permeability: efflux and metabolism in the intestinal cells as well as high lipophilicity.

Receptor-mediated permeation offers an attractive pathway and has been studied for many drugs and compounds under evaluation (see Chap. 27.2.6).

The old view that the majority of compounds enter the organism by passive diffusion is no longer valid, taking into account the complexity of intestinal membranes and number of transporters discovered during the last 10 years.

27.1.4 In Vitro Models to Predict Membrane Permeability

As mentioned above due to the increased number of hits in several projects, it is not feasible to test all compounds in in vivo experiments. Even cassette dosing does not solve the issue of limited in vivo capacities. In situ models like rat perfusion or inverted out gut segments have also only a limited capacity of throughput. They are used to solve special issues in projects.

Many different models have been introduced to assess permeability of a compound: human intestinal cells (Hidalgo and Borchardt 1990; Artursson and Karlsson 1991), intestinal mucosal tissue or intestinal segments (Smith et al. 1998; Fisher and Parsons 1949), in situ models with perfused intestinal mucosa (Lennernäs et al. 1996); Griggiths et al. 1996), and cellular models (T-84, HT-29, TC7, and others, Zweibaum et al. 1985; Meunier et al. 1995).

The majority of permeability screening is based on cellular assays mimicking intestinal adsorptive cells: CACO-2 cells (human colon carcinoma) and the CACO-2 clone TC7, HT-29, T84, IL-6, or MDCK cells (Madine Darby Canine Kidney). In these widely used and accepted cellular assays, compounds are classified into three classes of permeability: high, medium, and low. Moreover, the absorption potential of compounds within a chemical series can be compared concerning their apparent permeability coefficients (Artursson 1991; Hillgren et al. 1995; Artursson and Borchardt 1997).

CACO-2 are characterized by easy handling and at the same time resemble morphological and biochemical characteristics of intestinal cells.

Among 20 cell lines tested, CACO-2 cells were the only once to differentiate spontaneously to intestinal enterocytes (Chantret et al. 1988). They resemble many characteristics of small intestinal epithelial cells (Hidalgo et al. 1989) and are still the most widely accepted model in industry and academia (Artursson and Karlsson 1991; Artursson et al. 1996; Audus et al. 1990; Gan and Thakker 1997; Artursson and Borchardt 1997 and many others). Reduced demands for compound volumes in cellular assays allow for screening (Stevenson et al. 1995; Kuhfeld et al. 1994). CACO-2 cells predict permeability with reasonable accuracy and are used in many different test designs.

Their growth is characterized by the sequence of proliferation, confluency, and differentiation. Morphologically, they reveal typical brush border cells with columnar shape and microvilli, polarization, cobblestone morphology with flower-like clusters (Pinto et al. 1983; Hidalgo et al. 1989), presence of tight junctional and adherence junctional complexes (Daugherty and Mrsny 1999), and biochemical features of intestinal cells and typical transporters expressed at permeability controlling membranes. Among biochemical markers of intestinal cells, lumenally expressed sucrase isomaltase, alkaline phosphatase, and aminopeptidase N increase in activity after proliferation phase with reaching confluency (Pinto et al. 1983; Zweibaum et al. 1983). Distribution of proteins to polarized membranes in intestine is a typical marker of differentiation. In CACO-2 cells, sorting to apical membranes involves trans-Golgi network (for sucrase isomaltase) or additional routes (aminopeptidase N and dipeptidylpeptidase IV; Matter et al. 1990).

Other polarization factors characterizing CACO-2 cells are growth factor receptors (Hidalgo et al. 1989), bile acid transporters (Hidalgo and Borchardt 1990; Wilson et al. 1990), glucose transporters (Blais et al. 1987; Mahraoui et al. 1994), lipoproteins (Traber et al. 1987), and neutral amino acid transporters (Hidalgo and Borchardt 1990). Additional enzymes and transporters like dipeptide transporter (Dantzig and Bergin 1990), PEPT1 (Saito and Inui 1993; Thwaites et al. 1994), vitamin B12 carrier (Dix et al. 1990), nucleoside transporters (Ward and Tse 1999), P450 enzymes (Boulenc et al. 1992), sulfotransferase (Baranczyk-Kuzma et al. 1991), and UDP-glucuronyltransferase (Peter and Reolofs 1992) complete the biochemical and enzymatic barrier of CACO-2 cells.

Cytosolic enzymatic activities (chymotrypsin-like, trypsin-like, cucumsin-like) were detected in CACO-2 cells at higher activities than in colonic and rectal mucosae (Bai 1995). These enzymes contribute to first-pass effect in CACO-2 cells. At confluency in CACO-2 cells, glutathione-S-transferase isoenzymes were detected with high activity. Interestingly, in non-confluent cells, the placental π-form, characteristic for colonic cells, was found, whereas in confluent, differentiated monolayers, the μ-form was active being characteristic for intestinal cells (Peters and Reolofs 1989). Cytochrome P450 enzyme 1A1 was present and highly inducible in CACO-2 cells whereas CYP 1A2 was not active (Boulenc et al. 1992; Rosenberg and Leff 1993). Phenol sulfotransferase was expressed in mature cells (Baranczyk-Kuzma et al. 1991).

The major detoxification enzyme CYP 3A is expressed to a different degree in CACO-2 cells and clones: only clone MTX of HT-29 cells and TC-7 of CACO-2 cells exhibited significant activity of CYP 3A (Boulenc et al. 1992; Carriere et al. 1994). CACO-2 cells express antioxidant enzymes like superoxide dismutase, glutathione peroxidase, glutathione reductase, and catalase (Grisham et al. 1990; Baker and Baker 1992). Induction and expression of UDP-glucuronosyltransferase (UGT1A1) and glutathione transferase GST A1 were studied in CACO-2 cells (Svchlikova et al. 2004).

Efflux pumps from the ABC-transporter family are expressed: multidrug resistance protein MDR1 (=Pgp), ABCG2 (=BCRP), MRP1, and MRP2 (Cordon-Cardo et al. 1990; Hunter et al. 1993 and others).

In 2008, 10 different laboratories compared mRNA expression of 72 drug and nutrient transporters using RT PCR (Hayeshi et al. 2008). Rank order of top 5 expressed genes was HTP1 > GLUT3 > GLUT5 > GDT1A > OATP-B. Tests for functionality showed differences between laboratories for atenolol permeability (paracellular), whereas Gly-Sar uptake was shown only in five labs (PEPT1); efflux of bromosulfophthalein was shown only in three labs (MRP2 functionality). For MDR1 (talinolol) and PEPT1, functionality and mRNA expression correlated well; on the other hand, for OATP-B and MRP2, there was no correlation between functionality and mRNA. Concerning rank order of clinically most important transporters, the study was in agreement with Sun et al. (2002) and Calvagno et al. (2006): OATPB > MRP2 > PEPT1 > MDR1.

It is important to note that many transporters showed in this study a several fold variability, for example, SGLT1, PAT2, MCT3, GLUT5, and IBAT showed several hundred fold variability among the labs, NTCP, MRP3, GLUT3, BCRP, OCTN1, MRP5, PEPT1, OAT2, ENT1, MRP2, and OST alpha and even MDR1 more than tenfold variability. A very careful characterization and validation of the in vitro model used is therefore a prerequisite for an acceptable in vitro in vivo correlation as pointed out for all assays in this chapter.

In summary, CACO-2 cells express many enzymes and transporters characteristic for intestinal cells involved in drug metabolism. The major drug-metabolizing enzyme, CYP 3A, is active only in selected clones pointing to polyclonal origin of CACO-2 and the necessity to characterize CACO-2 cells extensively for growth and experimental conditions used for given experiments.

While in the 1990s the CACO-2 cell model has been widely characterized and used for different purposes, Artursson and Borchardt (1997) raised in a review several questions to modify existing technologies. They discussed several questions which have been solved in the meantime in industry: small amounts of compounds for permeability experiments and the need for miniaturization of permeability tests, developing routine methods for testing compounds with low solubility, new cell growth and permeability test equipment, introduction of generic LC-MS analytical methods, and acquisition and storage of data in a time frame consistent with high throughput pharmacological screening. Today, we use less than 40 μl of a 10-mM solution of the test compound; the permeability tests consider solubility of the compound in automated solubilization steps leading to prepared compound plates all over the world at different company sites. Many companies use 24-well plates or even 96-well plates for permeability experiments. Pipetting robots (TECAN and others) have been designed to perform all experiments automatically. Cell feeding robots have been introduced. Data storage and handling can be performed at different sites of a company at the same time. Screening of libraries was used to get an overview on a large amount of compounds, but in the meantime, strategies have changed, and the trend is rather to support teams by secondary assays and sometimes sophisticated procedures differing from the high throughput method.

The experimental procedures which will be presented now consider only manual use. Protocols using robotic systems are not described due to great differences in the robotic systems. Nevertheless, many details refer to the use in an industrial environment.

27.2 Cellular In Vitro Methods to Predict Permeability

27.2.1 Starting and Maintaining CACO-2 Cells

PURPOSE AND RATIONALE

CACO-2 cells from ATCC at passages 20–50 are used. CACO-2 cells are stored in cryovials in liquid nitrogen. Original cryovials from ATCC are handled as described in the ATCC procedure (see also

Chen et al. 2002). This ensures constant cell source for many years once cells have been splitted, grown under the same conditions, and then frozen in liquid nitrogen.

PROCEDURE

Cryotubes containing 2 Mio cells/ml are taken from liquid nitrogen tank and placed in a 37°C water bath for approximately 5 min. After thawing up, the suspension is transferred to a 50-ml centrifuge tube containing complete cultivation medium at 37°C. As cell seeding/feeding, medium DMEM/GlutaMAX I is used (Gibco, high glucose content, HEPES 25 mM) with following supplements:

- 1% NEAA (nonessential amino acids)
- 10% FBS (fetal bovine serum)
- 40 µg/ml gentamicin (antibiotic additive)

The suspension is mixed carefully and then centrifuged at 150 g for 5 min. The cell pellet is resuspended after discarding freezing medium in cultivation medium and placed in a 175-cm^2 cultivation flask containing 80 ml complete medium. Cells are cultivated at 37°C, 95% humidity, and 10% CO_2.

Medium change is performed every 3 days. After 10 days, cells are splitted.

Cell splitting starts with washing the attached cells with 20 ml PBS for 2–4 min. After removal of PBS, trypsin/EDTA is added (20 ml) for 2 min. After removal of trypsin/EDTA, 2 ml of trypsin/EDTA are added and incubated for 5 min at 37°C with gently shaking the flasks. Trypsinization is stopped when cells start to detach by suspending the cells in 20 ml complete medium while trypsinization procedure stops. After a centrifugation step (to remove trypsin) at 150 g for 5 min, cells are resuspended in complete medium and splitted to three flasks of 175 cm^2 ($2.4–2.6 \times 10^6$ cells per flask).

After 7 days of cultivation with medium changes every 3 days (confluency 80–90%), cells are trypsinated and prepared for use in 24-well plates.

EVALUATION

To ensure a constant and comparable viability, cells are counted, and cell viability is determined with trypan blue exclusion method. Results are compared from 1 week to the next.

MODIFICATION OF THE METHOD

Several modifications of the method are described in the literature (Artursson and Karlsson 1991; Hidalgo et al. 1989 and many others). Modifications include cell culture medium, time of cultivation and frequency of medium change, variations of trypsinization methods, and others. In an industrial environment, cell cultivation methods are maintained over many years constant to reduce variability and ensure constant results in quality assessment protocols. Additionally to quality control parameters like TEER and permeability markers, expression levels of major enzymes and transporters are checked.

27.2.2 Growth of CACO-2 Cells on 24-Well Plates

PURPOSE AND RATIONALE

Transport studies are performed at 24-well or 96-well formats. Cells grown in 175-cm^2 flasks are moved to filter inserts and after 21 days of feeding and cultivation used in transport studies. The following method applies for use of 24-well filters of BD Falcon TM HTS 24-Multiwell Insert System. Alternatively, Costar 24-well filter systems could be used (non-coated, Transwell system). In many pharmaceutical companies, cell permeability tests and feeding are performed with automatization equipment.

PROCEDURE

Trypsinization is performed as described above. Cells in the suspension are counted and prepared in a suspension containing $4.2–6.7 \times 10^4$ cells/cm^2. To each apical well of the 24-well plate, 400 µl of the cell suspension are added apically. The Feeder Tray contains 40 ml of complete medium (feeding cells from the basolateral side).

Every 3 days, medium is changed. Cells are cultivated in an incubator at 37°C, 95% humidity, and 10% CO_2.

After 21 days of cultivation and control measurements of monolayers cell density, the permeability experiment can be performed.

EVALUATION

Control measurements of the monolayer include measurements of transepithelial resistance with an Endohm Meter (World Precision Instruments, New Haven) and permeability measurements of mannitol and polyethylenglycol 4000 (marker for low permeability) and of metoprolol (marker for high

permeability), for example. Permeability experiments can start if the resistance measured is >250 Ohm/cm^2. Permeability coefficient of mannitol, a standard permeating by passive diffusion, should be in a defined range before permeability experiments start. Several laboratories start permeability tests if permeability coefficient for mannitol is below 1 × 10E-06 cm/s.

MODIFICATIONS OF THE METHOD

Modifications of the method include manual or automated cell feeding in 24-well plates, media modifications, possible coating of filter surfaces, and pore size of filter membranes. Other modifications include quality assurance criteria (TEER, permeability values).

CRITICAL ASSESSMENT OF THE METHOD

The decision for selection of filter support membranes, coating, pore size, and medium additives depends on the design of the study. In an industrial environment, manual coating is not performed due to labor intensity; precoated filters are cost intensive. It is known that in vivo cells are growing on an extracellular matrix and that in vitro mimicking these conditions by coating with collagen I, II, III, or IV improves cell attachment, spreading, migration, and time to reach confluency (Hidalgo et al. 1989; Basson et al. 1992). On the other hand, decision for experimental procedures is also driven by factors like costs, labor intensity, and time.

Different filter supports have been tested: nitrocellulose (NC), polycarbonate (PC), aluminum oxide (AO), and polyethyleneterephtalate (PET). NC filters have shown reduced nonspecific binding compared to AO filters but seem to interact with marker PEG and steroids (Nicklin et al. 1992). AO filters displayed only half of permeability of PC for taurocholic acid. Reproducibility of binding and transport experiments was improved with PC filters (Hidalgo et al. 1989). Pore size is an important factor which needs to be considered and tested: CACO-2 cells migrate through pores >1 μm (Tucker et al. 1992; Hilgers et al. 1990). PET filters are translucent and allow microscopic observation as well as staining procedures.

Cells grown on PC showed lower TEER and about threefold higher permeabilities for a series of thrombin inhibitors (Walter et al. 1995).

CACO-2 cells display a heterogenicity from batch to batch and as a function of time and culture conditions due to different selection pressure (Vachon and Beaulieu 1992; Wilson et al. 1990; Jumarie and Malo 1991; Karlsson et al. 1994). Therefore, the cells have to be characterized carefully for those parameters important in a study design. Not only TEER and permeability of marker compounds are important characteristics of the system (for review, see Delie and Rubas 1997) but also expression of enzymes, transporters, and proteins as a function of time and experimental conditions. Delie and Rubas (1997) point in their review to importance of passage number of CACO-2: several authors described changes in morphology, TEER, proliferation, and permeability characteristics with increased passage number of cells (Walter and Kissel 1995). In an industrial environment where a test system is used over many years and necessarily data need to be compared within and between projects over a long time, a test system needs to be robust and well controlled with quality standards and cell cultivation standards (passage number etc.).

EXAMPLES

Examples of CACO-2 cultivation for use in permeability tests are given in Artursson and Karlsson (1991), Artursson (1991), Hilgers et al. (1990), Stevenson et al. (1995), Walter et al. (1995), and Wilson et al. (1990).

27.2.3 Permeability Assay Conditions

PURPOSE AND RATIONALE

Permeability of compounds across a cell layer is measured in order to determine the absorption potential of a compound or a chemical series and select compounds for in vivo studies. Apparent permeability coefficients can be used to compare compounds within a series for ranking. Between different laboratories, comparison of compounds should be done only on the basis of classification (high, medium, low) since permeability coefficients can differ between the labs (Artursson et al. 2001; see "Critical Assessment of the Method").

PROCEDURE: PERMEABILITY EXPERIMENT

The design of the 24-well plates containing filter supports is shown in Fig. 27.2.

As experimental buffer for washing and permeability assay HBSS, pH 7.4 is proposed.

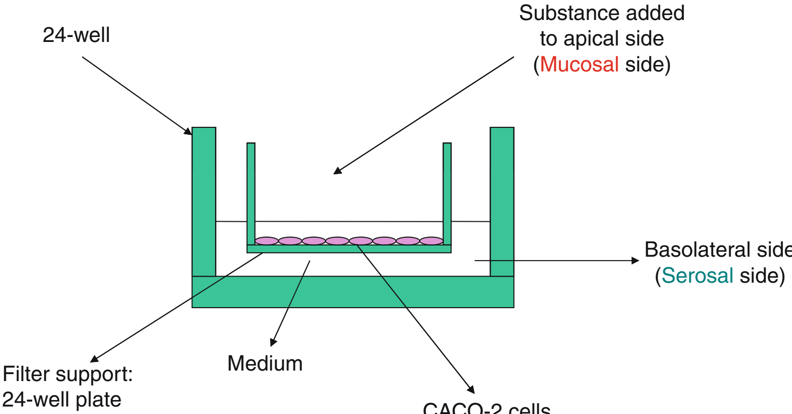

Fig. 27.2 Filter insert system for permeability studies

Compound dilutions should be performed from 10 mM compound stock solutions in DMSO at the day of experiment. Compounds should be taken from microwell plates prepared by the different robot systems; dilution is prepared with buffer or intermediate steps (containing DMSO) to avoid precipitation of compounds with low solubility. Final DMSO concentration should not exceed 0.5%. Alternatively, compound dilutions are prepared manually to result in maximal final concentration of DMSO of 0.5%.

Compound concentration should be chosen on the basis of solubility data. Compound concentrations of 50 μM should not be exceeded in routine tests. Concentrations lower than 6.25 μM should be avoided due to possible analytical limitations.

As an example, four different categories of compound concentrations could be used due to differences in projects and compound characteristics: 50, 25, 12.5, and 6.25 μM.

As assay time of 1 h is proposed.

In an industrial environment, very often, one-time-point determinations are performed in triplicate using incubator conditions (37°C, 1 h) with shaking or non-shaking conditions.

Samples are collected in triplicate from both the basolateral and apical compartments after 1 h.

Triplicate samples are also taken from the dosing solution.

PROCEDURE: ANALYTICAL METHODS

All analytics should be performed on LC-MS systems: in industrial labs, very often, ion traps or quadrupole systems are used. Single ion monitoring in either positive or negative mode (compound dependent) is used in HTS conditions. Local LC conditions (injection volume, mobile phase gradients) should be applied to accommodate variations in LC equipment. The selected LC column stationary phase can be used routinely in different labs (e.g., C-18; phase selection is compound dependent).

Mobile phase consists of varying amounts of ammonium acetate (5–10 mM) or formic acid and acetonitrile.

All samples should be kept in a stack cooler during injection routine. According to limited solubility of compounds in projects, compounds could be screened at different concentrations (as described above). Analytical samples should be run than at either 6.25, 12.5, 25, or 50 μM, depending on solubility results of plate/project.

Dosing and apical samples will be diluted routinely to a final concentration of not more than 2.5 μM (depending on linearity of LC-MS measurement range and MW of compound).

One injection per sample should be done (for the procedure described, routinely, ten samples will be acquired per compound: buffer blank, 3-basolateral 1 h, 3-apical 1 h, and 3-dosing solution).

EVALUATION

Apparent permeability coefficients (Papp in cm/s) are calculated according to the following equation:

$$\mathrm{Papp(cm/s)} = (\mathrm{dQ} \times \mathrm{V})/(\mathrm{dt} \times \mathrm{S} \times \mathrm{C_0})$$

where S is the surface area of the filter in cm^2, C_0 is the initial concentration of the compound on the donor

Table 27.1 In vitro Papp (cm/s) values corresponding to 20% and 80% in vivo permeability data from sigmoidal correlation curve with standard compounds

% Human absorption	Rating	Laboratory 1	Laboratory 2	Laboratory 3
20%	Low	*<3.2 × E-07*	<0.3 × E-06	*<8 × E-07*
20–80%	Moderate	3.2 × E-07 to 1.25 × E-06	0.3 × E-06 to 3.9 × E-06	8 × E-07 to 6 × E-06
80%	High	*>1.25 × E-06*	>3.9 × E-06	*>6 × E-06*

side, dQ/dt is the amount of compound transported during the 60 min experiment, and V is the volume of the receiver chamber.

In industrial labs, standardized worksheets are used, and results automatically appear in databases (globally or at a certain site of the company). Results are then given, for example, as mean Papp (single point, cm/s) with standard deviation ($n = 3$), absorption rating (low, medium, high), mean % transport/h, mean % mass recovery, and mean % remaining donor.

Mean % mass recovery is calculated from the sum of the basolateral and apical quantities of compound at 1 h as a % of the original dosing solution at 0 h.

Mean % remaining donor is calculated as quantity of compound remaining in the apical compartments at 1 h as a % of the original dosing solution at 0 h.

Each recovery should be individually checked to see if it falls within a predefined threshold. The partial recovery is calculated as the sum of the percent transport and the percent remaining donor (peak area donor 1 h + receiver/donor 0 h). As quality assurance criteria, for example, partial recovery >65% and partial recovery <125%, could be accepted, and then, the result value is included in the calculation of the average transport/h or the average Papp/single point.

If the recovery for two or more wells falls outside of 65–125% range, then no result can be reported, and experiment is usually repeated.

The assay is evaluated in all laboratories by correlating in vivo absorption data of standard compounds with in vitro permeability values (see Artursson and Karlsson 1991). Since CACO-2 cells differ due to cultivation procedures and possible selection of populations/clones of cells, this correlation curve should be established in every laboratory. It is not possible to use a curve from literature for prediction of in vivo permeability from in-house in vitro data. Every laboratory should use its own curve. A comparison of Papp values from different labs for compound ranking is not possible (Artursson et al. 2001). Therefore, many industrial labs use a classification of compounds into three classes of permeability: high, medium, and low. This classification is very well comparable between different laboratories. Test compounds analyzed in different labs should be classified into the same class. On the basis of correlation curve between in vivo absorption and in vitro permeability data, a sigmoidal curve can be calculated, and two important thresholds are usually set: at in vitro Papp values corresponding to 20% in vivo permeability and to 80% (Artursson et al. 2001; Bailey et al. 1996 and others). Other labs use 90% threshold values according to a FDA proposal. Compounds with in vitro Papp below the first threshold value (at 20% in vivo permeability from standard curve) are classified as low permeable, compounds with Papp values above the higher threshold are classified as high permeable, and compounds with permeability values between the two thresholds are classified as medium. An example of different permeability values in laboratories is given in the table below (Table 27.1).

Due to a high throughput in industrial laboratories, very often, so-called mean Papp single point is calculated from three filters with standard deviation meaning that only one time point (60 min) is used for calculations. Alternatively or in addition, mean % transport/h can be calculated from three filters.

If two or more filters do not meet acceptance criteria, compound assay should be repeated (exception: compounds with unusual features causing, e.g., a discrepancy in mass balance due to high plastic binding).

Standard markers should be included in all experiments. Usually, marker compounds for different permeability classes are used like metoprolol for high permeability and radioactive mannitol for low permeability. Quality assurance criteria define accepted upper permeability values for mannitol (in the case of mannitol, many laboratories use 1.0 × E-06 cm/s). Permeability values higher than upper limit should lead to rejection of the test.

Integrity control of the monolayer is based on measurements of both TEER (transepithelial resistance measurements) and permeability for a standard marker (radioactive mannitol or Lucifer yellow as nonradioactive alternative).

TEER is usually measured at the beginning (0 h) and end of the assay (1 h). Monolayers with TEER values below an acceptance value should be rejected (e.g., TEER <250 Ohm/cm^2 at 0 h could be used as criterion to exclude cell monolayers from experiment). TEER acceptance criteria should also be defined (e.g., +/− 30% change in TEER at 1 h from TEER value at time zero means that the experiment cannot be accepted).

Again, quality criteria should be defined in every lab independently: while Papp values (upper permeability criteria) and TEER limits cannot be transferred from one lab to another one, recovery data (% of start solution) are comparable.

Additional comments are usually included like leaky monolayer, solubility below 6.25 μM, variability in data.

Recently, in some industrial labs, the blind probe test has been introduced: five selected standards are analyzed in permeability tests at different sites, and results are compared (rating, recovery). The qualification and classification of the compounds to the criteria low permeability (<20%), moderate (20–80% permeability), or high (>80% permeability) should not differ among different labs. This blind probe tests can be used as quality assurance if repeated several times a year.

MODIFICATIONS

Modifications include all details described in the method above (time of permeability experiment, concentration ranges, shaking, quality criteria, and acceptance parameters).

Modifications to the analytical procedure presented are of course necessary if different equipment is used or if a compound class cannot be analyzed with the standard procedure proposed.

CRITICAL ASSESSMENT OF THE METHOD

In vivo as well as in vitro permeability is reduced due to the aqueous boundary layer or unstirred water layer (UWL). Shaking can reduce the UWL using different shaking frequencies (Hidalgo et al. 1991; Karlsson and Artursson 1992). However, the experimental conditions need to be tested carefully to avoid damage of monolayers. In side-by-side diffusion systems, the UWL was 52 μm (Karlsson and Artursson 1992). In vivo thickness of UWL was found 40 μm (Strocchi and Levitt 1991).

TEER, normalized to surface, was 188–221 Ohm/cm^2 in CACO-2 cells and 78–125 Ohm/cm^2 in colon (Rubas et al. 1996). The presence of villi and crypts in vivo with a higher surface and a different cellular composition (goblet cells, M cells, higher permeability in crypts) compared to a cell monolayer might lead to higher permeability. Tanaka et al. (1995) compared permeability of FITC-Dextran (MW 4000) in CACO-2 cells and rat jejunum and colon: the permeability was tenfold decreased in CACO-2 compared to jejunum and fivefold lower than in colon. TEER in CACO-2 was 470 Ohm × cm^2 in this study, 40 Ohm × cm^2 in rat jejunum, and 80 Ohm × cm^2 in rat colon. Permeability of standard markers like PEG was compared between CACO-2 cells and colon (Artursson et al. 1993). The conclusion for cellular studies is to select cells with acceptable TEER and permeability values and to perform quality assurance tests on a regular basis.

Several authors compared permeability of CACO-2 with in situ perfused intestine or everted intestinal rings (Lennernäs et al. 1996; Rubas et al. 1993; Jezyk et al. 1992). Their conclusion is that CACO-2 cells with TEER below 300 Ohm/cm^2 give permeabilities for hydrophilic drugs comparable to intestinal tissue. The trend for hydrophilic compounds concerning permeability was CACO-2 > colon > small intestine.

Further limitations of cellular layers in comparison to in vivo conditions are absence of mucus and different expression of enzymes (lack of CYP 3 in CACO-2) and transporters. There have been attempts to introduce mucus-secreting cells (HT29) to the CACO-2 permeability system (Wikman-Larhed and Artursson 1995; Behrens et al. 2001; Pontier et al. 2001). Cells with a higher permeability than CACO-2, for example, IEC-18 cells (Ma et al. 1992; Duizer et al. 1995) or immortalized cells 2/4/A1 (Milovic et al. 1996), have been studied. These attempts were only partly successful: in coculture systems, cells did not mix as in vivo, goblet cells produced not enough mucus, and permeabilities for standards increased more than expected.

However, these systems need further evaluation. For an industrial environment, coculture systems need to be robust and reliable being at the same time

easy to handle. On the other hand, convincing advantages have to be shown to change the monolayer system to a coculture model or to change the cell system used. In many companies, CACO-2 cells are used since many years, and an immense database is available.

Another aspect to consider is the effect of food, increasing or decreasing uptake characteristics of a compound. Diet, physiological status, and diseases influence permeability as well.

Prognosis of a compound's permeability should be made, stressing limitations of the model. There is no bioavailability prognosis from in vitro data—a cellular assay can provide only permeability potential through a biological membrane. The membrane, in most cases CACO-2 cells, is very similar to what we observe in vivo in the small intestine and resembles many characteristics to in vivo enterocytes. CACO-2 cells can be used for prediction of different pathways across intestinal cells. Best correlation occurs for passive transcellular route of diffusion. Passive paracellular pathway is less permeable in CACO-2, and correlations are rather qualitative than quantitative for that pathway. CACO-2 cells are an accepted model for identification of compounds with permeability problems, for ranking of compounds, and for selection of best compounds within a series. Carrier-mediated transport can be studied as well using careful characterization of transporters in the cell batch or clone as a prerequisite for transporter studies.

There are advantages of cell culture models in permeability testing which should be exploited adequately. Differentiated human cells with similarities to human intestinal epithelia can be used for screening procedures, tests for absorption enhancers and sensitive cytotoxicity screening, uptake and secretion studies, as well as functional bioassays to study proteins, transporters, or enzymes generating reproducible data. Mechanistic studies are increasingly introduced to clarify issues and enable studies for structure-activity relationship for a selected issue.

In the last decade, knowledge about transporter expression and impact on a drug's permeability and/or absorption has increased. Therefore, additional tools like the BDDCS might be helpful during drug development. BDDCS (Biopharmaceutics Drug Disposition Classification System) was proposed by Les Benet modifying BCS (Biopharmaceutical Classification System) by introducing metabolism and transporters in addition to solubility and permeability of a compound in order to predict in vivo pharmacokinetic behavior. While BCS is a system to determine probability of a biowaver for a given drug, BDDCS could be used a guidance for probability of drug-drug interactions and transporter-related interactions.

For class 1 compounds, having high solubility and permeability and showing high metabolism, interaction with transporters in intestine and liver is rather minimal (Benet 2009). Class 2 compounds with low solubility, high permeability, and high metabolism have a high probability of interacting with efflux transporters in the gut and uptake as well as efflux transporters in the liver. For class 3 compounds with high solubility but low permeability and low metabolism uptake transporters are important determinants for intestinal absorption and uptake into the liver. However, due to poor permeability, efflux transporters might also be involved in elimination. And finally, class 4 compounds need uptake and efflux transporters due to their low solubility, poor permeability, and poor metabolism (Shugarts and Benet 2009).

In 2011, Benet and Oprea published an extensive list of drugs and metabolites (927 drugs and 30 active metabolites) and correlated the pharmacokinetic data with physicochemical properties like log P, log D-7.4, polar surface area, and number of hydrogen bond acceptors and donors. The goal is to use BDDCS and physicochemical properties to predict drug disposition characteristics of novel compounds (Benet et al. 2011).

EXAMPLES

Examples of CACO-2 permeability tests are given in Artursson and Karlsson (1991), Artursson (1991), Hilgers et al. (1990), Stevenson et al. (1995), Walter et al. (1995), and Wilson et al. (1990). Additionally, CACO-2 has been used in testing excipients (Saha and Kou 2000) and applying simulated intestinal fluid (Ingels et al. 2004).

27.2.4 Efflux Experiments Using CACO-2 Cells

RATIONALE

Multidrug resistance (MDR) is an important and common cause of drug resistance in cells. MDR is mediated by the increased expression of energy-dependent drug efflux pumps from the ABC-transporter family (Borst et al. 1999). Efflux transporters like P-glycoprotein (P-gp or MDR1), encoded by the MDR1 gene; multidrug resistance-associated proteins (MRP1 and 2); lung resistance protein (LRP); and breast cancer resistance protein (BCRP = ABCG2) are efflux transporters present in the gastrointestinal tract (Ambudkar et al. 1999; Borst et al. 2000; Jonker et al. 2000; Doyle et al. 1998). For review, please refer to Schinkel and Jonker (2003).

MDR1 is a 170-kDa transmembrane protein member of the ATP binding cassette (ABC) transporter family. It is localized at the apical secretory surface of various tissues (e.g., liver, kidney, gastrointestinal tract, blood-brain barrier) where it mediates the active transmembrane transport of a variety of lipophilic substrates, which tend to be large, aromatic, and amphiphilic. MDR1 can extrude/exclude a wide range of structurally diverse drugs (Ambudkar et al. 1999). MDR1 limits the oral absorption of a number of drugs by transporting them back from the intestinal cells into the gut lumen. Recent studies have revealed the overlapping substrate specificity of CYP3A4 and MDR1, and many substrates of CYP3A4 are also

substrates or inhibitors of MDR1. The functional expression of MDR1 has also been shown in CACO-2 cells.

MDR1 and members of the MRP family have substantial substrate overlaps (Borst et al. 2000).

MRP1 and MRP2 have substrate specifity overlaps for amphiphilic anions, glutathione, glucuronate, or sulfate conjugates (König et al. 1999). The transporter cMOAT (canalicular multispecific organic anion transporter, i.e., cMRP or MRP2), responsible for the active excretion of amphiphatic anionic conjugates formed by phase II conjugation into bile, is also found in the intestine.

For MRP2, the following substrates have been identified and characterized so far: glutathione disulfide, leukotrienes (C4, D4, E4, *N*-acetyl E4), glutathione conjugates (DNP, BSP, metals Sb, Bi, As, Cd, Cu, Ag, Zn), glucuronide conjugates (bilirubin, T3, p-nitrophenol, grepafloxacin), bile acid conjugates (glucuronides, sulfates), and organic anions (folates, methotrexate, ampicillin, ceftriaxone, cefadoxine, grepafloxine, pravastatin, temocaprilate).

BCRP is an ABC half-transporter and is expressed at very high levels in the intestine, liver, kidney, and blood-brain barrier. The identified list of substrates and/or inhibitors is constantly growing: mitoxantrone, methotrexate, topotecan, doxorubicin, flavopiridol, SN-38, Lysotracker green, BBR 3390, BODIPY-prazosin, rhodamine 123, pheophorbide A, PhPI, estrone sulfate, estradiol-17 beta-glucuronide, cimetidine, and dipyridamole. As inhibitors, GF 120918, Ko143, nelfinavir, and fumitremorgin C were identified (Doyle et al. 1998; Litman et al. 2000; Poguntke et al. 2010).

In the small intestine, expression data for MDR1, ABCG2, MRPs, and LRP have been detected (Kool et al. 1997; Doyle et al. 1998; Fromm et al. 2000; Maliepaard et al. 2001).

In 2008, ten different laboratories compared mRNA expression of 72 drug and nutrient transporters using RT PCR (Hayeshi et al. 2008). Concerning efflux transporters, efflux of bromosulfophthalein was shown only in three labs (MRP2 functionality). For MDR1 (talinolol), functionality and mRNA expression correlated well; on the other hand, for MRP2, there was no correlation between functionality and mRNA. Concerning rank order of clinically most important transporters, the study was in agreement with Sun et al. (2002) and Calcagno et al. (2006): OATPB > MRP2 > PEPT1 > MDR1. Interestingly, in this comparison, BCRP was expressed at the same amount as MDR1, although in previous papers, expression levels seem to be higher (see citation in Hayeshi et al. 2008, reference in Chap. 1).

Efflux studies are very often performed in cellular systems which are tight enough to perform flux and efflux studies (CACO-2, MDCK). Taipalensuu and colleagues were the first to study expression and quantitative relationship in detail for CACO-2 cells in comparison to jejunal levels (2001).

Jejunal transcript levels of the different ABC transporters are spanning a range of three log units with rank order: BCRP ~ MRP2 > MDR1 ~ MRP3 ~ MRP6 ~ MRP5 ~ MRP1 > MRP4 > MDR3 (Taipalensuu et al. 2001). Transcript levels of 9 of the ABC transporters correlate well between CACO-2 cells and jejunum, only BCRP exhibits a 100-fold higher expression in the in vivo system (Taipalensuu et al. 2001).

Many laboratories use CACO-2 cells as a standard method for assessment of efflux. Since the standard CACO-2 cell assay is very well established, easy to use, reproducible, and reliable, the corresponding efflux assay can give valuable and helpful data for project support in a screening approach. A prerequisite for the interpretation of efflux data is a characterization of efflux transporters present in the system used and a set of standard efflux markers checked regularly (like digoxin for MDR1).

Moreover, while for identification of inhibitory characteristics vesicle studies are well accepted and used, cellular efflux studies are recommended by the FDA and the International Transporter Consortium White paper also for compounds in development to justify clinical drug-drug interaction studies (see Giacomini et al. 2009 and FDA Draft Guidance 2006).

PROCEDURE

As experimental buffer for washing, permeability, and efflux assay HBSS, pH 7.4 is proposed.

Compound dilutions should be performed from compound stock solutions in DMSO, 10 mM at the day of experiment. Compounds should be taken from microwell plates prepared by the different robot systems; dilution is prepared with buffer or intermediate steps (containing DMSO) to avoid precipitation of compounds with low solubility. Final DMSO concentration should not exceed 0.5%. Alternatively,

compound dilutions are prepared manually to result in maximal final concentration of DMSO of 0.5%.

Compound concentration should be chosen on the basis of solubility data. Compound concentrations of 50 μM should not be exceeded in routine tests. Concentrations lower than 6.25 μM should be avoided due to possible analytical limitations.

As an example, four different categories of compound concentrations could be used due to differences in projects and compound characteristics: 50, 25, 12.5, and 6.25 μM.

In contrast to permeability tests, compounds are added not only to apical compartment (to determine flux A-B) but in an additional experiment to basolateral compartment (efflux B-A). As assay time of 2 h is proposed.

Further experiments are usually performed if efflux is observed increasing concentrations (depending on compound solubility) or determining inhibitor effects.

Care should be taken when performing additional experiments to determine active efflux. Usually, flux and efflux assays are performed at 4°C in comparison to 37°C. Since membrane fluidity is changing at 4°C compared to 37°C, results have to be interpreted with caution (Seelig et al. 2005).

As for the standard CACO-2 assay, very often, one-time-point determinations are performed in triplicate using incubator conditions (37°C, 2 h).

Samples are collected in triplicate from both the basolateral and apical compartments after 2 h. Triplicate samples are also taken from the dosing solution. Analytics are performed as described in Sect. 27.2.3.

EVALUATION

Apparent permeability coefficients (Papp in cm/s) are calculated according to the following equation:

$$\mathrm{Papp(cm/sec)} = (\mathrm{dQ} \times \mathrm{V})/(\mathrm{dt} \times \mathrm{S} \times \mathrm{C_0})$$

where S is the surface area of the filter in cm^2, C_0 is the initial concentration of the compound on the donor side, dQ/dt is the amount of compound transported during the 60-min experiment, and V is the volume of the receiver chamber.

Ratio of B-A/A-B is calculated and compared to the ratio of standard compounds.

As standards, digoxin, etoposide, or paclitataxel (all for MDR 1); estradiol-17 beta-glucuronide or furosemide (for MRP2); and methotrexate or estrone sulfate (for ABCG2) can be used as substrates. Inhibitors being used as validation of the test assay might be PSC 833 or elacridar for MDR1, Ko 143 or fumitremorgin C for ABCG2, and probenecid for MRP2. Efflux ratio of the compound is compared to ratio of standards, and inhibitors could help to identify the transporter involved in the efflux.

MODIFICATIONS OF THE METHOD

Modifications include all details described in the method above (time of permeability experiment, concentration ranges, shaking, use of standards, quality criteria, and acceptance parameters). Since in CACO-2 cells efflux for standard compounds varies due to heterogenicity and batch variations, several teams used selected CACO-2 cells. Cells set under selection pressure with vincristine (Eneroth et al. 2001) or digoxin (Tanaka et al. 2000). Other teams selected subclones of CACO-2 cells with higher expression rates of MDR1 (Horie et al. 2003).

Other teams prefer the use of overexpressing cell lines. In this case, a careful characterization of the test system and a validation of the assay using substrates and inhibitors mentioned is a prerequisite for correct identification of compounds as substrates and/or inhibitors in vitro.

CRITICAL ASSESSMENT OF THE METHOD

Cellular efflux assays have a lower throughput as binding studies or competition studies. The calcein assay used very often to identify MDR1 substrates can offer interactions only with one binding site of MDR1. Consequently, the test fails in identification of those substrates or inhibitors interacting with the second binding site, with both or with a so-called interaction site (Litman et al. 2001). Two very important studies have been performed by Schwab et al. (2003) and Polli et al. (2001) comparing several different MDR1 assays for identification potential toward known substrates/inhibitors of MDR1. Both studies conclude that HTS assays such as calcein or rhodamine 123 assay are not sufficient to detect MDR1 interacting compounds. ATPase assay can provide additional information but fails also for some known MDR1 interacting compounds. In the ATPase assay, colchicine, digoxin, etoposide (Schwab et al. 2003), cyclosporin A, GF120918, doxorubicin, and vincristine (Polli et al. 2001) were not identified. Inhibition (or competition) assays such as calcein assay failed to identify

colchicine, digoxin, etoposide (Schwab et al. 2003), vincristine, taxol, and others (Polli et al. 2001). Rhodamine 123 assay again did not identify colchicine, digoxin, etoposide, ranitidine, and others (Schwab et al. 2003). The rank order for compounds in MDR1 efflux (based on a comparison of efflux ratio B-A/A-B in both studies) is different between both test systems used (MDR1-MDCK cells in Polli's study and LLC-MDR1 and LLC-mdr1a cells in Schwab's study). Compounds with high intrinsic permeability (midazolam, nifedipine) could overcome efflux and were not identified as MDR1 interacting compounds (Schwab et al. 2003). Verapamil was not effluxed due to high membrane partitioning, too (Polli et al. 2001). Both studies conclude that it is not sufficient to rely on one HTS assay. The authors propose to perform several assays in a cascade strategy: first, HTS assays using fluorescent readouts (calcein, rhodamine) followed by ATPase assay and/or cellular transport assays. However, following this strategy, etoposide, colchicine, and digoxin would have been not identified as interacting MDR1 substrates. Therefore, at the stage of early drug candidate identification, efflux assays using well characterized cell systems are very useful. Given that the rank order of effluxed compounds was different (taking ratio as comparison), it is necessary to stay in one efflux system for comparative studies and to check in overexpressing cell systems such as MDCK and LLC-PK1 protein sequence and molecular weight of transfected efflux transporters. Other efflux transporters should be checked as well because due to transfection, they could be over- or underexpressed or be expressed in a different glycosylation form. FDA Draft Guidance for Industry and the International Consortium White paper recommend bidirectional transport assays using polarized monolayers with expression or overexpression of efflux transporters (Giacomini et al. 2009; FDA Draft Guidance, 2006).

ABCG2 (BCRP) is able to establish only a small concentration gradient which complicates the identification of ABCG2 substrates (Poguntke et al. 2010). Moreover, due to the different partly overlapping binding sites and electrostatic interactions with potential substrates (electrostatic funneling), for ABCG2, the use of a combination of assays is recommended to identify substrates or inhibitors, such as ATPase assay, vesicle inhibition assays, and cellular assays in CACO-2 and/or overexpressing cells (review of Poguntke et al. 2010).

Please pay attention to the critical assessment part in efflux inhibition studies (Sect. 27.2.5).

An international Pgp working group including 22 pharma companies and CROs was the pioneer for validation of the first efflux transporter in an interlaboratory comparison: MDR1. Different assays were compared (vesicles, cells—CACO-2, MDR1-MDCK, MDR1-LLCPK1) and analyzed statistically. C. Lee presented at the AAPS Workshop on Drug Transporters 2011 first results showing a very high variability of IC50 values (about 200-fold variation). That makes it difficult to establish risk factors for in vitro in vivo correlation even for the best studies transporter Pgp. Determination of drug-drug interaction risks (resulting in clinical studies) needs a lot more validation in industry and CROs for Pgp and for other clinically relevant transporters as well.

EXAMPLES

Examples of efflux studies using CACO-2 and other cells expressing efflux transporters are given in the studies of Schwab et al. (2003), Polli et al. (2001), and Pachot et al. (2003 and others).

27.2.5 Efflux Inhibition Experiments Using CACO-2 Cells

RATIONALE

Once a compound is identified in an efflux assay, it is sometimes of importance to discriminate between efflux and inhibition potential and to determine the efflux transporter responsible for efflux of the compound.

Concerning selectivity of transporter inhibitors interacting efficiently with only one efflux or uptake transporter, there was clear progress during the last years. Cellular inhibition assays are still used very often as a first step to characterize efflux and/or identify the efflux transporter involved (Table 27.2).

The list of substrates and inhibitors for MDR1 is extensive due to the fact that we are aware of different binding sites (two binding sites minimum) and interacting sites (capacity of competition or inhibition at an additional site of MDR1, see Litman et al. 2001).

Two published studies from Roche (Schwab et al. 2003) and Glaxo (Polli et al. 2001) showed limitations in studying MDR1 by simplified HTS methods: several compounds known as substrates or inhibitors of MDR1 were not clearly identified, others were identified only by one or two of the test methods (either ATPase assay or calcein efflux or rhodamine efflux or cellular efflux studies).

Best prediction is still achieved with cellular efflux assays comparing permeability in A-B and B-A directions. However, cellular efflux assays do

Table 27.2 Frequently used efflux standard substrates and inhibitors

Efflux transporter	Compound	Substrate (S)/inhibitor (I)
MDR1 (Pgp)	Digoxin	S
	Paclitaxel	S
	Cyclosporin A	S/I (multiple interactions)
	GF 120918	I (interacts with BCRP)
	Verapamil	S/I (multiple interactions)
	Zosuquidar	S/I
	Vinblastine	S/I (interaction with MRP)
	PSC833	S/I
ABCG2 (BCRP)	Fumitremorgin C	I
	Ko143	I
MRP2	Probenecid	I (interacts with other MRPs and OATPs)

not have high throughput capacity and can be applied only for a limited number of compounds. Please refer also to critical assessment part of Sect. 27.2.4.

PROCEDURE

The conditions for inhibition assays using CACO-2 cells are as described above for efflux assays.

In contrast to permeability tests, compounds are added not only to apical compartment (to determine flux A-B) but in an additional experiment to basolateral compartment (efflux B-A). As assay time of 2 h is proposed. At the same time, an inhibitor is added, and results of permeability and efflux assays are compared to results obtained without inhibitor. Additionally, a selection of inhibitors covering different efflux transporters is used. After a preincubation period used in many studies (e.g., 15 min), test compounds are added and flux/efflux studies performed.

As for the standard CACO-2 assay, very often, one-time-point determinations are performed in triplicate using incubator conditions (37°C, 2 h).

Samples are collected in triplicate from both the basolateral and apical compartments after 2 h. Triplicate samples are also taken from the dosing solution. Analytics are performed as described in Sect. 27.2.3.

EVALUATION

Apparent permeability coefficients (Papp in cm/s) are calculated according to the following equation:

$$\text{Papp(cm/s)} = (dQ \times V)/(dt \times S \times C_0)$$

where S is the surface area of the filter in cm^2, C_0 is the initial concentration of the compound on the donor side, dQ/dt is the amount of compound transported during the 60-min experiment, and V is the volume of the receiver chamber.

Ratio of B-A/A-B is calculated and compared to the ratio of standard compounds. In addition, B-A/A-B ratio determined in the inhibition experiment is compared to efflux ratios determined without inhibition. Given that efflux of a compound cannot be inhibited by an inhibitor, one should conclude that more than one efflux transporter are involved in the efflux. Adding two or more inhibitors at the same time provides maximal inhibition.

As a standard inhibitor, cyclosporin A is used very frequently; as also PSC833, Zosuquidar, or GF120918, all for MDR 1); fumitremorgin C or Ko143 for ABCG2; and probenecid for MRP2.

MODIFICATIONS OF THE METHOD

Modifications for efflux inhibition studies are as frequent as efflux studies and include all parts of the method (permeability time, inhibitors, determination of Papp at single time point versus several time points).

Tang et al. (2002a, b) used [3H]-vinblastine as a substrate for MRP2 studies (Evers et al. 1998). Inhibitors were cyclosporin A (25 μM) for MRP2 and MDR1 (Tanaka et al. 2000; Nies et al. 1998; Smith et al. 1998), GF120918 (2 μM) for MDR1 (Hyafil et al. 1993; Utsunomiya et al. 2000), and MK571 (50 μM) for MRP2 (Walle et al. 1999).

CRITICAL ASSESSMENT OF THE METHOD

In Chap. 27.2.4, dealing with efflux studies, it was discussed that rank order of effluxed compounds was different in different test systems (taking ratio as comparison). The conclusion was to stay in one efflux system for comparative studies and to check in overexpressing cell systems such as MDCK and LLC-PK1 protein sequence and molecular weight of transfected efflux transporters. Other efflux transporters should be checked as well because due to transfection, they could be over- or underexpressed or be expressed in a different glycosylation form. It was noted that animal cells transfected with a human gene express a protein migrating to a lower molecular weight (Evers et al. 1996). Pig kidney epithelial cells LLC-PK1, when overexpressed with MDR1, expressed a protein with a MW at 120 kD.

Tang et al. (2002a, b) detected in MDCK-MRP2 overexpressing cells, in MDCK-WT, and in CACO-2 cells 2 bands (cross-reaction of the MRP2 antibody): at 150 and 190 kD. In MDCK-MRP2 cells, only the band at 150 kD was overexpressed. The authors discuss possible differences in glycosylation as a reason for this phenomenon. In the same study, it was found that Michaelis-Menten constants Km and Vmax differed between CACO-2 and MDCK-MRP2 cells for vinblastine. Similar observations were reported by Soldner et al. (2000) for losartan and by Lentz et al. (2000) for vinblastine in MDR1 studies. Affinities for the inhibitors cyclosporin A, MK 571, vincristine, and etoposide were lower in CACO-2 cells compared to MDCK-MRP2 (Tang et al. 2002a, b). On the other hand, reserpine had no affinity in MDCK cells at all, and daunorubicin showed lower affinity in MDCK-MRP2 compared to CACO-2. Summarizing all data, authors discuss as a possible reason for those differences between CACO-2 and MDCK cells a different lipid composition of the membrane which could lead to a different orientation of MRP2 and MDR1. Additionally, drug partitioning into membranes may be different resulting in differences in substrate/inhibitory specificity and binding kinetics (Romsicki and Sharom 1999; Ferte 2000; Tanaka et al. 1997; Tang et al. 2002a, b).

Moreover, since in the Schwab study, differences in the human MDR1 and mouse mdr1 were detected concerning substrate recognition (ritonavir and saquinavir were negative in mdr1a cells, and verapamil, terfenadine, and quinidine were less active in mdr1a than in MDR1), differences occurred between porcine brain endothelial efflux and LLC-PK1-MDR1 (Vinblastine) in the future efflux systems containing animal transporters have to be considered, too. In addition, we have to keep in mind that in rodents, two efflux transporters correspond to human MDR1: mdr1a and mdr1b which have both different substrate specificities (for cyclosporin A, terfenadine, verapamil, vinblastine). And, complicating the story even more, some compounds have been identified in mdr1a as strong substrates for mdr1a but were not good substrates for human MDR1. Keeping in mind that in pharmacokinetics, studies are performed in rats and mouse before going into dogs or mini pigs PK parameters could be different between the species due to different substrate specificity of transporters.

However, for MDR1, ABCG2, and MRP2, we have a panel of studies available, and we are aware of complications and considerations. There are several models addressing binding sites and modulatory sites. Concerning in vitro in vivo correlation of results and calculation of risk factors for drug-drug interaction studies, we have to expand knowledge and add more validation studies in vitro as well clinical studies (see also Sect. 27.2.4).

EXAMPLES

Examples of efflux studies using efflux inhibitors are given in Tang et al. (2002), Tanaka et al. (1997), and others.

27.2.6 Transporter Uptake Studies Using CACO-2 Cells

RATIONALE

Many uptake transporters as well as efflux transporters have been described in the GI and especially in the small intestine. They allow uptake of ions, amino acids, peptides, nucleic acids, sugars, organic acids, vitamins, cofactors, and nucleosides. On the other hand, efflux transporters ensure protection of the organism from unwanted pathogen or compound delivery. Subsequently, cellular systems have been used to study uptake in mechanistic studies in more detail. Additionally, inhibition studies provide hints on potential drug-drug interactions.

CACO-2 cells resemble many features of enterocytic intestinal cells. In gene chip analyses, 38% of 11,559 genes were detected in 16-day-old CACO-2 cells. One hundred and seventy of those genes were transporters and channels, and 443 were transporters, channels, and metabolic enzymes (Sun et al. 2002). In human duodenal probes, 44% of the total of 12,559 gene sequences were detected. Permeability values between CACO-2 and duodenum which were compared resulted in good correlation for passively absorbed drugs whereas correlation coefficients for actively absorbed drugs were lower in CACO-2 than in duodenum.

Nevertheless, several uptake transporters have been studied successfully in CACO-2 cells as possible drug delivery systems. CACO-2 cells are a suitable model for uptake studies given that they are characterized for the studied transporter (Anderle et al. 2003). Whereas permeability values for actively transported compounds may differ substantially from in vivo situation, a ranking of compounds for higher or lower permeability seems to be possible.

PROCEDURE

As experimental buffer for washing and permeability assay HBSS, pH 7.4 is proposed. For uptake studies, pH 6.5 might be required for those transporters which need a pH gradient (PEPT1).

Compound dilutions should be performed from compound stock solutions in DMSO, 10 mM at the day of experiment. Compounds should be taken from microwell plates prepared by the different robot systems; dilution is prepared with buffer or intermediate steps (containing DMSO) to avoid precipitation of compounds with low solubility. Final DMSO concentration should not exceed 0.5%. Alternatively, compound dilutions are prepared manually to result in maximal final concentration of DMSO of 0.5%.

Compound concentration should be chosen on the basis of solubility data. Uptake experiments should be performed using Petri dishes or filter supports. In the case of filter supports, a permeability experiment has to be performed at the same time to control basolateral amount of compound.

Uptake studies for peptides have been performed by adding the compound to the apical side of the filter (pH 6.5 for optimal function of oligopeptide transporter). The pH at the basolateral side was 7.4. After a preincubation period (10 min, 37°C), cells should be washed and incubated for 15 min (or for a shorter time period) with the compound under evaluation. After incubation period medium is removed, cells are washed three times with ice-cold pH 7.4 buffer to stop further uptake and to remove unbound compound (for details, see Tamura et al. 1996). Cells should be scraped and dissolved in ice-cold buffer. If a radioactive compound is studied, cells and filters are dissolved in a Ready-Safe scintillation cocktail, and radioactivity is determined in a liquid scintillation counter. Alternatively, for nonradioactive compounds, LC-MS or HPLC detection is recommended.

An alternative is a time-dependent study where cells are scraped and uptake is stopped at different times over 15 min. In both cases (in time-dependent studies and one-time-point determinations), protein content is used to express uptake in nmol/mg protein.

In another study, uptake of biotin was studied with confluent CACO-2 cells cultured on 12-well plates (Balamurugan and Said 2003). Labeled and unlabeled biotin was added to cell monolayers, and reaction terminated after 3 min by adding ice-cold buffer (2 ml). Cells were rinsed twice in ice-cold buffer, digested with 1 ml of 1 N NaOH, neutralized with HCl, and then counted for radioactivity. Protein content of cells was determined with a Bio-Rad kit (Richmond, US).

A comparable uptake assay to study uptake of peptides and compounds via peptide transporter was described by D'Souza et al. (2003).

EVALUATION

The uptake is expressed in nmol/mg protein and compared to standard drugs. In addition, time-dependent uptake experiments provide uptake kinetic parameters.

MODIFICATION OF THE METHOD

Modifications are used to study different uptake transporters. Inhibition studies provide information about transporters involved in uptake. An alternative are cells overexpressing uptake transporters or oocyte studies with one expressed uptake transporter.

CRITICAL ASSESSMENT OF THE METHOD

An uptake assay using CACO-2 monolayers grown on filter dishes needs to be combined with permeability studies to assess the amount of compound permeating during the short time of uptake. Studies with cells grown on Petri dishes or multi-well plates have the disadvantage that they may be performed with cells not fully differentiated. Uptake and efflux transporter expression increases with differentiation. Moreover, some transporters require pH gradients and the three-dimensional filter geometry to function with optimal activity.

Transporter studies have been performed with CACO-2 cells for many different transporters of the Solute Carrier system (SLC). The use of transporters as drug targeting systems to increase bioavailability is discussed since several years. Many transporters from the SLC family are being evaluated for their drug targeting use. The following part of the critical assessment will deal with SLC transporters identified in the intestine and their possible role in respect to drug targeting.

27.2.6.1 Uptake Transporters in the Intestine

Figure 27.3 illustrates the most important transporters and enzymatic systems identified in enterocytes.

Subsequently, several of the transporters have been used as drug delivery systems.

27.2.6.2 Amino Acid Transporters

Several uptake amino acid transporters have been identified at the apical side of brush border membrane enterocytes: heterodymeric amino acid transporters (HAT system) with apical transporters LAT1-4F2hc and b0. + AT and the systems PAT, B0, Beat/Taut, A, and B0+. At the basolateral side, the HAT transporters y + LAT1-4F2hc, LAT2-4F2hc, and ASC1-4F2hc are expressed together with other systems: A, y+, XAG-, and Tat (for overview, see Steffansen et al. 2004). In Table 27.3, the transporters mentioned are listed with gene name and substrate specificity. However, the capacity of amino acid transporters seems to be limited for an effective oral delivery approach. On the other hand, substrate specificity is limited as well. For review, refer to Verrey (2003), Palacin and Kanai (2003), Verrey et al. (2003), Halestrap and Meredith (2004), and Ganapathy et al. (2001).

Table 27.3 Amino acid transporters, substrates, and localization. *A* apical side of the membrane, *B* basolateral side of the membrane

Transporter	Gene name	Specificity	Substrates	Cellular localization
LAT1-4F2hc	SLC7A5/SLC3A2	Large NAA	Gabapentin, melphalan, baclophen, L-dopa	A/B
LAT2-4Fhc	SLC7A8/SLC3A2	NAA	Cys	B
B0. + AT	SLC7A9/SLC3A1	CAA	Gabapentin	A
ATB0	U75284	NAA	Pregabalin	A
CAT1	SLC7A1	CAA		B
Y + LAT1-4F2hc	SLC7A7/SLC3A2	CAA		B
Y + LAT2-4F2hc	SLC7A6/SLC3A2	CAA		B
		NAA		
A	SLC5A4	NAA	Glu, amino acids	A/B
ATB0.+	SLC6A14	NAA, CAA	Pregabalin	A
TAUT	SLC6A6	Tau	Tau, Ala	A
TAT1	SLC16A10	AAA	L-dopa	B
EAAC1	SLC1A5	Asp/Glu	Asp-3	B
ASC1-4F2hc	SLC7A10/SLC3A2	Ala, Ser, Cys, Gly, Thr	Aminobutyric acid, β-alanine, D-Ser	B
PAT1	SLC36A1	NAA	D-Ser, D-cycloserine, GABA	A

27.2.6.3 Nucleoside Transporters

At the apical side of intestinal enterocytes, concentrative nucleoside transporters CNT1, CNT2, and CNT3 are identified, whereas at the basolateral membrane, equilibrative nucleoside transporters ENT1 and ENT2 are localized. Table 27.4 gives an overview on nucleosides, nucleobases, and drugs being transported by nucleoside transporters (for a detailed review, see Steffansen et al. 2004; Ritzel et al. 1997, 2001).

The capacity for drug transport by nucleoside transporters is different: the CNTs are discussed as potential drug uptake candidates since they have micromolar affinities. Several antiviral and anticancer drugs are transported by CNTs like 3-azido-3-deoxythymidine (AZT) and gemcitabine by CNT1, 2,3-dideoxyinosine by CNT2 and 5-fluorouridine, zebularine, gemcitabine, cladribine, and fludarabine by CNT3 (Ritzel et al. 2001).

Table 27.4 Nucleoside transporters, substrates, and localization. *A* apical side of the membrane, *B* basolateral side of the membrane

Transporter	Gene name	Specificity	Substrates	Cellular localization
CNT1	SLC28A1	Purine nucleosides	Zaltidabine, cytarabine, cladribine, gemcitabine, 5 deoxy-5-fluorouridine	A
CNT2	SLC28A2	Pyridine nucleosides	Adenosine, cladribine, didanoside	A
CNT3	SLC28A3	Purine and pyridine nucleosides	5-fluorouridine, floxuridine, zebularine, gemcitabine, zalcitabine	A
ENT1	SLC29A1	Purine, pyrimidine nucleosides	Cladribine, cytarabine, fludarabine, gemcitabine, zalcitabine, didanoside	B
ENT2	SLC29A2	Purine, pyrimidine nucleosides	Gemcitabine, didanoside	B

27.2.6.4 Sugar Transporters

Hexose transporters are divided into two families: the sodium-dependent glucose transporters (SGLT, transport of hexoses against a concentration gradient) and the Glut family (transport of hexoses down a concentration gradient). At the apical membrane of enterocytes SGLT1, Glut2 and Glut5, and SGLT6 have been identified. Basolaterally, hexoses are transported by Glut5 and SGLT6. The localization of SGLT3 and SGLT4 is unknown. SGLT1 transports D-glucose, D-galactose, alpha-methyl-D-glycopyranoside, inositol, proline, pantothenate, iodide, urea, myo-inositol, and glucose derivatives. SGLT6 is capable of transporting D-glucose. SGLT3 transports D-glucose and myo-inositol. Glut5 transports D-fructose whereas Glut2 identifies D-glucose, D-fructose, and streptozotocin. For reviews, please refer to Wright et al. (2003), Wright and Turk (2004), Uldry and Thorens (2004), and Stuart and Trayhurn (2003). Examples of drugs being transported by hexose transporters are rare so far.

27.2.6.5 Peptide Transporters

In the intestine, the following peptide transporters have been identified: PEPT1, peptide/histidine transporter PHT1, PHT2, and the peptide transporter PT1 (Herrera-Ruiz et al. 2001, and others). PT1 belongs to the cadherin family; all other peptide transporters belong to the solute carrier family SLC15A.

For PEPT1, an impressive list of compounds (drugs and prodrugs) has been presented during the last years all of which in retrospective have been identified as PEPT1 substrates (e.g., beta-lactam antibiotics, cephaslosporins, ACE and renin inhibitors, thrombin inhibitors, bestatin, and prodrugs of acyclovir and ganciclovir) (Friedman and Amidon 1989; Walter et al. 1995; Bretschneider et al. 1999; Brandsch et al. 2004 and others). A very comprehensive overview is given in Nielsen et al. (2002). Several reviews deal with PEPT1 as a potential drug delivery target and show therapeutic applications and prodrug approaches (Daniel and Kottra 2004; Nielsen et al. 2002; Steffansen et al. 2003, 2004).

27.2.6.6 Monocarboxylate Transporters (MCT)

Eight different monocarboxylate transporters have been identified playing an important role in the cellular metabolism by transporting endogenous substrates like monocarboxylates, pyruvate, L-lactate, propionate, and butyrate (Halestrap and Price 1999). The best studied transporter, MCT1, is localized basolaterally (according to Tamai et al. 1995). Other authors detected MCT1 in apical intestinal membranes (Ritzhaupt et al. 1998). Tamai studied the uptake and kinetics of several organic acids like benzoic acid, nicotinic acid, pravastatin, and salicylic acid (Tamai et al. 1995). Some beta-lactam antibiotics like cefdinir, phenethicillin, and carindacillin have been proposed as MCT1 substrates (Tsuji et al. 1993; Itoh et al. 1998; Li et al. 1999).

27.2.6.7 Fatty Acid Transporters

In the intestine fatty acid translocase (FAT), fatty acid transporting protein (FATP4) and fatty acid binding protein (FABPpm) have been identified (for review, see Stahl 2003). Natural substrates are long chain fatty acids like myristate, oleate, and palmitate.

27.2.6.8 Organic Anion Transporters and Transporting Polypeptides

In the intestine, only few members of the large group of organic anion transporters have been found: OAT2 (SLC22A7) and OATP-B (SLC21A9) responsible

for the transport of many different compounds (Burckhardt and Wolff 2000; Tamai et al. 2000; Kobayashi et al. 2003). Drugs like fexofenadine, methotrexate, pravastatin, and ouabain are substrates of OATPs (Cvetkovic et al. 1999; Abe et al. 2001; Bossuyt et al. 1996; Dresser et al. 2002). Members of organic anion transporters present in the gut are OAT2 (colon, duodenum, ileum, jejunum), OAT3 (colon), URAT1 (ileum, jejunum), OAT10 (colon, jejunum), which all have been detected at mRNA level (see review of Burckhardt and Burckhardt 2011).

27.2.6.9 Organic Cation Transporters

The family of organic cation transporters is represented at the apical membrane of intestinal cells by OCTN2, whereas the basolateral membrane is equipped with OCT1 (Sekine et al. 1998). In the liver, OCT1 plays a crucial role in uptake of positively charged drugs and compounds preparing hepatic metabolism and elimination. In the intestine, this transporter is localized basolaterally, making a drug targeting questionable: compounds once entering the cells would be identified by OCT1 and excreted via sinusoidal membrane directly for uptake into hepatocytes (for review, see Koepsell and Endou 2004; Koepsell et al. 2003).

OCTN2 was identified as a Na+/carnitine cotransporter and is also located in the apical membrane of proximal tubular cells. Substrates of OCTN2 are TEA, verapamil, pyrilamine, choline, and quinidine (Koepsell et al. 2003).

Other organic cation transporters identified at mRNA level were OCT1, OCTN1, and OCTN2 (small and large intestine) and OCT2, OCT3, and OCTN3 (small intestine)—for a review, see Koepsell et al. (2007).

27.2.6.10 Phosphate Transporters

It is believed that the major part of inorganic phosphor absorption in the intestine occurs via Na^+-dependent phosphate cotransporter NaPi-Iib (SLC34A2, Xu et al. 1999). Small drugs like phosphocarbonic acid and foscarnet are transported by this transporter (Swaan et al. 1995; Tsuji and Tamai 1996). However, the substrate range is rather limited including only inorganic phosphate compounds.

27.2.6.11 Bile Acid Transporters

Bile acids are reabsorbed from the intestine by the bile acid transporter ASBT (SLC 10A2). Substrates are cholate, taurocholate, glycoursocholate, and glycodeoxycholate (Craddock et al. 1998; Wong et al. 1996). Conjugation of oligopeptides to bile salts increased their bioavailability substantially (Kramer et al. 1994). However, it is important to ensure that possible ASBT-mediated drug uptake should not interfere with bile salt absorption. It is known that patients with decreased bile salt uptake have higher risk for colorectal carcinomas may be due to increased bile salt concentration in the GI (Wang et al. 2001).

27.2.6.12 Vitamin Transporters

Several vitamin transporters are expressed in the intestine: SVCT1 responsible for ascorbic acid uptake (Wang 2000) and THTR-2 (SLC 19A3) showing high affinity for thiamine (Eudy et al. 2000; Nguyen et al. 1997; Said et al. 1996). Biotin is transported by the SMVT (Balamurugan and Said 2003). The vitamin transporters are discussed for possible drug targeting although their uptake capacities are low.

27.2.6.13 Transports with Unknown Localization

Several transporters have been identified in intestinal tissue without defining the localization: SGLT3 and SGLT4 for glucose, PHT2 (PTR3) for peptide/histidine, MCT8 for monocarboxylates/thyroid hormone, FABpm for fatty acids (oleate, myristate, palmitate, stearate, arachidonate, linoleate), RFC1 for folate, THTR2 for thiamine, and SMVT for biotin (Steffansen et al. 2004).

28.1 General Considerations

The ability to permeate a biological membrane is a prerequisite for orally administered drugs. A number of active transport processes involving many different transporter proteins have been described in the last years. However, the primary absorption pathway for the majority of drugs after oral dosage still seems to be the passive *transcellular diffusion* pathway (for a detailed discussion, see Sugano et al. 2010).

Biological membranes consist of lipid bilayers featuring a polar headgroup region at the interface to the aqueous phases and a nonpolar region in the center of the bilayer. The main constituents of these membranes are amphiphilic phospholipids and cholesterol.

In order to cross a biological lipid bilayer membrane, drugs have to interact with the hydrophilic headgroup region of the membrane and enter it subsequently from the water environment (unstirred water layer (UWL)). This is followed by diffusion through the hydrophobic region of the bilayer. Consequently, the drugs have to exit the hydrophilic headgroup region again into the water environment at the inner side of the membrane. The overall process is driven by the concentration gradient of the compound across the membrane.

The passive *permeability* of a drug is determined by its lipophilicity, which is the physicochemical property that influence all of the steps involved in the transcellular diffusion. Lipophilicity is a mixed parameter reflecting both hydrophobic and polar membrane affinity properties as well as hydrogen bonding and ionization properties of the drug depending on the lipophilicity scale and lipophilicity measurement method used (Liu et al. 2011).

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_32, © Springer-Verlag Berlin Heidelberg 2013

Lipophilicity is traditionally expressed as the partition coefficient between water and n-octanol which is called logP (see Chap. 44.3). However, a number of alternative assays for estimating lipophilicity (and predicting absorption) expressed as partition coefficients have been proposed (other organic solvents as isotropic partitioning media, reversed phase HPLC using anisotropic media for partitioning). Artificial membrane preparations or real lipid bilayer membranes (liposomes) have also been used for partition experiments. The intention of these assays is to find improved correlation of lipophilicity values to passive transcellular absorption of drugs than using the classical octanol-water partitioning system by taking into account the ionization characteristics of phospholipid membranes.

In other assays, the permeation of a compound is followed directly by estimating the amount of compound on either side of the membrane barrier. The results of these experiments (e.g., parallel artificial membrane permeation assay, PAMPA, or liposome permeation studies) are expressed as permeability values rather than lipophilicity values even if partition coefficients can be calculated from these studies and the PAMPA permeability results themselves might also be regarded as another lipophilicity scale.

A number of review articles and books described recently the methods used in pharmaceutical research to early on estimate the absorption potential of a compound by means of a variety of cell-free techniques:

28.2 *HPLC* Methods for *Lipophilicity* Determination

PURPOSE/RATIONALE

Lipophilicity is a main parameter influencing a drug's passive intestinal absorption and is traditionally expressed as the *partition coefficient logP* between water and n-octanol (Hansch and Fujita 1964). The partition coefficient logP is used if the partition behavior of the neutral form of an analyte is considered; the *distribution coefficient logD* is used if a mixture of differently charged forms of the same analyte is under investigation. LogD values take the ionization state of a compound into account by measuring the distribution behavior of a given compound at a fixed pH. A wide range of correlations between lipophilicity expressed as logD(P) octanol-water ($logD(P)_{OW}$) values and biological properties of compounds have been described over the years including biological absorption and membrane partitioning (Kerns 2001b). The partition coefficient $logP_{OW}$ or the distribution coefficient $logD_{OW}$ between water and n-octanol is determined traditionally by the shake-flask method (see Chap. 44.3). The shake-flask method is a rather labor-intensive method and not suited for high-throughput analysis needed in pharmaceutical research. An alternative way is the determination of logD(P) values based on chromatographic retention.

The use of hydrophobic stationary phases and aqueous mobile phases in *chromatography* on reversed

phase (RP) materials is widely established. *Reversed phase* materials typically consist of alkyl chains (mainly C18 in length) immobilized on silica material. The chromatographic retention of a solute on such a system directly depends on its partition between the aqueous mobile and the hydrophobic solid phase (Berthod and Carda-Broch 2004). Therefore, lipophilicity (expressed as partition coefficient logP between stationary and mobile phase, Eq. 28.1) can be estimated from the retention behavior of the solute of interest on reversed phase material as reviewed by Nasal et al. (2003).

$$\log P = \log k - \log\left(\frac{V_s}{V_m}\right) \tag{28.1}$$

V_m and V_s are the volumes of the stationary and mobile phase, respectively; k is the *retention factor* that is derived from the retention time (t_R), taking the dead time (t_0) into account.

$$k = \frac{t_R - t_0}{t_0} \tag{28.2}$$

The advantage of using a chromatographic system is much higher throughput compared to shake-flask assays. The retention time of an analyte is concentration independent, and therefore, no quantification has to be done to establish lipophilicity values. Chromatographic measurements are easily automated including peak picking and data evaluation. Another advantage is that disturbing impurities are separated from the compound of interest during the chromatographic experiment and will not interfere with the estimation of lipophilicity. However, the volume of the stationary phase cannot be estimated easily, so that the partition coefficients have to be calibrated using a set of compounds with known partition coefficients in order to achieve comparable results.

PROCEDURE

The lipophilicity of compounds can be measured with any commercially available HPLC equipment traditionally using octadecyl-bonded silica (ODS) columns (but also other column materials like polymer-based materials without residual silanol groups (Donovan and Pescatore 2002) or monolithic materials have been described, discussed in the review by Kaliszan 2007); most commonly, UV absorption is used as detection system for the chromatography but also LC/MS coupling was described (Camurri and Zaramella, 2001; Kerns et al. 2003). The use of mass spectrometry as detection method offers the possibility to determine the lipophilicity of a mixture of analytes in one run. Recently, the use of ultra-high-pressure liquid chromatography (UHPLC) coupled with mass spectrometry was described in order to decrease the time needed for the analysis (Henchoz 2009b).

The retention factor of a compound is the analytical parameter determined to measure lipophilicity (Eq. 28.1). To measure the retention factor, the retention time of the compound under investigation has to be determined reproducibly together with the dead time. The dead time is determined using the retention time of a not retained substance on reversed phase columns like buffer salts. In principle, injecting a solute onto a reversed phase system using a purely aqueous mobile phase would directly determine the partition coefficient. However, to cover a broad range of lipophilicity, a variety of mobile phase mixtures have to be used as most of the drug substances do not elute from reversed phase columns using purely aqueous mobile phase. Organic cosolvents in the mobile phase have a strong influence on the measured partition between lipophilic stationary phase and mobile phase and have to be considered. Generally, a number of different experiments with increasing percentage of organic solvent (not exceeding about 50–70% organic solvent) have to be carried out, and the determined retention factors are plotted against the organic solvent ratio (φ) used in the respective experiment. The retention factor k_w extrapolated to 0% organic solvent is taken from this plot. Using methanol, the retention factors k and k_w are linearly correlated with a constant factor S, depending on the analyte and the organic modifier (Kaliszan 2007).

$$\log k = \log k_w - S * \varphi \tag{28.3}$$

Valko et al. (1997) and Du et al. (1998) showed that instead of using a number of different isocratic experiments at different organic solvent ratios, one fast gradient experiment on short reversed phase columns could be applied. If a fast gradient is used, any retention time defines a specific mixture ratio of organic and aqueous solvent. Therefore, the retention index k_w was determined directly from one experiment just by measuring the retention time. Short reversed phase

columns are recommended in order to keep the organic solvent ratio low at the point of elution from the column.

Different buffer systems at different pH values (mainly 6.8 or 7.4) with organic modifiers are used as mobile phase. Results obtained with methanol as cosolvent were shown by Baczek et al. (2000) to correlate better to octanol-water partitioning data than results using acetonitrile as organic cosolvent. The H-bonding capabilities of the alcohol seem to be the reason for that.

EVALUATION

The variety of stationary phases available commercially and the lack of standardization between different laboratories make it difficult to compare the retention factors *k* directly as comparison of lipophilicity. Therefore, different lipophilicity scales obtained from chromatographic data (isocratic or gradient elution) have been introduced.

The determination of log k_w as the retention factor at 0% organic modifier estimated from isocratic chromatographic analysis was described earlier. Log k_w is one of the widest used chromatographic lipophilicity parameters and is usually correlated to Log P_{OW} values estimated using the traditional shake-flask method. OECD guidelines (1989) suggest a calibration of k_w values with experimental $logP_{OW}$ values and the expression of reversed phase chromatographically estimated partition coefficients directly as logP values.

The lipophilicity index φ_o was defined by Valko and Slegel (1993). φ_0 is the volume percent of organic modifier in the mobile phase by which the retention time is twice the dead time, which means the retention factor k is equal to 1. It was reported that using the φ_0 scale, the inter-laboratory comparability was improved compared to using log k_w. The correlation with traditionally determined $logP_{OW}$ values was shown to be better (Valkó 1993) using the φ_0 index. The analytical advantage of the φ_0 value is that it can be estimated from bracketing experimental results and not from extrapolation to 0% organic modifier.

The *CHI* index was introduced by Valko et al. (1997) in order to match the lipophilicity index φ_0 of isocratic experiments with results from gradient elution. The lipophilicity results from gradient elution experiments are calibrated using standard compounds with known φ_0 value estimated using isocratic elution. The CHI scale was used for neutral drugs and also for acids and bases (Fuguet et al. 2007; Pallicer et al. 2011).

The results of chromatographic lipophilicity measurements using gradient elution are often directly expressed as logD values. In that case, estimated retention factors are calibrated with known $logD_{OW}$ values of a standard set of compounds used as external or internal standards. However, it has to be pointed out that the correlation between estimated logD values from reversed phase chromatography and octanol-water distribution coefficients $logD_{OW}$ depends on proper selection of calibration standards and maybe low for a diverse set of compounds (Valko et al. 1997). The reason is the different organic partition media used in the experiments.

Several review articles recently summarized the use of reversed phase chromatography (also discussing the most important stationary phases used) to measure partition coefficients (Valkó 2004; Berthod and Carda-Broch 2004; Nasal et al. 2003; Kaliszan 2007; Henchoz et al. 2009).

CRITICAL ASSESSMENT OF THE METHOD

The lipophilicity measurements using reversed phase HPLC are fast and reliable, and the equipment for the analysis is available in almost every laboratory dealing with drug discovery. Using reversed phase chromatography in the gradient mode, the high throughput needed to cope with the high numbers of compounds delivered from combinatorial or parallel synthesis can easily be achieved. As LCMS analysis on fast generic gradients is used nowadays as the standard tool for purity estimation in drug research, the very same method offers a very robust way to estimate lipophilicity of high numbers of compounds (even mixtures) on the run (Kerns et al. 2003). Good correlation between octanol-water partition coefficients and chromatographic retention factors (isocratic or gradient) for neutral molecules ($logP_{OW}$) can be achieved if a proper calibration set was chosen. For charged analytes ($logD_{OW}$), the reversed phase HPLC system may be only an approximate model mainly when structurally diverse compound sets were analyzed (Valkó 2004) and even more when gradient mode was applied. However, for comparison measurements and ranking of lipophilic properties of a high number of compounds, the reversed phase chromatography technique using fast gradient elution seems to be the method of choice even if the correlation to $logD_{OW}$ maybe not perfect under these conditions.

There are obvious differences between the classical octanol-water partition system and the reversed phase chromatographic partition system mainly due to the different nature (isotropic partition vs. anisotropic partition) of the partitioning media. Related to drug absorption, both classical octanol-water partition coefficients and lipophilicity values using the different chromatographic scales have shown to be predictive. In summary, Taillardat-Bertschinger et al. (2003) stated in their review that the best lipophilicity descriptor used to predict membrane permeation differs according to the compounds under investigation. Wang et al. (2009) added that it is not shown yet which lipophilicity descriptor was best suited to predict membrane permeability for a large diverse set of compounds. Therefore, a number of different methods and stationary phases (including biopartitioning columns, see "Modifications of the Method") might be suitable for a given class of drugs, and the use of a number of different scales was recommended in literature as discussed by Valko (2004).

MODIFICATIONS OF THE METHOD

In order to improve the correlation between isocratic $\log k_w$ values and $\log P_{OW}$ values for diverse sets of compounds, Lombardo et al. (2000, 2001) used an octanol-saturated mobile phase and a Supelcosil LC-ABZ (polar amide column) as stationary phase. Isocratic separation is used in their work. The obtained $\log_w$ data are calibrated with known logD/logP values of a training set, and the obtained lipophilicity data from unknown samples are reported as *ElogP* (ElogD) values. These authors pointed out that *ElogD* values correlate very well with traditionally obtained $\log D_{OW}$ values in case of neutral and basic compounds. Benhaim (2008) expanded this concept by using a modified silica column which can be used over a broad pH range (pH 2–12) and allowed to study the lipophilicity of the neutral form of acids and bases.

Apart from the hydrophobic interactions provided by the alkyl part of the molecule, octanol has also hydrogen bond acceptor and donor functions like lipid membranes have. This property of n-octanol made the octanol-water distribution coefficient that is widely used. However, neither n-octanol nor reversed phase materials can mimic the interfacial character of the bilayer structure. The ionic interactions between charged membrane *phospholipids* and ionisable solutes are also not represented in the properties of octanol or reversed phase materials. To overcome this issue, alternative stationary phases have been developed to determine lipophilicity values more related to intestinal absorption than to classical $\log P_{OW}$ values.

Those stationary phases are made of silica material with covalent bond phospholipids mimicking a cell membrane surface as introduced by Pidgeon et al. (1989). These *immobilized artificial membrane* (*IAM*) stationary phases having diacetylphosphatidylcholine (PC) with or without glycerol backbone bound to silica are also commercially available (Regis Technology, Morton Grove, IL). Kararli et al. (1995) showed that PC is relevant to intestinal absorption as PC together with PE (phosphatidylethanolamine) comprises a major portion of the intestinal brush border membranes.

The lipophilicity measured using IAM columns generally is expressed as the retention factor k_{IAM} or k_{IAMw} of a solute following Eqs. 28.2 and 28.3, respectively, using IAM columns. Valkó et al. (2000) also applied gradient elution to IAM columns, and a CHI_{IAM} index was defined similar to the CHI values as described for reversed phase chromatography. Log k_{IAMw} values of neutral solutes often correlate with other lipophilicity scales, but acidic solutes generally result in different values using different lipophilicity scales (Sun 2008). Log k_{IAM} values have been correlated successfully with blood-brain barrier distribution, small intestine absorption, and Caco-2 cell permeation as summarized by Stewart et al. (1998). Modeling of Caco-2 permeability was proven by the use of IAM chromatography together with other descriptors like polar surface area (PSA) (Chan 2005). The respective correlations were shown to be superior to the correlation with octanol-water partition coefficient or HPLC-determined lipophilicity in another review by Yang et al. (1996). Liu (2008) studied the retention behavior of almost 50 diverse drugs on an IAM column and described the influence of the ionization state of the analytes on their retention. Kotecha et al. (2008) used the highest k_{IAMw} value in the pH range from 4.5 to 7.5 ($\log k'_{IAM}{}^{4.5-7.4}$) in combination with PSA to predict oral absorption for divers set of drugs. IAM chromatography has been reviewed by Giaganis and Tsantili-Kakoulidou (2008).

Also, liposomes as real lipid bilayers (compare next chapter) have been used in chromatography-based lipophilicity assays (ILC, immobilized liposome chromatography) as reviewed recently by Cserhati (2010).

Österberg (2001) compared liposome partition with ILC and other lipophilicity scales. An excellent correlation between liposome partitioning data and ILC results was shown. Beigi (1998) immobilized liposomes onto sepharose material by gel-bead swelling and used it as solid phase in chromatography experiments (*immobilized liposome chromatography*, *ILC*). A bell-shaped correlation between the retention behavior on the liposome columns and human fraction absorbed was reported by these authors. However, the immobilization of liposomes using gel-bead swelling is not very stable over an extended time range, and column-to-column reproducibility seems to be an issue. Liu (2002) coupled avidin covalently to sepharose material and used biotin-tagged phospholipids to immobilize liposomes on this stationary phase. They reported improved column stability compared to the gel-bead swelling approach. Good correlation to human fraction absorbed was shown using these results. Even extracted biological membranes have been used in ILC experiments by Engvall and Lundahl (2004); however, the stability of the columns was shown to be limited. Instead of covalent immobilization, also dynamic coating of liposomes onto reversed phase columns has been described, and improved column stability was reported. Techniques and applications have been reviewed recently (Godard 2011).

Lazaro et al. discussed in 2006 the differences between reversed phase materials compared with IAM material and described a theoretical measure to decide which tool might be the best choice depending on the nature of the biological barrier to be predicted (BBB, intestinal absorption, skin absorption, etc.). Lipid membrane mimicking chromatography (biopartitioning chromatography) methods have been reviewed in detail by Sun (2008).

In addition to the described chromatography-based methods, a number of electrically driven systems have been described recently (Ornskov 2005) using different pseudo-stationary phases. The separation of neutral molecules is achieved due to partition into the charged micelles. MEKC (micellar electrokinetic chromatography) using SDS (sodium dodecyl sulfate) as pseudo-stationary phase or LEKC (liposome electrokinetic chromatography) has been described. For details, refer to the review articles by Henchoz et al. (2009b) and Cserhati (2010).

28.3 Lipophilicity Determination Using *Liposomes*

PURPOSE/RATIONALE

Lipophilicity expressed as logP_{OW} correlates with membrane affinity and other biological properties as summarized in Kern's (2001) review on physicochemical profiling. However, the interfacial (anisotropic) character of bilayer membranes and the ionizable phospholipid headgroups of biological membranes influence the partition properties of drugs. These effects are not reflected using octanol-partitioning experiments. To analyze these influences, the partition of solutes between water and charged bilayer membranes should be measured.

For this purpose, liposomes are used as lipid phase. Unilamellar liposomes are artificial lipid bilayer vesicles. They can be considered as real model bilayer membranes as they ideally consist of a circular bilayer membrane. The hydrophobic acyl chains are assembled in the hydrophobic core of the liposome, whereas the hydrophilic headgroups point to the water in the inner and outer side of the vesicle. Liposomes can be

produced from a variety of lipids and from mixtures of lipids. This possibility allows studying the influence of membrane constituents on the partition of solutes. Krämer et al. (1997) studied the influence of the presence of free fatty acids in membranes on the partition behavior of propranolol. The influence on α-tocopherol in membranes on the partition behavior of desipramine has been reported recently (Marenchino et al. 2004) using a liposome model.

Balon et al. (1999a) reported improved correlation between liposome partition and human intestinal absorption in comparison to the correlation of intestinal absorption to $logD_{OW}$. Tammela et al. (2004) showed a good agreement between Caco-2 permeation results and liposome data.

The general use of liposomes and the evaluation of the obtained data have been recently reviewed by Plember van Balen et al. (2004) and Krämer (2001).

PROCEDURE

For liposome partition experiments, freshly prepared liposomes of defined size are incubated with an aqueous solution of the analyte. The partition coefficient is calculated from the ratio of compound present in aqueous environment and lipid environment in equilibrium.

In order to prepare liposomes, the lipid preparation is dried at low temperature under an inert gas atmosphere (protect the lipid from oxidation). The lipid film is swollen with water or buffered aqueous solution, and several freeze-thaw cycles are carried out to get optimal rehydration of the lipid. The rehydrated lipid preparation is filtered using membrane filters with defined pore size. After repeated filtration steps (extrusion), a unilamellar liposome preparation with a defined size distribution is obtained. Large unilamellar vesicles (LUVs) are produced in this way. LUVs are about 100 nm in size; the thickness of the lipid bilayer is about 4 nm. Even smaller liposomes can be derived from sonication (sonication probe or ultra-sonication bath). Separation of the prepared liposomes according to size using sepharose chromatography or ultracentrifugation ensures a homogenous size distribution of the liposomes (Krämer 2001). Balon et al. (1999b) used these sonicated small unilamellar vesicles (S-SUV) for partition experiments.

Several methods are used to determine the partition coefficient of solutes between water and liposomes.

Equilibrium dialysis is used in a number of examples to analyze the ratio of lipid-bound to free analyte. Krämer et al. (1998) described the use of equilibrium dialysis by separating the liposome suspension and the water phase by a semipermeable membrane. The analyte is dissolved in the water compartment of the system and diffuses into the liposome compartment. If equilibrium is reached, the remaining concentration of the analyte in the water compartment is determined by means of a quantification method (mainly HPLC or LC/MS, fluorescence techniques) and the partition coefficient is calculated. Krämer et al. (1997) used a radio tracer substance as analyte to quantify the compound in both compartments using liquid scintillation counting.

The partitioning behavior of an ionizable compound can also be followed directly using a two-phase *potentiometric titration* using commercial instrumentation (Sirius Analytical Instruments) as shown by Avdeef et al. (1998).

EVALUATION

The partition experiments are generally evaluated in terms of a partition coefficient that is calculated from the concentration ratio of analyte bound to liposomes or dissolved in the aqueous phase. For calculating the partition coefficient, the amount of lipid in the system has to be known.

Using equilibration dialysis, the distribution coefficient logD is calculated using the following equation (Plemper van Balen et al. 2004):

$$\mathrm{LogD} = \log\left(\frac{V_{LB}(C_{LB} - C_B)}{V_{Lipo} \cdot C_B} + 1\right) \qquad (28.4)$$

C_{LB} and C_B represent the analyte concentration in the liposome-containing compartment and the aqueous compartment, respectively. V_{LB} is the volume of the liposome-containing compartment, and V_{Lipo} defines the total volume of lipid phase (total amount of lipid used).

The distribution coefficient logD expresses the distribution of a solute if a mixture of ionization states of the analyte molecule is present at a defined pH value. The partition coefficient logP is strictly expressed for a specific ionization state of a solute. LogP values can be obtained from liposome partition experiments if experiments are carried out under a number of defined pH conditions.

Using the potentiometric titration approach (the same approach is also used to determine $logP_{OW}$ values

and described in the paragraph about physicochemical properties), first, the substance in aqueous solution is titrated against standard acid or base in order to obtain the pKa value. In presence of liposomes, the experiment is repeated, and a shift in the observed pKa value (pKa^{app}) might be noted as analyte has disappeared from the aqueous phase into the liposome phase. From the shift in observed pKa^{app} value, the partition coefficient of protonated analyte and neutral analyte can be calculated (Plemper van Balen et al. 2004).

$$pKa^{app} = pKa - \log\left(\frac{1 + r \cdot P^{B}}{1 + r \cdot P^{BH+}}\right) \qquad (28.5)$$

The ratio of organic to aqueous phase is expressed as r; P^B is the partition coefficient of the unionized and P^{BH+} is the partition coefficient of the protonated analyte. Using this approach, depending on the nature of the analyte, several titrations (for monoprotic compounds, at least two experiments) using different ratios of lipid to water phase have to be carried out in order to determine the partition coefficients of the solute. The result is a partition coefficient-pH profile for the compound and its distinct ionization states.

CRITICAL ASSESSMENT OF THE METHOD

Using liposomes for membrane affinity studies has the great advantage that liposomes are a nearly one-to-one model of biological bilayer membranes. Liposomes can be generated from a variability of lipids and mixtures of lipids in order to study the influence of the membrane constituents on the partition behavior of drug candidates.

Mainly the electrostatic interactions of liposomes are closer to those of biological membranes than in the case of n-octanol or reversed phase solid phases. The partition coefficients for neutral molecules mainly correlate well with n-octanol-partitioning data or chromatographic lipophilicity scales including IAM, whereas for charged or zwitterionic molecules, strong differences between partitioning in liposomes and octanol were described. Using liposomes, the difference between charged and uncharged molecules concerning their partitioning coefficient is much lower as compared to the $\log P_{OW}$ case. Therefore, the use of liposomes might help in understanding the role charged species play in the overall membrane permeation process of drugs. Balon et al. (1999a) showed that the correlation of liposome partition data with human intestinal absorption is superior to n-octanol partition experiments in some cases, whereas Österberg (2001) showed equivalent correlation of different lipophilicity scales including IAM and liposome partitioning compared to human fraction absorbed. Plemper van Balen et al. (2004) pointed out that the mechanism for permeation might be different for different ionized species of the same molecule or members of the same chemical series, which makes correlation of data complicated.

However, the throughput of liposome partition assays is limited as preparation and validation of liposomes are very time consuming. That seems to be the main reason why liposome partitioning is not widely used in the pharmaceutical industry to date. On the other hand, the results obtained using liposome partitioning show that liposomes are unique tools to study the bilayer *membrane affinity* (MA) of drugs and their correlation to intestinal membrane absorption.

MODIFICATIONS OF THE METHOD

The use of *solid-supported lipid membranes* (*SSLMs*) to measure membrane affinity was recently reported by Loidl-Stahlhofen et al. (2001a, b). To produce solid-supported lipid membranes, a single phospholipid bilayer membrane is noncovalently attached to a solid support. In contrast to covalent immobilization of liposomes on solid materials for ILC or the impregnation of lipids on filter materials (PAMPA), the solid-supported lipid membrane is reported to retain the physiological fluidity and its unilamellarity. SSLM material for membrane affinity measurements is commercially available as *TRANSIL®* material by Sovicell (Leipzig, Germany). The compounds under investigation are incubated in buffered solution with TRANSIL® material of known lipid amount (V_{lipid}) provided by the manufacturer in a 96- or 384-well format. After incubation, the concentration in the aqueous phase (N_{water}/V_{water}) and in the solution before incubation (N_{total}) is determined by HPLC, and *membrane affinity* is calculated using the following equation (Loidl-Stahlhofen et al. 2001a):

$$MA = \frac{c_{lipid}}{c_{water}} = \frac{V_{water}}{V_{lipid}} \times \frac{N_{total} - N_{water}}{N_{water}} \qquad (28.6)$$

A good correlation between $\log MA_{SSLM}$ and logMA estimated from equilibrium dialyses using liposomes in solution was reported. The TRANSIL®

approach is a unique use of liposome-like real bilayer membranes as high-throughput method for the estimation of membrane affinity. This technology was recently extended to the study of brain tissues binding to predict the permeability over the blood-brain barrier (Longhi et al. 2011).

Liposomes have also been attached to sensor chip surfaces used in *surface plasmon resonance* (SPR) instruments. *SPR biosensors* measure the quantity of a compound bound to an immobilized partner in real time without the need for fluorescent or radioactive labeling. SPR is an optical phenomenon that occurs when total internal reflection of light at metal surfaces is examined. Changes in SPR occur due to changes in the refractive index at the metal surface (up to about 300 nm). Binding of compounds to a metal-immobilized partner will change the refractive index near the metal surface. Therefore, binding of compounds to metal surface–immobilized partners can be determined as changes in the refractive index in SPR. Liposomes are attached to the dextran matrix that covers the gold surface of a SPR chip. In SPR experiments, the compound of interest is injected in buffered solution to a liposome and reference surface at low flow rates. The result of an SPR experiment is called sensogram, which shows the association and dissociation of an interaction partner to the immobilized system in real time. Baird et al. (2002) used blanc and liposome chip surfaces at the same time, and different sensograms between the control surface and a liposome surface were analyzed. The plateau binding response expressed as response units (RU) for the individual analytes is the measure for membrane affinity in these experiments. Membrane affinity expressed in RU has been successfully correlated to fraction absorbed in humans by Danelian et al. (2000). SPR also offers the unique possibility to study the kinetics of the membrane solute interaction if a dilution series of the compound under investigation is injected into the system. Abdiche (2004) clustered compounds with the same apparent partition coefficient K_D according to their *binding kinetics* and differentiated mainly between fast off and slow off rate drugs. The use of SPR in absorption and distribution studies has been recently reviewed by Bertucci et al. (2007).

Instead of the determination of partition coefficients using liposomes, also the permeation of solutes through liposomal membranes can be studied. This is possible in solution using a number of techniques including the use of radio tracers, fluorescence, or by separation techniques as reviewed by Krämer (2006). Liposomes prepared from egg phosphatidylcholine have also been deposited into the pores and onto the surfaces of a filter support in order to use this construct in a sandwich-like permeability study (Flaten et al. 2006) similar as in PAMPA studies (next chapter). This phospholipid vesicle-based barrier system was validated on 21 diverse drugs and was shown to be as predictive as double-sink PAMPA and the Caco-2 model concerning human oral absorption. In contrast to the PAMPA model, in the phospholipid vesicle-based barrier system, no organic solvent is present in the artificial membrane barrier. These barriers can be used in a broad pH range under steady-state conditions which make them an interesting tool to mimic different sections of the intestinal tract. This model was recently used to study the influence of formulations like solid dispersions on the permeability of poorly water-soluble drugs in comparison to Caco-2 cells (Kanzer et al. 2010).

28.4 *Parallel Artificial Membrane Permeability Assay (PAMPA)*

PURPOSE/RATIONALE

The use of partition coefficients between water and lipophilic media is of wide use in pharmaceutical research. As discussed in the last chapters, different lipophilicity scales depending on the partition media and the method of lipophilicity determination (Giaganis and Tsantili-Kakoulidou 2008) are used to describe the lipophilicity of a compound and relate it to its absorption behavior in vivo. Differences between the $\log P_{OW}$ and the partition coefficient of partitioning between artificial membranes and water (mainly determined using phospholipid liposomes, see Sect. 28.3) for diverse compounds have been described leading to the development of a number of methods using artificial membrane systems including methods using immobilized artificial membranes (e.g., IAM chromatography).

Artursson and Karlsson (1991) described the permeation across biological cell layers (Caco-2 system and other cell systems, see Chap. 27 "Absorption: In Vitro Tests - Cell Based") in order to predict the human intestinal absorption of a solute. However, the throughput of Caco-2 assays is limited due to the long-growing cycles of the cells and because the assay itself is very laboratory intense. Therefore, it is not easily applicable to the high throughput needed in drug research in a combinatorial chemistry and high-throughput-screening environment. The need for a fast, easy, and cheap method to assess permeability in vitro led to the development of the parallel artificial membrane permeability assay (PAMPA) that uses the filter-immobilized membrane concept to analyze membrane permeation. PAMPA is a permeability assay, whereas the assays described until now in this chapter were partition assays. The difference mainly is that partition coefficients tell you that the molecule should go through the membrane, whereas permeability studies tell you that the molecule did go through the membrane (from Box 2006) which makes interpretation of PAMPA results very intuitive. However, the different PAMPA assays can also be viewed in a global sense as lipophilicity scales (Avdeef et al. 2007) which link PAMPA to the assays using artificial membranes described in the section before.

The development of PAMPA was possible because of the former work by Thompson et al. (1982) and

others about filter-supported lipid bilayers (black lipid membranes, BLM) that showed that stable lipid layers can be formed on filter supports and that the lipid layer is able to close the filter pores enabling measuring the permeation across this lipid layer barrier. Permeation across a biological membrane is the sum of several partition events between the aqueous environment and the membrane plus the diffusion event within the biological membrane and the passage through the unstirred water layer at both sides of the membrane. Using octanol as barrier, partition between octanol and water and permeation through octanol immobilized on filters were correlated by Camenisch et al. (1997), and a sigmoidal relationship was encountered similar to the correlation between logD and Caco-2 permeability, indicating the importance of directly measuring permeation of solutes through *artificial membranes* instead of solely correlating partitioning data.

Kansy et al. (1998) first proposed a high-throughput permeation assay called parallel artificial membrane permeation assay (PAMPA) using an artificial phospholipid membrane brought onto a supporting hydrophobic filter. They presented a promising hyperbolic correlation between human absorption and PAMPA permeability however with a steep initial slope. The correlation allowed classifying compounds in classes of low, intermediate, and high permeability. Today, PAMPA is used in a variety of labs worldwide in drug research and development labs, and a commercial instrument and software are available (pION Inc.). A number of review articles summarized the different uses of the PAMPA assay (Faller 2008; Avdeef 2005). A critical article and rebuttal commentary was published in 2007 (Galinis-Luciani et al. 2007 answered by Avdeef et al. 2007).

PROCEDURE

PAMPA is generally carried out in the 96-well format using a PAMPA sandwich construction. The sandwich consists of a standard 96-well plate and a filter plate put on top (Microtiter plate filter plates that are commercially available). The bottom standard 96-well plate is filled with buffer so that the liquid surface will be in contact with the filter material of the filter plate put later on top. The filter material is impregnated with a lipid solution (e.g., 1–20% egg lecithin) in an organic solvent (e.g., dodecane) and put carefully on top of the donor plate in order to avoid any air bubbles between the liquid surface and the filter plate (Kansy et al. 1998). Then the filter plate is filled with buffer, and the permeation experiment is started by the addition of the analyte to the donor plate on top of the sandwich. The concentration of the analytes in the donor and the acceptor wells after incubation is determined. The analyte concentration in the acceptor well after permeation is compared to the analyte concentration in the donor solution before incubation to estimate permeation of the analyte under investigation.

As the focus of PAMPA is on high throughput, the concentration of the analytes in the acceptor wells after incubation is determined classically by fast UV measurements at various wavelengths using a UV plate reader. However, for up to 40% of the tested compounds in the pharmaceutical industry, no permeability coefficient could be determined mainly due to low solubility of the compounds or low UV response (Mensch et al. 2007; Faller 2008). HPLC-UV (Zhu et al. 2002) and HPLC-MS (Liu et al. 2003) have been used as alternative for the quantification in PAMPA studies. HPLC MS/MS and UHPLC MS/MS which are extensively used as quantification methods in other ADME studies are also widely used in the quantification of PAMPA studies. The high specificity and sensitivity of UHPLC MS/MS offers the possibility to pool compounds (cassette approach) to further increase the throughput (Mensch et al. 2007). SPE-MSMS as described by Lim et al. (2010) can also be used for PAMPA studies and can be integrated with a number of various ADME methods (Luippold et al. 2011). A number of alternative mass spectrometry methods as reviewed by Shou and Zhang (2010) might be used as detection systems for PAMPA studies as well.

PAMPA is often used at various pH values in order to measure *permeability pH profiles* as the permeability of ionizable compounds depends heavily on the pH of the buffer. As the pH range of the intestinal tract varies between pH 6 and pH 8, this is the range of pH values that mostly is used. Kerns et al. (2004) recommended to measure from pH 4 to pH 7.4 in order to predict both bases and acids correctly. Ruell et al. (2003) used permeation pH profiles from pH 4 to pH 9 together with the pKa values of the compounds under investigation to establish the optimum pH value for a single pH PAMPA measurement. The double-sink PAMPA method (Bermejo et al. 2004) applies a pH gradient between donor and acceptor plate together with an ionic surfactant in the acceptor plate to minimize membrane retention.

EVALUATION

The permeation in PAMPA experiments can be followed directly as the percentage of compound permeated into the acceptor compartment after a given time (%T) as described in the original work by Kansy et al. (1998) which reflects an equilibrium analysis at a given time point.

$$\%T = 100 \times \frac{C_A{}^{end}}{C_D{}^{start}} \qquad (28.7)$$

$C_A{}^{end}$ is the concentration of the solute under investigation in the acceptor well after incubation, and $C_D{}^{start}$ is the concentration of the analyte in the donor well at the beginning of the experiment.

Permeation in PAMPA experiments is also expressed as a flux rate P_{app} with the unit [cm/s] under the assumption that transport equilibrium is not reached and back transport can be neglected in course of the experiment. P_{app} values represent kinetic information and describe the flux of compounds over the membrane.

$$\mathrm{Papp} = \frac{V_A}{A \times (C_D - C_A)} \times \frac{dC_A}{dt} \qquad (28.8)$$

V_A is the volume in the acceptor well, A is the filter area, C_D is the concentration of analyte in the donor compartment at the beginning of the experiment, C_A is the concentration of analyte in the acceptor compartment at the beginning of the experiment and (dC_A/dt) is the increase of drug concentration in the acceptor compartment during the course of the experiment (Camenisch et al. 1997).

P_{app} values are often calculated from the ratio of analyte signal in the acceptor compartment at a single time point divided by the analyte signal in equilibrium without membrane barrier. Also %T and P_{app} values are related to each other following the equation taken from Zhu's et al. (2002) work:

$$P_{app} = \frac{V_D \times V_A}{(V_D + V_A) \times A \times t} \times \ln\left[\frac{100 \times V_A}{100 \times V_D - \%T(V_D + V_A)}\right] \qquad (28.9)$$

Both P_{app} and %T values have been correlated to fraction absorbed in human, and hyperbolic curves were encountered. This correlation is calibrated using a set of compounds with known human absorption properties, and unknown solutes are classified according to their position on the hyperbolic correlation curve into groups of high-/low-/medium-absorbed compounds.

Avdeef et al. (2001) described the influence of membrane retention of solutes observed in PAMPA experiments on the data evaluation. *Membrane retention* is analyzed using a mass balance between compound left in donor compartment after incubation and compound determined in acceptor compartment after incubation. For calculating P_{app} under consideration of membrane-bound fraction, Avdeef et al. (2001) used an equation different from Eq. 28.8, where the total amount of solute is substituted by the nonmembrane-bound fraction of solute in the equation.

CRITICAL ASSESSMENT OF THE METHOD

The PAMPA technology started to evolve with Kansy's et al. (1998) work published in 1998, and since then, the number of published work and the use of the technique in industry and academia grew tremendously. The development of a commercially available instrument/software (pION Inc.) shows the impact the development of PAMPA had on the drug research. Nowadays, PAMPA is the method of choice for high-throughput in vitro cell-free permeability assays in the discovery phase in pharmaceutical industry. The high-throughput possibilities offered by PAMPA are superior to the other in vitro techniques described in this chapter (including logP (D) measurements using RP-HPLC) at least if UV absorbance is used as analytical tool.

Also, the fact that only passive transcellular permeation is regarded in PAMPA experiments (even if a paracellular component can be added in silico, Sugano et al. 2002) is valuable as it allows comparing PAMPA results to cellular permeation experiments that feature all possible permeation mechanism including paracellular permeation and active transport by carrier proteins (active transport and active efflux). Kerns et al. (2004) recommended this comparison to get an insight into the permeation mechanism applied by a compound under investigation. The possibility to obtain permeability pH profiles is helpful to identify the relevant permeability value of a compound. The full pH profile cannot be determined by cellular assays due to the limited pH range usable with living cells.

PAMPA is relatively insensitive to DMSO percentage or other solubility mediating formulations in donor or acceptor compartment which gives the possibility to study the permeability of compound from different formulations which is not easily possible using living Caco-2 cells. This approach, in conjunction with LCMS analyses, was used to study the permeability of poorly soluble compounds in different recipients (Liu et al. 2003; Avdeef et al. 2008).

On the other hand, PAMPA is a purely artificial method, and PAMPA membranes do not perfectly reassemble real lipid bilayer structures. The thickness and material of the supporting PVDF filters also influence artificially the permeation of compounds depending on the lipophilicity of the compounds more than the thin polycarbonate filter does in Caco-2 experiments. Also, the best choice of membrane constituents for PAMPA experiments is still under investigation. One has to take into account that PAMPA today is a summary term on a lot of different methods applied in different laboratories using different membrane constituents, *sink conditions*, permeation times, etc., which makes inter-laboratory comparison difficult.

Therefore, the knowledge of the lipophilicity expressed as $logP_{OW}$ will still be of high interest in drug research. Pampa will not be able to substitute Caco-2 or other cell types for the study of permeation, but it will be able to deliver reproducible and predictive data about passive transcellular permeation of a high number of analytes. More time can then be used for the cell-based assays to investigate in depth the mechanism of permeation or efflux of compounds of interest.

MODIFICATIONS OF THE METHOD

The PAMPA permeability depends heavily on the artificial membrane used in the experiment. Today, the lipid choice varies between the labs. Kansy et al. (1998) used a solution of 1–20% lecithin in dodecane or hexadecane for their work. Sugano et al. (2001) presented improvements on the used membrane composition in terms of better correlation of the permeability data to the % absorption data in human and higher overall permeability. These authors used a so-called biomimetic lipid made from phosphatidylcholine (0,8%), phosphatidylethanolamine (0,8%), phosphatidylserine (0,2%), phosphatidylinositol (0,2%) and cholesterol (1%) dissolved in 1,7 octadien. The commercially available membrane system used in pION systems (*double-sink* PAMPA™) consists of 20% phospholipid mixtures in dodecane featuring 16% negative charge on the surface (Bermejo et al. 2004). Recently, a three-lipid-component PAMPA system was described consisting of 2.6% 1,2 dioleoyl-sn-glycero-3-phosphocholine, 0.9% 1,2 dioleoyl-sn-glycero-3-[phospho-L-serine] and 1.5% cholesterol in n-dodecane (Teksin 20101) which showed good agreement between PAMPA permeability coefficients and Caco-2 permeability coefficients. A so-called tri-layer artificial membrane was proposed by Chen et al. (2008). This artificial membrane consists of a hexadecane layer in between two lipid layers in a PVDF filter. The hexadecane layer stabilizes the bilayer-type structure. The lipid layers were prepared in volatile solvents which evaporate after coating, removing all excess solvent. Using this membrane preparation which is commercially available as precoated plates from BD Biosciences, an improved predictability of human absorption and decreased membrane retention compared to lipid solution–based strategies were reported (Chen et al. 2008).

Whereas, generally, PAMPA is used with artificial membranes composed of mixtures of phospholipids with organic solvents, Wohnsland and Faller (2001) used a permeation screen using pure hexadecane, Ottaviani et al. (2006) used isopropyl myristate with silicone oil as barriers. The use of a pure alkane as barrier for permeation allows to measure the permeation through the alkane barrier and partitioning between the alkane phase and water in the same experiment. The permeation data using hexadecane were correlated to % absorption in human, and a good correlation was reported showing the predictive character of this assay (Wohnsland and Faller 2001). The partition coefficient $logP_{ow}$ can be estimated from PAMPA assays directly as described by Faller (2001 and 2005) and discussed by Avdeef et al. (2007).

Also, the filter support was proven to have influence of the permeability determined by PAMPA experiments. Zhu et al. (2002) used a hydrophilic PVDF membrane as support and obtained permeability results yet after 2 h of incubation in contrast to 15 h using the hydrophobic filter materials used by other authors. Wohnsland and Faller (2001) used polycarbonate material instead of PVDF because of the reduced thickness of the polycarbonate material and more uniform surface structure as compared to the PVDF filters. Ruell et al. (2003), Wohnsland and Faller (2001), and others discussed the influence of the

unstirred water layer on both sides of the filter plate on the results from PAMPA assays. Avdeef et al. (2004) introduced individual stirring in each well of the 96-well plate using stirring disks rotating parallel to the membrane surface for PAMPA experiments. PAMPA experiments as short as 15 min due to the intense stirring were reported.

In intestinal absorption, the concentration gradient over the lipid membrane is the driving force for permeation of compounds. Low compound concentration is generally found at the basolateral side. This low local concentration at the inner side of the membrane is achieved by removal of compound with the blood flow or binding of the compound to plasma proteins, bile acids or lipids (Youdim et al. 2003). These sink conditions are mimicked in some PAMPA protocols by trapping the analytes in the acceptor compartment using a pH gradient between donor and acceptor well. Zhu et al. (2002) presented a method where acids and bases have to be analyzed under different sink conditions aiming in trapping an ionized species in the acceptor compartment. Double-sink™ conditions are offered commercially by pION. This method combines pH gradients between donor and acceptor compartments depending on the acid/base properties of the analytes with the use of a surfactant in the acceptor compartment mimicking serum albumin and trapping mainly neutral compounds.

PAMPA assays were also used for the prediction of other systems than intestinal absorption which involve membrane permeation as a key limiting factor, e.g., blood-brain barrier permeation and skin permeation. These barrier systems differ to the intestinal absorption system by the order of magnitude of the concentration sink in the acceptor compartment as well as in the lipid composition of their lipid barrier and the thickness of the unstirred water layer.

Li et al. (2003) used porcine brain lipids as artificial membrane to investigate blood-brain permeation and showed correlation between in vivo assays for brain permeation and PAMPA assay. Recently, Tsinman (2011) expanded the use of porcine brain lipid extracts and reported the use of an in-combo (PAMPA results combined with calculation of H-bond descriptors) approach for passive BBB permeability prediction. A number of different PAMPA systems have been compared by Mensch (2010) concerning BBB permeability prediction, and the recommendation was to combine PAMPA results with efflux data from cell-based adsorption assays. Skin permeability was studied using PAMPA by Ottaviani et al. (2006) and Alvarez-Figueroa (2011). However, for the prediction of skin permeability, the solubility of the solutes should be taken into consideration in addition to the permeability results (Alvarez-Figueroa 2011).

29.1 Introduction

The use of radiolabeled molecules allows a drug and its labeled metabolites to be followed throughout the body and excreta over time. The radioactivity concentration can be tracked in blood and plasma as well as in tissues. Whether the drug with its specific radioactivity administered to the body is completely captured can be proven by calculating the so-called mass balance.

Whereas the radioactivity measurement alone does not allow distinguishing between drug and metabolite(s), samples obtained from the described studies should be also used for standard determination of the drug and its known metabolites, receiving information about the drug and the known metabolite kinetics directly. The gap between radioactivity concentrations and the concentrations determined by direct bioanalytical methods defines the contribution of unknown metabolites.[1]

Using one and the same set of studies with equally withdrawn samples for determination of all radiokinetic and pharmacokinetic data possible is not only economically favorable, but allows illuminating comparisons with a minimum of assumptions and therefore high confidence to interpretation.

Radiokinetic studies deliver the key data of absorption and elimination to which all data and statements of other investigations have to fit—or in case of conflict need a plausible explanation at least.

As examples in the following chapter, the frequently used radiokinetic studies in dogs and rats are described, including placental transfer and milk transfer in rats. Investigations in other species can often be performed similarly. The final choice of species should be done in consensus with toxicology (at a later stage of development including cancerogenicity and segment II studies), regarding the metabolic patterns of in vitro cross-species comparisons and regarding the pharmacological in vivo model.

A suggestion of necessary types of radiokinetic studies and general hints for conducting those animal ADME studies can be found in Campbell and Jochemsen (1994). More insight and aspects regarding mass balance studies are given by Beumer. For general introduction in the mechanisms and physiology of drug absorption, refer to Bermejo or Granero.

29.2 Choice of the Radiolabel

^{14}C is the label of choice for most drugs since it is stable biologically (when the right labeling position is chosen), the detection is comfortable,[2] and in case of combustion of samples, the produced $^{14}CO_2$ can be nicely absorbed quantitatively. ^{3}H labeled drugs are easier to synthesize sometimes, but they are often less stable biologically or at least worse to predict in their biological stability. Because of its much higher specific activity, the ^{3}H-label is favorable in the case of high molecular weight drugs and/or very low doses. ^{35}S, ^{33}P, ^{125}J are used comparatively seldom.

The position of the label should be away from sites chemically unstable or from sites of metabolic attack to ensure that the label is kept in the main metabolic fragments. Of course, this is difficult for complex molecules, especially when the metabolic attack takes part in the center of the drug molecule. Then it can become necessary to introduce a second label and to repeat the set of radiokinetic studies. A double-labeling strategy to minimize the number of radiokinetic studies has normally to be refused due to complexity of interpretation of the data.

A quality control including stability of the radiolabeled drug is mandatory. The chemical degradation and also the radiolysis can be responsible for a short expiry date. The higher the purity and the content of the labeled drug is, the better the results of the radiokinetic studies can be interpreted.[3]

[1]The estimation of the drug absorption (not to be mixed up with bioavailability) using non-radiolabeled drugs and not using the mass balance approach would be much less reliable, since the entity of metabolites cannot be captured in the matrices necessary to be followed, normally.

[2]Half-life of 5,730 year for ^{14}C, making an half-life correction unnecessary. As a weak β – radiator (up to 156 keV) the risk of handling is an acceptable compromise in the laboratory (protection area!).

[3]Imagine the case of a projected nonabsorbable drug, for instance, for topical application, and the situation of having detected 3% absorption with a radioanalytical purity of the labeled drug of 97%. Or imagine the case of a minor part of radioactivity with a long terminal half-life suggesting a metabolite with an accumulation potency. The radioactivity represents the sum of the original compound and/or radioactive-labeled metabolites and not to forget possible synthetic side-products which can be present in traces (depending on the purity and content of the synthetic material). Discussing traces of

The stability and homogeneity of the radiolabeled compound should be tested also in the galenic formulation intended to be used.

29.3 Determination of the Radioactivity Concentration

Radioactivity measurements radioactivity measurements determination of the radioactivity concentration are carried out by the liquid scintillation counting procedure in β-spectrometers using an external standard device which permitted the counting efficiency to be determined by the channel ratio method (explained, for instance, by Dyer (1980)).

Samples are either measured directly after adding a commercial scintillation cocktail[4] or after dissolution and discoloration[5] or after combustion in suitable combustion machines.[6]

A thorough calibration of the β-spectrometer regarding different sample matrices and sizes, the scintillator used, different dissolutions, different colorations of the samples, different amounts of CO_2 after combustion and of course different radioactivity concentrations should be ensured. Calibration and control samples can be set up by using internal standard kits (for instance, ^{14}C-ORG Standard capsules from PerkinElmer).

Blank samples (of every type of matrix) have to be measured in the batches with the study samples. Their mean value can be used as background value to estimate the limit of quantitation.

The definition of the limit of quantitation (LOQ) is handled quite differently. For example, an easy, often used approach is the definition of using the double of the mean blank value as LOQ. This definition sounds simple and a scientific theoretical justification seems not to be available. However, the thus defined LOQ is then a reasonable value when standard deviation (SD) of the blank values is low ($<10\%$, according to own experience). More sophisticated is the following definition: The mean blank value plus 3 times the standard deviation is required for a limit of detection (LOD) and the mean blank value plus 10 times the standard deviation is required for LOQ (see, for instance, Krull (1998)). Outliers can be identified, for instance, by the Grubbs test (for instance, explained in www.graphpad.com).

radioactivity, for instance, traces crossing the placenta, keep in mind that these traces may be due to synthetic side-products. Thus, whenever possible try to use radiolabeled compound as clean as possible.

[4]For instance, in case of urine samples when the quench is in the range of the calibration curve or bile samples.

[5]For instance, with Solvable® from Perkin Elmer for dissolution and H_2O_2 for discoloration.

[6]For instance, with a Tri-Carb® 307 combuster which can be equipped with a robot unit for automatic sample handling from Perkin Elmer. Since carry-over effects are not negligible in case a low radioactivity sample follows a high radioactivity sample, a reasonable arrangement of samples in a sequence is essential.

29.4 Control of Applied Dose

For small animals or dosing of a large number of animals, individual doses are determined by weighing the syringes containing the galenic formulation prior to and after each administration; stability and homogeneity of radioactive formulation is determined on aliquots before and after each series of administration. (The choice of the dose used is matter of opinion and has often to be decided between the (expected or already determined) pharmacodynamically active dose and the NOAEL of the subchronic or chronic safety studies. In the latter case and the oral route, a suspension formulation will be most often applied (also for the purpose of resulting a similar exposure like in safety studies) which has to be characterized chemically and physically (solid state properties) to guarantee reproducibility and comparability to other studies with the drug substance. A second group of animals are often dosed intravenously in parallel. Limited by the necessary dissolution in the i.v. formulation, the doses are lower, normally.)

For individual dosing of larger animals/few animals, the radiolabeled drug is directly weighed in separate devices regarding the individual weight of the animal. All used devices for administration are collected and washed with solvent. The collected solvents are used for back-measurement (dose loss) of radioactivity. The radioactivity found is subtracted from the originally calculated dose.

29.5 Radiokinetics and Mass Balance in Dogs

PURPOSE AND RATIONALE

To evaluate the pattern and the rate of excretion and to investigate the time course of radioactivity concentrations in blood and plasma with the aim of getting information about the absorption process, the AUC, C_{max}, and the elimination half-life of radioactivity in blood and plasma. Possibly, indices for enterohepatic cycle or for metabolites with much different volume of distribution than the original compound may be found. An estimate of the absorption rate comparing dose-normalized AUCs or the renal excretion after i.v. and oral (or any other) administration can be done and a major binding to formed blood elements can be noticeable by comparison of blood and plasma concentrations. Samples for metabolic profiling and metabolite structure elucidation can be collected during this study ideally.

The route of administration projected to be used therapeutically should be applied. If possible—and the solubility of the drug allows—the study should also be performed after intravenous administration. The results of both routes should be compared. Since the oral administration is the most prominent route of administration, this route is described here. The method can be adapted for other routes of administration.

Normally, the radiokinetic study is performed administering a single dose per administration route.

PROCEDURE

Three healthy male beagles receive an intravenous dose into a jugular vein or into the vena cephalica antebrachii. After a washout period dependent on the duration of excretion of the drug/metabolites (typically 4 weeks at minimum), the same animals are dosed orally by using a stomach tube. Normally, 5–10 MBq/animal is a sufficient radioactive dose for a ^{14}C-label, in case of ^{3}H about 50 MBq/animal could be used. Up to 168 h after administration, blood, urine, and feces are collected. At each collection time, about 3.5–5 mL of blood are taken for radioanalysis (2–3 aliquots) and for processing plasma for subsequent radio- and bioanalysis and metabolite investigation. The plasma is aliquoted immediately after centrifugation without warm-up.

29.5.1 Proposal for Standard Collection Times

Blood: 0 h (before administration), 0.25 h, 0.5 h, 1 h, 2 h, 3 h, 4 h, 6 h, 8 h, 24 h, 48 h, 72 h, 144 h, 168 h after oral administration and 0 h (before administration), 0.083 h, 0.25 h, 0.5 h, 1 h, 2 h, 3 h, 4 h, 8 h, 24 h, 48 h, 72 h, 144 h, 168 h after intravenous administration.

Urine: 0 h (before administration), 0–8 h, 8–24 h, 24–48 h, 48–72 h, 72–96 h, 96–120 h, 120–144 h, 144–168 h after administration.

Feces: 0 h (before administration), 0–24 h, 24–48 h, 48–72 h, 72–96 h, 96–120 h, 120–144 h, 144–168 h after administration.

Cage washing: 0–24 h, 24–48 h, 48–168 h after administration.

Radioanalysis is performed by the liquid scintillation procedure either directly after addition of a scintillator (urine, cage washing) or following combustion and addition of a scintillator (blood, plasma, feces).

29.5.2 Details of the Oral Administration

29.5.2.1 Material

- Bulge tube (stomach tube) for oral dosing of dogs (soft, transparent plastic tube with a diameter of about 1 and 60 cm of length)
- Nonreturn valve
- Disposable gloves
- Highly absorbent paper
- Glass funnel
- Bottle with tap water

29.5.2.2 Procedure

The dog is placed on an undersheet and its head is secured by an assistant. The upper and lower jaws are

separated by exerting pressure on the lips with both hands. The stomach tube moistened with mains water is introduced into the open throat. Caution: Do not introduce the tube in the trachea. Pour mains water into the glass funnel fitted on the stomach tube over the nonreturn valve to check that the tube is correctly positioned. If outflow difficulties occur, adjust the position of the tube by moving it slightly backward and forward. Then introduce the test substance to be administered. Then rinse the tube and remove.

29.5.3 Details of the Intravenous Administration into the Vena Cephalica Antebrachii or the Vena Saphena Parva

29.5.3.1 Material

- Curved scissors
- Disposable gloves, Kleenex
- Disposable syringe with formulation for administration with fixed cannula
- Electric hair clippers

29.5.3.2 Procedure

An assistant fixes the dog. The vena saphena parva (hindlimb vein) or the vena cephalica antebrachii is excised from hairs. The vein is compressed using a rubber tubing tourniquet or by firmly encircling the limb with the hand above the vein. Insert the needle of the disposable syringe containing the study substance preparation to be administered into the congested vein, release the tourniquet, and check that the needle is in the correct position by aspirating a small amount of blood into the syringe. Then carefully administer the substance and remove the needle and syringe. Prevent secondary bleeding by exerting pressure on the skin injection site with a Kleenex swab.

29.5.4 Details of Sample Collection of Excreta (Urine, Feces, Cage Washing)

29.5.4.1 Material

- Metabolism cage
- Two liter urine collection container (cooled)
- Dash bottles containing warm mains water
- Polyethylene bottles in various sizes
- Labels, plastic feces scraper, large glass beaker or polyethylene bag, disposable gloves, Kleenex, scrubbing brush with handle, cooling device for the urine tube
- Mixer

29.5.4.2 Procedure

The urine is collected according to the preinstructed collection intervals directly from the urine collection container of the metabolism cage. The samples are weight and directly after stirring and homogenizing the urine, aliquots are taken for radioanalysis. The remainder is bottled and frozen for additional investigations planned (metabolite profile and identification and/or bioanalysis).

The feces are collected from the sitting device and the ground plate using the plastic scraper. In case of direct processing of the feces sample, the feces are collected in a weight glass beaker. In case a direct processing is not possible, the feces are collected in a weight plastic sac and are frozen.

The weights are determined and registered as raw data. To homogenize the feces each sample is diluted with demineralized water—according to the consistence with the two- to four-fold of the feces weight. The weight of the filled bottle is determined and the data stored until evaluation.

The sample with the mixture of feces and distilled water is homogenized with a mixer which should be cleaned rigorously before using it again and which is proven to be without contamination.

For preparation of samples for combustion, preweighted combustion cones were filled with an appropriate amount of homogenate (typically about 250 mg). The combustion cones and covers including the homogenate are weight again and the data stored until evaluation.

The cage washing is done after removal of feces and urine with the help of warm tap water dash bottle (about 2 L). Cleaning of the cage is done with the scrubbing brush starting with the walls, the sitting device, and followed by the ground plate. The fluid is weight and after thorough mixing, aliquots are filled in scintillation cups for radioactivity measurement.

29.5.5 Details of Sample Collection (Blood, Plasma)

29.5.5.1 Material

- Monovets with sine use cannulas (butterfly)
- Tourniquet loop

- Disposable gloves, Kleenex, hair clipper
- Needle, needle holder, surgical suture material, scissors, protective collar for dogs, antibiotic powder

29.5.5.2 Procedure

The site for blood collection has to be different from the site of intravenous administration. Thus, the vena cephalica antebrachii can be used for collection and the vena saphena parva for administration (or vice versa). The dog is kept by one person and the hairs at the selected veins at the forelimbs or hindlimbs are removed by gently clipping. The vein on the dog's limb is compressed by the assistant by encircling the limb with the hand or applying a rubber tourniquet loop. The puncture procedure is then performed. Blood should be withdrawn slowly by aspirating gently.

When the monovet is sufficiently filled, remove the compression and withdraw the needle. Secondary bleeding is prevented by immediately exerting compression on the puncture site with a Kleenex swab.

29.5.6 Alternative Route for Blood Sample Collection

A favorable, safe method for multiple blood collection is a permanent catheter in the vena jugularis. The dog is fixed in a frame with a hammock. An assistant fixed the head upward, slightly stretched to the opposite site to which the vein puncture should be done. The animal's neck is shaved with clippers over the jugular vein and wiped with a commercial skin disinfectant solution. After applying the tourniquet loop at the base of the neck, the jugular vein is clearly prominent. The jugular vein is then fixed between two fingers and punctured toward the heart with a split needle. The catheter is located inside the split needle and, as soon as blood is visible, is inserted into the vein. The split needle is then carefully withdrawn and opened. The base of the catheter is secured to the skin with surgical suture material. After the syringe has been inserted, aspirate until blood is visible in the syringe. Then rinse out the catheter with sterile physiological sodium chloride solution (about 2 mL). The correct position of the catheter can be checked by repeating this operation if required. Then seal the base of the catheter with a closure cap. To prevent obstruction when pronounced coagulation occurs, a drop of anticoagulant can be added to the NaCl solution.

For restless animals, the catheter can be prevented from being removed by the dog by fitting with a protective collar of the type commonly used in veterinary practice. Dusting the puncture site and fixation suture with antibiotic powder prevents inflammation.

Catheter insertion should be carried out under the most aseptic conditions possible.

Before blood sampling, the physiological saline solution has to be removed from the catheter using a syringe. This is done by withdrawing 0.5 mL from the catheter before collecting the actual sample with the prepared monovet. After blood collection, the catheter is rinsed and filled again with about 2 mL of physiological sodium chloride solution.

For generating plasma, part of the collected blood is transferred into a centrifuge tube and treated in the centrifuge with 1,500 G.

29.5.7 Animal Maintenance

During the study period, the animals are maintained on metabolism cages, one in each cage with a separating device for urine and feces, allowing to collect the excreta separately. Conventionally, these cages consist of several parts which have to be cleaned carefully before assembling (box, device for sitting, food, water, urine collection). It has shown to be favorable to control the cleanness by rinsing the cage with an alcohol-water mixture and subsequent determination of radioactivity of the rinsing solution.

Before study start, the animals should have time for acclimatization, depending on the extent of changes in the surroundings and the type and duration of transport. In case of a maintenance in a lab in the neighborhood under similar conditions as in the study, an acclimatization time of at least 1–2 days might be sufficient.

The feed (500 g commercial pelleted diet about noontime, such as ALLCO Vollkost Menü or sniff® Spezialdiäten GmbH; D-59494 Soest, Deutschland) and tap water ad libitum is given about 20 h before administration.

Following conditions should be controlled throughout the study duration:

- Room temperature
- Lighting time

Proposed values for these conditions (according to the guideline 2010/63/EU of the European Parliament

and the Council, Sept 22 2010 and the recommendation 2007/526/EG of the Commission, June 18 2007):

- Room temperature: 15–21°C
- Lighting time: 6°am–6°pm (light), 6°pm–6°am (dark)

EVALUATION

The concentrations of radioactivity expressed as µg equivalents of drug per g of matrix (µg equiv./g) and alternatively as part of dose eliminated (% administered dose) are determined in each matrix and collection interval.[7] The temporal course of the excretion and the radioactivity concentration in blood and plasma are represented by graphs[8] and tables using either Windows Excel function, a specific pharmacokinetic software program (like WinNONLIN; www.pharsight.com) or using the laboratory management system in case the functionality is given directly (such as DEBRA from LabLogic Systems Ltd. Sheffield England www.lablogic.com). The software also allows calculation of the half-lives of radioactivity elimination via urine and feces (when appropriate),[9] to generate cumulation plots or general survey plots like bar diagrams (see "Example").

In case that an essential part of dose is excreted via urine, an estimation of absorption is often done giving the ratio of urine excretion (oral/intravenous) as absorption rate. It should be compared with the ratio of the dose-normalized plasma AUCs (oral/intravenous).

All these data are finally drawn together for detailed discussion and evaluation. Special attention has to be taken on major differences of data following intravenous and oral administration.

An essential requirement for the quality of the study is a balance value near to 100%. A value >95% and <105% is reasonable. Balance values of 90–95% or 105–110% are often accepted too, but they should indicate the investigator that something might run out of control or the process/handling could be optimized. Balances much worse than those should be explained.

In case an essential concentration is available in blood and plasma at early time points after oral administration (may be C_{max} is reached soon also), a rapid onset of absorption can be stated.

When there is no continuous decline of concentrations after intravenous administration, this might be an indication for:

- An inappropriate administration or a precipitation of the drug from the formulation at the application side or just behind the side in the blood stream. This might be the case when there is a plateau concentration or even an increase at early collection times.
- An enterohepatic circulation when a side maximum exists (time depending on absorption and elimination rate, often seen 4–8 h after administration).
- One or more of the generating metabolites have a much smaller volume of distribution than the original drug.
- Other (often more complex) explanations.

In case of a drug concentration ratio (in plasma/blood) distinctly lower than expected from hematocrit, a binding of the drug or its metabolites to formed blood elements is indicated.[10]

CRITICAL ASSESSMENT OF THE METHOD

Always keep in mind that the radioactivity represents the sum of the original compound and/or radiolabeled metabolites and not the drug itself. Therefore, it is worthwhile to determine also the drug and known metabolites directly by bioanalytical methods with samples withdrawn from the same study.

[7] It might be necessary to use a normalized apparent collection interval for graphical reasons in case of dissimilar collection intervals.

[8] Instead of the collection interval, the mean time of the collection period is often used in the graphic presentations.

[9] Via determination of the rate constant which is calculated by linear regression of ln concentration on time using a least three data points which appeared to be randomly distributed about a single straight line. Half-lives were calculated as ln2/rate constant.

[10] The following equation describes the percent of total radioactivity in plasma relative to total radioactivity in blood

$$\text{Plasma/Blood}\,(\%) = \frac{(V_B) \times (P \times [1 - HCT])}{(V_B \times B)} \times 100 = \frac{P \times (1 - HCT)}{B} \times 100$$

where
V_B = volume of blood
P = drug concentration in plasma
B = drug concentration in blood
HCT = hematocrit

The comparison of both, the radioactivity concentrations and the sum of concentrations determined by specific methods, allows estimation of the gap (of unknown metabolites) which often develops time-dependently: For instance, at the beginning of the study (after intravenous administration), radioactivity concentrations in plasma should fit to the drug concentration. Usually, the gap (as a percentage of the total radioactivity at a certain time point) between both concentrations increases with time.

The estimation of absorption via the ratio of dose-normalized plasma AUCs (of radioactivity) after oral and intravenous administration is based on the assumption that:

1. A first pass effect including an instant excretion via bile does not exist.
2. The metabolic pattern is comparable independent of the route of administration.[11]
3. The distribution (drug and metabolites) and the metabolism in special tissue are not effected by the bolus i.v. administration with high initial concentrations (see, e.g., Chiou (1989)).
4. Dose-exposure linearity exists (under a more stringent view even a first order kinetic is demanded).

When these criteria are not fulfilled, then either the absorption can be underestimated (for instance, when precondition (1) is not true (2) or distinctly overestimated up to a calculated "super-absorption" for more than 100% (possible, for instance, when precondition (3) or (4) are not true)).

Only AUCs obtained from the same "type of blood" samples should be used. For instance, do not compare central arterial blood with venous peripheral blood (Chiou 1989) as long as one is not sure that both are virtually comparable.

Certainly, every radiokinetic as well as any in vivo pharmacokinetic study depends on the galenic formulation used. Aqueous solutions, solutions with organic water-miscible components, solutions with surfactants, emulsions, microemulsions, or suspensions can be responsible for distinct differences of radiokinetics (pharmacokinetics). Therefore, a conscious choice of galenic vehicle and formulation procedure is critical!

MODIFICATIONS OF THE METHOD

The radiokinetic and mass balance study can also be applied to other non-rodent species.[12] The framework is similar to the study described above. Often monkeys, mini-pigs, and rabbits are used. Instead of or additional to the oral administration, the method can be adopted to other routes of administration.

Similar basic procedures including evaluation are described by Webber et al. (2004); additionally, the investigation of biliary excretion and tissue distribution was integrated within the study.

Blood collection from the femoral artery is mentioned by Davis et al. (1994) after surgically preparing vascular access ports to the femoral artery. Using dogs with surgically instrumented indwelling venous access ports into the femoral vein and using a 6-min infusion instead of an intravenous bolus injection is mentioned by Krishna et al. (2002). Occasionally, such a short-term infusion is recommended instead of a bolus intravenous administration (Chiou 1989, p. 283). The advantage is to avoid high blood concentrations shortly after intravenous administration which may be in conflict with the assumed linear dose-exposure relationship (validity of linear relation at border concentration?). The advantage of the intravenous bolus injection is the lower/shorter stress situation for the animals (and may be also for the experimenter) which might influence the reproducibility of the study results.

Sometimes several dose levels are investigated with the described method: a low dose for which a pharmacological response is expected or a possible much higher dose at the NOAEL (for concomitant metabolic profiling and estimation of metabolite/drug concentration ratios at this relevant level of exposure). In the case of evaluation of altered routes of elimination at toxic doses, studies with doses and retrieving toxic metabolites higher than NOAEL may considered as an exception.

Determination of blood, plasma, and feces samples not using combustion but either direct measurement (plasma) or solubilizing and de-coloration, the samples is mentioned, for instance, by Okuyama et al. (1997).

---

[11] An example where this assumption is not fulfilled is described by Okuyama et al. (1997); consequently the authors only mention the ratio of AUCs after oral and intravenous administration and do not correlate this ratio to absorption.

[12] Mass balance results in rats, mice, dogs, monkeys, and humans after administration of the same drug, including bile excretion results from rat, dog, monkey, and human (!), are described by Donglu Zhang.

EXAMPLE

AVE 3559 was developed for the treatment of obesitas. It was ^{14}C-labeled and investigated in a dog radiokinetic study to determine the time course of radioactivity concentrations in blood/plasma and to determine the pattern and rate of excretion, the residual concentrations at the end of the study, 168 h after administration, and the mass balance following oral and intravenous route of administration.

Three healthy male Harlan beagles weighing 15–16 kg received an approximate dose of 10 mg/kg ^{14}C-AVE 3559 orally by using a stomach tube (exact weights and doses see table). The identical animals received approximately 2 mg/kg ^{14}C-AVE 3559 into a jugular vein 5 weeks following the oral administration. The pharmaceutical preparation used for both the oral and intravenous route was a solution in transcutol/water (25/75 w/w). The drug concentration in the formulation was about 2 mg/g. Thus, the animals received about 75-g formulation orally and 15 g intravenously. The radiolabeled drug was blended with non-labeled drug in such a way that each dog received about 7.5 MBq radioactivity.

Blood, urine, and feces were collected as described above. The remaining parts of samples were used for bioanalysis and metabolism studies.

Three aliquots from each (processed) sample were used for radioactivity determination. The aliquots from the urine samples were measured directly in the liquid scintillation counting procedure after addition of the scintillator Roth-rotiszint eco plus (Roth, Karlsruhe, Germany). The other matrix aliquots taken up on Combusto Cones (Perkin Elmer), weighed, dried at room temperature, were combusted in a Tricarb® combuster (Perkin Elmer, Model 307) and the $^{14}CO_2$ formed was absorbed by Carbo-Sorb® (Perkin Elmer). The subsequent radioactivity measurements were carried out by the liquid scintillation counting procedure in a β-spectrometer (Perkin Elmer2500 TR) after addition of the scintillator Permafluor E+® (Perkin Elmer).

29.5.8 Evaluation and Discussion

As an example for the numerous generated graphs, the time course of the mean radioactivity blood and plasma concentration values (including standard deviation) after intravenous and oral administration is given in the summary graph (Fig. 29.1). Additionally, the mean amounts of dose excreted in urine and feces depending on time after administration is given in Fig. 29.2.

The pharmacokinetic values were calculated by the pharmacokinetics software WinNonlin, and were summarized in Table 29.1.

Already 15 min after oral administration mean radioactivity concentrations of 5.60 μg equiv./g (range: 3.9–7.4 μg equiv./g) and 8.47 μg equiv./g (range 5.8–11.1 μg equiv./g), respectively, were present in blood and plasma indicating a rapid onset of absorption. C_{max} was interindividually different (see table) and reached 0.5–4 h after administration. The mean maximum concentrations amounted 8.4 μg equiv./g in blood and 11.7 μg equiv./g in plasma. The AUCs (until the last concentration point) amounted to mean values of 178 μg equiv./g × h for blood and 254 μg equiv./g × h for plasma.

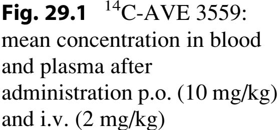

Fig. 29.1 ^{14}C-AVE 3559: mean concentration in blood and plasma after administration p.o. (10 mg/kg) and i.v. (2 mg/kg)

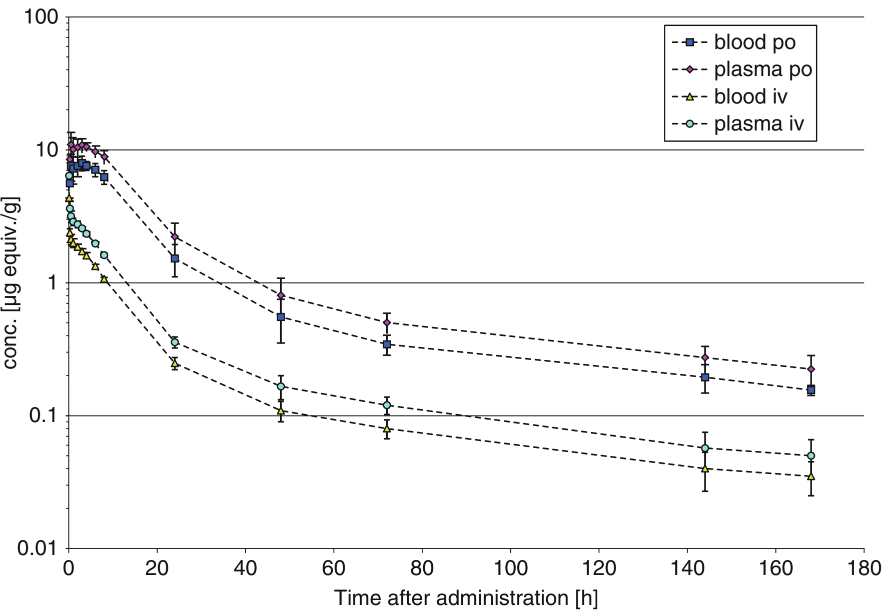

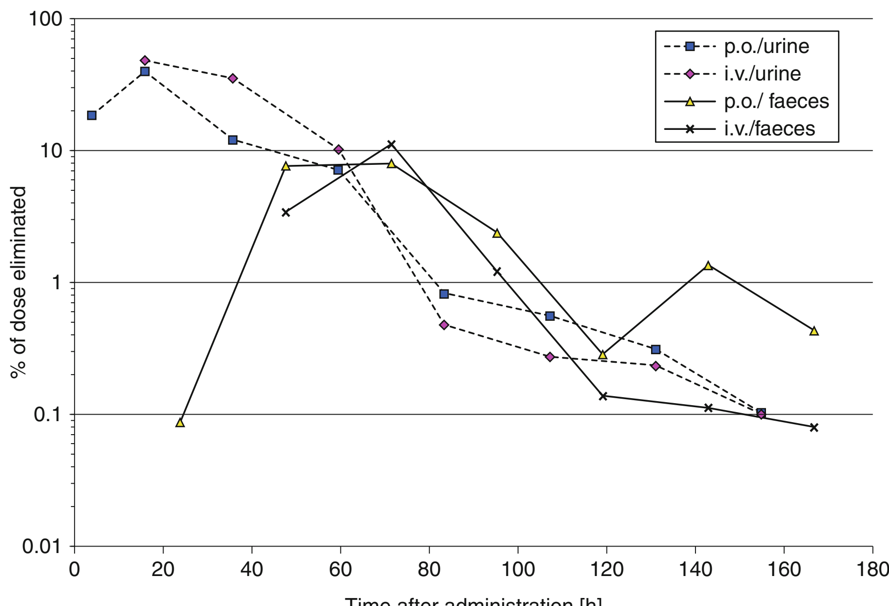

Fig. 29.2 ^{14}C-AVE 3559: mean% of dose eliminated via urine and feces after administration p.o. (10 mg/kg) and i.v. (2 mg/kg)

After reaching peak concentrations, the radioactivity was eliminated in a first elimination phase with mean half-lives of 8.1 h from blood and 8.4 h from plasma and with mean half-lives of about 84 h from blood and plasma in a terminal elimination phase.

These half-lives correspond to the elimination processes and half-lives found after intravenous administration with mean half-lives of 7.3 and 7.5 h in blood and plasma for the first elimination process and 71 and 74 h for the terminal elimination phase. Mean C_{max} values 5 min after administration were 4.3 and 6.4 µg equiv./g. The mean AUCs (until last concentration point) amounted 34.8 and 52.7 µg equiv./g $\times$ h.

Table 29.1

Route of administration	Oral				Intravenous

The higher plasma than blood concentrations at all measuring points (especially at the last measuring time points) after oral and intravenous administration make a strong binding of a radioactive component (drug or metabolite) to blood cells in dog unlikely.

After both routes of administration, the main part of the administered radioactivity was excreted renally with means of 79% and 81% (oral and intravenous route). In the feces, an average of 17% after oral and 15% after intravenous administration were found.

The recovery rate after oral administration amounted to a mean of 99%. Following intravenous administration the mean balance was 98%.

An absorption of radioactivity between 88% and 97% based on plasma AUC could be calculated. Based on urinary excretion data a mean absorption rate of 98% could be computed.

29.6 Mass Balance Study in Rats

PURPOSE AND RATIONALE

To evaluate the pattern and the rate of excretion, the residual concentration of the drug in the body 1 week after administration, and the estimation of the absorption in case of a relevant renal excretion. The kind of study is obligatory for the registration as a drug when the rat is chosen as the rodent model (in toxicology or as a relevant pharmacological model[13]).

The route of administration projected to be used therapeutically should be applied also in the mass balance study. If possible and solubility allows, the study should also be performed after intravenous administration and the results of both routes should be compared. Since the oral administration is the most prominent route of administration, this route is described here. The method can be adapted for other routes of administration.

Normally, the mass balance study is performed administering a single dose per administration route. In case of extraordinary circumstances, for instance, when there is a suspicion of an accumulation of any metabolite, a mass balance with repeated dosing can be considered.

The study is performed separately from the radiokinetics blood/plasma study in rats not to influence the results by collecting blood during the study course.

PROCEDURE

29.6.1 Animal Study Part

Out of eight healthy male Sprague Dawley rats weighing about 200 g corresponding to an age of 6–10 weeks, four rats receive an oral dose of the radiolabeled drug by using a stomach tube (typically 10 mg/kg body weight; 2 mg/g formulation; total radioactivity of about 1–2 MBq/animal in case of ^{14}C-label). Four other animals receive an intravenous dose into a tail vein (typically 2–5 mg/kg body weight). In this description the i.v. and oral administration is described in more detail.

29.6.1.1 Material for Oral Administration

- Bulge tube (stomach tube) for oral dosing of rats
- Syringes
- Undersheet and disposable gloves
- Drug formulation

29.6.1.2 Procedure of Oral Administration

- The drug formulation is transferred into a syringe with the bulge tube put on the top of the syringe.
- The rat is held tight on its neck above the undersheet.
- Slightly turning, the bulge tube is introduced into the throat of the animal.
- Syringe content is administered intra-gastrally.
- If appropriate a rinsing solution might follow the drug administration.

29.6.1.3 Material for Intravenous Administration into the Tail Vein

- Fixation tube for rats adjusted to the size of the rat
- Electrically warmed and controlled water bath (42°C)
- Kleenex, cellulose, disposable gloves
- Syringe containing the formulation (solution!) for administration
- Syringe with pyrogen-free, physiological saline solution
- Vein-dwell-cannula consisting of Teflon (about 0.8-mm diameter)

29.6.1.4 Procedure for Intravenous Administration

- The rat is placed into the fixation tube. The tail of the animal is fixed outside the tube.
- The tail is put into the water bath with a constant temperature between 40°C and 42°C.
- This procedure causes the appearance of the tail vein without burdening the animals.
- The vein is punctured with the dwell-cannula so that blood at the end of the leading-cannula appears. During extracting, the leading-cannula blood should also arrive in the dwell-cannula.
- For additional control of the correct position of the dwell-cannula, 0.2–0.3 mL of physiological saline solution is administered. The administration has to occur easily, the aqueous saline solution has to flow into the vein immediately.

[13]For an example of a mass balance study in mice (besides rat and dog) refer to Miraglia L.

- The syringe is changed cautiously by the syringe containing the drug formulation. The content is administered.
- Also this syringe is changed cautiously against a second syringe containing physiological aqueous saline solution. Again 0.2–0.3 mL is administered to transfer the formulation which rested in the cannula completely into the body.

Note: To avoid an injury of the tail vein, all the administrations should be conducted with caution.

29.6.2 Animal Maintenance

During the study period, the animals are kept in metabolism cages, one in each cage with a separating device for urine and feces, allowing collection of the excreta separately. Conventionally, those cages consist of several parts which have to be cleaned carefully before assembling (cage cylinder, device for sitting, funnel and separation device, cover, drinking bottle, tubing to the food vessel, and food vessel). It has shown to be favorable to control the cleanliness by rinsing the cage with an alcohol-water mixture and subsequent determination of radioactivity of the rinsing solution.

Before study start, the animals should have time for acclimatization (default 7 days), depending on the extent of changes in the surroundings and the type and duration of transport. In case of a maintenance in a lab in the neighborhood under similar conditions as in the study, an acclimatization time of at least 1–2 days might be sufficient. In case of longer transport or from a different environment, acclimatization times up to 14 days can become necessary. One animal is housed per metabolism cage.

Before administration of the drug, the animals should have an empty stomach but not go hungry, so that the food is withdrawn 3–4 h before the administration in the morning (for instance, achieved by a timer-controlled unit withdrawing the food). The feed (commercial pelleted diet, for instance, sniff® Spezialdiäten GmbH; D-59494 Soest, Deutschland) and tap water is provided ad libitum.

Following conditions should be controlled throughout the study duration: room temperature, relative humidity, lighting time.

Proposed values for these conditions (according to the guideline 2010/63/EU of the European Parliament and the Council, Sept 22, 2010 and the recommendation 2007/526/EG of the Commission, June 18 2007):

- Room temperature: 20–24°C
- Relative humidity: 45–65%
- Lighting time: 6 am–6 pm light, 6 pm–6 am (dark)

Animal identification has to be ensured, e.g., by permanent marking on the tail root with the animal number. Prior to the start of the study, the animals have to be assessed and have to show no clinical abnormalities.

29.6.3 Collection and Sample Preparation of Excreta

29.6.3.1 Material for Collection of Urine, Cage Washing, and Feces

- Clear collection of excreta plastic bottles (100 mL) with covers, with appropriate labeling and registered tare weight (e.g., entered in LIMS)
- Bottles for spraying deionized water
- Precision balance
- Kleenex, disposable gloves
- If necessary: cooling device and light protection box
- Ultra-Turrax® or mixer

29.6.3.2 Urine Collection

Typical collection intervals are: 0–8 h, 8–24 h, 24–48 h, 48–72 h, 72–96 h, 96–120 h, 120–144 h, 144–168 h after administration.

During each collection interval, the excreted urine is collected from the separation device in a labeled plastic bottle. To collect also the dried adherent parts of the urine on the surface, all contaminated devices are rinsed with deionized water until the clear plastic bottles are filled to about three-quarters. The weight of the filled bottle is determined and the data stored until evaluation.

29.6.3.3 Cage Washing

Typical collection intervals are: 0–24 h, 24–48 h, 48–168 h after administration.

At predetermined occasions, additional washings of the cage are performed. The collection is done during the change of the bottles containing the urine. When necessary (in case of very hydrophobic drugs or metabolites) the rinsing fluid may contain organic, water-miscible fluids. The cage washing samples are treated in the same way like the urine samples.

29.6.3.4 Feces Collection and Sample Preparation

Typical collection intervals are: 0–24 h, 24–48 h, 48–72 h, 72–96 h, 96–120 h, 120–144 h, 144–168 h after administration.

During each collection interval, the excreted feces pellets are collected from the separation device in a labeled plastic bottle. The weights are determined and registered as raw data. To homogenize the feces each sample is diluted with demineralized water, according to the consistency with the two- to four-fold of the feces weight. The weight of the filled bottle is determined and the data stored until evaluation.

The sample with the mixture of feces and distilled water is homogenized with the Ultra-Turrax® intensively. The Ultra-Turrax® should be cleaned rigorously before using it again.

For preparation of samples for combustion, pre-weighted combustion cones were filled with an appropriate amount of homogenate (typically about 250 mg). The combustion cones and covers including the homogenate are weighed again and the data stored until evaluation.

29.6.4 Preparation of the Carcass

29.6.4.1 Material

- Standard commercial small meat mincer
- Ultra-Turrax® (e.g., from Ika, Staufen, Germany)
- Precision balance
- Evaporation basins, scissors, pincer, spatula, Kleenex, disposable gloves, plastic bottles, or glass bottles

29.6.4.2 Procedure

After exsanguination/killing any organs and tissues of each rat planned to be investigated separately are removed and stored in a pre-weighed small evaporation basin. The rest of the body is ground with the meat mincer. In order to minimize the residues in the mincer, three Kleenex wipes are ground in the mincer afterward and are added to/in evaporation basin. The mincer is disassembled and residuals are removed with pincer and spatula. The residuals are added also to the evaporation basin. To homogenize the residues, each sample is diluted with deionized water, according to the consistency with the two- to four-fold of the carcass weight and mixed intensively with the Ultra-Turrax®. The Ultra-Turrax® should be cleaned rigorously before using it again. All weights have to be registered thoroughly. The weights of the removed organs and the blood of exsanguination also have to be collected.

For preparation of samples/aliquots for combustion, pre-weighted combustion cones (as from Perkin Elmer) are filled with an appropriate amount of homogenate (typically about 250 mg) or blood/plasma of exsanguination. The combustion cones and covers including the homogenate are weight again and the data stored until radioanalytical evaluation.

Radioanalysis is performed by the liquid scintillation procedure either directly after addition of a scintillator (urine, cage washing) or following combustion and addition of a scintillator (carcass, blood, plasma, feces).

EVALUATION

The concentrations of radioactivity expressed as μg equivalents of drug per gram of matrix and alternatively as part of dose eliminated (in percentage of the administered dose) are determined in each matrix and collection interval.[14] The temporal course of the eliminated parts of excretion is represented by graphs[15] and tables using either Windows Excel function, a specific software program like Winnonlin (www.pharsight.com) or using the laboratory management system in case the functionality is given directly (such as DEBRA from LabLogic Systems Ltd. Sheffield England www.lablogic.com). They also allow calculation of the half-lives of radioactivity elimination via urine and feces (when appropriate),[16] to generate cumulation plots or general survey plots like bar diagrams (see “Example”).

These data and the radioactivity in carcass, blood and plasma of exsanguination, special organs/tissues, cage washing, and the balance are finally drawn together for detailed discussion and evaluation.

[14] It might be necessary to use a normalized apparent collection interval for graphical reasons in case of dissimilar collection intervals.

[15] Instead of the collection interval, the mean time of the collection period is often used in the graphic presentations.

[16] Via determination of the rate constant which is calculated by linear regression of ln concentration on time using a least three data points which appeared to be randomly distributed about a single straight line. Half-lives were calculated as ln2/rate constant.

Special attention has to be taken on major differences of data following intravenous and oral administration.

In the case that an essential part of dose is excreted via urine, an estimation of absorption is often done giving the ratio of urine excretion (oral/intravenous) as absorption rate.

An essential requirement for the quality of the study is a balance value near to 100%. A value >95% and <105% is reasonable. Balance values of 90–95% or 105–110% are often accepted as well, but they should indicate the investigator that something might run out of control or the process/handling could be optimized. Balances much worse than these should be explained.

CRITICAL ASSESSMENT OF THE METHOD

Always keep in mind that the radioactivity represents the sum of the original compound and/or radiolabeled metabolites and not the drug itself. Therefore, it is worthwhile to determine also the drug and known metabolites directly by bioanalytical methods with samples withdrawn from the same study. The comparison of both the radioactivity concentrations and the sum of concentrations determined by specific methods allows the estimation of the gap which often develops time-dependently: For instance, in the beginning of the study, radioactivity concentrations in plasma should fit to the drug concentration. Usually, the gap (as percentage of the total radioactivity at a certain time point) between both concentrations increases with time.

The estimation of absorption based on the urine excretion ratio (oral/intravenous) should be compared with the ratio of dose-normalized plasma AUCs after i.v. and oral administration from the rat radiokinetic study. In case of major differences between both methods of absorption determination, a thorough investigation/discussion of a route of administration-dependent metabolism and/or volume of distribution might help to explain the apparent discrepancy.

Both methods of absorption calculation mentioned are based on the fact that after absorption the drug/metabolites reach the central circulation. In case of oral administered drugs targeting the liver and being eliminated biliary instantly, it is obvious that both methods mentioned fail. In such a special case, an absorption estimation might be possible via a biliary excretion study.

Certainly, every radiokinetic as well as any in vivo pharmacokinetic study depends on the galenic formulation used. Aqueous solutions, solutions with organic water-miscible components, solutions with surfactants, emulsions, microemulsions, or suspensions can be responsible for very distinct differences of radiokinetics (pharmacokinetics). Therefore, a conscious choice of galenic vehicle and formulation procedure is critical!

MODIFICATIONS OF THE METHOD

Instead of or additional to the oral administration the method can be adopted to subcutaneous, inhalation, intratracheal or dermal route (as, for instance, described by Dix et al. (2001), Simonsen et al. (2002), Mathews (1998), Koyama (2010), Hoffmann (2010), Gledhill (2005)), or any other route of administration.

Sometimes several dose levels are investigated with the method described: a low dose for which a pharmacological response is expected or a possible much higher dose at the NOAEL (for concomitant metabolic profiling and estimation of metabolite/drug concentration ratios at this relevant level of exposure). In case of evaluation of altered routes of elimination at toxic doses and retrieving toxic metabolites, studies with doses higher than NOAEL may be considered as exception. Determination of blood, plasma and feces samples not using combustion but either direct measurement (plasma) or solubilizing and de-coloration of the samples is mentioned, for instance, by Okuyama et al. (1997) or Mathews et al. (1998).

The in situ absorption from different segments of the gastrointestinal tract by dosing the radiolabeled drug directly into "digestive tract loops" is explained by Mano et al. (2004) to get information about the ability for absorption along the different parts of the gut.

EXAMPLE

HMR 1556 was a drug candidate developed for treatment of hypertension. It was ^{14}C-labeled and investigated in a rat mass balance study to determine the pattern and rate of excretion, the residual concentrations at the end of the study, 168 h after administration, and the mass balance following oral and intravenous route of administration.

29.6.5 Choice of Formulation

Because of low solubility of the compound in pure water, for the oral administration, a suspension in an aqueous solution of hydroxyethylcellulose (0.5%) was used. The solid state physical parameters (particle size, surface area, amorphicity, and crystal modification) and the suspension properties (agglomeration tendency, homogenicity, and dissolved part of the drug) had to be investigated. For the intravenous administration, an aqueous solution containing saline, DMSO, and PEG 400 was used as formulation.

29.6.6 Animal and Radioanalytic/Kinetic Study Part

Of 8 healthy male Sprague Dawley rats weighing between 187.4 and 197.6 g, four animals received an approximate dose of 10 mg ^{14}C-HMR 1,556/kg body weight orally by using a stomach tube. Four other animals received a dose of approximately 5 mg/kg intravenously into a tail vein. For further details, see Table 29.2. Urine samples (0–8 h, 8–24 h, 24–48 h, 48–72 h, 72–96 h, 96–120 h, 120–144 h, 144–168 h after administration), feces samples (0–24 h, 24–48 h, 48–72 h, 72–96 h, 96–120 h, 120–144 h, 144–168 h after administration), cage washings (0–24 h, 24–48 h, 48–168 h after administration), blood and plasma samples after exsanguination and carcass were collected and weighed as described above. Three aliquots from each (processed) sample were used. The aliquots from the urine samples were measured directly in the liquid scintillation counting procedure after addition of the scintillator Roth-rotiszint eco plus (Roth, Karlsruhe, Germany). The other matrix aliquots were combusted in a Tri-Carb® 307 combuster (Perkin Elmer, Model 307) and the $^{14}CO_2$ formed was absorbed by Carbo-Sorb® (Perkin Elmer). The subsequent radioactivity measurements were carried out by the liquid scintillation counting procedure in a β-spectrometer (Perkin Elmer 2500 TR) after addition of the scintillator Permafluor E+® (Perkin Elmer).

29.6.7 Evaluation and Discussion

As an example for the numerous generated graphs, the linear cumulation plot (% of dose amount excreted) and the semilogarithmic plot of drug amount (given as dose amount excreted during a 24-h interval) excreted in urine depending on time after intravenous administration is given in Fig. 29.3a, b.

After the oral administration of approximately 10 mg ^{14}C-HMR 1,556/kg body weight, between 42.8% and 50.8% (mean 46.05%) of the administered radioactivity was excreted via the urine (including cage washings). In the feces, between 46.9% and 58.3% (mean 51.2%) was found. After the intravenous administration of approximately 5 mg ^{14}C HMR 1,556/kg body weight, between 52.3% and 63.9% (mean 56.9%) of the administered radioactivity was excreted via the urine (including cage washings). In the feces, between 33.4% and 43.2% (mean 38.6%) was found.

Study objectives	Mass Balance Excretion via urine and faeces Residues in carcass							

The calculated absorption rate based on the comparison of the urine excretion after oral and intravenous administration amounted to approximately 80%.

The calculated half-lives for the renal elimination amounted to a mean of 12.2 h (oral dose) and 9.0 h (intravenous dose). The fecal elimination took place with mean half-lives of 10.3 h and 8.8 (oral and intravenous dosing).

After both routes of administration, only very low amounts of the total radioactivity administered were to be found in the carcasses and blood of exsanguination (0.2%).

The recovery rate after oral administration of approximately 10 mg/kg body weight amounted to a mean of 97.4%. Following intravenous administration of approximately 5 mg/kg, the mean balance was 95.7%.

The main results are summarized in Fig. 29.4 and Table 29.3.

29.7 Blood/Plasma Radiokinetics in Rats

PURPOSE AND RATIONALE

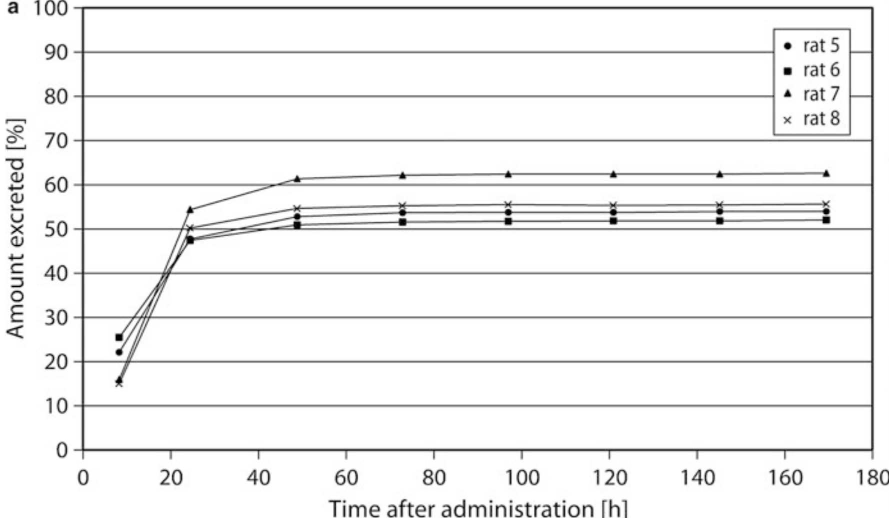
Investigate the time course of radioactivity concentrations in blood and plasma with the aim to getting information about the absorption process, the AUC, C_{max}, and the elimination half-life of radioactivity in blood and plasma. Possibly indices for enterohepatic cycle or for metabolites with very different volume of distribution from the original compound may be found. An estimate of the absorption rate comparing dose-normalized AUCs after i.v. and oral (or any other) administration can be done and a major binding to formed blood elements can be noticeable by comparison of blood and plasma concentrations.

This type of study is obligatory for the registration as a drug when the rat is chosen as rodent model (in toxicology).

Since the oral administration is the most prominent route of administration, this route is described here. The method can be adapted for other routes of administration. If possible, and solubility allows, the study should also be performed after intravenous administration and the results of both routes should be compared.

Normally, the radiokinetic study is performed administering a single dose per administration route.

The study is performed separately from the mass balance study in rats, in order not to influence the balance by collecting blood during the study course.



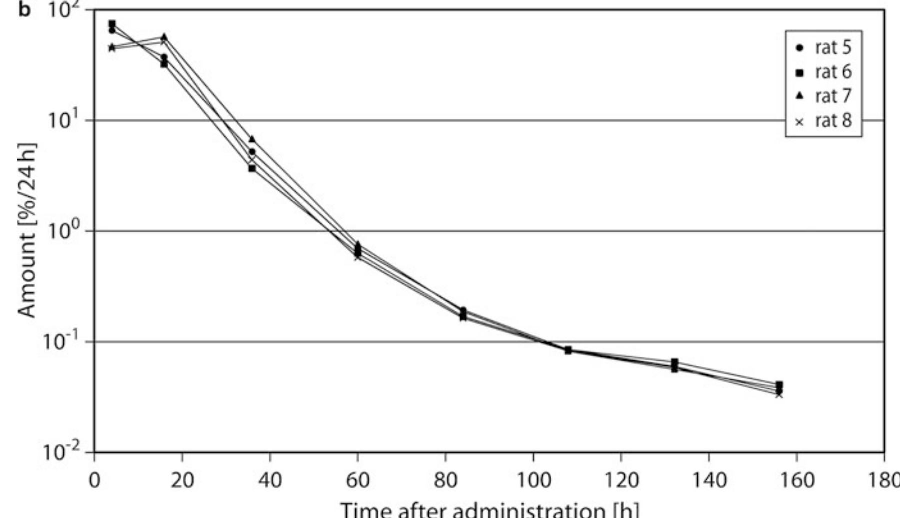


Fig. 29.3 ^{14}C-HMR 1556: excretion via urine following intravenous administration of approx. (**a**) cumulative plot (**b**) amount (%/24 h)

PROCEDURE

29.7.1 Animal Study Part

The radiolabeled drug is administered to 54 healthy Sprague Dawley rats per gender (weighing about 200 g corresponding to an age of 6–10 weeks); 27 animals receive an oral dose by stomach tube (for instance, 10 mg/kg bw) and 27 animals receive an intravenous dose into a tail vein (for instance, 1–5 mg/kg; total radioactivity of about 2 MBq/animal in case of ^{14}C-label).

The administration and the animal maintenance can/may follow the procedure and description given for oral and intravenous administration of the mass balance study.

29.7.2 Collection and Sample Preparation

29.7.2.1 Material

- Box for anesthesia with Isofluran
- Scalpel
- Disposable gloves
- Small evaporating basins

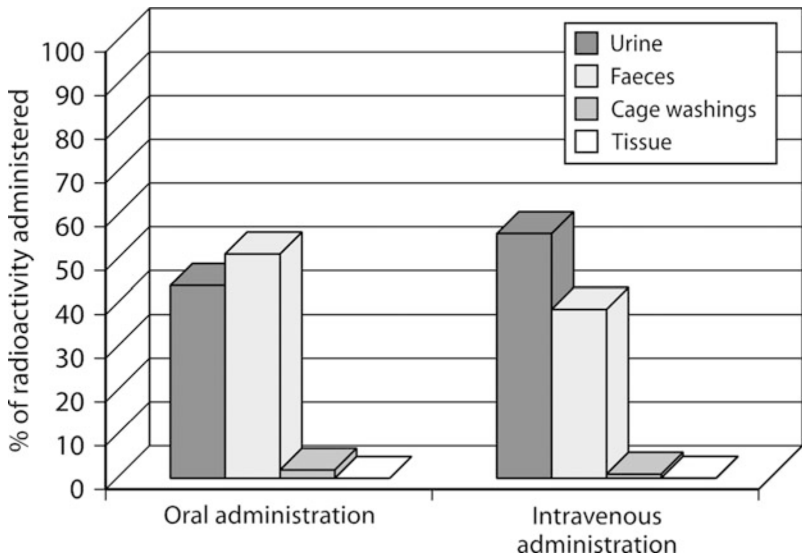

Fig. 29.4 ^{14}C-HMR 1556: Balance after oral administration of approximately 10 mg/kg body weight and intravenous administration of approximately 5 mg/kg body weight to male rats

Table 29.3 ^{14}C-HMR 1556. Excretion in urine and feces, cage washings, and amount of radioactivity in blood of exsanguination and carcass after oral administration of approximately 10 mg/kg and intravenous administration of approximately 5 mg/kg body weight to male rats (% of administered radioactivity)

- Commercially available aggregation inhibitor like heparin-sodium or sodium citrate
- Small centrifuge tubes
- Centrifuge

At each observation time point three rats are put in the box for anesthesia separately (especially critical at early time points; a staggered approach makes sense), which is permanently flushed with narcosis gas. The cover is closed and the rat is left there until complete apnea. Taking the rat outside the box again the reflex cornealis is proven. When the reflex is extinguished the vessels lateral below the throat are cut with the scalpel. The blood pouring out is collected in the small evaporating basins which already contain small amounts of heparin-sodium in cases where plasma preparation is intended (instead of serum).

Alternatively, blood can be collected from the abdominal aorta after anesthesia and cerebral

dislocation directly into syringes/containers containing a small amount of lithium or sodium heparin by abdominal incision at linea alba, and putting abdominal viscera aside. For generating plasma, part of the collected blood is transferred into centrifuge tubes and treated in the centrifuge with 1,500 G.

For typical sample collection time points in a 48-h study see example below.

Blood and plasma samples are taken up prepared for combustion (e.g., aliquots are transferred on cones for combustion), weighed, dried at room temperature, combusted, and the $^{14}CO_2$ formed is absorbed by Carbo-Sorb (Perkin Elmer). The subsequent radioactivity measurements are carried out after addition of scintillator to the samples.

Remaining blood and plasma are suitable for concomitant metabolism and bioanalytical studies.

EVALUATION

The concentrations of radioactivity expressed as µg equivalents of drug per g of matrix at all collection times and in blood and plasma are determined. The temporal course of the concentrations is represented by graphs and tables using either Windows Excel functions, a specific pharmacokinetic software program like Winnonlin (www.pharsight.com) or using the laboratory management system in case the functionality is given directly (such as DEBRA from LabLogic Systems Ltd. Sheffield England www.lablogic.com). They also allow calculation of the half-lives of radioactivity and the AUCs (see "Example"). The ratio of the dose-normalized AUCs (oral/intravenous) is used as the extent of absorption.

All these data are finally drawn together for detailed discussion and evaluation. Special attention has to be taken to major differences of data following intravenous and oral administration.

In the case that an essential concentration is available in blood and plasma at early time points after oral administration (e.g., C_{max} is reached soon) a rapid onset of absorption can be stated.

When there is no continuous decline of concentrations after intravenous administration, this might be an indication for:

- An inappropriate administration or a precipitation of the drug from the formulation at the application side or just behind the side in the blood stream. This might be the case when there is a plateau concentration or even an increase at early collection times.
- An enterohepatic circulation when a side maximum exists (time depending on absorption and elimination rate—often seen 4–8 h after administration).
- One or more of the generating metabolites show a much smaller volume of distribution than the drug itself.
- Other (often more complex) explanations.

In case of a drug concentration ratio (in plasma/blood) distinctly lower than expected from hematocrit, a binding of the drug or its metabolites to formed blood elements is indicated.[17]

CRITICAL ASSESSMENT OF THE METHOD

Always keep in mind that the radioactivity represents the sum of the original compound and/or radiolabeled metabolites and not the drug itself. Therefore, it is worthwhile to determine also the drug and known metabolites directly by bioanalytical methods with samples withdrawn from the same study. The comparison of both the radioactivity concentrations and the sum of concentrations determined by specific methods allows the estimation of the gap which often develops time-dependently: For instance, in the beginning of the study after intravenous administration, radioactivity concentrations in plasma should fit to the drug concentration. Usually the gap (as a percentage of the total radioactivity at a certain time point) between both concentrations increases with time.

The estimation of absorption via the ratio of dose-normalized plasma AUCs after oral and intravenous administration based on the assumption that:

1. A first pass effect including an instant elimination via bile does not exist.
2. The metabolic pattern is comparable independently of the route of administration.

[17]The following equation describes the percent of total radioactivity in plasma relative to total radioactivity in blood:

$$\text{Plasma/Blood}\,(\%) = \frac{(V_B) \times (P \times [1 - HCT])}{(V_B \times B)} \times 100 = \frac{P \times (1 - HCT)}{B} \times 100$$

where:
V_B = Volume of blood
P = Drug concentration in plasma
B = Drug concentration in blood
HCT = Hematocrit

3. The volumes of distribution (drug and metabolites) and the metabolism in special tissue are not effected by the bolus i.v. administration with high initial concentrations (Chiou 1989).
4. Dose-exposure linearity exists (under a more stringent view even a first order kinetic is required).

When those criteria are not fulfilled, then either the absorption can be underestimated (for instance, when precondition (1) is not true (2) or distinctly overestimated up to a calculated "super-absorption" for more than 100% (possible, for instance, when precondition (3) or (4) is not true)).

Only AUCs obtained from the same "type of blood" samples should be used. For instance, do not compare central arterial blood with venous peripheral blood (Chiou (1989)).

Certainly, every radiokinetic as well as any in vivo pharmacokinetic study depends on the galenic formulation used. Aqueous solutions, solutions with organic water-miscible components, solutions with surfactants, emulsions, microemulsions, or suspensions can be responsible for very distinct differences of radiokinetics (pharmacokinetics). Therefore, a conscious choice of galenic vehicle and formulation procedure is critical!

When establishing the method, one should cautiously practice the collection of blood by the cut lateral below the throat. In any circumstances injuring the esophagus has to be avoided, since small parts of formulation remaining in the esophagus (for instance, because of reflux or a sticky formulation) can contaminate the blood of exsanguination.

MODIFICATIONS OF THE METHOD

There are several methods of collecting blood from other sites.[18] Each method has advantages and disadvantages. Whereas central blood of exsanguination enables additional bioanalytics and metabolism from the same original sample (5–7 mL of blood), the collection of tail vein blood[19] (sample sizes of about 100–150 µl) enables intraindividual radiokinetics to be obtained.

In case of using preoperated animals (such as animals with jugulars and/or carotis catheter, see, for instance, Davis et al. (1994), Krishna et al. (2002) or Mun (2009) using an automated blood sampling system also for a radiokinetic study), the physical suitability has to be assessed critically. The reproducibility of these studies is much more critical and excellently prepared and recovered animals are constantly necessary. The comparison of results from central arterial blood (carotis), for instance, with peripheral venous blood, is questionable (Chiou (1989)).

Sometimes it is recommended to use a short-term infusion instead of a bolus intravenous administration. The advantage is to avoid high blood concentrations shortly after intravenous administration which may be in conflict with the assumed linear dose-exposure relationship (validity of linear relation at border concentration?). The advantage of the intravenous bolus injection is the lower/shorter stress situation for the animals (and may be also for the experimenter) which again has consequences for the reproducibility of the study results.

The determination of the volatile radioactivity in urine, feces, and expired air can be performed within the framework of the radiokinetic study (for instance, with the animals provided for the 24 h sample) (About 60% of exhaled radioactivity is mentioned by Xu et al. (2009) after administering radiolabeled dimethyl fumarate to rats and human. An example with a distinct difference of exhalation between mice and rats is described by Chen et al. (2007)). The air of the metabolism cage is continuously extracted, therefore, (for instance, with 3.5 L/min) and measured using a gas flow counter (Exhalameter, Raytest, Straubenhardt, Germany).

[18]For instance, blood of exsanguination collected after heart puncture; jugularis puncture, jugularis or carotis catheter, retroorbital blood, blood from the vena femoralis, sublingual blood after short narcosis or blood from the tail vein.

[19]Caution: The administration should not be done at the site of sample collection to avoid contamination. For instance, an i.v. administration into the vena femoralis after a short transient anesthesia can be recommended.

EXAMPLE

HMR 1766 is a guanylate-cyclase activator and is being developed for treatment of hypertension. It was ^{14}C-labeled and investigated in a rat radiokinetic study to determine the time course of radioactivity concentrations in blood and plasma.

29.7.3 Animal and Radioanalytic/Kinetic Study Part

Of 54 healthy male Sprague Dawley rats weighing between 165 and 216 g, 27 animals received an approximate dose of 12 mg ^{14}C-HMR 1,766/kg body weight orally by using a stomach tube; 27 other animals received a dose of approximately 2 mg/kg intravenously into a tail vein. In both cases, an aqueous solution containing PEG 400 was used as formulation. As an example for which details of data are collected during administration see Table 29.4 for the data for intravenous administration (analogously the data from the p.o. administration part are recorded).

Blood samples (0.25 h, 0.5 h, 1 h, 2 h, 4 h, 6 h, 8 h, 24 h, 48 h after oral administration and 0.083 h, 0.25 h, 0.5 h, 1 h, 2 h, 4 h, 8 h, 24 h, 48 h after intravenous administration) were collected. Parts of the blood samples were processed to obtain plasma samples. Of each sample and matrix 3 aliquots were generated, taken up on Combusto Cones (Perkin Elmer), weighed, dried at room temperature, combusted in a Tricarb® combuster (Perkin Elmer, Model 307), and the $^{14}CO_2$ formed was absorbed by Carbo-Sorb® (Perkin Elmer). The subsequent radioactivity measurements were carried out by the liquid scintillation counting procedure in a β-spectrometer (Perkin Elmer 2500 TR) after addition of the scintillator Permafluor E+® (Perkin Elmer).

29.7.4 Evaluation and Discussion

The time course of the mean radioactivity blood and plasma concentration values of three animals is given in the summary graph Fig. 29.5.

Half-lives were calculated by the pharmacokinetics' software WinNonlin. In case of the intravenous administration, a two compartmental model was chosen; in case of oral administration, a non-compartmental model. The AUCs were calculated using the linear trapezoidal rule. The results are summarized in Table 29.5.

Already 15 min after oral administration, radioactivity concentrations in blood and plasma (5.90 and 10.67 μg equiv./g, resp.) were found indicating a fast absorption. The maximum concentrations (C_{max}) occurred 0.5 h after administration and amounted to a mean of 9.34 μg equiv./g (blood) and 16.95 μg equiv./g (plasma). The elimination of radioactivity from blood and plasma was biphasic. The half-lives for the first phase amounted to 1.1 h (blood) and 0.9 h (plasma), for the second phase half-lives of 7.5 and 6.3 h were calculated. In all animals, radioactivity concentrations were detectable up to the last measuring time 48 h after dosing and showed averages of 0.025 and 0.024 μg equiv./g (blood and plasma, respectively).

After intravenous administration, the maximum radioactivity concentrations were measured at the first measuring time 5 min after administration, exhibiting mean concentrations of 4.79 and 7.64 μg equiv./g (blood and plasma). Following the peak values, the radioactivity decreased in a biphasic process with mean half-lives of 0.4 h for phase I and 10 h (blood and plasma, respectively) for phase II. In all animals, blood and plasma levels were observed up to 48 h after administration (0.006 and 0.007 μg equiv./g in blood and plasma, respectively)

The extent of absorption after oral dosing was determined by using the dose corrected comparison of the mean areas under the blood (and plasma)—radioactivity concentration curves after oral and intravenous administration (AUC values). This comparison revealed an absorption rate of more than 90% depending on AUC values used for calculation (blood or plasma). This value was very similar to the result in a mass balance study where the absorption was calculated by a comparison of the renally excreted radioactivity following oral and intravenous administration.

Since all plasma radioactivity concentrations are distinctly higher than the corresponding blood values,

there is no indication for a major binding of radioactivity to formed blood elements in this study.

Since the intravenous administration ensures the maximum exposure especially in case of anesthetized or preoperated animals, this route is often favored.

29.8 Bile Fistula Study in Rats

PURPOSE AND RATIONALE

To investigate the rate and the extent of the excretion of the drug/metabolites with the bile. If required, the investigation can be supplemented to study the enterohepatic circle. The bile fistula study becomes necessary when relevant parts of the administered radioactivity are eliminated fecally suggesting a considerable biliary excretion during the mass balance study in rats.

PROCEDURE

29.8.1 Part 1 (Collecting and Investigating the Bile)

Four healthy male anesthetized Sprague Dawley (or Wistar) rats weighing about 300 g (10–12 weeks old) and provided with a permanent bile fistula receive an intravenous dose (such as 5 mg/kg; for

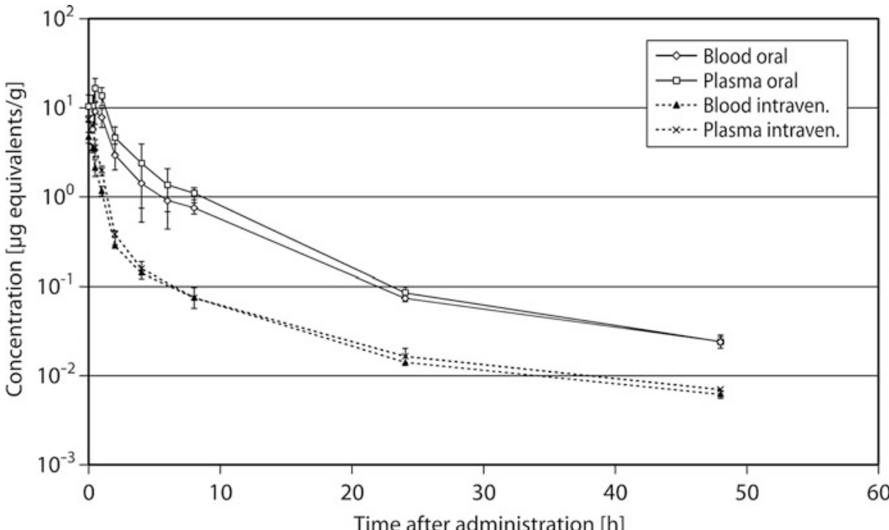

Fig. 29.5 ^{14}C-HMR 1766: Blood and plasma radioactivity concentrations after oral administration of approximately 12 mg/kg and after intravenous administration of approximately 2 mg/kg body weight to male rats. The variability (SD) of the animal values (n = 3) is given as bars

Table 29.5

[a]In brackets: mean value of 27 animals each

instance, into the tail vein, procedure see Sect. 29.6 without the necessity to use the described tube for the animals).

Details of installing the permanent bile fistula:

29.8.1.1 Material

- Ketamin (for instance, Hostaket® from Intervet)
- Midazolam (for instance, Dormicum® V from Roche)
- Disposable syringes, disposable gloves, disposable cannulas
- Small Braunülen (= indwelling venous cannulas)
- Skin disinfectant
- Heatable operating table for small animals
- Surgical microscope
- Electric clipper with 1/2 mm cutter head (for instance, from Aesculap Favorita)
- Surgical instruments: scalpel, surgical shears of various sizes, bent forceps, iridectomy scissors, surgical skin staples, stapling forceps, surgical gloves, swabs
- Catheter consisting of polythene tubing ID 0.28 mm, OD 0.61 mm (for instance, from Portex, Hythe, Kent, GB) or similar material (like flexible silicon catheter)

The rats are fasted for about 4 h and are anesthetized with 80 mg/kg bw Ketamin plus 5 mg/kg Midazolam administered intravenously into the tail vein via an indwelling venous catheter. The amount corresponds to a volume of about 0.3 mL. Anesthesia is monitored by checking the reflexes and is maintained by repeat dosing of ketamine/midazolam.

The abdomen of the anesthetized rat is shaved, the rat is then fixed in dorsal position on the heated operating table (thermostat set to 37°C), and the abdomen is disinfected with a commercial skin disinfectant.

Laparotomy is carried out at the linea alba, the catheter is introduced into the common bile duct

and fixed at such a distance from the hilus that the flow of pancreatic juice is not hindered. The animals are kept on heating pads to maintain body temperature throughout the experiment.

The test compound is injected into a tail vein. The study period is 8 h as from the time of dosing. At the end of the study period, the animals are killed painlessly by an overdose of the anesthetic.

The bile removed leads to fluid depletion of the organism. The corresponding volume was thus substituted for by intravenous infusion of isotonic sodium chloride solution (about 1 mL/h).

The bile of each animal is collected separately under cooled conditions during, for instance, four intervals (0–2 h, 2–4 h, 4–6 h, 6–8 h) via the permanent bile fistula. The samples are weighed and aliquots thereof measured directly after the addition of a commercial scintillation cocktail and water. In addition, the amounts of radioactivity in urine (0–8 h) are determined.

The remainder of the bile is used for metabolic profiling and structure elucidation of metabolites and, if necessary, for the investigation of the enterohepatic circulation as described in the following.

29.8.2 Part 2 (Enterohepatic Circulation)

Enterohepatic circulation of the non-diluted bile obtained in parts are pooled in order to receive a representative mixture of metabolites on one hand (that is from different collection intervals) and on the other hand a radioactivity concentration as high as possible.

The pooled bile is intensively homogenized, the homogenicity and the exact concentration proven by radioanalysis of several aliquots. The amount for application (about 1 g/animal) is withdrawn. The receiver animals are prepared like the animals in the first part of the study. However, the pooled bile is administered intra-duodenally via a flexible tubing. This tube is advanced from the mouth through the stomach as far as the beginning of the duodenum. During the administration, the tube is fixed with the fingers inside the duodenum to prevent reflux of the administered bile into the stomach.

Bile samples are collected and processed as described in part 1 of the study.

EVALUATION

29.8.3 Part 1

With the knowledge of the amount of bile, the concentrations determined are converted into percentages of administered radioactivity. The results can be displayed graphically (versus time). In case of portions of administered radioactivity of at least three time points being distributed about a single straight line in the semilogarithmic plot, the rate constant can be calculated by linear regression and subsequently the half-lives.

The data are finally drawn together for detailed discussion and evaluation with special attention to known results from other radiokinetic studies: such as the mass balance study and the obtained fecal elimination or the quantitative whole body autoradiography.

29.8.4 Part 2

The part of dose found in the bile of the receiver animals dosed with a part of the bile withdrawn from the donor animals gives an estimate about the magnitude of the enterohepatic circulation.

CRITICAL ASSESSMENT OF THE METHOD

The anesthesia slows down processes of the liver. It has to be assumed that liver clearance and elimination are faster when animals are awake. Therefore, models with woken animals are sometimes favored (see "Modifications of the Method").

A rough estimation whether anesthesia might relevantly misrepresent the situation of an awake animal should be performed comparing the bile excretion with the excretion via feces from the mass balance study (see "Example"), the urine excretion or the radioactivity concentration in blood. (So the bile fistula study should be extended to collect also body fluids such as terminal blood or the urine during the anesthesia.)

The estimation of enterohepatic circulation can be valid only when biliary excretion is virtually complete in the observed time interval.

MODIFICATIONS OF THE METHOD

The intravenous administration ensures a "complete" absorption and is therefore often the favored route of

dosing in this type of study. However, metabolism, distribution, and excretion may change with the route of administration and might impact the results of a bile fistula study. Thus, it has to be considered which route of administration or even two routes have[20] to be chosen. The comparison of the metabolic pattern in plasma or even in feces after different routes of administration may support this decision.

It may be worthwhile to dissect and measure additional tissues/organs/excreta at the end of the study, for instance, to investigate whether a direct secretion into the bowels took place (might be seen after i.v. administration), whether the liver retained radioactivity or to balance the radioactivity over urine, bile, and carcass (without bowels) to estimate the absorption more precisely.

Alternative models with woken animals during bile collection (Johnson et al. (1978) or for instance: Tse FLS et al. (1983) or as used in Bruin (2008)) are sometimes favored excluding the influence of anesthesia. However, those models often also cannot represent the situation of a "normal" rat, since operation and catheterization may also impact the study result.[21]

EXAMPLE

Hoe 642 is an inhibitor of cellular Na+/H+ exchange and thus a drug with cardioprotective activity.

^{14}C-HOE 642 was intravenously injected into a tail vein (5 mg/kg; 1 MBq/animal) to 4 healthy male, anesthetized Wistar rats (approx. 320 g) with bile fistula. For administration, the test compound was used as aqueous solution with 0.9% saline (3.5 mg/g formulation; approximately 0.5 g formulation/animal) adjusted to pH 7 with sodium hydroxide.

Bile samples were collected as described above, weighed, diluted with water, weighed again, and aliquots were measured after addition of scintillator.

The radioactivity measurements were carried out by the liquid scintillation procedure, using a β-spectrometer of type BF 5000 (Berthold, Wildbad, Germany). As scintillator Rotiszint eco plus (Roth, Karlsruhe, Germany) was used. Blank values were concurrently measured in the studies and deducted from those measured. These blank values originated from bile fluid of the animals taken before dosing.

The amounts of radioactivity that were excreted with the bile are illustrated in the graph in Fig. 29.6.

During the study period between 6.9% and 7.9% (mean = 7.6%) of the radioactivity administered were excreted with the bile. The major part thereof was eliminated within the first 2 h after injection. The portion of radioactivity excreted with the bile decreased at later measuring intervals. In the last collection interval, i.e., 6–8 h after dosing, an average of 0.09% of the radioactivity administered was still present in the bile.

Half-lives were calculated. They were based on a monophasic process with values between 0.7 and 1 h. A previous mass balance study with ^{14}C-HOE 642 revealed a fecal elimination of about 17% (2% up to 8 h, 14% between 8 and 24 h, and 1% at later time points) following intravenous injection (comparable dose). Since in the bile fistula study the portion still present in the bile in the last collection period was only about 0.1%, it was assumed that biliary secretion is virtually complete. The difference to the excreted fecal elimination obtained in the mass balance study may be due to the general anesthesia of the rats in the bile study or radioactivity may reach the gastrointestinal tract by other ways (direct secretion into the intestine or the stomach, secretion by the salivary glands with subsequent swallowing of the saliva. The salivary glands are known to exhibit high radioactivity concentrations after intravenous injection from radioluminography studies with ^{14}C-HOE 642).

[20]Instead of an oral an intra-duodenal administration should be chosen, when using anesthetized animals.

[21]The procedure as described in the main part still has supporters. See Hoehle et al. (2009).

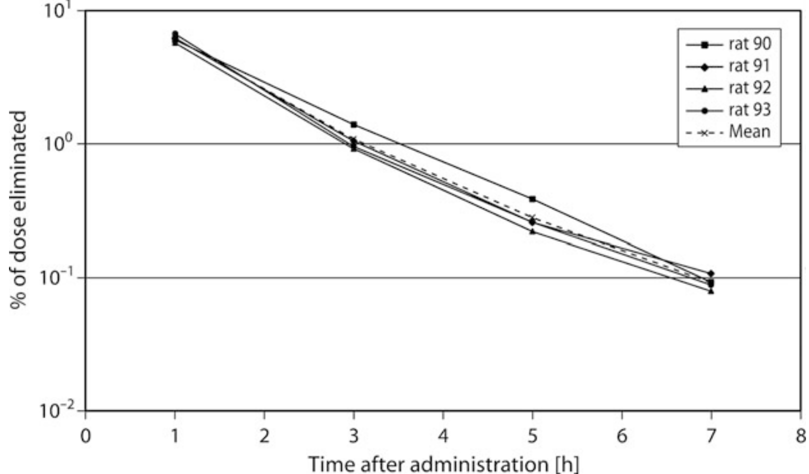

Fig. 29.6 ^{14}C-HOE 642: amount of dose excreted via bile after i.v. (5 mg/kg) administration to rats (the lines between the data of the measuring points should be understood as trend lines)

The presence of a lower radioactivity portion in the bile than in the feces and the virtually monophasic elimination process makes the existence of an enterohepatic circulation improbable.

29.9 Diaplacental Transfer Study in Rats

PURPOSE AND RATIONALE

To obtain information about the distribution of a drug and/or its biotransformation products in dams and fetuses in relation to time.

PROCEDURE

Nine healthy female, 18 days pregnant Sprague Dawley rats weighing about 300 g (approximately 12 weeks old) receive the radiolabeled compound through the route of administration projected to be used therapeutically (for oral or intravenous administration to rats and animal maintenance, see the procedure described in the rat mass balance study).

29.9.1 Material

- Box for anesthesia with CO_2 or with Isofluran
- Scalpel, scissors straight and curved
- Bone shears, pincers
- Gloves for single use
- Small evaporating basins
- Plastic tubes and commercially available aggregation inhibitor like heparin-sodium
- Centrifuge tubes and centrifuge
- Disposable syringes and cannulas
- Dash bottle with ethanol/water 1:1

Three animals/time point are killed painlessly (CO_2 anesthesia, exsanguination as described in the "blood/plasma radiokinetic study in rats") and are each immediately dissected.

The rat is placed in a dorsal position on an undersheet and the fur is moistened with ethanol/water. The abdominal cavity is opened and the abdominal wall folded back. The uterus is exposed and the amniotic fluid is withdrawn by puncturing the amniotic sac with a syringe. The uterus is then placed on a plastic film and opened. The placentas with the fetuses are detached from the uterus. The placentas are then detached from the fetuses. After removing the fetal membranes the fetuses are removed and immediately killed under CO_2 atm. The amniotic fluid is aspirated with a disposable syringe.

The organs and tissues listed below are removed. The number of fetuses is determined and documented. The fetuses per dam and their organs, respectively, are pooled. The order of removal is prescribed in the following dissection schedule.

- Blood/plasma (from exsanguination, see study "blood/plasma radiokinetics in rat")
  Opening of the abdominal cavity
- Liver
- Extraction of uterus
- Amniotic fluid
- Remove/kill fetuses immediately with CO_2-gas

- Fetal blood/plasma
- Fetal liver
- Fetal carcass
- Placenta

Examinations are performed concerning the radioactivity concentrations and portions.

29.9.2 Processing of Samples

Blood and plasma samples are taken on cones for combustion, weighed, dried at room temperature, combusted, and the $^{14}CO_2$ formed is directed into an absorption fluid. The subsequent radioactivity measurements are carried out after addition of scintillator to the samples.

After removal, larger organs and tissues are homogenized with Ultra-Turrax® appliances (for instance, from Ika, Staufen, Germany) after addition of deionized water, the amount of which depends on the consistency of the tissue. Smaller tissues are finely cut. The specimens are dissolved in volumetric flasks at 60–70°C in Solvable® (Perkin Elmer) and water. Ethanol is added if required to prevent foam formation. Addition of approximately 0.2 mL Perhydrol® (Riedel de Haën, Seelze, Germany) or hydrogen peroxide, respectively, is sufficient to remove discolorations. Measurements are then performed after addition of the scintillator.

EVALUATION

The radioactivity concentrations in the collected samples are determined. They are expressed in µg equivalents of drug/g and in % of administered radioactivity. The temporal course of the concentrations and the portions of radioactivity found can be represented by graph and tables. In cases where mean portions of administered radioactivity of a tissue/body fluid of all three time points are distributed about a single straight line in a semilogarithmic plot (ln concentrations on time), the rate constant can be calculated by linear regression and subsequently the half-life (ln2/rate constant).

The data are finally drawn together for detailed discussion and evaluation with special attention on the placenta border: Do significant amounts of radioactivity cross the placenta and are the fetuses exposed to drug/metabolites? Does the radioactivity remain in the fetus/organs/body fluids longer than in the dams?

CRITICAL ASSESSMENT OF THE METHOD

The radioactivity represents the sum of the original compound and/or radioactive-labeled metabolites and not to forget possible synthetic side-products which can be present in traces (depending on the purity and content of the synthetic material). Discussing traces of radioactivity, for instance, traces crossing the placenta, keep in mind that these traces may be due to synthetic side-products. Thus, whenever possible, try to use radiolabeled compound as clean as possible.

MODIFICATIONS OF THE METHOD

The described procedure may be seen as a minimum for investigation of the placental transfer. Of course, whenever necessary or useful, the procedure may be enlarged by additional time points and organs/tissues/body fluids (such as ovary, kidney of dams) to be investigated.

The radioactivity of the organs can also be determined after combustion alternatively. Normally the method of digestion, discoloration, and direct determination of radioactivity is a little bit more sensitive, in case more material can be used than in the combustion process.

Instead of the aforementioned procedure of a common quantitative distribution study, the placental transfer can be investigated well also by whole body autoradiography (see the section on autoradiography and, for instance, Endo et al. (1992), or Umehara (2008). The quantitative whole body autoradiography was extended also for the use of pregnant rabbits (Herman 1998).

A bidirectional placental (maternal to fetal and fetal to maternal) transfer was described, for instance, by Thomas (1995).

Younger rats (8–10 weeks) and performing the investigation already on day 12 of gestation is mentioned, for instance, by Pohland (1991).

EXAMPLE

HWA 486 (Leflunimide, Arava) is a compound against rheumatoid arthritis.

Nine healthy female 18 days pregnant Sprague Dawley rats weighing between 270.0 and 317.9 g received ^{14}C-HWA 486 in an approximate dose of 20 mg/kg body weight. The compound was administered orally by a stomach tube. As formulation a suspension in starch mucilage was selected. Examinations were performed concerning the radioactivity concentrations and portions in blood, plasma, and liver of the dams as well as in amniotic fluid, placenta, and in blood, plasma, liver, and carcass of the fetuses.

Details of the dose and study design are given in Table 29.6.

Samples were processed, the radioactivity determined, and data evaluated as described above.

The radioactivity concentrations found in the different tissues/organs/body fluids are summarized in the graph (Fig. 29.7).

Taking the weight of the investigated tissues/organs/body fluids into account and expressing the observed radioactivity as part of the dose administered (in %), the graph (Fig. 29.8) shows the amount of drug/metabolites reaching the tissues/organs/body fluids:

At the first measuring time (6 h after dosing), the highest levels for dams were detected in the plasma (mean 58.99 µg equiv./g), followed by the liver (43.50 µg equiv./g) and the blood (38.16 µg equiv./g) indicating a considerable extent of absorption. In the placenta, a mean of 16.10 µg equiv./g was found, in the amniotic fluid 3.06 µg equiv./g (0.30%). Concentrations in fetal plasma (13.96 µg equiv./g), fetal blood (11.19 µg equiv./g), fetal carcass (7.39 µg equiv./g), and fetal liver (6.31 µg equiv./g) were lower than the concentration in the maternal blood. Thus, a close barrier function of the placenta with complete retention of radioactivity in this organ was not present.

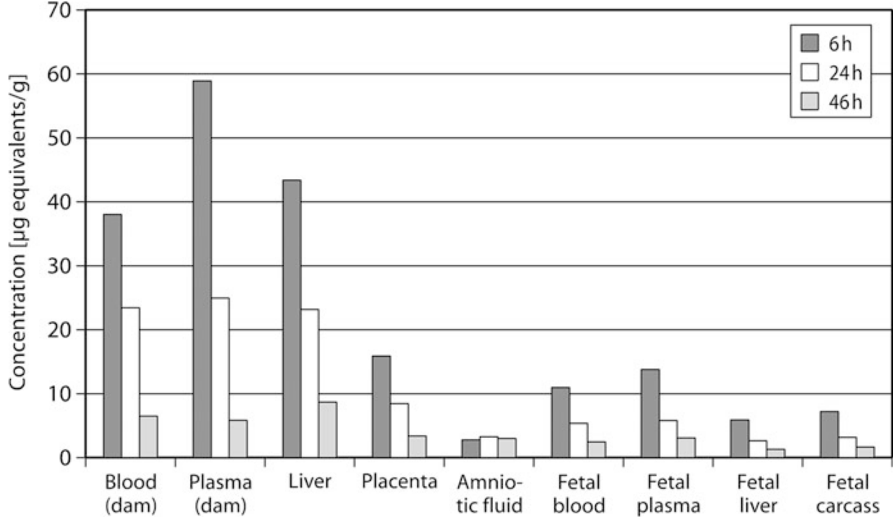

Fig. 29.7 ^{14}C-HWA 486: radioactivity concentrations in tissues/organs/body fluids from pregnant rats

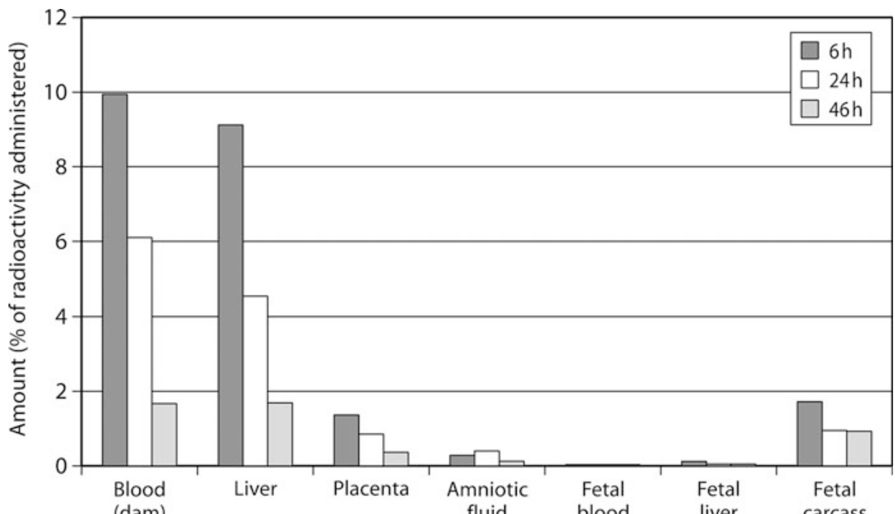

Fig. 29.8 ^{14}C-HWA 486: amount of dose in tissues/organs/body fluids from pregnant rats

Twenty-four hours after administration, the concentrations in all examined organs of dams had decreased as compared to the first measuring time. The concentrations in plasma (25.26 µg equiv./g) were slightly higher than in blood (23.84 µg equiv./g). The liver was in a similar range (23.22 µg equiv./g) and the placenta showed 8.71 µg equiv./g. Fetal liver, fetal blood and plasma, and fetal carcass also showed lower concentrations than at the first measuring time. All concentrations were below the concentration in maternal blood.

At the last measuring time, 48 h after dosing, the concentrations in maternal organs had decreased further: The highest concentrations were detected in the liver (8.83 µg equiv./g, corresponding to 1.7% of radioactivity administered), followed by the blood (6.63 µg equiv./g; 1.7%), and the plasma (5.97 µg equiv./g). In the placenta, 3.45 µg equiv./g (0.4%) were found. Concentrations in fetuses had dropped further. All measured concentrations were considerably below the concentrations in the maternal blood: Fetal blood (2.57 µg equiv./g), fetal plasma (3.28 µg equiv./g), fetal liver (1.36 µg equiv./g), and fetal carcass (1.63 µg equiv./g).

Since the concentrations showed a virtual linear decrease of radioactivity with time in the semilog scale (see Fig. 29.9) the estimation of half-lives made sense (with the exception of the amniotic fluid). The half-lives ranged from 13 h (plasma, dam) to 20 h (plasma, fetus).

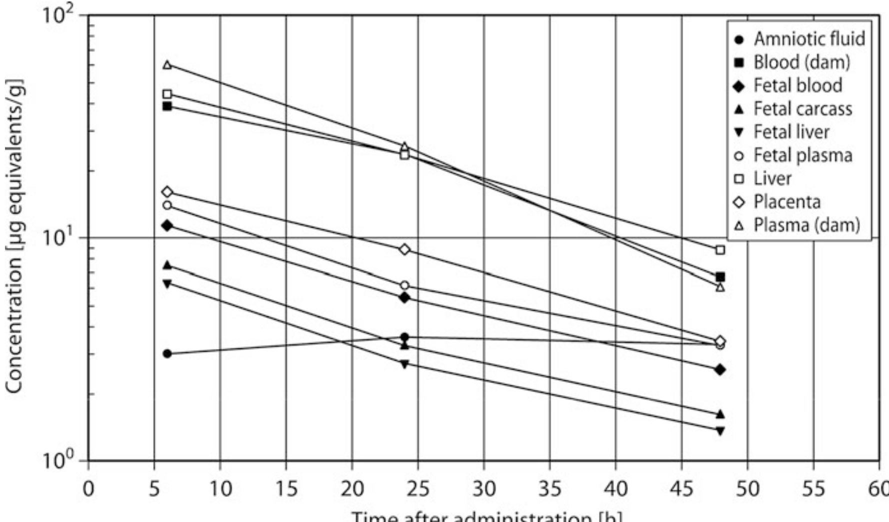

Fig. 29.9 ^{14}C-HWA 486: concentration-time profile of tissues/organs/body fluids from pregnant rats

In summary, it may be stated that after oral administration of ^{14}C-HWA 486 to the dams the compound was well absorbed. The absorbed radioactivity was able to penetrate into the fetuses. The concentrations in the maternal tissues were considerably higher than in the fetus at all measuring times. The radioactivity departs from the maternal organism parallel to the fetal organism. Only in the amniotic fluid, no clear decreasing tendency could be observed.

29.10 Milk Transfer Study in Rats

PURPOSE AND RATIONALE

For registration of a drug, data are required on excretion with the milk as well as data about the correlation between the blood and milk level.

PROCEDURE

Ten lactating healthy female Sprague Dawley rats weighing about 300 g (approx. 13 weeks old; day 11 post partum) receive the radiolabeled compound through the route of administration projected to be used therapeutically. For oral or intravenous administration to rats as well as details concerning animal maintenance see Sect. 29.6.

About 5 min before the selected milking times, each dam receives about 0.03 mL oxytocin (for instance, Oxytocin Injektionslsg.10 IE/mL; Vetoquinol GmbH; Germany, www.vetoquinol.de Ravensburg) subcutaneously, because the amounts are otherwise insufficient for analysis. At the examination times (such as given in the example), milk was first taken by manual milking, and blood then gained from the tail tip. The animals not being accustomed to the milking procedure, milk could not be obtained at each examination time.

For milking, the animals were held by the nape. A sucking pump[22] was put alternately onto the individual teats to collect the withdrawn milk into an Eppendorf® tube. When the vacuum was interrupted at regular intervals with a finger, the device operated like a milking machine. The appropriate partial vacuum and rhythm had to be established for each animal. Higher milk flow was obtained by massaging and thus stimulating the teats with the fingers prior to actually beginning milking.

In cases where the milking and blood sampling are very narrow at first, it is recommended to use two alternative groups of animals.

[22]Can be easily constructed connecting a water-jet pump with a microwash bottle; an Eppendorf vessel is placed under the inlet tube; at the other end the inlet tube is fitted with a polyethylene tube and a microfunnel.

The "microwash bottle" can be assembled from a 15-mL scintillation vessel with two openings in the lid and polyethylene tubing.

29.10.1 Blood and Milk Samples

Blood and milk samples were taken on cones for combustion, weighed, dried at room temperature, combusted in a combuster, and the $^{14}CO_2$ formed is directed into an absorption fluid. The subsequent radioactivity measurements are carried out after addition of scintillator to the samples. Blank values are concurrently measured in the studies and deducted from those measured. These blank values originated from identical material from untreated animals.

EVALUATION

The radioactivity concentrations of the collected samples are determined. They are expressed in µg equivalents of drug/g matrix. The temporal course of the concentrations can be represented by graph and tables. With a specific pharmacokinetic software program like Winnonlin (www.pharsight.com) or using the laboratory management system in case the functionality is given directly (such as DEBRA from LabLogic Systems Ltd. Sheffield England www.lablogic.com), the half-lives and the AUCs of the radioactivity in blood and milk can be calculated.

To calculate the portion of administered radioactivity excreted with the milk, it is necessary to know the quantitative milk secretion of each particular rat. However, this is not possible within the present study due to the stress inflicted on the animals by the unusual milking procedure which leads to milk retention. Assuming values known from literature (Mepham 1983), the portion excreted with the milk per day can be estimated at 23 mL.

CRITICAL ASSESSMENT OF THE METHOD

Keep in mind that the radioactivity represents the sum of the original compound and/or radiolabeled metabolites and not the drug itself.

MODIFICATIONS OF THE METHOD

Milking rats under anesthesia in milk transfer studies is mentioned, for instance, by Endo (1992), Tanayama (1974), Saillenfait (1997), or Wang (2011). Even milking of mice seems possible (Oskarsson 2004). Milk from mice or rat pups' stomach is used, for instance, by Gonzalez (2011) and Sumner (2010). Additionally, the distribution in the pups can be investigated by quantitative whole body autoradiography as mentioned, for instance, by Bruin (2008).

EXAMPLE

HWA 486 (Leflunimide, Arava®) is a compound against rheumatoid arthritis. The oral route of administration was selected for this study because this was the route planned in humans.

Ten lactating healthy female Sprague Dawley rats weighing between 265.0 and 351.2 g received HWA 486-[^{14}C] in an approximate dose of 16 mg/kg body weight. The compound was administered orally by a stomach tube in form of a suspension in starch mucilage. For details of the study conducted, see Table 29.7.

The concentrations of radioactivity in blood and milk were determined at different times up to 24 h after dosing.

Table 29.7 HWA 486 study conduct

29.10.2 Blood and Milk Samples

Blood and milk samples were taken on Combusto Cones® (Perkin Elmer), weighed, dried at room temperature, combusted in a Tri-carb® combuster (Perkin Elmer, Model 307,.), and the $^{14}CO_2$ formed was absorbed with Carbo-Sorb® (Perkin Elmer). The subsequent radioactivity measurements were carried out after addition of scintillator to the samples.

29.10.3 Radioactivity Measurements

Radioactivity measurements were carried out by the liquid scintillation counting procedure in a β-spectrometer (Perkin Elmer TRI-CARB 2500 TR and T 2700), using an external standard device which permitted the counting efficiency to be determined by the channel ratio method.

The scintillator Permafluor E+ recommended by Perkin Elmer for their automatic combustors was used in the case of combusted samples. The scintillator Roth-rotiszint eco plus (Roth, Karlsruhe, Germany) was used for the samples measured directly.

Blank values were concurrently measured in the studies and deducted from those measured. These blank values originated from identical material from untreated animals.

The resulting mean concentrations (bars indicate SD) are given in Fig. 29.10.

The pharmacokinetic values in the blood and milk given in Table 29.8 were calculated by the pharmacokinetics' software WinNonlin, using the mean concentrations, a noncompartmental model, and the linear trapezoidal rule.

Already at the first measuring time (30 min after dosing), the concentrations in milk were considerably higher than the corresponding levels in blood in all

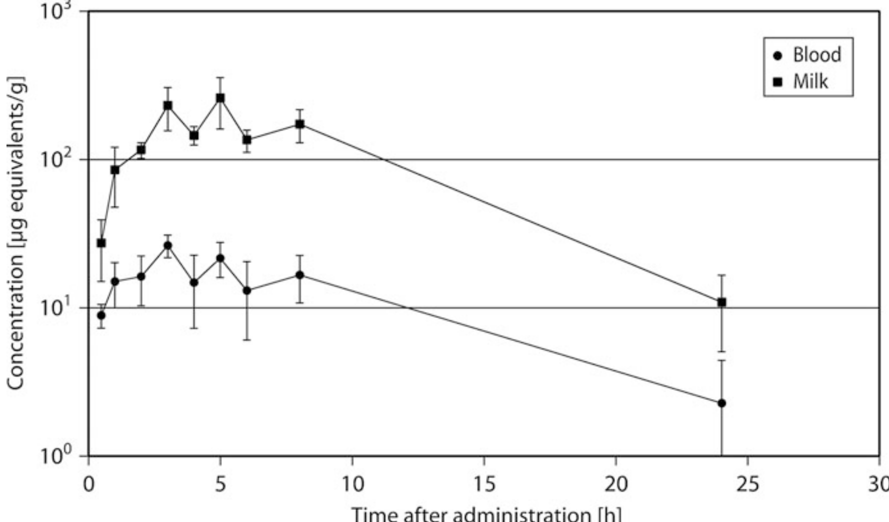

Fig. 29.10 ^{14}C-HWA 486: concentration-time profile of blood and milk from lactating rats

Table 29.8

Parameters	Blood	Milk
C_{max} (µg equiv./g)	26.3	252.9
t_{max} (h)	3	5
$t_{1/2}$(h)	6.4	4.4
Conc.$_{24\ h}$ (µg equiv./g)	2.28	10.8
AUC (µg equiv./g × h)	282.4	2,635.5
AUC_{inf} (µg equiv./g × h)	303.5	2,704.2

animals examined. The mean values amounted to 27.01 µg equiv./g in milk and 8.85 µg equiv./g in blood. This indicates a rapid penetration of the compound into the mammary gland and a rapid onset of the elimination via the milk.

The highest mean concentrations in the blood were observed at 3 h after dosing amounting to 26.3 µg equiv./g. In the milk, the detected mean C_{max} concentrations were approximately nine times higher and amounted to 252.9 µg equiv./g. They were present at 5 h after dosing. At all measuring times, the concentrations in blood were considerably lower than in the milk, indicating an accumulation of the compound and/or its metabolites in milk.

The concentrations in the milk and in the blood decreased after reaching of the C_{max} concentrations in a similar way and speed. The calculated half-lives (from C_{max} to 24 h after dosing) amounted to 4.4 h for the elimination from the milk and 6.4 h for the elimination from the blood, indicating a continuous providing of new radioactivity from the blood to the milk. There was no retention in the mammary gland longer than in the blood. A rough estimation of the amount of radioactivity administered excreted via the milk amounted to $>25\%$.

Analogous to the C_{max} concentrations, the calculated AUC values in the milk were approximately 9–10 times higher than those in the blood.

30.1 Introduction

The quantitative determination of analytes in biological matrices such as blood and urine is called bioanalysis. Bioanalysis regulatory authorities and International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) guidance requires that the concentration-time profiles of drugs and/or metabolites in man or in animals are studied so their respective pharmacokinetics can be calculated and used as a basis for the evaluation of preclinical (especially toxicological) and clinical studies.

Gas chromatography (GC) is a chromatographic technique that is used to separate volatile organic compounds. A gas chromatograph consists of a mobile (gas) phase, an injection port, a separation column containing the stationary phase, and a detector. The organic compounds are separated due to differences in their partitioning behavior between the mobile gas phase and the stationary phase in the column. Mobile phases are generally inert gases such as hydrogen, helium, argon/methane, or nitrogen. The upper part of the injection port is sealed with a rubber septum through which a syringe needle is inserted to inject the sample. The injection port is maintained at a higher temperature than the boiling point of the least volatile component in the sample mixture. Since the partitioning behavior is dependent on temperature, the separation column is positioned in a programmable, thermostat-controlled oven. Starting at a low oven temperature and increasing the temperature over time to elute the high-boiling point, components accomplish separation of analytes showing a wide range of boiling points.

Gas chromatography columns are of two different designs: either packed or capillary. Packed columns are typically glass or stainless steel coils (typically 1–5 m total length and about 5 mm inner diameter) that are filled with the stationary phase. Capillary columns are thin fused-silica (purified silicate glass) capillaries (typically 5–50 m in length and 250 μm inner diameter) that have the stationary phase coated on the inner surface. Capillary columns provide much higher separation efficiency (a typical 25-m wall-coated open tubular GC column gives about 50,000 theoretical plates[1]) than packed columns (an average packed column of 5 m has only 5,000 theoretical plates), but are more easily overloaded by too much sample.

After the components of a mixture are separated using gas chromatography, they must be detected as they exit the GC column. There exist a number of detectors, which can be used in gas chromatography. Different detectors give different types of selectivity: *Nonselective* detectors like the thermal-conductivity (TCD) detector or the flame-ionization (FID) detector, which are the two most common detectors in gas chromatography, respond to all (organic) compounds except the carrier gas. On the contrary, a *selective detector* responds to a range of compounds with a common physical or chemical property. Representatives of the latter group of detectors are the nitrogen–phosphorus detector (NPD), the electron-capture detector (ECD), the mass-selective detector (MSD), and—last, but not least—the tandem mass spectrometer (MS/MS).

However, gas chromatography is not usually the method of choice in the bioanalytical field because it requires the vaporization of the analytes, and—unfortunately—most analytes in bioanalysis are not very volatile. This low volatility may result from the sheer size of the molecules and thus from large dispersion forces holding the molecules together (Knapp 1979). For smaller molecules (as for the many drug candidates), the observed low volatility may result from strong intermolecular attraction between polar groups (e.g., N − H, O − H, and S − H groups that can undergo hydrogen bonding).

It is beyond the scope of this chapter to describe the theory of GC; for a detailed description, the reader is referred to one of the many textbooks devoted to this topic, but the textbook *Analytical Gas Chromatography* (Jennings 1987) with its detailed discussion of capillary GC is strongly recommended.

As mentioned earlier, given the limitations of GC, alternative methods such as high-performance liquid chromatography (HPLC) with ultraviolet (UV) or with fluorescence (FL) detection and—particularly in the past few years —high-pressure liquid chromatography with tandem mass spectrometric detection (LC-MS/MS) have evolved as the major bioanalytical techniques for the bioanalysis of analytes in biological

[1]The number of theoretical plates is the number of discrete distillations that would have to be performed to obtain an equivalent separation. This number is commonly used as a measure of separation efficiency and is a valuable number to use when comparing the performance of various chromatographic columns.

matrices. Nevertheless, due to the inherent advantages of modern fused-silica capillary columns in terms of resolution, inertness, and detection limits, in combination with different detectors like the flame-ionization detector (FID), the nitrogen–phosphorus detector (NPD), the electron-capture detector (ECD), the mass-selective detector (MSD), or even the tandem mass spectrometer (MS/MS), GC continues to play a role in modern bioanalytics (Venn 2000, p. 131). An example of the implementation of each of the above-mentioned GC detectors will be discussed in this chapter but necessarily not in the referred order.

To overcome the already mentioned low volatility of a number of analytes, one approach has been to generate more volatile derivatives before the actual bioanalysis. Although derivatization cannot increase the volatility of large molecules, for smaller molecules, masking of polar groups by derivatization can yield dramatic increases in volatility. Polar N − H, O − H, and S − H groups that can undergo hydrogen bonding contribute significantly to intermolecular attraction and thus low volatility. Replacement of hydrogen in these groups by alkylation, acylation, or silylation significantly increases volatility, especially in compounds with multiple polar groups. The monosaccharides are a prime example of a group of relatively low molecular weight compounds that exhibit low volatility even up to temperatures at which they begin to decompose. Replacement of the active hydrogens with trimethylsilyl groups yields volatile products that readily undergo GC analysis (Knapp 1979). Carboxylic acids are another molecule class, which can easily be derivatized using diazomethane (CH_2N_2) to yield the respective methyl esters, which often are volatile enough to allow the use of GC. In 1984, Hajdù et al. introduced a specific GC assay, which allowed the rapid analysis of ramipril, an angiotensin-converting enzyme (ACE) inhibitor in human urine. To our knowledge, this was the first time that an ACE-inhibitor bioanalysis was performed directly using GC and not by either radioimmunoassay (RIA) (Hitchens et al. 1981; Ribeiro et al. 1996) or a discontinuous enzyme assay (Horiuchi et al. 1982; Tocco et al. 1982).

30.2 Urinary Analysis of Ramipril Using Gas Chromatography with Nitrogen–Phosphorus Detection (GC-NPD)

PURPOSE AND RATIONALE

This assay is used for the quantitative determination of the angiotensin-converting enzyme (ACE) inhibitor ramipril, (2-[N-[(S)-1-ethoxycarbonyl-3-phenylpropyl]-L-alanyl]-(1S,3S,5S)-2-azabicyclo[3.3.0]octane-3-carboxylic acid), and its pharmacologically active metabolite, ramiprilat, in human urine using capillary gas chromatography with nitrogen-specific detection (NPD).

Ramipril

Ramiprilat

Note: The nitrogen–phosphorus detector responds to nitrogen–phosphorus compounds about 100,000 times more strongly than normal hydrocarbons. Due to this high degree of selectivity, the NPD is commonly used to detect pesticides, herbicides, and drugs.

The NPD is similar in design to the FID (flame-ionization detector), except that the hydrogen flow rate is reduced to about 3 mL/min, and an electrically heated thermionic bead (NPD bead) is positioned near the column orifice. Nitrogen or phosphorus containing molecules exiting the column collides with the hot bead and undergo a catalytic surface chemistry reaction. The resulting ions are attracted to a collector electrode, amplified, and output to the data system. The NPD is 10–100 times more sensitive than FID.

30.2.1 Reagents

Ramipril, ramiprilat, and the internal standard were supplied by Hoechst AG[2] (Frankfurt, Germany). Analytical grade reagents were used at all times; methanol and chloroform were redistilled before use. Vac Elut and Bond Elut C18 and Si extraction columns are proprietary products manufactured by Varian Incorporated (Harbor City, CA, USA) and obtained from ICT (Frankfurt/Main, Germany). Dimethyldichlorosilane (DMCS) and trifluoroacetic anhydride (TFAA) were purchased from Macherey-Nagel & Co. (Düren, FR Germany) and used without further purification. N-Methyl-N-nitroso-p-toluenesulfonamide (Diazald), for diazomethane generation, was supplied by Aldrich (Milwaukee, WI, USA). As internal standard, 2-[N-[(S)-1-ethoxycarbonyl-3-phenylpropyl]-L-alanyl]-spiro-[5,6]-2-azadecane-3-carboxylic acid was used.

- Buffer solution pH = 1.0: 3.73 g KCl and 134 mL 0.1 mol/L HCl were filled up to 1 L with redistilled water.
- Water pH = 3.3: Redistilled water was adjusted to pH = 3.3 with buffer solution 1.0.
- Elution mixture: Redistilled chloroform and methanol were mixed in the ratio 2:1 (v/v).
- n-Hexane/toluene: n-Hexane and toluene were mixed in the ratio 1:3 (v/v).
- Diazomethane: Ethereal diazomethane solution was prepared by the diazomethane generator kit.

[2] Successor company: Aventis Pharma Deutschland GmbH.

30.2.2 Assay

The need to isolate the analytes from the biological matrix in a form suitable for GC bioanalysis constitutes the most labor-intensive step. The isolation procedure is largely independent of the chromatographic technique, i.e., is not specific to the employed GC method. The only GC-specific requirement is that the final extract is obtained in a relatively volatile solvent and, because of injection volume constraints, in the smallest practical volume (about 50 µL). For the extraction of ramipril and of ramiprilat from urine, disposable C18 columns were used. After derivatization with diazomethane (Albro and Fishbein 1969), the sample was purified by the use of a Si column, to eliminate a number of endogenous impurities from urine, which are not removed during purification over the C18 column. After a second derivatization step with trifluoroacetic anhydride (Walle et al. 1972), both compounds were analyzed in form of their methyl ester-, trifluoroacetyl derivatives by capillary gas chromatography using a nitrogen-specific detector.

PROCEDURE

1. To prevent adsorption of the compounds at the glass surface, the centrifuge tubes are treated with 2 mL n-hexane/DMCS (5%) for at least 10 min prior to use, rinsed with methanol, and subsequently dried.
2. To 1 mL urine in a centrifuge tube, 2 µg internal standard dissolved in 50 µL redistilled water are added and then adjusted to pH = 1.4–1.5 with 0.1 mol/L HCl.
3. The sample thus prepared is applied onto a C18 column—which has been preconditioned with methanol (6 mL) followed by redistilled water (6 mL) and 0.1 mol/L HCl (3 mL)—and slowly sucked through under vacuum (using the Vac Elut System at about 20-kPa pressure drop).
4. Subsequently, the column is washed with 4 × 3 mL redistilled water at the same reduced pressure.
5. The pressure drop is increased to 50–60 kPa, and the column is sucked dry for 10 min.
6. The column is placed into a centrifuge tube, and the sample is eluted with 2 × 0.75 mL elution mixture.
7. The column is dried by centrifuging at 4,000 rpm for 1 min, whereby the entire eluate is collected in the tube.

8. The eluate is methylated by adding 0.5 mL ethereal diazomethane solution at room temperature for about 10 min and subsequently evaporated to dryness at 40°C under N_2 gas.
9. The residue is taken up in 100 μL methanol followed by adding 1 mL n-hexane/toluene.
10. The sample is applied onto a Si column—which has been preconditioned with methanol (5 mL) followed by chloroform (5 mL) and n-hexane (5 mL)—and slowly sucked through under vacuum (20-kPa pressure drop).
11. The pressure drop is increased to 50–60 kPa, and the column is sucked dry.
12. The column is placed into a conically tapered centrifuge tube, and the sample is eluted with 2 × 2 mL chloroform.
13. The eluate is evaporated to dryness at 60°C under N_2 gas.
14. The residue is taken up in 250 μL ethyl acetate, treated with 1 mL n-hexane/TFAA (5%).
15. For derivatization, the stoppered tube is placed into a heating block of 60°C for about 30 min.
16. Subsequently, the sample is evaporated to dryness at 60°C under N_2 gas and taken up in 50 μL toluene, 2 μL of which is injected.

30.2.3 GC System

Hewlett–Packard 5880A gas chromatograph with nitrogen-specific detector (NPD), (Hewlett–Packard, Palo Alto, CA, USA)

Column: Cross-linked fused-silica capillary column, Hewlett–Packard OV 101, 12 m × 0.21 mm inner diameter (ID)

Injection: Split mode

Gases: Carrier gas (helium), inlet pressure 10 psi

Split ratio: 1:20 mL/min

Septum rinsing (helium): 3 mL/min

Detector makeup (helium): 20 mL/min

Detector (hydrogen): 3 mL/min

Detector (air): 60 mL/min

Temperatures: Injection port 250°C

Detector: 300°C

Oven program:

Initial temperature: 160°C

Heating rate: 16°C/min

Final temperature: 260°C (4 min)

Detection: NPD detector

Sample size: 2 μL

Analysis time: About 12 min per sample

EVALUATION

Ramipril and ramiprilat were admixed with human urine in concentrations of 0.050–10,000 μg/mL. The urines were divided into five aliquots and analyzed.

Precision: The standard deviation (SD) is used as a measure of precision; the respective data are as follows:

For values less than 1,000 μg/mL, the precision was 2.4% of the measured value for ramipril and constant 0.003 μg/mL for ramiprilat.

From 1,000 μg/mL upward, the precision can be formally divided into an absolute and a relative error term:

Ramipril: 0.01 ± 2.1% of the measured value

Ramiprilat: 0.033 ± 1.8% of the measured value

Accuracy: The bias served as measure. The largest deviation was for ramipril, 8.0% relatively; for ramiprilat, 13.2% relatively.

Linearity: In the measuring range given, the results obtained by this method were linear.

Limit of detection: About 0.020 μg/mL was found as limit of detection. This corresponds to a signal-to-noise ratio of 3:1.

Specificity: The method is specific and permits simultaneous determination of both compounds. Even a tenfold excess of one compound does not impair the results.

CRITICAL ASSESSMENT OF THE METHOD

The NPD can detect compounds like drugs that contain nitrogen or phosphorus in the ppb range. However, the NPD requires regular maintenance; reduced sensitivity often indicated the depletion of the active element on the thermoionic bead.

The NPD is a destructive detector that can be used in series only after nondestructive detectors (e.g., ECD). The NPD is sensitive to water that affects the condition of the thermoionic bead. The active element of the bead eventually will become depleted (especially when using halogenated solvents like dichloromethane, chloroform, etc.) and requires replacement.

MODIFICATION OF THE METHOD

Due to the discovery of two further urinary metabolites of ramipril (the respective diketopiperazine derivatives of ramipril and ramiprilat), the above-described method was slightly modified (Schmidt and Keller 1985). Instead of the rather time-consuming second

extraction step by means of a disposable Si column, the sample is cleaned by a liquid/liquid extraction step. After methylation of the compounds with diazomethane, the eluate is evaporated to dryness at 40°C under N_2 gas. Subsequently, the residue is dissolved in n-pentane/diethyl ether (3:2. v/v) and washed with 5% hydrogen carbonate solution. After separation of the upper organic layer, this is evaporated to dryness at 40°C under N_2 gas and then treated with 1 mL n-hexane/TFAA (5%) as described before (Hajdù et al. 1984). This method allows the selective determination of ramipril and its three metabolites in human urine; the limit of quantification amounted to 0.020 µg/mL for each of all four analytes. Using this assay, thousands of urine samples originating from phase I–III clinical studies were analyzed.

In the following assay, the application of capillary gas chromatography for the determination of another ACE inhibitor, but this time in human plasma and with mass-selective detection, is described.

30.3 Plasma Analysis of Benazepril Using Gas Chromatography with Mass-Selective Detection (GC-MSD)

PURPOSE AND RATIONALE

This assay is used for the quantitative determination of benazepril and its active metabolite, benazeprilat, in human plasma by capillary gas chromatography–mass-selective detection (Pommier et al. 2003). Benazepril hydrochloride, 3-{[1-ethoxycarbonyl-3-phenyl-(1S)-propyl]amino}-2,3,4,5-tetrahydro-2-oxo-1-(3S)-benzazepine-1-acetic acid hydrochloride, is a prodrug-type angiotensin-converting enzyme (ACE) inhibitor which, on absorption, is hydrolyzed to a pharmacologically active metabolite, the dicarboxylic acid (benazeprilat).

N H O OC_2H_5 N O O HO

Benazepril

N H O OH N O O HO

Benazeprilat

Note: Mass spectrometers use the difference in mass-to-charge ratio (m/z) of ionized atoms or molecules to separate them from each other. Mass spectrometry (MS) (or mass-selective detection) is therefore useful for quantitation of atoms or molecules and also for determining chemical and structural information about molecules. Molecules have distinctive fragmentation patterns that provide structural information to identify structural components.

The general operation of a mass spectrometer is:

- Create gas-phase ions
- Separate the ions in space or time-based on their mass-to-charge ratio
- Measure the quantity of ions of each mass-to-charge ratio

30.3.1 Reagents

Benazepril, benazeprilat, and the corresponding deuterium-labeled internal standards (IS) were supplied by Novartis (Basle, Switzerland). All the chemicals were of analytical grade. Hexane and toluene (Pestipur SDS) were obtained from Solvants Documentation Synthèse (Pépin, France). Methyl

tert-butyl ether and 2 mol/L trimethylsilyldiazomethane solution in hexane were purchased from Fluka (Saint-Quentin Fallavier, France). Hydrochloric acid (0.1 mol/L), 0.5 mol/L sulfuric acid, and sodium carbonate were from Merck (Darmstadt, Germany). 3M Empore C18-SD 96-well disk plates containing 12 mg C18 were obtained from Varian (Les Ulis, France).

30.3.2 Assay

An analytical method for the determination of benazepril and its active metabolite, benazeprilat, in human plasma by capillary GC with mass-selective detection was developed and validated according to international regulatory requirements (Guidance for Industry 2001; Shah et al. 2000). After addition of the internal standards, the compounds were extracted from plasma by solid-phase extraction using automated 96-well plate technology. Unlike earlier published gas chromatography–mass spectrometry (GC-MS) methods (Kaiser et al. 1987; Sioufi et al. 1988), the present method halved the volume of plasma (0.5 mL instead of 1 mL formerly required) without diminishing the lower limit of quantification (LLOQ) and reduced considerably the volume of solvent for conditioning, washing, and eluting. After elution, the compounds were converted into their methyl ester derivatives by means of a safe and stable diazomethane derivative (Blau and Halket 1993; Rimmer et al. 1996), trimethylsilyldiazomethane solution. The methyl ester derivatives were determined by mass-selective detection at m/z 365 for benazepril and benazeprilat and m/z 370 for D_5-benazepril and D_5-benazeprilat.

PROCEDURE

1. To 0.5 mL plasma in a polypropylene tube, successively 100 µL of the internal standard solution (150 ng) and 100 µL of 0.1 mol/L hydrochloric acid are added.
2. All tubes are then placed on the platform of the Packard MultiPROBE II, and a 96-well disk plate is placed on top of a vacuum manifold.
3. The 96-well disk plate is conditioned automatically with 100 µL of methanol, and 300 and 80 µL of 0.1 mol/L HCl.
4. Then, 500 µL of the prepared samples is loaded onto the 96-well disk plate.
5. The loaded samples are washed with 100 µL of water, and then, the analytes and the internal standards are eluted twice with 500 µL of methanol.
6. The eluates are transferred into extraction tubes, and 300 µL of trimethylsilyldiazomethane solution are added.
7. The reaction runs at room temperature in a dry bath for 30 min, and the reaction mixture is evaporated to dryness under N_2 gas at 40°C.
8. To the dry derivatized plasma sample, add 0.5 mL of 0.5 mol/L sulfuric acid and 1 mL of hexane.
9. The mixture is shaken mechanically for 5 min at 240 rpm and centrifuged at 1,600*g* for 2 min.
10. The upper organic phase is discarded, and the aqueous phase is alkalized with 1 mL of 2 mol/L sodium carbonate and shaken with 2 mL methyl *tert*-butyl ether for 5 min at 240 rpm.
11. After centrifugation at 1,600 g for 5 min, the organic phase is separated and evaporated to dryness under nitrogen at 40°C.
12. The residue is dissolved in 100 µL toluene, 2 µL of which is injected onto the gas chromatograph.

30.3.3 Robotic System

For sample preparation, a Packard MultiPROBE II liquid handling robotic system was used (Packard Instruments, Meriden, CT, USA) using the WinPREP software.

30.3.4 GC System

Hewlett–Packard 5890 Series II gas chromatograph equipped with a capillary inlet system and an HP 7673 automatic sampler was used (Hewlett–Packard, Palo Alto, CA, USA).

Column: Fused-silica capillary column, Restek Rtx-1, 15 m × 0.25 mm inner diameter (ID); (Restek, Evry, France)

Injection: Splitless mode, 30 s splitless period
Gases: Carrier gas (helium); inlet pressure 8 psi
Split flow: 1:50 mL/min
Septum rinsing (helium): 3 mL/min
Temperatures: Injection port 280°C
Detector: 300°C

Oven program:

Initial temperature: 190°C (0.5 min)

Heating rate: 30°C/min

Final temperature: 290°C

Detection: Hewlett–Packard 5970B mass-selective detector (MSD), the MSD was maintained at 280°C

The detector was turned on from 3.5 to 5 min after injection. The selected ions monitored for the methyl ester derivatives were m/z 365 for benazepril and benazeprilat and m/z 370 for D_5-benazepril and D_5-benazeprilat. These fragments are obtained by cleavage of the carboxyethyl [M–73] or carboxymethyl group [M–59] in the side chain.

Sample size: 2 μL

Analysis time: About 6 min per sample

EVALUATION

Daily calibration standards were prepared at six different concentrations, in duplicate, in the range of 2.5–1,000 ng/mL for benazepril and benazeprilat. Calibration curves ($y = ax + b$) were presented by plots of the peak area ratios (y) of the methyl ester derivative of benazepril or benazeprilat to the methyl ester derivative of the I.S. versus the concentration (x) of the calibration standards and were generated using weighted ($1/x^2$) linear least-squares regression as the mathematical model. Concentrations in quality control (QC) samples were calculated from the resulting peak area ratios and the regression equation of the calibration curve. Inter-day repeatability was determined on three different days. Good agreement between the nominal and the back-calculated concentration for calibration samples was observed. The precision ranged from 2.1% to 7.4%, and mean accuracies were within 8% of the nominal value for the two compounds.

The accuracy and precision were studied from replicate sets of analyte samples of known concentrations at levels corresponding to the lowest (2.50 ng/mL), near the lowest (7.50 ng/mL), near the middle (200 ng/mL), and the highest (900 ng/mL) concentrations of the calibration range. Accuracy was determined by calculating the mean recovery for the determined concentrations in standard samples. Precision was assessed from the relative standard deviation (RSD) as a percentage of the mean recovery. The following validation criteria for accuracy and precision were used to assess method suitability: mean recoveries should be within 85–115%, except at the lower limit of quantification (LLOQ), where it should not exceed 20% (Guidance for Industry 2001). Series of five quality control samples were prepared at four different concentrations in the range of 2.50–900 ng/mL (LLOQ) for benazepril and benazeprilat, by spiking drug-free plasma with the corresponding working solutions. It could be shown that the results met the acceptance criteria.

CRITICAL ASSESSMENT OF THE METHOD

The latter assay has several advantages in comparison to the first (which certainly is somewhat older):

The mass-selective detector is more specific and allows a lower limit of quantification than the nitrogen–phosphorus detector (NPD).

The use of trimethylsilyldiazomethane with methanol provides a less hazardous method for preparing methyl esters under mild conditions than ethereal diazomethane solution. Trimethylsilyldiazomethane is commercially available, obviating the need to synthesize diazomethane daily. It is a stable and safe substitute for either hazardous diazomethane or corrosive reagents containing boron trifluoride.

The procedure has a good throughput, with a combination of automated sample extraction with a 96-well disk plate using a Packard MultiPROBE II roboter.

30.4 Simultaneous Determination of Different Prostaglandins in Human Plasma Using Gas Chromatography/Negative-Ion Chemical-Ionization/Tandem Mass Spectrometry (GC-NICI-MS/MS)

PURPOSE AND RATIONALE

Prostaglandin E_1 (PGE_1) has been used therapeutically for the intravenous treatment of peripheral arterial occlusive disease (Hirai and Nakayama 1986) and of erectile dysfunction as an intracavernous (i.c.) injection (Porst 1996). PGE_1 is rapidly converted to 15-keto-prostaglandin E_0 (15-keto-PGE_0), the major circulating metabolite, and prostaglandin E_0 (PGE_0), a metabolite with activity comparable with PGE_1. The following assay is used for the sensitive (in the low pg range) and selective simultaneous routine determination of prostaglandin E_1, prostaglandin E_0 and 15-keto-prostaglandin E_0, in human plasma by capillary gas chromatography/negative-ion chemical-ionization/tandem mass spectrometry (GC-NICI-MS/MS) (Hammes et al. 1999).

Prostaglandin E_1 (PGE_1)

Prostaglandin E_0 (PGE_0)

15-keto-Prostaglandin E_0 (15-keto-PGE_0)

Note: Tandem mass spectroscopy has become to mean the mass spectrum of a mass spectrum, hence, *MS/MS*. Essentially in MS/MS, mass analyzers are coupled together via an interface known as a collision cell. Ions of a selected mass (precursor ions) are transmitted by the first mass analyzer into the collision cell. Here, they collide with the neutral atoms of an inert gas; generally, argon is used. In this process, a fraction of the translational energy inherent in the precursor ion is converted into internal energy. The internal energy is lost by the precursor ion decomposing or fragmenting into product ions. The product ions are transmitted through a second mass analyzer and subsequently determined quantitatively (Venn 2000, p. 256).

30.4.1 Reagents

PGE_1 was purchased from Acros Organics (St. Augustin, Germany), PGE_0 and 15-keto-PGE_0 from Cascade Biochem (Reading, UK). The deuterated internal standards D_6-PGE_1, D_4-PGE_0 and D_6-15-keto-PGE_0 were synthesized by the Chemistry Department (Schwarz Pharma, Monheim/Rhein, Germany). Ethyl acetate, acetonitrile, dichloromethane, hexane, and methanol were obtained from Promochem (Wesel, Germany); ethanol and formic acid from Merck (Darmstadt, Germany); and pentafluorobenzyl bromide (PFBBr), N, N-diisopropylethylamine (DIPEA), MOX reagent (2% methoxyamine hydrochloride in pyridine), and N, O-bis-(trimethylsilyl) trifluoroacetamide (BSTFA) from Pierce (Oud Beijerland, Netherlands). Indomethacin was from Sigma (Deisenhofen, Germany) and Biostabil from Biotrans (Dreieich, Germany). All chemicals were of the highest grade available and used without further purification. Bond Elut C18/Si cartridges were obtained from ICT (Frankfurt/Main, Germany). Water was purified with the NANOpure system delivered by Werner (B.-Gladbach, Germany).

30.4.2 Assay

An analytical method for the determination of PGE_1, PGE_0 and 15-keto-PGE_0 in human plasma by capillary GC with tandem mass spectrometry was developed and validated. After addition of the deuterated internal standards, the compounds were extracted from plasma by solid-phase extraction using C18 cartridges, followed by derivatization to the pentafluorobenzyl (PFB) ester methoxime. After evaporation of the derivatization reagents to dryness, the samples were purified on Bond Elut Si cartridges and converted to their trimethylsilyl (TMS) ethers. Quantitation was achieved by gas chromatography/negative-ion chemical-ionization/tandem mass spectrometry. The lower limit of quantification (LLOQ) was 2 pg/mL for PGE_1 and PGE_0, and 10 pg/mL for 15-keto-PGE_0, extracted from 2 mL of human plasma.

PROCEDURE

1. To 2 mL plasma in a centrifuge tube, 200 pg D_6-PGE_1/D_4-PGE_0 and 500 pg D_6-15-keto-PGE_0 as internal standards are added to the sample and then adjusted to pH = 3.0–3.5 with 200 μL 3% formic acid.
2. The sample thus prepared is applied onto a C18 column—which has been preconditioned with methanol (6 mL) followed by redistilled water (6 mL)—and slowly sucked through under vacuum.
3. Subsequently, the column is washed with 3 mL redistilled water and with 6 mL hexane.
4. The pressure drop is increased to 80 kPa, and the column is sucked dry for 10 min.
5. The analytes are eluted[3] with 3 mL ethyl acetate.
6. The eluate is evaporated to dryness at room temperature.
7. The residue is incubated with PFBBr (10 μL) and DIPEA (20 μL) in acetonitrile (70 μL) for 10 min at 40°C.
8. The sample is evaporated to dryness and converted to the methoxime with 200 μL of MOX reagent for 30 min at 70°C.
9. After evaporation to dryness, the sample is transferred three times by 1 mL dichloromethane to a Bond Elut Si cartridge, prewashed with 6 mL of dichloromethane.
10. The cartridge is washed with ethyl acetate-dichloromethane (5:95, v/v).
11. The analytes are eluted with 3 mL of ethyl acetate.
12. The extract is incubated with 100 μL of BSTFA for 60 min at 50°C.
13. It is evaporated to dryness at room temperature.
14. Subsequently, the sample is taken up in 40 μL of BSTFA, 1 μL of which is injected.

[3]Recovery over the concentration range validated: 95–100% for PGE_1, 86–89% for PGE_0, and 91–93% for 15-keto-PGE_0.

30.4.3 GC-MS/MS System

Finnigan TSQ 700 triple-stage mass spectrometer (Finnigan MAT, Bremen, Germany) equipped with a Hewlett–Packard HP 5890 Series II gas chromatograph, an HP 7673A autosampler (Hewlett–Packard, Palo Alto, CA, USA), and a temperature-programmable split/splitless injector (Gerstel, Mühlheim/Ruhr, Germany).

Column: Fused-silica capillary column, Hewlett–Packard Ultra 2, 12 m × 0.20 mm inner diameter (ID)

Injection: Splitless mode

Gases: Carrier gas (helium); inlet pressure 30 kPa

Reagent gas (methane); ion source pressure 120 Pa

Collision gas (argon); collision cell pressure 0.2 Pa

Temperatures: Injection port (programmed) from 150°C to 300°C at 10°C/s (held for 5 min)

Oven program:

Initial temperature: 150°C (held for 0.1 min)

Heating rate: 40°C/min

Final temperature: 300°C (7 min)

The transfer line, the manifold, and the ion source were kept at 300°C, 70°C, and 150°C, respectively.

Detection: The mass spectrometer was operated in the negative-ion mode with an emission current of 300 μA and an electron energy of 85 eV

Sample size: 1 μL

Analysis time: About 9 min per sample

For quantitation in the multiple ion detection (MID) mode, the precursor → product ions monitored in the negative-ion mode were m/z 626.4 → m/z 346.2 = $[P–2(CH_3)_3SiOH]^-$ion for PGE_1, m/z 483.3 → m/z 393.2 $[P–(CH_3)_3SiOH]^-$ion for 15-keto-PGE_0, and m/z 528.4 → m/z 438.2 = $[P–(CH_3)_3SiOH]^-$ ion for PGE_0.

EVALUATION

Linear calibration curves were obtained over the concentration range 2–100 pg/mL (PGE_1 and PGE_0) and 10–500 pg/mL (15-keto-PGE_0) of human plasma. The LLOQ (lower limit of quantitation) of the assay, i.e., the concentration with an accuracy and a precision $\leq 20\%$, was 2 pg/mL (PGE_1 and PGE_0) and 10 pg/mL (15-keto-PGE_0). The precision and the accuracy of the method were determined by analysis of blank human plasma (2 mL) spiked with PGE_1/PGE_0 in the concentration range 4–200 pg and with 15-keto-PGE_0 in the concentration range 20–1,000 pg. In any case, both the precision and the accuracy were $<17\%$ and indicated good reproducibility. The method has been applied successfully for the determination of PGE_1, PGE_0, and 15-keto-PGE_0 in human plasma after a 2-h IV infusion of 60 µg of PGE_1in order to investigate the pharmacokinetics of PGE_1, PGE_0, and 15-keto-PGE_0 in healthy volunteers.

CRITICAL ASSESSMENT OF THE METHOD

A highly selective and sensitive routine method for the simultaneous determination of PGE_1, PGE_0, and 15-keto-PGE_0 in human plasma is described. Compared to the recently developed GC-NICI-MS/MS assay (Schweer et al. 1994), the described method with a modified purification step of the PFB ester methoxime derivatives by means of Bond Elut Si cartridges allows the processing of at least 24 samples per day applying the available solid-phase extraction unit.

30.5 Determination of Calcium-Blocking Agents Using Gas Chromatography with Electron-Capture Detection (GC-ECD)

PURPOSE AND RATIONALE

Nifedipine (NF), nitrendipine (NT), and nimodipine (NM) belong to the dihydropyridine group of calcium-blocking agents. The main indications are treatment of angina pectoris and for the treatment of arterial hypertension (Krebs 1982); the main indication for NT is the treatment of hypertension (Stoepel et al. 1981). NM acts mainly on cerebral vessels (Langley and Sorkin 1989). The assay was developed by Rämsch et al. (1986) to investigate the pharmacokinetics and the metabolism of calcium-blocking agents like nifedipine (NF), nitrendipine (NT), and nimodipine (NM) using capillary gas chromatography with electron-capture detection (ECD).

nifedipine (NF)

nitrendipine (NT)

nimodipine (NM)

Note: The ECD detector consists of a sealed stainless steel cylinder containing radioactive ^{63}nickel. The ^{63}nickel element emits beta particles (electrons), which collide with the carrier gas molecules, ionizing them in the process. This forms a stable cloud of free electrons in the ECD cell. When organic molecules that contain electronegative functional groups, such as halogens, phosphorus, and nitro groups, pass by the detector, they capture some of the electrons and reduce the current measured between the electrodes. The ECD is by far more sensitive than the FID (flame-ionization detector) but has a limited dynamic range (about 10^4-fold) and finds its greatest application in analysis of halogenated compounds, like pesticides, herbicides, and drugs.

30.5.1 Reagents

The 1,4-dihydro-2,6-dimethyl-4-(2- or 3-nitrophenyl)-3,5-pyridine-dicarboxylate derivatives nifedipine (NF), nitrendipine (NT), and nimodipine (NM) were supplied by Bayer AG (Wuppertal, Germany). Analytical grade reagents were used at all times; toluene AR (Riedel-de-Haën AG, Seelze, Germany) was distilled over a 50-cm Vigreux column before use. Sodium hydroxide, 0.5 mol/L, was purchased from J.T.Baker Chemical Co. (USA), and the amber screw-cap autosampler bottles (2 mL) were obtained from Pierce Biotechnology Inc. (Rockford, IL, USA) and rinsed with acetone before use.

30.5.2 Assay

Nifedipine, nitrendipine, or nimodipine were extracted from alkalized plasma directly into toluene containing the respective internal standard: nitrendipine or nimodipine (NT for the quantification of NF and NM for the detection of NT). Thereby, it is important to take into account that the samples have to be protected from daylight and from fluorescent light to prevent formation of photodecomposition products (Ahnoff and Persson 1990; Le Guellec et al. 1992). Under the action of daylight and of fluorescent light, e.g., nifedipine is converted into the corresponding nitrosophenylpyridine (Testa et al. 1979).

Subsequently, the compounds were analyzed by capillary gas chromatography using an electron-capture detector.

PROCEDURE

1. To 0.5 mL plasma in a 2-mL autosampler bottle, 50 μL 0.5 mol/L NaOH and 1 mL toluene containing 50 ng of the respective internal standard (NT for the quantification of NF and NM, and NM for the detection of NT) are added.
2. The bottle is covered with a piece of aluminum foil instead of the usual silicon or rubber disk and closed with the screw cap.
3. Subsequently, the bottle is shaken for 5 min.
4. The bottle is transferred without opening—or any centrifugation—directly into the autosampler.
5. 2 μL of the upper toluene phase is injected into the gas chromatograph.

Using 300-μL micro-vials and one tenth of the reagents, 50 μL of plasma can be extracted to give the same sensitivity!

30.5.3 GC System

Hewlett–Packard 5840A gas chromatograph equipped with a ^{63}Ni electron-capture detector (ECD), an HP 7672A autosampler (Hewlett–Packard, Palo Alto, CA, USA), and a temperature-programmable split/splitless injector (Gerstel, Mühlheim/Ruhr, Germany). The needle tip of the autosampler dipped only into the upper third of a sample bottle to prevent the injection of any of the aqueous phase into the GC column.

Column: Fused-silica capillary column, Durabond DB-1 (0.1-μm film thickness), 30 m × 0.32 mm inner diameter (ID); (J & W Scientific, Folsom, CA, USA)

Injection: Splitless mode (1 min)

Gases: Carrier gas (helium), 3 mL/min

Electron-capture detector gas (argon/methane): 50 mL/min

Temperatures: Injection port 250°C

Detector: 300°C

Oven program:

Initial temperature: 160°C. Splitter closed; duration 1 min

Heating rate: 10°C/min

Final temperature: 270°C (20 min)

Detection: ECD detector
Sample size: 2 μL
Analysis time: About 32 min per sample

EVALUATION

The pharmacokinetics of the three dihydropyridine calcium blockers, nifedipine, nitrendipine, and nimodipine, was investigated using the GC assay presented above. The retention times of the three compounds amounted to 18.6 min for NF, 20.8 min for NT, and to 24.2 min for NM. The detection limits were at least 1 ng/mL, but for NT and for NM, limits of 100 pg/mL could also be achieved.

In spite of the structural and physiochemical similarity of the three compounds, they differ in their pharmacokinetic behavior. NF, a relatively polar molecule with the lowest volume of distribution and highest plasma levels in relation to dose, has the greatest bioavailability. On the other hand, NT and NM, with a threefold to fourfold lower solubility in water, have a low bioavailability, low plasma concentrations, and a larger volume of distribution (Rämsch et al. 1986).

CRITICAL ASSESSMENT OF THE METHOD

Analogous to the majority of dihydropyridines, nifedipine's, nitrendipine's, and nimodipine's chemical structures—a 2- or 3-nitrophenyl substituent in the 4-position combined with the dihydropyridine diester structure—results in a high response in electron-capture detection (ECD), thus allowing high detection sensitivity and sufficient assay specificity toward endogenous compounds, metabolites, or common co-medications (Mück and Bode 1994).

However, because it contains 5 mCi of ^{63}nickel, the ECD is covered by a "General License" requiring a periodic "wipe test" and the filing of a form with the respective state's Department of Health or with another adequate authority. Its advantages are (Venn 2000):

- It is selective for halogens, nitro groups, peroxides, and quinones.
- It is extremely sensitive.
- It is nondestructive (in contrast to the NPD, FID, or MS).

Its disadvantages are:

- A limited dynamic range, 10^4-fold.
- It is prone to contamination.
- It is radioactive; leakage must be checked regularly.

MODIFICATION OF THE METHOD

Since the calcium channel blockers are highly potent drugs, their concentration in human plasma and other biological fluids is generally low (high pg/mL to low ng/mL range) thus requiring analytical techniques of high sensitivity and specificity. The numerous publications, which have appeared until the end of the eighties describing various setups of gas and liquid chromatographic procedures, have been thoroughly reviewed by M. Ahnoff and Persson (1990). Their conclusion may be summarized that a simple liquid/liquid extraction followed by gas chromatography with electron-capture detection (GC-ECD) or mass spectrometric detection (GC-MS), preferably in the negative-ion chemical-ionization mode (NICI) (Fischer et al. 1986) is usually an adequate and efficient way to provide drug concentrations for pharmacokinetic evaluation and therapeutic drug monitoring. If not restricted due to its generally inferior limit of quantification, high-performance liquid chromatography with UV or amperometric detection (HPLC-UV resp. HPLC-ELCD) can be an attractive alternative for the quantification of dihydropyridines in biological fluids (Mück and Bode 1994).

However, as already mentioned earlier, high-pressure liquid chromatography with tandem mass spectrometric detection (LC-MS/MS) has evolved in the last few years as the major bioanalytical technique for the bioanalysis of analytes in biological matrices. This is reflected also in a number of LC-MS/MS assays for the determination of dihydropyridine calcium antagonists in biological fluids (Carvalho et al. 2001; Schug et al. 2002; Kang et al. 2004).

30.6 Determination of Diethylcarbamazine (DEC) Using Gas Chromatography with Flame-Ionization Detection (GC-FID)

PURPOSE AND RATIONALE

Single doses of diethylcarbamazine (DEC) in combination with albendazole have been found safe and efficacious for the treatment of *Brugia malayi* infection (Shenoy et al. 1999), and single-dose treatment of DEC with ivermectin is effective against adult *Wuchereria bancrofti* (Dreyer et al. 1998). However, since DEC is a compound that lacks a chromophore, spectroscopic methods of analysis that utilize chromophores, like HPLC with UV detection, are not suitable for the bioanalytical determination of the compound. In order to achieve the sensitivity and specificity for the determination of DEC in plasma, a number of gas chromatographic methods have been developed (Bogan 1977; Nene et al. 1984; Lee et al. 1997), partly with nitrogen phosphorus detection. To overcome the regular maintenance that is required for the nitrogen–phosphorus detector (NPD), which made it difficult to apply the method to clinical pharmacokinetic studies with high-sample throughput requirements, a sufficient sensitive, selective, accurate, and reproducible gas chromatographic assay using flame-ionization detection (FID) for the determination of DEC in human plasma was reported in 2001 by Miller and Fleckenstein (2001).

diethylcarbamazine (DEC)

1-diethylcarbamyl-4-ethyl-piperazine (IS)

Note: The FID detector was the first successful universal GC detector to be developed and remains the most widely used. The effluent from the column is mixed with hydrogen and air, and ignited. Organic compounds burning in the flame produce ions and electrons, which can conduct electricity through the flame. A large electrical potential is applied at the burner tip, and a collector electrode is located above the flame. The current resulting from the pyrolysis of any organic compounds is measured. The FID is a useful general detector for the analysis of organic compounds[4]; it has high sensitivity, a large linear response range, a low noise, and it shows a similar response for most analytes. It is generally robust and easy to operate, but because it uses a hydrogen diffusion flame to ionize compounds for analysis, it destroys the sample in the process.

30.6.1 Reagents

All solvents and chemicals were HPLC grade. Organic solvents, sodium carbonate (anhydrous), and sodium

[4] It responds to any molecule with a carbon–hydrogen bond, but not at all or poorly to compounds such as H_2S, CCl_4, or NH_3.

bicarbonate were purchased from Fisher Scientific (Fair Lawn, NJ, USA). Carbonate buffer, pH = 10.0, was prepared using the sodium carbonate (anhydrous), and sodium bicarbonate. A solution of 0.1% triethylamine in methanol was made for the elution solvent. Diethylcarbamazine citrate was obtained from Sigma and used to make stock solutions (St. Louis, MO, USA). The internal standard, 1-diethylcarbamyl-4-ethylpiperazine (E-DEC), was synthesized by the Division of Medicinal and Natural Products Chemistry at the University of Iowa, College of Pharmacy. Ultrapure analytical grade type I water was produced by a Milli-Q Plus water system (Millipore Corporation, Bedford, MA, USA). For the extraction of DEC and of its internal standard, Alltech Extract, Clean C18 cartridges, 500 mg with a 2.8 mL reservoir, and an SPE vacuum manifold (Alltech, Deerfield, IL, USA) were used.

30.6.2 Assay

DEC and the internal standard (IS), 1-diethylcarbamyl-4-ethyl piperazine HCl (E-DEC), were extracted from human plasma—that has been alkalized with carbonate buffer—after loading onto a conditioned C18 solid-phase extraction cartridge, rinsed with water, and eluted with methanol. After evaporation under a stream of nitrogen and reconstitution in methanol, 3 μL was injected into the GC system and detected using a flame-ionization detector (FID). The retention time for DEC was 5.5 min, and for the internal standard (E-DEC), it was 7.28 min.

PROCEDURE

1. To 0.5 mL human plasma in a disposable centrifuge tube, 25 μL of the working solution of the internal standard (21 μg E-DEC/mL) and 1 mL of carbonate buffer pH = 10.0 are added, and the sample is mixed on a vortex mixer for 30 s.
2. The sample thus prepared is applied onto a C18 column—which has been activated by aspirating 1 cartridge volume (~3 mL) methanol followed by 1 cartridge volume of HPLC grade water—and slowly sucked through under vacuum (at about 20-kPa pressure drop).
3. Subsequently, the column is washed with 2.5 mL of HPLC grade water at the same reduced pressure and allowed to dry for 10 min under vacuum.
4. For sample elution, 2 mL of 0.1% triethylamine in methanol is added to each cartridge and allowed to pass through the cartridge into 5 mL disposable centrifuge tubes under low vacuum.
5. After elution, the eluate is evaporated to dryness at 40°C under a gentle stream of N_2 gas.
6. The residue is taken up in 50 μL methanol and mixed on a vortex mixer for 60 s.
7. 3 μL of the reconstituted residue is injected into the GC.

30.6.3 GC System

Hewlett–Packard 5890 Series II Plus gas chromatograph equipped with a flame-ionization detector (FID) and an HP 7673 autosampler (Hewlett–Packard, Palo Alto, CA, USA).

Column: Fused-silica capillary column, Heliflex AT-35 capillary column (0.25-μm film thickness), 30 m × 0.32 mm inner diameter (ID); (Alltech, Deerfield, IL, USA)

Injection (*split*/*splitless*): No information available

Gases: Carrier gas (helium): 1.5 mL/min; inlet pressure 11 psi

Detector makeup (helium): 25 mL/min

Detector (hydrogen): 35 mL/min

Detector (air): 420 mL/min

Temperatures: Injection port 180°C

Oven: 160°C

Detector: 240°C

Detection: FID detector

Sample size: 3 μL

Analysis time: About 22 min per sample

EVALUATION

Calibration curves for DEC in human plasma were linear using unweighted linear regression in the concentration range of 100–2,000 ng/mL, with correlation coefficients greater than or equal to 0.9934 for all curves. The limit of quantification (LOQ) in human plasma was accepted as 70 ng/mL. Plasma samples were spiked to a nominal concentration of 70 ng/mL with DEC working solution and internal standard and carried through the extraction procedure. At the LOQ, the CV ($n = 6$) of the measured concentration was 4.5%, and the deviation of the mean of the measured concentrations from the nominal value was −6.1%.

Precision, accuracy, and recovery were evaluated by conducting repeated analysis ($n = 6$) of spiked plasma samples at three different concentration levels: 120, 1,000, and 2,000 ng/mL. For an intra-day run ($n = 6$), the coefficient of variation of DEC at 120, 1,000, and 2,000 ng/mL had been shown to be 4.5%, 1.3%, and 1.6%, respectively. The deviation of mean values from nominal ($n = 6$) was –4.4%, 2.0%, and 1.4%, for DEC concentrations 120, 1,000, and 2,000 ng/mL, respectively. The CV results for inter-day precision at the same concentrations were all less than 7% ($n = 12$). The deviation of mean values from nominal ($n = 12$) was –1.7%, 2.6%, and 0.8%, for DEC concentrations 120, 1,000, and 2,000 ng/mL, respectively.

Recovery was tested at low, medium, and high concentration of DEC and internal standard. Absolute recoveries were determined by comparing the peak areas of extracted QC samples with the peak areas of recovery standards (unextracted equivalents of extracted QC samples). The mean recoveries for DEC and the internal standard were 84.8% and 85.5%, respectively.

Autoinjector stability was carried out for over 13 h by repeated injection of the same extracted plasma sample at room temperature (nominally 25°C); the results showed that the extracted specimens remained stable over the course of the study. QC samples containing 120 and 2,000 ng/mL DEC in plasma were subjected to 3 freeze/thaw cycles. Samples were frozen at −20°C for 24 h and thawed unassisted at room temperature. When completely thawed, the samples were transferred back to the original freezer and kept refrozen at least 24 h. Freezing and thawing of the QC samples appeared to have no effect on quantitation of the analyte. In addition, QC samples containing 120 and 2,000 ng/mL DEC in plasma were subjected to storage at −20°C for 12 weeks. Plasma samples ($n = 6$) were taken for DEC analysis at 0, 2, 4, 9, and 12 weeks. The QC samples stored in a freezer set to maintain −20°C remained stable for the duration of the study period.

CRITICAL ASSESSMENT OF THE METHOD

The assay has been validated, and the results of validation demonstrate that the standard curve is linear over the concentration range of 100–2,000 ng/mL. The assay is reproducible and accurate, with recovery of the analyte and internal standard in the range of 80–90%. The analysis requires 0.5 mL of plasma and has a limit of quantification of 70 ng/mL. The stability of plasma samples stored at −20°C has been demonstrated for up to 12 weeks. Autoinjector stability has been demonstrated for over 13 h, and freeze–thaw stability has been demonstrated for 3 freeze–thaw cycles. The procedure has a sample throughput of at least 30 specimens per day. The assay meets the guidelines for bioanalytical methods validation for human studies (Shah et al. 1991).

PURPOSE AND RATIONALE

Powerful analytical techniques are one key requirement for successful drug research and development. The concentration of drugs, prodrugs, and metabolites has to be determined in very diverse matrices such as plasma (blood), urine, feces, and also in different organ tissues (depending on the nature of the drug and on the targeted organs).

A wide set of analytical tools has been used for this purpose. Gas chromatography, in combination with different detection techniques such as mass spectrometry, FID (flame ionization detector), and others, has been successfully used for this purpose (Jennings 1987) as well as liquid chromatography (LC), in combination with UV or fluorescence detection and others (Dorschel et al. 1989; Chu et al. 1999; Jin et al. 2004; Abu-Qare and Abou-Donia 2001).

However, these techniques have certain limitations. One prerequisite for a successful GC analysis is often the need for one or several chemical derivatization steps, since most analytes are not volatile enough for GC separation. Liquid chromatography, in combination with, for example, UV-, fluorescence-, or radioactivity detectors, is usually sensitive and does not require any sample derivatization. The only common drawback in this method is the lack of analyte specificity and in some cases also sensitivity.

The technique which is currently used predominantly is liquid chromatography coupled to mass spectrometry (LC-MS or LC-MS/MS). Consequently, this chapter describes the use of LC-MS in detail. However, it should be mentioned here that other very powerful techniques such as immunoassays, ELISAs, and chromogenic enzyme assays are used as well, and these types of bioassays are coming more and more into focus since biomolecules are being developed in a rapidly increasing number, which fuels the need for assays that specifically allow the sensitive analysis of biomolecules. The increasing number of biomolecules such as proteins in drug development also brought the possibility of analyzing these compounds by LC-MS/MS into focus. The possibilities and limitations of LC-MS/MS in this application are also discussed in this chapter.

PROCEDURE

31.1 Ionization

A big step in resolving this issue was achieved by the introduction of electrospray ionization (ESI) mass spectrometry and atmospheric pressure chemical ionization (APCI) mass spectrometry (and recently also atmospheric pressure photo ionization—APPI; Bruins 2000; Raffaelli and Saba 2003) as a detection system for liquid chromatography. These techniques, established in the late 1980s (Lim and Lord 2002; Dole et al. 1968; Whitehouse et al. 1985; Cole 1997; Gaskell 1997; Robb et al. 2000) have very rapidly become the method of choice for drug quantification throughout the drug research community and in the pharmaceutical industry (Tiller et al. 2003; Hopfgartner and Bourgogne 2003).

The basic principle is a soft ionization (no or almost no fragmentation of the analyte molecules is usually happening during the ionization step) of samples out of the liquid phase (ionization occurs in the liquid phase in case of ESI or in the gas phase after solvent evaporation in case of APCI). Samples are separated and purified using liquid chromatography. The eluent of the LC is transferred into the mass analyzer via a capillary. Usually, no sample derivatization is needed. As a result of the ionization process, analytes will form predominantly protonated or deprotonated molecular ions ($[M + H]^+$ or $[M-H]^-$) and also adducts such as $[M + Na]^+$, $[M + NH_4]^+$, and other adducts. In addition to that, and depending on the size of the molecules, multiple charging might also occur (Lim and Lord 2002; Cole 1997; Gaskell 1997).

31.2 Mass Analyzers

A large variety of mass analyzers has been tested and is in use for all kinds of bioanalytical assays. The type of detector predominantly used throughout the pharmaceutical community for drug quantification is the triple-quadrupole mass spectrometer. This type of mass analyzer has several key advantages for the analysis of biological samples in combination with liquid

chromatography. Triple quadrupole mass analyzers allow for the selection of one or several analytes, which can be filtered in the first quadrupole, allowing only ions of a certain mass to charge ratio to pass this first quadrupole (first mass filter). In a second step, the filtered ions can be fragmented in a collision cell by collisions with background gas molecules. The fragmentation pathway is a characteristic property of a chemical compound or chemical compound class, which allows the use of fragment formation as a fingerprint for a specific compound or compound class. In a third step, the fragments formed during this process can be filtered again in order to let only one specific fragment ion reach the detector of the mass analyzer. In this way, a substantial reduction of background is achieved in combination with a very high selectivity against interference of endogenous compounds in the analyte matrix. Multiple compounds can be analyzed in one run since the instruments are able to switch within milliseconds from one ion/fragment to the other and back. As a result, a separate chromatogram is yielded for each and every analyte, which can be integrated and processed (Venn 2000; Willoughby et al. 1998).

Besides the triple quadrupole instruments, other types of mass spectrometers might be used as well. Examples for these types of instruments are ion traps, time of flight mass spectrometers, and also single quadrupole mass analyzers. Due to the characteristic and specific advantages and disadvantages of different instrument types, the overall assay performance (e.g., sensitivity, dynamic range, and selectivity) may vary quite a bit from one instrument type to the other.

A new technique that has been introduced recently is the "FAIMS" (High-*F*ield *A*symmetric waveform *I*on *M*obility *S*pectrometer) technology (Guevremont 2004). The FAIMS interface works in combination with ESI and APCI ion probes in order to increase selectivity in challenging assays in combination with LC-MS/MS. FAIMS is an atmospheric pressure ion separation technology. In FAIMS, the ions are separated according to their properties while drifting in very high electric fields. Simply stated, each type of ion has an ion mobility which is a constant in low electric fields. At high fields, the mobility of each ion deviates from its low-field value. The extent of that deviation is the key to ion separation in FAIMS. Using FAIMS can help to overcome selectivity issues which are not solvable by LC-MS/MS alone. Although signal intensities with FAIMS are typically lower, the elimination/reduction of chemical noise might still provide a better sensitivity through an improved signal-to-noise ratio.

31.3 Internal Standards

In order to compensate for variations during sample analysis (e.g., thermal instabilities, variability in flow rate, and also electronic instability in the mass analyzer), samples are usually analyzed together with an internal standard, which is always added to the sample in the same amount. All measured peak areas or peak heights can be normalized on the signal of the internal standard, which helps to eliminate fluctuations during the individual measurement and compensate for matrix effects and recovery variations.

Two different types of internal standards are used. The first and usually ideal choice is a stable isotope of the analyte itself. In most cases, ^{13}C or ^{2}H isotopes are used for this purpose. It is important to note that the number of atoms replaced by the stable isotope should be large enough in order separate the isotope distribution of the internal standard from the natural isotope distribution of the analyte. The replacement of 6 ^{12}C or 6 ^{1}H atoms by ^{13}C or ^{2}H is usually a good choice for most pharmaceutical analytes ($m/z < 500$). Such isotopes are deemed ideal as internal standards since they will have the best probability for similar properties not only in terms of the ionization efficiency and sensitivity, but also in terms of the sample preparation procedure (solubility, extraction rate, and so forth). They will have an identical retention time and will therefore correct any fluctuations on the chromatography to the best possible extend (Venn 2000). Caution should be applied when dealing with deuterated ($^{2}H-$) standards. In some cases, a small shift in retention time is observed, which can limit the effect of such a standard. Unfortunately, the synthesis of labeled compounds can be difficult, time consuming, and expensive. In case that no stable isotope of the analyte is available, another compound has to be chosen as standard. For this purpose, one should look for a compound with similar structure, preferably from the same compound class, since such a molecule will

have the best chance for similar physical and chemical properties like ionization efficiency, retention time, and so forth. The difference in retention time should be small in order to correct for fluctuations in the LC-MS/MS system. However, in case of multiple analytes, this might not be achievable. Therefore, it will be necessary for some analytical problems to use more than one internal standard.

The use of an analog compound as internal standard will be the method of choice when it comes to the analysis of biomolecules, such as proteins, by LC-MS/MS since a stable isotope labeled standard is typically not available due to the fact that a large number of, for example, hydrogen atoms would need to be replaced by deuterium in order to achieve a mass difference which is large enough to prevent an overlay of the natural isotopic distribution with the stable isotope pattern. An iodine-labeled compound would be an option to overcome this hurdle. Otherwise, an analog standard will be the choice, which, for example, has a difference in one amino acid.

31.4 LC Conditions

In drug analysis, LC-MS usually means reversed phase liquid chromatography (RP-LC) coupled to mass spectrometry. Although normal phase LC can be used as well (especially in combination with atmospheric pressure chemical ionization—APCI), predominantly RP-LC is used in drug research and drug analysis due to the typical physical and chemical properties of the analytes (e.g., polarity, size).

Gradients of aqueous and organic mobile phases are typically used for LC-MS/MS analysis of drug compounds and metabolites. The most common aqueous solvents are water with 0.1% formic acid or 0.1% acetic acid (v/v) or volatile buffers like 5 mM ammonium acetate or ammonium formate often adjusted to a certain pH value with the corresponding acid or base (the pH of the eluents will have to be optimized with respect to the polarity of the analytes, since ionic species will have very low or no retention on the reversed phase LC-columns). Other volatile buffers can be used as well. Nonvolatile buffers are typically not useful; they will deposit in the ion source housing and will eventually lead to system contamination/breakdown. Phosphate buffer should also be avoided, since it will cause suppression of the ionization and thus lead to very bad analytical performance (Venn 2000). Reagents like triethylamine should also be avoided as mobile phase or as part of mobile phases. They induce ion suppression as well. In terms of the organic solvents, methanol and acetonitrile are very widely used and they are very well suitable for LC-MS. Other solvents can be used as well, as long as they are compatible with the materials used in the LC-MS system.

The gradients used are typically as short as possible (often less than 5 min) in order to realize a short analysis time and high sample throughput. A chromatographic separation of all components is usually not required since the analyzer is mass selective and very specific. The LC-method is mainly necessary for sample cleanup, which in most cases means the separation of matrix-related compounds from the analyte molecules. In terms of the flow rates, a very wide range can be used. Depending on the instrument used and on the source design, flow rates can typically vary between 10 or 20 μL/min and 5,000 μL/min or more. LC-columns should be selected with respect to the flow rate that is going to be used (inner diameter, particle size and length of the column). A very broad variety of packing materials is in use. However, C_{18}-reversed phase columns are probably the basic standard columns that are in use (Venn 2000; Willoughby et al. 1998).

The newest developments in LC techniques have significantly shortened analysis time without compromising chromatographic resolution or sensitivity. For that purpose, short LC columns with small particles (e.g., C_{18} columns with 50 mm length, a particle size of 1.8 μm and an inner diameter of about 3 mm) are used. These kind of columns are used at higher temperatures of about 60°C in order to reduce back pressure. Using this techniques, analysis times per sample can be reduced to less then 2 min in many cases, allowing for high sample throughput. This type of LC, often referred to as "UPLC" or "Rapid Resolution HPLC" (Hüsgen 2006; Swartz 2005), needs special LC-equipment in order to keep up with the higher pressure (>400 bar) that is caused by the higher flow rates.

31.5 Sample Preparation

Sample cleanup and sample preparation is a crucial step for a successful analysis. Three major approaches are used on a routine basis in many assays, which have

been reported in the literature (O'Connor 2002; Venn 2000; Chambers et al. 2007).

(a) Protein precipitation/dilution (PP)
(b) Solid phase extraction (SPE)
(c) Liquid-liquid extraction (LLE)

31.5.1 Protein Precipitation/Dilution

Protein precipitation is a very simple method of sample preparation. The sample (typically a plasma or urine sample) is spiked with internal standard solution and, in case of the calibration standard or quality control samples also with analyte solution. In case of unknowns, pure solvent is added instead of the analyte solution. Following this step, samples are diluted with an organic solvent (in most cases acetonitrile or methanol), which leads to protein precipitation. Samples are typically centrifuged after this step and the resulting supernatant is either analyzed directly by LC-MS/MS, or a dilution step is implemented prior to sample analysis (Beck et al. 2004; De Jonge et al. 2004; Viberg et al. 2004; Crommentuin et al. 2004; Stovkis et al. 2004; Hou et al. 2004; Kasel et al. 2004; Jamal et al. 2000). In many cases, this kind of sample preparation proved to be sufficient. However, more advanced sample cleanup might be necessary, depending on the matrix and analytes that need to be handled.

31.5.2 Solid Phase Extraction (SPE)/Mixed Mode SPE

Another simple and effective method for sample preparation is the solid phase extraction (SPE). In a typical approach, samples will be mixed with aqueous internal standard solution and with a small amount of acid (typically 0.2% formic acid). The resulting sample will be loaded on to the SPE extraction column (columns need to be conditioned before use, typically by flushing with methanol and water). After loading the sample on to the column, the loaded column is washed with water. Finally, the sample is washed off using an organic solvent combination such as $CHCl_3$/methanol (e.g., 2:1 v/v with 0.1% formic acid). The resulting sample solution is lyophilized in order to yield the solvent-free sample. The dry sample is reconstituted with mobile phase and is now ready for LC-MS/MS analysis. In many cases, an online approach is used as well, where the sample is eluted from the SPE cartridge directly onto the analytical LC-column (Venn 2000; Sottani et al. 2004; Pichini et al. 2004; Ding and Neue 1999; Kollroser and Schober 2002). However, using SPE might not always be sufficient in order to remove endogenous matrix constituents (such as proteins and phospholipids) or exogenous compounds (e.g., drug dosing vehicles such as PEG 400 or Tween 80), which can lead to ion-suppression or ion-enhancement effects during LC-MS/MS analysis. Mixed-mode SPE uses a dual retention mechanism to extract ionizable drugs from biological fluids. This approach allows a rigorous interference elution procedure to be used, selectively removing interfering compounds from the SPE column, prior to elution of drugs of interest. Mixed-mode SPE can significantly improve sample cleanup compared to SPE based on a single retention mechanism (Chambers et al. 2007). However, the more complicated sample workup for mixed mode SPE is not in general justified. It should be considered on an assay by assay basis.

31.5.3 Liquid-Liquid Extraction (LLE)

A general recipe for sample preparation by liquid-liquid extraction is not available, since the necessary procedures (solvents, pH, etc.) are depending on the chemical nature of the analyte that needs to be extracted (e.g., pK_a; it could be an acidic or basic compound or might be neutral) and of course also on the properties of the matrix that is present. However, when a basic compound needs to be extracted out of plasma samples, the following steps might be appropriate in many cases. Typically, in a first step, the internal standard is added to the unknowns. In case of the calibration standards and quality control samples, the blank matrix samples should be spiked with the analyte as well. This will guarantee that all extraction steps following this step will be applied on the standard and analyte. In case of a basic analyte, the sample pH should be basic. This can be achieved by adding, for example, 0.05% NH_3-solution. In case of acidic compounds, the use of formic acid or acetic acid is recommended. Following the addition of the acid or base, the samples can be extracted with CH_2Cl_2 (or another organic solvent). After shaking and centrifugation, the aqueous phase should be removed and the remaining organic phase (which should contain

the analyte) could be evaporated in order to yield the purified dry sample. The sample will then be reconstituted by adding a suitable solvent (e.g., starting mobile phase for the LC) (Stovkis et al. 2004; Keller et al. 2003; Bonato et al. 2003; Baker et al. 2004; Xia et al. 1999; Laurito et al. 2004). In any case, a recovery experiment should be performed in order to assess the efficacy of the extraction procedure. Recovery can be assessed by comparing the results for an extracted sample of known concentration with an unextracted sample, containing the theoretical concentration (assuming 100% recovery) in the mobile phase. In cases where fat or fatty tissues need to be analyzed, a washing step for the samples (e.g., with pentane) might be implemented as well in order to remove as much of the fat as possible (Getie and Neubert 2004). In these cases, one needs to make sure that the analyte is not too lipophilic. Otherwise it might be extracted as well. Methods for the determination of compound levels in different tissues are also often needed. Liquid-liquid extraction is used in these cases very often (Getie and Neubert 2004; Boner et al. 2003; Barratè et al. 2004; Bogialli et al. 2003; Hows et al. 2004; Ito et al. 2004). Recovery considerations are of special importance in these cases in order to get an idea on the completeness of the compound extraction procedure.

Eleven Steps on Method Development

1. Compound: Obtain information on the test article: solubility, purity, polarity, and stability in order to avoid analytical problems due to compound precipitation or compound decomposition. One should also estimate, which lower limit of quantification (LLOQ) will be required for the assay and it should be estimated which calibration range is desirable (the calibration range should reflect the expected sample concentration range).
2. Tune compound on your mass spectrometer: Optimize the intensity of the precursor ion as well as the selected product ion. If necessary, try positive and negative ionization as well as different ionization sources such as electrospray, APCI, APPI, and also the combination with FAIMS if available. Usually, the most intense fragment ion is selected as the product ion mass. Make sure that the selected product ion mass is not too close to the mass to charge ratio (m/z) of the precursor ion (e.g., loss of water, -18, is not characteristic and might question the selectivity of the method. Fragments with very low mass to charge ratio are also less characteristic and might sacrifice specificity.
3. Solvent selection: Select solvents for method development. A mixture of 0.1% formic acid/acetonitrile is usually a good starting point.
4. Optimize chromatography (column, solvents, flow rate, gradient) using a solution of the analyte in mobile phase.
5. The response for the selected transition of analyte(s) and internal standard(s) should be optimized by repeated flow injections of a dilute solution in the mobile phase (resulting in a weak signal of may be 10:1 signal-to-noise) of analyte and standard. All instrument parameters (gas flows, temperature, source position, etc.) should be optimized for maximum response according to the specific instrument type that is used.
6. Sensitivity in different ionization modes and with different ion sources should be tested as well in order to choose the best setup for the method.
7. Sample preparation: Depending on the analyte (SPE, Liquid-liquid, protein precipitation, dilution).
8. Run first matrix samples in order to identify LLOQ, dynamic range, analyte recovery and confirm suitability of the chromatographic setup.
9. Tests on sample stability, carryover, specificity, matrix interference, sample stability (freeze/thaw stability and so forth).
10. Run validation samples (batch to batch reproducibility, within batch reproducibility).
11. Validation report.

31.6 Sample Preparation for "Large Molecules"

Large molecules (MW > 500 Da) are becoming more and more important in research and development of drug candidates as well as biomarker candidates (van den Broek 2008; Ezan 2009). Peptides, proteins, and certain sugars are usually analyzed by immunological methods due to their high sensitivity and rapid sample throughput, but one major disadvantage is their potential for cross-reactivity (e.g., metabolites, other compounds). Mass spectrometry is much more selective but cannot compete with the sensitivity of the immunological methods in general. However, mass

spectrometrical methods are increasing in the literature since the sensitivity of immunoassays is not always required and new LC-MS/MS instruments are performing much better (Zhang 2008). Nano-LC in combination with LC-MS/MS results in an increase of sensitivity, but with longer run times as compared to the usual HPLC methods.

Sample cleanup of large molecules is rather challenging (Yang 2007). Proteins and peptides adsorb on various surfaces during sample extraction and inside the LC-MS/MS-systems. It should be tested, if dilutions of the stock solution are linear and if the analyte binds to extraction vials (usually glass or polypropylene) or pipette tips. Binding inside the LC-MS/MS-systems results in a severe carryover problem. The adsorption can be controlled by using other solvents, pH, surfactants, ionic strength, other material (glass <-> polypropylene), or addition of serum albumin. For compounds, which bind to polypropylene tubes and glass tubes, low-binding polypropylene might be an option. The lower the concentration of the protein or peptides in aqueous solutions, the higher is the adsorption rate to tube surfaces in general.

The major extraction techniques for small molecules (protein precipitation, solid phase extraction, and liquid-liquid extraction) can be used for large molecules, but the use of organic solvents can result in an unintentional precipitation and loss of the analyte. In addition to the three basic extraction methods, immunoaffinity purification is frequently used to extract and clean the analyte from biological matrices (Dubois 2008; Thevis 2008; Whiteaker 2007). In many cases, an antibody which is directed against the analyte is immobilized on a surface (e.g., magnetic beads) or on a gel matrix. The biological sample will be incubated with the antibody which binds the analyte. After several washing steps at physiological pH, the analyte is eluted from the matrix with an acidic pH. The resulting eluate can be used directly for LC-MS/MS-analysis or will be further cleaned up by SPE, PP, LLE, TFC (turbo flow chromatography), or a 2D approach. Since the presence of “antidrug-antibodies” in the biological matrix can reduce the unbound fraction of the analyte/drug, immunoaffinity purification extracts only the non-antibody-bound fraction of the analyte/drug. Depending on the selectivity of the antibody, structural analogs of the analyte, ^{127}I labeled analyte, or stable isotopic labeled internal standard (SILS) can be used as internal standard. A second approach is the quantification of an antibody itself where a receptor has been coupled to magnetic beads (Dubois 2008).

The most sensitive triple quad mass spectrometers are limited to 1,250–1,500 m/z, but most proteins and peptides have a molecular mass above 1,500 Da. One solution is the detection of multiply charged ions (e.g., $[M + 3H]^{3+}$ to $[M + 8H]^{8+}$) of the intact protein or an enzymatic digestion of the protein. The first approach may be used with smaller peptides (MW $<$ 7,000–10,000 Da) and the second approach must be used with peptides and proteins with a MW $>$ 10,000 Da. During the enzymatic digestion the peptide is incubated with a proteolytic enzyme (e.g., trypsine, pepsine, Lys-C, Glu-C, or others) under its specific cleavage conditions and the much smaller peptide fragment can be quantified by LC-MS/MS, usually with an increased sensitivity. The optimal internal standard is of course the stable isotopic labeled internal standard to cover the whole cleavage process, but another possibility is to add an SILS for the smaller peptide fragment after the enzymatic digestion has been performed. In the second way, the SILS does not cover the enzymatic reaction.

31.7 Sample Preparation from “Dried Blood Spots”

Another method of sample preparation for LC-MS/MS analysis is the so called “Dried Blood Spot” (DBS) technique. In this technique, a droplet of blood is spotted onto a paper card and dried. Small pieces of paper can be cut out (punched out) of these dried blood spots and the analyte might be extracted from these dried blood spots using an appropriate solvent. This technique is currently under investigation in many pharmaceutical companies and it is already very likely that this technique will replace at least some part of the classical blood sampling as it is currently done on a routine basis. There are several potential advantages of this technique: Only a very low volume of sample is needed (only one or a few droplets of blood per sampling time compared to typically 1 or 1.5 mL of blood per time point). Another advantage might be the sample handling, since the resulting papers are a lot easier to store, handle, and ship compared with frozen blood samples. Moreover, the DBS technique might also

allow the sampling of other populations, such as children, where it otherwise might be difficult for ethical reasons. The number of experiments and analyses per subject might potentially also be increased due to the low volume of blood that is consumed. Preliminary tests also indicate that samples might even be more stable in dried blood spots than in frozen plasma. However, there are also limitations: Due to the limited amount of blood per blood spot, the sensitivity of a DBS assay is typically not as good as the corresponding plasma assay. In addition to that, a thorough validation needs to be done in order to cover variability induced by different types of sampling cards and a potentially uneven distribution of blood over the dried blood spot or by variations in the hematocrite.

31.8 Evaluation

31.8.1 Validation

LC-MS/MS methods are usually subjected to a validation procedure before they are used for routine analysis. In case of GLP studies or clinical studies, a validation is considered to be mandatory. During the validation procedure, the assay is evaluated with respect to the overall performance. The following tests might be considered as a standard set of tests for the validation of a bioanalytical method (EMA Guideline on bioanalytical method validation 2012; Shah et al. 2000; FDA Guidance for Industry 2001; Viswanathan et al. 2007; Shah 2007). However, additional tests or modifications of tests might be necessary since the regulatory requirements are not identical in all countries, although the guidances from the FDA are widely accepted:

- Determination of the regression model and weighting factor
- Assessment of assay accuracy and precision (assay variability)
- Analyte stability in plasma at 37°C over 24 h (or other appropriate temperature)
- Investigation of ionization efficiency (effect of analyte matrix on ionization)
- Efficiency of extraction procedure
- Assay specificity and selectivity
- Test of matrix variability (different lots of plasma or other analytical matrix)
- Test of assay robustness (largest batch size)
- Stability of analyte in stock solutions and working solutions
- Whole blood stability of test compound
- Vacutainer effect/container binding (investigation of, e.g., potential adsorption effects)
- Stability over typically three or more freeze/thaw cycles
- Show the ability to dilute samples with blank matrix in order to extend the calibration range
- Characterization of autosampler carryover
- Effect of hemolysis on analysis (in case of plasma samples)
- Multicomponent analysis test in order to show that different analytes do not influence each other
- Assess the effect of potential co-medications on the analysis of the compound of interest
- Signal-to-noise ratio (5:1 for lowest calibration standard or better)
- Long-term frozen stability of spiked samples
- Incurred sample reproducibility
- Incurred sample long-term frozen stability

CRITICAL ASSESSMENT OF THE METHOD

31.9 General Acceptance Criteria

31.9.1 Accuracy and Precision

Accuracy is defined as the percent difference (%D) from nominal at each concentration level, according to the following equation:

$$\%\mathrm{D} = \frac{(\text{Observed concentration} - \text{Expected concentration}) \times 100}{\text{Expected concentration}}$$

Mean percent differences (M%D) are reported for all data sets.

Precision is defined as the percent coefficient of variation (%CV) for each data set and will be calculated by the following equation:

$$\%\mathrm{CV} = \frac{\text{Standard deviation} \times 100}{\text{Mean}}$$

%CV values will be reported for all data sets.

31.9.2 Assay Variability

No more than 33.3% of individual validation samples within a given concentration level may be greater than ±15.0% of nominal, except at the LLOQ, where the acceptance criterion is ±20.0% of nominal. The point estimates for accuracy (bias) and variance (precision) for each validation level cannot be greater than ±15.0%, except at the LLOQ where the acceptance criterion is ±20.0%. Within-run, between-run, and total variances are estimated by equating observed and expected mean squares with a one-way random effects analysis of variance (ANOVA) for each concentration separately. A statistical test (Lund) for outliers can be performed and points determined to be outliers can be removed prior to ANOVA analysis. If an outlier is observed, data should be reported with and without the outlier.

31.9.3 Assay Robustness

If a data point appears to be anomalous and if an n of 6 or greater per observation is obtained, the Lund test for outliers will be performed and points determined to be outliers will be removed prior to calculation of mean statistics. No more than 33.3% of individual validation samples within a given concentration level may be greater than ±15.0% of nominal, except at the LLOQ where the acceptance criterion is ±20.0% of nominal. The mean estimates for accuracy (bias) and variance (precision) for each validation level cannot be greater than ±15.0%, except at the LLOQ where the acceptance criterion is ±20.0%.

31.9.4 Matrix Variability

The acceptance criteria for the matrix variability test apply to each individual lot. For the individual lot, no more than 33.3% of individual samples can be greater than ±20.0%, that is, no more than two out of the six within a lot can be outside the specifications. The mean, SD, %CV and M%D will be calculated for each matrix lot. The point estimates for accuracy (bias) and variance (precision) cannot be greater than ±20.0%. If a data point appears to be anomalous, the Lund test for outliers will be performed and points determined to be outliers will be removed prior to calculation of mean statistics.

The acceptance criteria for the analysis of the blank samples from the six individuals are based on the raw peak areas found at the retention times of the analyte and internal standard. No more than 10.0% of the blank samples can have raw peak areas that are greater than 20.0% of the average peak area of the analyte in the LLOQ validation samples.

31.9.5 Acceptance Criteria for Stability, Dilution, Hemolysis, and Concomitant Medications

For the tests listed below, no more than 33.3% of individual validation samples within a given concentration level could have been greater than ±15.0% of nominal, except at the LLOQ where the acceptance criteria is ±20.0% of nominal. The point estimates for accuracy (bias) and variance (precision) for each validation level should not be greater than ±15.0%, except at the LLOQ where the acceptance criterion is ±20.0%.

- Stability in stock solutions
- Freeze/thaw stability
- Stability at 37°C for 24 h
- Frozen stability
- Stability in extraction buffer
- Processed sample stability
- Dilution
- Hemolysis
- Specificity against concomitant medications
- Binding
- Multicomponent analysis (if applicable)

31.9.6 Blood Stability

The limit of stability is estimated as the time at which the 90% two-sided lower confidence bound for the estimated stability from time zero intersects the lower specification limit of 85%. If blood cell partitioning is high, an upper specification limit of 115% will be considered in the event that significant blood cell lysis occurs.

31.9.7 Vacutainer Effect

At each nominal concentration, the blood collection tubes will be determined to be equivalent to the

polypropylene (control) tubes if the 90% confidence interval for the estimated ratio falls entirely within the 15% specification limits (0.85, 1.15).

31.9.8 Autosampler Carryover

No more than 33.3% (i.e., two out of six) of individual LLOQ-1 samples (injected immediately after a HIGH QC sample) should be greater than ±20.0% of the nominal. The point estimates for accuracy (bias) and precision (variance) for all LLOQ-1 samples may not be greater than ±20.0%.

31.9.9 Process Efficiency

There is no fixed criterion for extraction (process) efficiency as well as the matrix effect. However, both effects should be determined and they should be on a constant level over the entire concentration range. Matrix effects might be acceptable to some extent when stable isotope labeled standards are used, since this should correct for these effects.

31.10 Matrix Effects

Although there is usually no need for any chemical derivatization, caution has to be applied when LC-MS/MS data are reviewed. The ionization of analytes might be affected and altered by endogenous compounds, which can be present in the matrix and which might coelute together with the analyte or internal standard. This can lead to ion suppression (predominantly observed with ESI ionization) as well as ion enhancement, which more often is observed when APCI-ionization is used. Matrix effects can lead to false results if analyte and the corresponding internal standard show different matrix effects. Such matrix effects are typically well compensated when a stable isotope internal standard is used. In case of analog compounds, which are often used in case no stable isotope labeled standard is available, the likelihood of an uncompensated matrix effect is a lot higher. For this reason, the usage of stable isotope labeled internal standards is becoming more and more a routine procedure.

Matrix effects are sometimes not obvious to recognize, which is one of the major pitfalls when using LC-MS/MS. The most practical experiment is probably a recovery experiment. A spiked matrix sample is analyzed and the result is compared to a spiked solvent sample. If no matrix effect is present, the same analytical response for the analyte and internal standard should be found in both samples.

In case the matrix effects are present (or in case the absence of matrix effects should be shown), samples can be diluted and reanalyzed. Matrix effects are usually concentration dependent. Lowering the sample concentration in many cases helps to minimize matrix effects. If this does not help, other measures have to be taken in order to eliminate matrix suppression. Such measures could be the use of a different sample preparation/sample cleanup procedure or change of LC-column or the LC-conditions (gradient, solvents). One important source of matrix effects could be the drug formulation as well. Especially when plasma samples originating from intravenous administration are analyzed, effects of the vehicle (e.g., PEG-400 or Transcutol, Solutol and others), which can be present in the samples of the first time points in substantial amounts, should be considered. These compounds can falsify the analytical results. A reanalysis of the samples in dilution should be considered in order to reveal a potential matrix effect (Dams et al. 2003; Pascoe et al. 2001; Annesley 2003; Hopfgartner and Bourgogne 2003; Schuhmacher et al. 2003; King et al. 2000; Liang et al. 2003).

One way to compensate for matrix effects is also the use of stable isotopes as internal standards. Since the standard will coelute with the analyte, the signal suppression or enhancement should have the same effect on analyte and standard, which will usually compensate quite well for the matrix effect.

31.11 Sample Analysis (Routine Application of the Assay)

A series of unknown samples is usually measured together with two sets of calibration standard samples (covering the concentration range for the assay, usually two sets of six or more calibration standards) and two or more sets of quality control samples. The calibration standard samples will be used to establish the calibration for the unknowns. Quality control samples (usually at least 5% of number of unknowns) are

matrix samples of known concentration, which are equally distributed over the analytical run (usually two sets of three different concentration levels; two to three times the LLOQ, mid-concentration range, and close to the upper limit of quantification). They establish a set of control samples in order to verify the assay performance within the run. Typically, the calibration standards and quality control samples should be within ± 15% of the nominal value. However, in typical assays, it is considered to be acceptable, if 75% of the standards are within the ± 15% criteria. Outliers will not be used for the calculation of the calibration curve. Not all standards at one concentration should be excluded. A similar criterion is applied for the quality control samples: two out of three of the quality control samples should be within ± 15% of their nominal value. In any case, at least 50% of the QCs at one level must be acceptable. This leads to the conclusion, that it is not advisable to use odd numbers of QC sample sets, since three QC sets will still fail the criteria in case more than one QC at one level is out of criteria.

Special consideration should be given to the placing of quality control samples (concentration levels), especially in cases where most of the unknown samples have concentration levels between the same two QCs. In these cases, it can be necessary to revalidate the assay with a narrower calibration range, or additional QC levels might be introduced in order to better characterize the calibration in the concentration range of interest (Viswanathan et al. 2007; Shah 2007).

Processing of analytical data such as chromatograms is another new and very critical quality criterion. Usually, data are processed by integration of chromatograms and subsequently by applying a standard regression and weighting to the data. For these steps, the same parameters should be used, which were established during method development and method validation. However, it might be necessary to change integration parameters on a run-by-run basis in order to achieve proper integration of all data. If this is done, it is considered to be mandatory to document the data before and after manual modification of the integration. Moreover, it is typically not accepted if more then 30% of the samples in a run are modified. In order to avoid problems in routine analysis, the quality of chromatography (e.g., peak shape) should be an important point to consider during method development.

31.11.1 Incurred Sample Reproducibility (ISR)

A rather new topic, which is now already considered to be a regulatory requirement for GLP studies as well as clinical studies, is the conduct of the so-called ISR-Test, incurred sample reproducibility test (and also ISA and ISS – incurred sample accuracy and incurred sample stability) (EMA Guideline on bioanalytical method validation 2012; Viswanathan et al. 2007; Shah 2007). The term "Incurred samples" describes samples that are obtained after actual dosing of the compound of interest. ISR samples are natural samples which are not artificially prepared (spiked). In fact, incurred samples are nothing else but regular specimens from a GLP study or clinical study.

The samples that are used during method validation are typically spiked samples which do not contain any metabolites of the drug administered. In addition to that, variability in the matrix of patients might be high, which could lead to analytical problems as well. For these reasons, it is now considered to be mandatory to perform the ISR.

Assessment of incurred specimen reproducibility (ISR) is usually performed for each analyte and matrix (plasma, serum, urine, etc.) in several studies and with the respective validated assay:

- Primary rodent toxicology study (typically rat)[1]—with an exploratory assay
- Primary non-rodent toxicology study (typically dog)—with an exploratory assay
- Primary rodent GLP toxicology study (typically rat)
- Primary non-rodent GLP toxicology study (typically dog)
- All first-in-man studies with healthy volunteers—single dose
- All first-in-man studies with healthy volunteers—repeated dose
- All studies with special patient populations, for example, renally or hepatically impaired patients
- All drug-drug interaction studies
- All bioequivalence studies

[1]Depending on the assay validation strategy, at the time of the exploratory non-GLP study only an exploratory assay may be available.

Ten percent of the total numbers of study samples of each matrix should be selected for ISR testing in studies with up to 1,000 samples. In studies with more then 1,000 samples, 5% of samples in excess of 1,000 should be selected in addition to the 100 samples selected up to 1,000 samples (e.g., 150 samples for a study with 2,000 samples). Based on the precision of the validated assay, a statistical approach may result in a different number of study samples which should be used for ISR testing. ISR testing is described in the study plan and reported in the bioanalytical phase report for the study.

The ISR is performed during or at the end of the study and the same validated assay (in case of primary non-GLP studies this could be exploratory assays) have to be used for the selected ISR samples and the study samples. The selected samples for ISR must have an acceptable analytical result which has been obtained without dilution of the respective sample and the result should be within three times the LLOQ and the ULOQ of the validated assay. A sufficient volume to perform the ISR should be left and samples must be within the documented stability period. Additionally, the selected samples should origin from different animals or subjects and should represent the pharmacokinetic profile of the respective analyte. The ISR concentrations are only used for ISR assessment and are not used for pharmacokinetic or toxicokinetic analysis.

$$\%\mathrm{D} = \frac{(\text{repeat concentration} - \text{original concentration}) \times 100}{\text{mean concentration}}$$

After acceptance of the run acceptance criteria for calibration and quality control samples, no more than 33% of the ISR samples from each study can have a concentration greater than ± 20% (physico-chemical) or ± 30% (bioassay) of the mean of both determination. Any individual ISR sample with a concentration outside of the acceptance limit will not be reanalyzed, provided that the total number of ISR samples failing does not exceed 33%. However, in those cases where more than 33% of ISR results exceed the acceptance limit, an investigation into the cause of ISR failure will be initiated. The impact of ISR failure on existing specimen data must be assessed and documented.

31.11.2 Incurred Sample Accuracy (ISA)

Assessment of short-term incurred specimen analyte stability (ISA) is usually performed for each analyte and matrix (plasma, serum, urine, etc.) in several studies and with the respective validated assay:

- Primary rodent toxicology study (typically rat)[2]—with an exploratory assay
- Primary non-rodent toxicology study (typically dog)—with an exploratory assay
- Primary rodent GLP toxicology study (typically rat)
- Primary non-rodent GLP toxicology study (typically dog)
- All first in man studies with healthy volunteers—single dose
- All first in man studies with healthy volunteers—repeated dose
- All studies with special patient populations, for example, renally or hepatically impaired patients
- All drug-drug interaction studies

Due to limited volume of study samples, the investigation of short-term stability of incurred specimen stability on individual incurred samples is not feasible and therefore a pooled stability sample is used for ISA assessment instead. ISA testing is described in the stability study plan and reported in the stability report.

The ISA is performed at the end of the study which includes acceptance of all study concentration data of the respective matrix and successful ISR testing with the same validated assay (in case of primary non-GLP studies this could be exploratory assays) as was used for study samples and ISR assessment. The selected samples for ISA must have an acceptable analytical result and must be representative of the study design (multiple time points, dosing days and dose groups, multiple subjects/animals, dosed subjects/animals only, impaired subjects only, etc.). As far as the study and ISR are accepted, the ISA samples are pooled to one bulk stability sample. The concentration of the bulk stability samples should be within the LLOQ and the ULOQ of the validated assay.

The ISA samples must be transferred into the same type of tubes which are used for the long-term storage of the study samples. Replicate aliquots ($n = 9$) of the

[2] Depending on the assay validation strategy, at the time of the exploratory non-GLP study only an exploratory assay may be available.

freshly prepared pooled bulk stability sample should be stored frozen (t_{0h} at approx. −20°C or other validated storage temperature) and the remainder stored for 24 h at room temperature (t_{24h}). Both the t_{0h} and t_{24h} samples are analyzed within the same run to reduce inter-assay variability.

After acceptance of the run acceptance criteria for calibration and quality control samples, the mean ratio of data at $t_{24\ h}$ versus the data at t_{0h} and its 90% confidence interval will be calculated using Fieller's theorem for each study type. Incurred short-term specimen analyte stability will be assured if the 90% confidence interval for the estimated ratio falls entirely within the 15% specification limits (85%, 115%).

The results of short-term incurred specimen stability, including the statistical results, are documented in the stability report.

MODIFICATIONS OF THE METHOD

The following table lists a selection of method changes that are often required during the course of drug development. These changes usually require some degree of method revalidation. The listed activities are only a guide. In all cases, judgment of the bioanalyst will be the key factor to determine the necessary steps in order to cover the required method change.

Change to validated method	Test required
Reduce LLOQ of assay, while maintaining similar dynamic range of assay (e.g., change a 1–500 ng/mL assay to a 0.1–50 ng/mL assay)	Perform full assay validation, including calibration model, core studies and all satellite studies.
	Perform and report as a new study
Increase LLOQ of assay, while maintaining similar dynamic range of assay (e.g., change a 1–500 ng/mL assay to a 10–5,000 ng/mL assay)	Perform calibration model, assay variability test, autosampler test, and dilution test.
Verification of analyst competency to perform assay (multiple species of same assay are deemed equivalent)	Assay verification test, e.g., run full calibration curve plus six replicates at all validation levels (LLOQ, LOW QC, MID QC, HIGH QC)
Verification of instrument (same platform, e.g., API4000 to API4000) to perform assay	Assay verification test, e.g., run full calibration curve plus six replicates at all validation levels (LLOQ, LOW QC, MID QC, HIGH QC)
Verification of instrument (new platform, e.g., API4000 to API5000 or API5000 to Quantum Ultra)	Full assay variability with statistical analysis. Consideration being given to performing calibration model

(*continued*)

Change to validated method	Test required
	if significant differences in sensitivity observed between platforms.
Change of autosampler	Perform autosampler test
Changes of assay consumable (tube type and or vendor, solvent vendor, plate vendor, etc.)	Assay verification test, e.g., run full calibration curve plus six replicates at all validation levels (LLOQ, LOW QC, MID QC, HIGH QC)
Additional freeze/thaw stability	Perform freeze/thaw stability test
Additional biological fluid stability	Perform additional biological fluid stability test
Additional processed stability	Perform additional processed sample stability
Additional dilution factor required	Perform dilution factor test
Additional major concomitant medication	Perform concomitant medication test
Chromatographic modification to resolve in vivo interference (gradient, flow, or modification of column geometry such as length, diameter, or particle size)	Assay verification test, e.g., run full calibration curve plus six replicates at all validation levels (LLOQ, LOW QC, MID QC, HIGH QC)
Change to assay specificity (e.g., chromatographic or extraction chemistry)	Full assay variability with statistical analysis
	Full matrix variability
Increase signal-to-noise (e.g., increase injection volume)	Assay robustness test
Decrease signal-to-noise (e.g., reduce injection volume)	Full assay variability with statistical analysis.
Increase run size	Assay robustness test
Additional anticoagulant (same species)	Full calibration curve with three to six replicates at the LOW and HIGH validation levels against a calibration curve prepared in the original anticoagulant.
Additional nonclinical species (same matrix)	Perform partial assay validation, including core study and all appropriate satellite studies.
	Perform and report as a new study.
Additional matrix (same species)	Perform full assay validation, including calibration model, core studies, and all satellite studies.
	Perform and report as a new study.
Physiological proxy matrices	Full assay variability with validated matrix as calibration samples and physiological proxy matrix as validation

(*continued*)

Change to validated method	Test required
	samples. Includes statistical analysis.
Addition of metabolite	Perform full assay validation, including calibration model, core studies, and all satellite studies.
	Perform and report as a new study.
Effect of stable labeled analyte (e.g., ^{2}H, ^{15}N or ^{13}C) on validated assay	Full assay variability with statistical analysis and cross-over test.
Effect of radiolabeled analyte (^{14}C) on validated assay.	Use ^{14}C standard as test article. Alternative approaches, such as ion summing, theoretical correction factor, etc., may be used when proven.
Change SRM transition in assay (either for analyte or stable labeled internal standard)	Full assay variability with statistical analysis. Full matrix variability
Transfer of assay from site to site	Perform full assay validation, including calibration model, core studies, and all satellite studies.
	Perform and report as a new study

32.1 Introduction

Immunoassays have become the most valuable analytical tool of medicinal in vitro diagnostics and are routinely employed for the detection of a wide range of analytes (e.g., hormones, peptides, proteins, viruses, pharmaceuticals). Further important areas of application are environmental pollutants and food analysis.

The radioimmunoassay (RIA) for the determination of insulin developed by Yalow and Berson (1959) combined for the first time the high sensitivity of a radioactively labeled compound with the high specificity of an immunological reaction by the formation of a thermodynamically stable antigen-antibody complex (dissociation constants are typically 10^{-9} to 10^{-12} M). In this way it was possible to detect quantitatively substances in the attomolar range even in the presence of an excess of other similar foreign substances without prior enrichment. The theoretical and practical aspects of RIA and related techniques including numerous examples are described by Moss et al. (1976), Jaffe et al. (1979), Travis (1979), Langone et al. (1981, vol. 73/74), Langone et al. (1983), Odell et al. (1983), and Chard (1990).

Antibodies are prepared by immunization of animals (e.g., rabbits, guinea-pigs, sheep, goats) with the analyte of interest. However, direct immunization is only possible with relatively large compounds (approximately > 1,000 Da). Since small molecules are not capable to trigger an immune response, the immunization is performed with hapten (compound)-carrier protein conjugates. Typical carrier proteins are keyhole limpet haemcyanin (MW = 4.5×10^5 to 1.3×10^7 Da), bovine serum albumin (68 kDa) and ovalbumin (45 kDa). The haptens are coupled to the carrier proteins via amino or carboxyl groups using appropriate reagents.

The immunization procedure (at least 12 weeks with booster injections, addition of oil based adjuvants to stimulate the immunogenic response) gives rise to an antiserum representing a mixture of polyclonal antibodies which are produced by different immunocompetent cells and thus have different binding sites and affinities.

Monoclonal antibodies generated by fusing mouse spleen cells to myeloma cells can be considered as a pure single reagent that is available in unlimited quantity. Drawbacks are high costs, clonal drift and often low affinity.

Further details to polyclonal/monoclonal antibodies are found in Langone et al. (1981, vol. 73/74), Langone et al. (1983), and Szentivanyi et al. (1986).

The use of a radioactive label (mainly ^{125}I) not only attributed to the excellent sensitivity of RIA but also to the excellent flexibility and precision of radiochemical labeling and its high robustness with regard to interferences because of the “hard” signal.

However, the disadvantages of radioactivity such as the required handling licenses, disposal costs, short half-life (60 days for ^{125}I), short shelf-life of labeled reagents, restricted sensitivity due to limited signal emission during the measuring time of usually only 1 min led to the development of nonisotopic immunoassays (e.g., enzyme/fluorescence/chemiluminescence/bioluminescence immunoassay – EIA/FIA/CIA/BIA) described by Engvall and Perlmann (1971), Langone et al. (1981, Part B/C), Langone et al. (1983), Van Dyke (1985, Vol. I/II), Hemmilä (1989), Schaap et al. (1989), and Stanley and Kricka (1991).

Nevertheless, RIA is still the first choice for research assays provided the required handling licenses are available and not the ultimate sensitivity is required.

Some of the new labels have not only facilitated replacement of radioisotopes but also a breakthrough in sensitivity (zeptomolar range attainable).

The most widespread alternative to RIA is EIA (Tijssen 1985). Since the introduction of EIA at the beginning of the 1970s a tremendous number of techniques have become available by using different enzymes (horseradish peroxidase – HRP, alkaline phosphatase – AP, β-D-galactosidase – GAL, luciferase) and substrates (chromogenic, fluorogenic, luminogenic).

EIA has the potential for higher sensitivity than RIA because enzymes produce a lot of signal-generating species. In practice, however, the sensitivity is determined by the signal to noise ratio. Time resolved fluorescence detection is a powerful technique to overcome this problem by using fluorophores (rare earth chelates) with a long fluorescent time (μs–ms) compared to the background fluorescence (ns) (Janssen 1997; Read 2001). In many enzyme immunoassays, specific signal and noise are amplified to a similar

extent with the consequence that no improvement in sensitivity compared to RIA could be achieved. EIAs are in principle less robust than RIAs because enzymes are bulky and can disturb the immunological reaction. Furthermore, enzymes are prone to interferences. The implementation of sophisticated techniques and automation (assays are usually carried out in the 96/384 well format under controlled conditions) resulted in comparable assay quality independent of the label used.

In routine analysis, EIA and other nonisotopic immunoassays have displaced the RIA in many fields more and more during the past years.

32.1.1 Immunoassay Principles

(a) Competitive Immunoassay with Analyte Tracer

Analyte and analyte tracer (structurally similar to analyte, mostly ^{125}I-analyte) compete for a small number of antibody binding sites in an equilibrium reaction. The lower the concentration of the analyte, the more antibody-analyte tracer complexes can be formed. Selective measurement of the signal emitted from the antibody-analyte tracer complex requires prior separation of uncomplexed analyte tracer.

This assay principle can be applied for compounds of low and high molecular weight.

(b) Competitive Immunoassay with Antibody Tracer

The main difference compared to the method described before is that the antibody carries the label (antibody tracer). Analyte (from the sample) and an unlabeled analyte derivative (sometimes only analyte bound to a solid phase) compete for a small number of antibody tracer. The lower the concentration of the analyte, the more analyte derivative-antibody tracer complexes can be formed.

This assay principle is advantageous in cases when labeling of small antigens renders difficult or leads to different immunological properties compared to the unlabeled antigen.

(c) Sandwich Immunoassay

This principle requires two different antibodies (capture and tracer antibody).

Both antibodies bind to the analyte at different sites (epitopes) and thus form a sandwich complex. An excess of the two antibodies is employed in order to shift the equilibrium in favor of the sandwich complex.

Sandwich immunoassays have distinct advantages in comparison to competitive immunoassays: Higher specificity (two antibodies for analyte recognition) and better sensitivity (favorable equilibrium due to the excess of reagents). Theoretically, every analyte molecule present in the sample can be bound to a tracer antibody allowing extremely limits of detection. Often a straight-line calibration curve can be achieved over many orders of magnitude. In addition, higher and easier labeling of an antibody (in particular with nonisotopic labels) compared to a small analyte is possible.

The sandwich principle achieved its breakthrough when monoclonal antibodies became available because of the need of higher amounts of antibody compared to competitive assays.

The major disadvantage of this method is the restricted applicability to only analytes with MW >approx. 5 kDa), since two antibodies cannot bind to a small compound for steric reasons.

32.1.2 Separation Methods

The selective measurement of labeled immune complexes necessitate a prior separation of the unbound analyte tracer (a), of antibody tracer not bound to the analyte derivative (b), or of unbound antibody tracer (c).

The first separation methods involved purification steps (chromatography or electrophoresis). Better manageable, but nowadays rarely found in commercial kits (however still used in research assays) are the methods in which the immune complexes are precipitated, e.g., by addition of salts, organic solvents or a second antibody directed against the first antibody. All these techniques require a cumbersome centrifugation step.

Modern methods employ solid phases (e.g., tubes, particles, microtiter plates).

Based on solid phase technologies numerous fully automated immunoassay systems which allow the determination of a broad spectrum of analytes are nowadays commercially available. While very

successful in the case of nonisotopic methods, attempts for automation in the RIA field more or less failed due to the properties of the radioactive label.

Alternatives for simple handling of immunoassays without the need of expensive instrumentation have been developed.

In the homogeneous immunoassays there is no separation step because they are based on a changing signal by formation of the immune complex. The first assay of this type was the EMIT method (enzyme-modulated immunoassay technology) described by Engvall et al. (1970). The main disadvantages of homogeneous assays are low sensitivity and a more pronounced susceptibility to interferences.

Dry tests and test strips described by Morris et al. (1987) and Litman (1985) contain all the reagents required for a quantifiable test on a strip or filter. Evaluation can be performed visually or be read out by a pocket reflectometer. Automated systems for a higher sample throughput are also available. The sensitivity of these tests is rather low (mg–µg/mL range) but sufficient for application as quick tests in clinical chemistry.

32.1.2.1 DATA EVALUATION

Competitive immunoassays give a sigmoidal standard curve with a linear concentration-binding range of about two orders of magnitude. Due to the sigmoidal shape, sophisticated curve-fitting and interpolation software is required. 4-PL logistic fitting is the most widely proposed whatever immunoassay device manufacturers.

A straight-line calibration curve over many orders of magnitude can often be found in the case of sandwich immunoassays with deviations from linearity only in the lower and higher concentration range.

32.1.3 Special Features

1. Immunoassays can allow the quantification of enantiomers of a racemic chemical entity – by using a stereospecific tracer and a serum raised against the mixture of enantiomers.
2. The immunogen design generating an antibody for a product-class immunoassay can also be applied for a wide spectrum immunoassay enabling high throughput in research phase or in early stage of development for chemical series reaching the chemical optimization phase. In principle, the "constant" scaffold of different compounds are being used as immunogen resulting in a serum containing antibodies for these compounds. In cases where high throughput combined with highest analytical sensitivity is required, a wide spectrum immunoassay (WSIA) could be the method of choice.

32.1.3.1 Future Trends in the Immunoassay Field

Chemical sensors utilize the immunological recognition principle by coupling with optical, electrochemical, or other transducer (signal transfer) described e.g., by Eggins (1996) and Rogers et al. (1998). A tendency to miniaturized formats ("chips") as part of the nanotechnology can be observed.

Phage libraries for antibodies enable the access to "monoclonal like" antibodies in unlimited quantities which can be produced within a period of 2 weeks without using animals (Marks et al. 1996). These antibodies are less immunogenic than monoclonal antibodies (mouse-human chimeras) because the amino acid sequences are entirely human.

A promising technique for the determination of small molecules in sandwich immunoassays is the use of monoclonal anti-idiotypic antibodies which recognize unique V region of antigen-binding antibody and mimic internal image of antigen (Vogel 2000). In recent years, antigen mimicry has been shown on a molecular level for some xenoantigens.

Molecular imprinting molecular imprinting is a technique in which the shape of a template molecule (analyte) is imprinted in a polymer, e.g., described by Kriz et al. (1997), Reid et al. (1998), Yano (1999), and Yan (2002). The imprinted polymer can be used as an antibody mimic for an immunoassay.

32.1.4 Advantages of Immunoassays

The immunoassay can be considered as the most sensitive bioanalytical method.

Its selectivity is very high (but limitations with regard to metabolites).

Immunoassays are easy to handle and allow high throughput in contrast to HPLC-based methods.

The throughput can be further increased by semi-or fully automated systems.

The running costs of immunoassays are distinctly lower compared to other sensitive bioanalytical methods.

32.1.5 Disadvantages of Immunoassays

The production of antibodies needs about 3 months/6–12 months for polyclonal/monoclonal antibodies.

Matrix effects lead to a decrease in binding of analyte to antibody resulting in reduced sensitivity and falsely increased or decreased concentration depending on the assay principle. The matrix effects can be reduced or eliminated by diluting the sample.

Cross-reactivity (e.g., due to metabolites) can only be eliminated by collecting appropriate fractions from HPLC separations or applying solid-phase extractions (SPE) preceding the immunoassay procedure.

The high-dose hook effect (HDH) evident as a decrease in signal with very high antigen concentration can be observed in sandwich immunoassays (in particular in single incubation assays). HDH can be prevented by diluting the samples or applying more steps in the assay.

A cross-validation with an accepted analytical method (e.g., GC, HPLC, LC-MS/MS) is required if the immunoassay could be subject to interference from matrix or metabolites.

32.1.5.1 Terms and Abbreviations

Terms and abbreviations used in the immunoassay field are sometimes ambiguous.

Radioimmunoassay (RIA)

(a) Competitive immunoassay with a radioactive analyte tracer (“classical” RIA)

(b) Generic term for all immunoassays with a radioactive label

Enzyme immunoassay (EIA)

See RIA, it is distinguished only by the type of label used.

Enzyme-linked immunosorbent assay (ELISA)

(a) Excess reagent assay

(b) Generic term for all immunoassays with an enzyme label

2-site IXMA: A synonym for sandwich assay; “immuno-x ... metric assay” (e.g., IRMA – immunoradiometric assay). The expression immunometric means that it is an assay with excess reagent.

1-site IXMA: Refers to a competitive assay with antibody tracer. The designation is not uniform because in 2-site IXMA, immunometric means an assay with excess reagent.

32.2 Competitive RIA of Apidra (Insulin Analogue) with Double Antibody Precipitation

PURPOSE AND RATIONALE

Apidra (HMR 1964) is a synthetic short-acting insulin (polypeptide) which is structurally very similar to human insulin and has an approximate molecular weight of 5,800 Da.

Quantitative insulin determination (Yalow et al. 1959) is useful for the diagnosis of diabetes mellitus and for monitoring therapy.

In the early development of Apidra a commercially available radioimmunoassay for the determination of rat insulin (Linco Research Inc. 14 Research RD, St. Charles, MO 6330, USA) was used for the analysis of Apidra in human serum because specific antibodies were not yet available.

Several RIAs for insulin had been compared before aiming at 100% cross-reactivity with Apidra. The rat insulin RIA from Linco showed similar reactivity for Apidra and human insulin. Therefore, this assay was used with only slight modifications; rat insulin standards were replaced by Apidra standards in an appropriate human serum matrix for calibration.

The assay described below in more detail uses the principle of a competitive immunoassay with a double antibody precipitation (Chard 1990). The antibody (from guinea pig) bound tracer is separated from the free tracer by the second antibody present in the precipitating reagent (goat anti–guinea pig antibody). After decanting the free tracer, the activity of the antibody-bound fraction is measured (B) and calculated as a fraction (B/B_0) of the noncompetitive binding (B_0). A standard curve is set up with increasing calibrator concentrations by plotting the measured B/B_0 fraction against concentration, and from this curve, the concentration of antigen in unknown samples can be calculated.

PROCEDURE

32.2.1 Reagents

Reagents of the Linco rat insulin RIA are used except the standards and control sera.

The test kit comprises reagents for 250 determinations. It contains:

One vial of ^{125}I-Insulin <185 KBq, lyophilized

One vial of guinea pig anti-rat insulin antiserum in assay buffer, 26 mL

One vial of assay buffer (0.05 M phosphosaline, pH 7.4, containing 0.025 M EDTA, 0.08% sodium azide, and 1% RIA grade BSA), 40 mL

One vial of label hydrating buffer (assay buffer containing normal guinea pig IgG as carrier), 27 mL

One vial of precipitating reagent (goat anti–guinea pig IgG serum, 3% PEG and 0.05% Triton X-100 in 0.05 M phosphosaline, 0.025 M EDTA, 0.08% sodium azide), 260 mL

Standards: stock solution: 20 ng/mL Apidra in insulin-free human serum; standard matrix: insulin-free human serum

Controls K1–K3 (low, medium, high): Apidra in human serum, concentration stated.

32.2.2 Preparation of Reagents

^{125}I-insulin tracer is dissolved in entire volume of label hydrating buffer.

Antiserum, assay buffer, and precipitating reagent are ready to use.

Standards: The stock solution of Apidra is prepared by dissolving about 500 μg (exact weight) Apidra in

5 mL of 0.1 M Tris/HCI buffer, pH 9. This solution (100 μg/mL) is further diluted in insulin-free human serum to a concentration of 20.0 ng/mL (nominal value). The standards (10, 5, 2.5, 1.25, 0.63, 0.31, 0.16 ng/mL) are prepared by serial dilution of the stock solution in insulin-free human serum matrix (e.g., WBAG Resources GmbH).

Controls: Control samples are prepared by spiking human sera (insulin content below 0.5 ng/mL) with Apidra stock solution to a concentration of about 0.5, 1.5, 5.0 ng/mL.

32.2.3 Assay Procedure

100 μl of standard/control/sample is incubated in a tube with 100 μl of ^{125}I-insulin tracer and 100 μl of antiserum for 20–24 h at 2–8°C.

Separation of the antibody-bound and free radiolabeled ligand is done by dispensing 1 mL of cold precipitating reagent in each tube. The tubes are vortexed and incubated for 20 min at 2–8°C. The precipitate is then centrifuged down at >1,500 g for 60 min at 2–8°C. The supernate is decanted immediately, and the remaining solution is allowed to drain by standing the tubes upside down on adsorbent tissue up to 15 s. Invert tubes only once. Pellets are fragile and slipping may occur.

The radioactivity is counted in a gamma counter for 1 min.

Total activity and nonspecific binding (blank) are also determined in each run.

EVALUATION

Control/sample concentrations are read-off from the standard curve by use of the immunoassay data management program MultiCalc (Wallac Oy/Berthold).

Fitting algorithm = 4–PL weighted

Blank correction is applied. NSB (nonspecific binding) counts are subtracted from each average counts, except total counts, prior to final data reduction.

32.2.4 Validation

Precision (within day): 2.2–7.2% (4.9% near LOQ).

Precision (between day): 1.6–4.7% (2.3% near LOQ).

Accuracy (between day): 91.8–101.4%.

Linearity: The test shows a good linearity over the whole concentration range as shown by dilution of serum samples with assay buffer.

Limit of quantitation (LOQ): 0.2 ng/mL (corresponding to ED-80 of the standard curve).

Specificity: No specific determination of Apidra (cross-reactivity with human/rat/porc insulin is 80.2/106.9/102.2%, respectively).

CRITICAL ASSESSMENT OF THE METHOD

The method described above could not differentiate Apidra from naturally occurring insulin/metabolites and precursors. This lack of specificity renders the characterization of the pharmacokinetics difficult. Therefore, a specific assay for the determination of Apidra was required for its further development.

MODIFICATION OF THE METHOD

Aventis Pharma contracted Linco Research Inc., 14 Research RD, St. Charles, MO 6330, USA, to design and produce a highly specific RIA for the accurate and precise routine determination of Apidra in human serum in commercial kit form ("Insulin Analog HMR 1964 RIA Kit").

This kit is very similar to the method described before with the exception that a highly specific antibody for Apidra (guinea pig anti-HMR 1964 antiserum prepared by Linco) is used. The antibody meets the specificity requirements (cross-reactivity, e.g., to human insulin <0.001%) and the sensitivity requirements (<0.2 ng/mL).

32.3 Competitive RIA of Free Anti-Insulin Antibodies with PEG Precipitation (Semiquantitative Assay)

PURPOSE AND RATIONALE

Anti-insulin antibodies (AIA) develop in the serum of many patients who are receiving insulin treatment (Berson et al 1956). In addition, insulin autoantibodies (IAA) are detected in insulin-dependent diabetes

mellitus (IDDM) or type I diabetes before insulin therapy (Palmer et al 1986).

The determination of circulating anti-insulin antibodies is of clinical importance for the following reasons:

1. Presence of free anti-insulin antibodies in serum interferes with the determination of insulin by immunoassays (Kuzuya et al. 1977).
2. High *titers* of AIA may induce a state of insulin resistence.
3. AIA may influence the quality of the glycemic control in diabetic patients by prolonging the half life of insulin.

The RIA described (in-house assay) is intended for the semiquantitative determination of free AIA in serum by the binding of the corresponding ^{125}I-Tyr-A 14-insulin tracer and precipitation of the complex by polyethylene glycol. It is useful for monitoring the development of AIA during immunogenicity studies in animals, toxicokinetic studies in animals, and clinical studies with patients receiving (synthetic) insulin.

PROCEDURE

32.3.1 Reagents

32.3.1.1 Controls

A blank control (TO) containing no anti-insulin antibodies is used to determine the nonspecific binding (NSB). Three titer controls (T1–T3) containing low, medium, and high levels of anti-insulin antibodies (guinea pig anti-porc insulin antiserum, e.g., Scantibodies Laboratory Inc. T 531 B, Part. 3 AK 025 in buffer solution) are measured in each run.

Buffer: 0.05 M phosphate buffer, pH 7.4, 0.5% BSA, 0.4% bovine IgG, 0.075% NaN_3

Preparation of Controls:

Stock solution: anti-insulin antiserum is diluted 1:100 in buffer.

Titer control T3 (high): stock solution is diluted 1:100 in buffer.

Titer control T2 (medium): titer control T3 is diluted 1:4 in buffer.

Titer control T1 (low): titer control T2 is diluted 1:8 in buffer.

Blank control TO: buffer.

The titer controls are stored in polystyrene tubes at −20°C. They are stable for at least 12 months.

^{125}I-Tyr-A14-insulin (e.g., human, porcine or bovine insulin) is prepared according to routine procedures. Aliquots in buffer solution (0.05 M phosphate buffer, pH 7.4, 1% BSA, 0.05% NaN_3) are lyophilized.

When stored at 2–8°C the tracer can be used for at least 6 weeks.

32.3.1.2 Specification

Specific activity: 13.320 MBq/mg (360 mCi/mg)
Activity: 37 kBq/mL (1~Ci/mL)
Concentration: approx. 2.8 ng/mL

32.3.1.3 Assay Buffer

7.8 g $Na_2HPO_4 \times 2H_2O$ and 0.75 g KH_2PO_4 are dissolved in 800 mL of water. After pH value has been adjusted to 7.4, 0.75 g NaN_3 is added and filled up to 1,000 mL with distilled water. 5.0 g BSA is added and dissolved.

32.3.1.4 Dilution Buffer

For sample dilution assay buffer containing 4 mg IgG/mL (bovine immunoglobulin) is used.

Storage:

Assay buffer can be stored at 2–8°C for at least 4 weeks.

Dilution buffer can be stored up to 1 week at 2–8°C.

32.3.1.5 PEG Solution

The PEG solution consists of 17.5% (w/v) polyethylene glycol (PEG 6000) in phosphate buffer (0.05 M, pH 7.5) containing 0.075% sodium azide and 0.5% bovine serum albumin.

It can be stored at 2–8°C for at least 6 months.

32.3.1.6 Preparation of Reagents

^{125}I-insulin tracer lyophilized is dissolved in 20 mL H_2O bidest. It can be stored up to 24 h at 2–8°C after reconstitution.

The titer controls (T0–T3) are thawed and homogenized.

Assay buffer and PEG solution are ready to use.

32.3.1.7 Assay Procedure

100 µl of control/sample is incubated with 200 µl of ^{125}I-insulin tracer and 200 µl of assay buffer for

19–24 h at room temperature. Separation of the antibody-bound and free radiolabeled ligand is performed by dispensing 1 mL of PEG solution in each tube. The tubes are vortexed several times until mixing is complete. The rapidly formed precipitate is then centrifuged down at 1,500 g for 15 min at room temperature. The supernate is decanted and the remaining PEG solution is allowed to drain by standing the tubes upside down on adsorbent tissue. The radioactivity is counted in a gamma spectrometer for 1 min.

EVALUATION

32.3.1.8 Calibration

Due to the different nature of insulin antibodies that can be formed a defined analyte does not exist and a calibration is not possible. The tracer binding test is a semiquantitative test without a standard curve. Three titer controls (T1–T3) containing low, medium and high levels of free anti-insulin antibodies and a blank control (TO) to determine the non-specific tracer binding (NSB) are measured in each run. Total activity of 200 μl tracer is also measured in each run.

32.3.1.9 Calculation of Results

The mean of duplicate determinations is calculated, rejecting obvious outliers. In cases CV >15%, analysis is repeated. The binding percentage of ^{125}I-insulin is calculated, according to the formula:

$$B/T(\%) = (\text{sample counts}/\text{total counts}) \times 100$$

32.3.1.10 VALIDATION

Precision (within day): 1.4–8.1% (in the range from 5% to 90% B/T in 10 determinations)

Precision (between day): 4.9–11.1% (for titer controls T1–T3, T0 and two human sera from 15 determinations on separate occasions

Accuracy: cannot be determined in a semiquantitative assay

Linearity: cannot be tested since no standard curve exists

Matrix effects: cannot be tested since no standard curve exists

Specificity: due to structural similarity of insulin analogues, cross-reactivity of antibodies is usually high

Limit of quantitation: cannot be defined for a semiquantitative method (precision of double determinations is below 15% down to the nonspecific binding and between-day precision of the negative serum controls (about 4% B/T) is below 10%

REFERENCE RANGE

The binding values of 20 healthy blood donors were determined e.g., with ^{125}I-human insulin tracer. It can be considered that a binding value higher than the mean value plus three standard deviations (e.g., 4.1% B/T found with a tracer lot for human-insulin tracer binding) indicates the presence of antibodies.

For evaluation of antibody positive samples a negative control has to be determined in each individual run.

An absolute change in binding values >10% B/T from baseline to endpoint (in clinical studies) when measured in the same run is considered as significant.

APPLICATION DATA

The binding values for Type II diabetic patients without prior insulin therapy ranged from 2.5% to 8.7% B/T (mean 3.6% B/T), whereas Type I diabetic patients that had been pretreated with insulin showed significantly elevated binding values before and after treatment ranging from 2.7% to 83.8% B/T (mean 21.5% B/T).

This is in agreement with published data that insulin antibodies are formed in IDDM (Type I diabetic patients).

Note: Insulin levels are determined to be lower in Type I compared to Type II patients since antibodies bind to the insulin administered and it is not available as free and acting insulin. On the other hand, the results cannot be interpreted as free insulin concentration because antibodies also interfere with the immunological determination of insulin by competition with the antiserum. Determination of free insulin (not bound to antibody) requires a pretreatment of serum with PEG.

METHOD COMPARISON

A commercially available RIA for determination of free anti-insulin antibodies (CIS bio international) was used for method comparison with insulin tracer binding test for Type I diabetic patients. The CIS test uses a ^{125}I-porcine insulin tracer for insulin antibody determination. Linear regression analysis yielded a correlation coefficient of 0.94 for human insulin antibodies. The absolute binding values were 10–15% lower in the commercial test than in the in-house test.

Note that absolute binding values cannot directly be compared between different tests due to the semiquantitative nature of the tracer binding test.

CRITICAL ASSESSMENT OF THE METHOD

A quantitative test for the determination of anti-insulin antibodies is not possible due to the different nature of insulin antibodies that can be formed. The criteria for evaluation of antibody positive samples are somewhat arbitrary, e.g., selected pool of healthy blood donors, definition of mean +3 standard deviations, varying binding with different tracer batches, consider an absolute change in binding values $>10\%$ B/T in clinical studies from baseline to endpoint when measured in the same run as significant.

MODIFICATION OF THE METHOD

A slightly modified method (MDS Pharma Services Switzerland AG, CH-8602 Wangen) was used in the development of Apidra (a synthetic short acting insulin).

This method is based on the same principle as described above with only minor changes in the assay procedure.

32.4 Immunoradiometric Assay (IRMA) of Ferritin with Bead Separation

PURPOSE AND RATIONALE

Ferritin, a macromolecule with a molecular weight of ~440,000 Da, is an iron storage protein which occurs ubiquitously in the organism. A protein shell (apoferritin) surrounds a nucleus containing iron oxyhydroxide phosphate. Every molecule can absorb up to 4,000 atoms of iron and can contain up to 20% of its weight as iron when saturated.

Functionally, ferritin, in conjunction with transferrin, regulates the movement of iron from the gastrointestinal tract to various tissues responsible for iron storage as well as to the bone marrow.

The ferritin found in each tissue has a characteristic structure and exists as isoferritin. Of special interest is the serum ferritin, which is considered to be different from any specific isoferritin. The serum ferritin level reflects the iron status of the body.

More detailed information to ferritin is given by Crichton (1973) and Jacobs et al. (1975).

The RIA-gnost Ferritin kit (no more commercially available) from formerly Behringwerke AG, Radiochemical Laboratory described below uses the principle of an immunoradiometric assay (IRMA). It is a two-site solid phase assay of the sandwich type, based on a plastic bead as solid phase to which the anti-ferritin antibody adheres. The antibody solid phase is incubated with standards or serum samples containing ferritin and in this process the ferritin in the solution is bound quantitatively to the solid phase via the antibody. The amount of ferritin bound to the solid phase is then determined by a reaction with ^{125}I-labeled anti-ferritin antibody. An antibody-ferritin-^{125}I-antibody complex is thus formed.

The RIA-gnost Ferritin kit uses anti-ferritin antibodies of two animal species, which have been raised against different organ isoferritins. Since the immunological characteristics of the ferritin circulating in the blood are not precisely known, it is necessary for the assay method to have broad specificity for organ isoferritins, measuring them all with practically equal potency. The antibodies used in RIA-gnost Ferritin meet this requirement.

It is typical for an immunoradiometric assay that a "high dose hook" effect occurs in the region of very

high concentrations. Therefore, sera with concentration above the highest standard S7 have to be diluted with the dilution serum included in the kit.

PROCEDURE

32.4.1 Reagents

The kit consists of:

100 plastic beads with anti-ferritin immunoglobulin from sheep ("anti-ferritin beads")

One anti-ferritin immunoglobulin from rabbit

Iodine-125-labeled, <4 μCi ("anti-ferritin-^{125}I-antibody"), lyophilized

Eight ferritin standards, S0–S7, concentration in the range of 0–400 ng ferritin/mL (related to the protein fraction of the molecule), lyophilizates from serum

One test serum, ferritin concentration declared, lyophilized

One buffer, pH 8.6, protein carrier solution, lyophilized

One diluent serum, lyophilized

One pair of forceps

32.4.2 Assay Procedure

- Number sufficient round-bottomed incubation tubes (3–5 mL) for 1 test serum, up to 41 serum samples and total activity. Assay duplicate samples.
- Place one anti-ferritin bead in each tube (exception: total activity) by means of the forceps contained in the kit.
- Add 200 μl buffer solution to each tube (exception: total activity)
- Dispense the standards, when completely dissolved, after mixing briefly on a rotary mixer, in aliquots of 100 μl into the tubes. Use a new pipette tip for each standard.
- Dispense 100 μl of test serum/serum sample, after mixing on a rotary mixer, into the tubes. Use a new pipette tip for each serum sample.
- Mix all tubes briefly on the rotary mixer; cover the whole test tubes rack with Parafilm and place the rack for the incubation on a horizontal shaker, shake for 2 h at room temperature (22 ± 5°C) with ~300 rpm (250–350 rpm).
- Carefully aspirate the incubates; it is best to use a Pasteur pipette (or a pipette tip) connected to a suction pump. The beads should remain in the tubes.
- 2 mL distilled water are dispensed into each tube (exception: total activity) in such a manner that each bead is agitated. Aspirate the water.
- Dispense 300 μl of the anti-ferritin-^{125}I-antibody solution into each tube and shake the test tubes rack briefly by hand. Then cover the rack with Parafilm and place it on the horizontal shaker and shake for 3 h at room temperature (22 ± 5°C) with ~300 rpm (250–350 rpm).
- Carefully aspirate the incubates (exception: total activity); the beads should remain in the tubes.
- Dispense 2 mL distilled water into each tube (exception: total activity) in such a manner that the bead is agitated. Aspirate the water.
- The tubes containing the beads and "total activity" are measured directly in a gamma scintillation counter for 2 min. Between 40,000 and 60,000 cpm are to be expected for the "total activity" tubes. This depends on the age of the kit and the efficiency of the counter.

EVALUATION

The cpm of the standards S0–S7 are calculated as a percentage of the cpm of the "total activity" and are plotted as individual values against the appropriate ferritin concentration. The "best fit" standard curve is drawn through these points.

The mean values are calculated for the two counts for the test serum and the patient serum samples. The ferritin concentrations per mL serum are read from the standard curve.

CRITICAL ASSESSMENT OF THE METHOD

The method described above was cumbersome in handling because of placing each individual anti-ferritin bead into the tubes by means of the forceps.

A data evaluation program with an appropriate fitting algorithm was not yet available.

MODIFICATION OF THE METHOD

Since the commercial distribution of the RIA-gnost Ferritin kit (beginning of the 1980s), improvements regarding easier handling, more sophisticated data evaluation and higher throughput have been made.

For instance, the next generation of RIA-gnost Ferritin was based on the coated tube technology which saved the manual transfer step of the anti-ferritin beads into the tubes. Further development led to semi- and fully automated assays based on enzyme/fluorescence and chemiluminescence immunoassays commercially available from several companies.

32.5 Specific Radioimmunoassay of 314d Isomer of Beraprost in Human Plasma

PURPOSE AND RATIONALE

Beraprost (*CAS*: 88475-69-8) is an equimolar mixture of two racemates (four isomers), APS-314d,l and APS-315d,l. Radioimmunoassays of the isomers of beraprost (an orally active prostacyclin PGI_2 analog which has antiplatelet and vasodilating effects) were carried out by combining a serum from a rabbit immunized with beraprost conjugated to bovine albumin and radioiodinated tracers prepared from each isomer. The main biological activity is contributed to the APS-314d isomer and the clinical daily dosing is in the range of 40–120 μg. APS-315d has a lower activity whereas APS-314 l and APS-315 l have almost no activity. The anti-beraprost serum contains three families of antibodies specific for the APS-314d and APS-315d isomers and for the mixture of the two l-isomers. The binding with either APS-314d, APS-315d or APS-315 l tracers made it possible to determine the plasma concentrations of APS-314d isomer, APS-315d isomer, and of the mixture of the two l-isomers during clinical studies (Mouren 1995).

Each assay method is specific with respect to the other stereoisomeric components of beraprost and related metabolites and also sensitive. The limit of quantification can be taken as 3 pg/mL for APS 314d, 12 pg/mL for APS 315d and 10 pg/mL for APS 314 l +APS 315 l, when applied to 0.1 mL of human plasma.

32.5.1 Reagents

- APS-314d Na
- Sodium chloride (Prolabo)
- Sodium azide (Merck)
- Sodium dihydrogen phosphate monohydrate (Carlo Erba)
- Anhydrous sodium hydrogen phosphate (Prolabo)
- Powdered gelatin (Merck)
- Triton X-100
- Sodium salicylate (Prolabo)
- Rabbit γ-globulins
- (Cohn's fraction II/III, G-0261, Sigma)
- Freund's complete and incomplete adjuvants (Difco)
- Human blank plasma

32.5.2 Preparation of Reagents

32.5.2.1 Immunogen and Rabbit Antiserum

Beraprost was linked to bovine serum albumin according to Erlanger et al. (1957).

A serum containing an antibody to APS-314d was produced in New Zealand rabbits. The immunogen (10 mg) was dissolved in 10 mL of a 0.9% sodium chloride solution and emulsified with 10 mL of Freund's complete adjuvant by repeated passages through a syringe. Each rabbit received 1 mL of emulsion (500 μg of immunogen) subcutaneously in 10 sites on the back. Three booster injections were given at 4-week intervals with the same dose of immunogen but using Freund's incomplete adjuvant. Blood sera were collected 3 weeks after the last booster and checked for titer, affinity and specificity without any purification.

The sera can be stored, either undiluted at −30°C for several years or diluted 1:100 in a buffer at +4°C for up to 6 months, without significantly losing activity. At the time of the assay, the selected serum is diluted 1:50,000 in assay buffer containing sheep anti-rabbit γ-globulins and rabbit γ-globulins.

32.5.2.2 Sheep Anti-Rabbit Gamma Globulins for Separation Step

An antibody to rabbit γ-globulins was raised by immunizing sheep with rabbit γ-globulins.

Each sheep initially received 5 mg of protein in multiple injections at intervals of 5 weeks until a serum with a satisfactory precipitating potency was obtained. Generally, two booster injections were sufficient and blood was withdrawn 15 days after the last booster. The serum was purified by precipitation of the immunoglobulins with half a volume of a saturated ammonium sulfate solution and then dialyzed for 4 days against a 0.9% sodium chloride solution which was replaced every day. It was stored at −30°C.

32.5.2.3 ^{125}I-APS-314d

The radioactive tracer used was obtained by iodine 125-labeling of the conjugate of APS-314d and histamine, according to Hunter and Greenwood's method (1962). Stored at −30°C, the iodinated tracer was stable for at least 3 months without any loss of performance. It was diluted extemporaneously in assay buffer to obtain a solution containing 80,000 cpm per mL.

32.5.2.4 Assay Buffer

The assay buffer was prepared by dissolving 9 g of sodium chloride, 1 g of sodium azide, 1 g of gelatin, and 2.5 g of sodium salicylate in 1 l of a 0.1 M phosphate buffer containing 0.01% (v/v) of triton X-100. It was stored at ambient temperature.

32.5.2.5 APS-314d Standard Solutions

A 100 μg/mL solution (M1) of APS-314d Na was prepared by dissolving the compound in demineralized water. This was stored at +4°C. Diluted 1:100 in phosphate-gelatine buffer, it yielded a solution (M2) of 1 μg/mL from which were obtained by 1:100 and 1:40 dilutions and then by successive 1:2 dilutions, solutions (A to J) containing 250–0.49 pg of APS-314d Na per mL of buffer. These solutions were prepared extemporaneously on the day of the assay.

PROCEDURE

Assays could be carried out with 0.1 mL of undiluted plasma samples or after dilution in human blank plasma. The standard curve was established in the presence of 0.1 mL of human blank plasma. The operating procedure is as follows (Table 32.1):

For calibration: to three replicates of:

0.1 mL of assay buffer (maximum binding Bo) or 0.1 mL of the M2 solution (nonspecific binding) or 0.1 mL of the standard solutions (i.e., 0.049–25 pg) were added in 12 × 65 mm glass test tubes, 0.1 mL of human blank plasma, and 0.2 mL of assay buffer.

For plasma samples: to three replicates of:

0.1 mL of undiluted plasma samples or to 0.1 mL of diluted plasma samples were added in 12 × 65 mm glass test tubes, 0.3 mL of assay buffer.

In all cases, the tubes were allowed to stand for 1 h at room temperature, following which iodinated APS-314d (4,000 cpm) was added in 0.05 mL of assay buffer to all tubes, as well as to three tubes labeled "total radioactivity." With the exception of the latter, the tubes were vortexed for a few seconds and then they received 0.05 mL of a mixture containing anti-beraprost serum (1:50,000 dilution), sheep anti-rabbit γ-globulins (200 μl/mL), and rabbit γ-globulins (200 μg/mL) (the quantity of rabbit γ-globulins involved depends on the quality of the purified sheep anti-rabbit γ-globulins serum and must be checked with each preparation of this second antibody).

After mixing the reagents, incubation was carried out at +4°C for 3 days. The bound fractions were then sedimented by centrifugation for 30 min at 3,000 rpm (about 2,200 g) at +4°C. The supernatant phases were eliminated by inverting the tubes which were then allowed to stand on cotton wool for 30 min.

The total amount of radioactivity involved and the amounts bound to the antibody were measured for 2 min on a well-type gamma counter. The found values were corrected for nonspecific binding, and the concentrations of APS-314d in samples were obtained from the calibration curve smoothed by a 4-PL model.

32.5.2.6 Validation and Cross-Reactivity Check

The assay method was validated and assay performance characterization established.

Accuracy: the absolute value of the difference within and between day was lower than or equal to 9.0%, and the limit of quantification can be taken as 3 pg/mL.

Precision: the within-assay coefficient of variation was between 4.0% and 10.1%, and the between-assay coefficient of variation was between 6.8% and 10.4% over the range 3.13–100 pg/mL.

Table 32.1

	Standard point	Samples	Human blank plasma	Assay buffer		Iodinated APS-314d	Mixture containing rabbit anti-beraprost serum, sheep anti-rabbit γ-globulins, and rabbit γ-globulins
Total radioactivity (three replicates)					Allow to stand for 1 h at room temperature	0.05	
Maximum binding Bo (three replicates)			0.1	0.3		0.05	
Nonspecific binding (three replicates)	0.1 (M2)		0.1	0.2		0.05	0.05
Standard curve (three replicates)		0.1		0.3		0.05	0.05
Samples (three replicates)		0.1		0.1		0.05	0.05
Quality controls (three replicates)							

Specificity: determined by Abraham's method (1974) at 50% inhibition of maximum binding, the percentage cross-reactions of the APS-315d Na, APS-314 l Na, and APS-315 l Na isomers in the assay of APS-314d Na were 2.4, 0.5 and 0.1%, respectively. This establishes, by comparing to the results using the beraprost (four isomers) as radiolabeled reagent, the complete fall down of the cross-reactivity and allows its use after administration of beraprost sodium in human.

CRITICAL ASSESSMENT OF THE METHOD

This way of using a single isomer labeled with high purity is an efficient alternative in order to achieve a stereospecific immunoassay. This immunoassay gives reliable information in terms of safety pharmacokinetics. The application in pharmacokinetic studies of each isomer can be made. Only few amounts of isomer for tagged molecule and standard curves are requested.

32.6 Enzyme Sandwich Immunoassay with Monoclonal Antibodies for the Detection of HBeAg and anti-HBe

PURPOSE AND RATIONALE

The commercially available Enzygnost HBe monoclonal kit (distributed by Dade Behring) can be considered as an example for an immunoassay which combines many favorable features, e.g., nonisotopic label, sandwich immunoassay principle, use of monoclonal antibodies, determination of antigen and anti-antigen antibodies in a single test, microtiter plate format, possibility for semi- and full automation.

HBeAg and the corresponding antibody anti-HBe are found exclusively in connection with hepatitis B virus infection.

Seroconversion from "HBeAg positive" to "anti-HBe positive" is a favorable sign indicative of convalescence and an uncomplicated course.

Further information is found in Hollinger (1990), Bruss et al. (1988), Carman et al. (1989), and Brunetto et al. (1990).

The Enzygnost HBe monoclonal kit is based on the sandwich principle. HBe antigen (HBeAg) in the sample binds to monoclonal anti-HBe antibodies to the surface of the walls in the microtitration plate. Unbound sample constituents are then removed by washing, peroxidase-conjugated monoclonal antibodies to HBeAg are added and bind to the remaining free antigen determinants.

The excess conjugate is washed out, hydrogen peroxide substrate with chromogen is added and reacts with the bound peroxidase producing a blue color. This enzymatic reaction is stopped by the addition of a stopping solution and the resulting yellow color is measured. The resultant color intensity is proportional to the concentration of HBeAg in the sample.

In the test for anti-HBe, anti-HBe antibodies in the sample block the HBeAg pipetted with the positive HBeAg reagent. When the resulting mixture is then used in the HBeAg test, no HBe antigen or minimal HBeAg is detected if the sample is positive for anti-HBe. The color intensity of the sample is inversely proportional to the concentration of anti-HBe.

PROCEDURE

32.6.1 Reagents

Enzygnost HBe monoclonal (test plate): microtitration plate coated with monoclonal antibodies to HBe antigen

Anti-HBe/POD Conjugate: Monoclonal anti-HBe, conjugated with peroxidase (POD), preservative: phenol (max. 1 g/L)

HBeAg reagent, positive: genetically engineered HBe antigen, stabilized with bovine serum albumin and Synperonic, lyophilized, preservative: phenol (max. 1 g/L)

Anti-HBe Control, positive: Human serum containing monoclonal antibodies to HBe antigen, preservative: phenol (max. 1 g/L)

HBe Control, negative: Negative human serum for the HBeAg and anti-HBe tests, preservative: phenol (max. 1 g/L)

Washing Solution POD (concentrate): Phosphate buffer solution (90 mmol/L) containing Tween (18 g/L), preservative: phenol (max. 1 g/L)

Buffer/Substrate TMB: Hydrogen peroxide (approx. 0.1 g/L in acetate buffer solution (25 mmol/L)), preservative: 1-butanol (max. 10 mL/L)

Chromogen TMB: Tetramethylbenzidine dihydrochloride (5 g/L)

Stopping Solution POD: 0.5 N sulphuric acid

32.6.1.1 Preparation of the Reagents

For each test plate, dilute 20 mL washing solution POD to 400 mL with distilled or demineralized water.

Working Chromogen Solution: For each test plate, dilute 1 mL Chromogen TMB with 10 mL Buffer/Substrate TMB in the empty plastic bottle supplied with the kit and store closed and protected from light.

Working solution of HBeAg reagent, positive: Before the test reconstitute a vial of HBeAg reagent, positive with 13 mL distilled or demineralized water. Shake gently to mix and ensure that the reagent has completely dissolved before use (approx. 30 min).

32.6.1.2 Equipment

Incubator: Covered water bath (+37 ± 1°C) or comparable incubation methods

BEP II: For automatic dispensing of reagent and washing

BEP III: For automatic processing of the test after dispensing the samples as well as for evaluation

BEP 2000: For fully automatic processing and evaluation of the test

32.6.2 Assay Procedure

32.6.2.1 Procedure for HBeAg test using the BEP II (detection of HBeAg):

1. Dispense samples: Pipette 100 μL/well HBe Control, negative into four wells, 100 μL of HBeAg Reagent, positive into the next well and then fill the following wells with 100 μL of undiluted sample. At the end of the series/plate, pipette 100 μL of HBeAg reagent, positive once more and cover with foil.
2. Incubate: Incubate at 37 ± 1°C for 60 ± 2 min.
3. Wash: Remove the foil, aspirate the wells, and wash two times with approx. 0.3 mL/well of diluted washing solution. Proceed immediately to the "Dispense conjugate" step.
4. Dispense conjugate: Fill each well with 100 μl of anti-HBe/POD conjugate, cover with fresh foil, and immediately place into the incubator.
5. Incubate: Incubate at 37 ± 1°C for 60 ± 2 min, then proceed immediately to the "Wash" step.
6. Wash: Remove the foil and wash four times as described in "3. Wash."
7. Dispense substrate: Pipette 100 μL of the working chromogen solution into each well and cover the plate with fresh foil.
8. Incubate: Incubate at +18 to +25°C for 30 ± 2 min, protected from light.

9. Stop reaction: Remove the foil and add 100 μL of stopping solution POD to each well, keeping to the same timing as in "8. Dispense substrate."
10. Read: At 450 nm within 1 h.

The use of a photometer with two wavelengths (measurement and reference beams) is to be recommended. The absorbances of the control samples and patient samples are to be measured at a wavelength of 450 nm. The wavelength recommended for the reference reading is 650 nm (if necessary between 615 and 690 nm).

32.6.2.2 Procedure for Anti-HBe Test Using the BEP II (Detection of Anti-HBe)

1. Dispense samples: Pipette 25 μL/well HBe control, negative into four wells, 25 μL of anti-HBe control, positive into the next well, and then fill the following wells with 25 μL of undiluted sample. At the end of the series/plate, pipette 25 μL of anti-HBe control, positive once more.
2. Binding of the anti-HBe: Directly after dispensing the samples, add 75 μL of HBeAg reagent, positive, (working solution) into each well containing the 25 μL of sample or control, then seal with foil.

Perform the subsequent steps as described for the HBeAg test, i.e., continue processing starting at "2. Incubate."

32.6.2.3 Test Procedure Using the BEP III

Before using the BEP III, perform the sample dispensing steps (Sect. 32.6.2.1 from "procedure using the BEP II"). Immediately afterward, place the uncovered test plates into the BEP III. The test is then processed fully automatically.

32.6.2.4 Test Procedure Using the BEP 2000

The sample dispensing steps and the subsequent processing of the test are performed fully automatically by the analyzer.

EVALUATION

The evaluations are performed automatically if the BEP III or BEP 2000 is used. The following sections apply if the measurements are carried out without a software.

32.6.3 HBe Test

Calculate the mean absorbance value of the negative controls, then calculate the cut-off value by adding 0.050:

$A_{(neg)} + 0.050 = \text{cut-off}$

Based on the criteria of the test, the samples are classed as follows:

1. $A_{sample} < \text{cut-off-}10\% = \text{HBeAg negative}$
2. $\text{cut-off-}10\% \leq A_{sample} \leq \text{cut-off} + 10\% = \text{HBeAg equivocal}$
3. $A_{sample} > \text{cut-off} + 10\% = \text{HBeAg positive}$

32.6.4 Anti-HBe Test

Calculate the mean absorbance value of the negative controls, then calculate the cut-off value by multiplication with 0.5:

$A_{(neg)} \times 0.5 = \text{cut-off}$

Based on the criteria of the test, the samples are classed as follows:

1. $A_{sample} > \text{cut-off} + 10\% = \text{anti-HBe negative}$
2. $\text{cut-off-}10\% \leq A_{sample} \leq \text{cut-off} + 10\% = \text{anti-HBe equivocal}$
3. $A_{sample} < \text{cut-off-}10\% = \text{anti-HBe positive}$

Samples with equivocal results must be retested in double determinations. If in the retest, the mean value of double determination is greater than or equal to the cut-off, or less than the cut-off, the initial equivocal result can be ignored and the sample to be considered reactive or negative as appropriate.

32.6.5 HbeAg

Precision (within day): 3.8–6.4%
Precision (between day): 8.7–11.4%

32.6.6 Anti-Hbe

Precision (within day): 3.2–7.4%
Precision (between day): 3.4–6.3%

CRITICAL ASSESSMENT OF THE METHOD

The method involves a lot of incubation and washing steps which is due to the use of the enzyme label. In addition, the incubation conditions (time and temperature) have to be kept very strictly to meet the product specifications. These requirements can hardly be fulfilled for longer sample batches by a manual procedure. Therefore, automation at least for the processes of dispensing of reagents and washing is

recommended. The best results, however, will be obtained with the analyzers optimized for product performance ("closed systems" with reagents and instrumentation from the same manufacturer). User-defined modifications are not supported by the manufacturer and may affect the assay results.

The example described above supports the general statement made in the introduction that EIAs which have to fulfill high-quality requirements with regard to sensitivity and robustness likewise need sophisticated techniques and/or automation.

MODIFICATION OF THE METHOD

The number of incubation and washing steps can be greatly reduced by employing "direct" instead of "indirect" labels (enzyme generates a signal only by reaction with a substrate). In addition to the radioactive label, nonisotopic alternatives with improved features (e.g., time-resolved fluorescent, chemiluminescent, electrochemiluminescent labels) have become available. Immunoassays based on these labels show an excellent performance even by manual procedure, automation is only required for a higher sample throughput. The advantages of luminogenic compared to chromogenic substrates (e.g., higher sensitivity and dynamic range of signal) are often used to replace the chromogens by luminophors in already available tests and systems.

An example for an anti-HBe test with a direct label is the electrochemiluminescence immunoassay "ECLIA" from Roche Diagnostics (automated on "Elecsys" immunoassay analyzer), whereas the Immulite anti-HBe test from Diagnostics Products Corp. represents an enzyme-amplified chemiluminescence immunoassay with sustained signal (automated on the Immulite chemiluminescent system).

PURPOSE AND RATIONALE

Toxicokinetics is defined as “the generation of pharmacokinetic data, either as an integral component in the conduct of nonclinical toxicity studies or in specially designed supportive studies, in order to assess systemic exposure. These data may be used in the interpretation of toxicology findings and their relevance to clinical safety issues” (ICH Guidance Toxicokinetics 1994).

PROCEDURE

33.1 Main Group or Satellite Animals?

Whenever possible, toxicokinetic measurements are performed in all animals of the toxicity study. This is the most representative approach, and it allows the individual PK data to be directly correlated with the toxicological findings. The second choice is the toxicokinetic measurement in representative subgroups or in satellite groups. Satellite groups are animals that are treated and housed under conditions identical to those of the main study animals. The use of satellite animals is indicated, for example, in small animals, where the collection of a relatively large volume of blood may influence the toxicological findings.

33.2 Number of Animals and Time Points?

In ICH Guidance Toxicokinetics 1994, it is stated: “The number of animals to be used should be the minimum consistent with generating adequate

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_37, © Springer-Verlag Berlin Heidelberg 2013

toxicokinetic data," and "The area under the matrix level concentration-time curve (AUC) and/or the measurement of matrix concentrations at the expected peak-concentration time C_{max}, or at some other selected time $C_{(time)}$, are the most commonly used parameters." In large animals (e.g., dogs), the number of animals is usually fixed by the number of animals, which is necessary for safety evaluation. The withdrawal of a sufficient number of blood samples (6–9) per animal is not a problem. However, in small animals like rodents, it is recommended not to collect more than 10% of the blood volume during the AUC sampling interval (BVA/FrAME/RSPCA/UFAW Working Group of Refinement 1993; Cayen 1995). According to a new guidance from Diehl et al. (2001), the volumes per day are specified according to the recovery period. Diehl et al. (2001) limit the total daily volumes of multiple sampling to 7.5% of the circulatory blood volume at a recovery period of 1 week, 10–15% at a recovery period of 2 weeks, and 20% at a recovery period of 3 weeks. The optimum number of time points is always a compromise between blood volume restrictions and reliable assessment of TK parameters (AUC and C_{max}). Pai et al. (1996) compared for three different compounds the AUCs from intensive (full) (10–15 time points with 4–5 rats/time point) with sparse sampling schemes (5 time points with 2 rats/time point). Using Monte Carlo simulation, Pai et al. (1996) could show that the deviation of AUC estimation of the sparse sampling scheme from the full sampling scheme was not larger than 10%. Thus, a sparse sampling scheme with 5–7 time points with 2–3 animals per time point is well suited for the reliable determination of systemic exposure in small animal toxicity studies.

The dried blood spot (DBS) technique was recently rediscovered and is under intensive investigation (Burnett 2011) and regulatory discussion (Beharry 2010), which may significantly impact the above-mentioned considerations. The dried blood spots approach to toxicokinetic and pharmacokinetic sampling requires less blood at each time point than for plasma or serum analysis, meaning that even for small animals, serial rather than composite TK profiles can be obtained from individual animals. A decision tree for choosing plasma or dried blood spot matrix depends on blood/plasma ratio and constancy in fraction unbound for plasma; constancy of hematocrit and blood cell affinity is given by G. Emmons and M. Rowland (2010).

33.3 Evaluation of Samples from Control Animals?

In note 8 of ICH Guidance Toxicokinetics 1994, it is stated: "It is often considered unnecessary to assay samples from control groups. Samples may be collected and then assayed if it is deemed that this may help in the interpretation of the toxicity findings, or in the validation of the assay method." In the introduction of the CPMP Guideline on the evaluation of control samples in nonclinical safety studies of the EMEA (2005) this topic is further elaborated in light of a survey conducted by the European Federation of Pharmaceutical Industry, which showed that controls contamination during toxicology studies often occurs. The guideline requests: "Controls sampling and analytical procedures should be integrated in the toxicokinetic evaluation normally conducted in support of nonclinical safety studies. The analysis of samples from controls may need to be performed simultaneously with those from dosed animals."

33.4 Analytical Methods

The analytical methods to be used in toxicokinetic studies should be specific for the entity to be measured and of adequate accuracy and precision. The limit of quantification should be adequate for the measurement of the range of concentrations anticipated to occur in the generation of the toxicokinetic data (ICH Guidance Toxicokinetics 1994).

33.5 Toxicokinetic Evaluation

The following aspects should be considered for toxicokinetic evaluation:

Pharmacokinetic profile of the compound (exposure)
Dose dependency of AUC and C_{max}
Chances of exposure during the course of the toxicity study
Gender differences

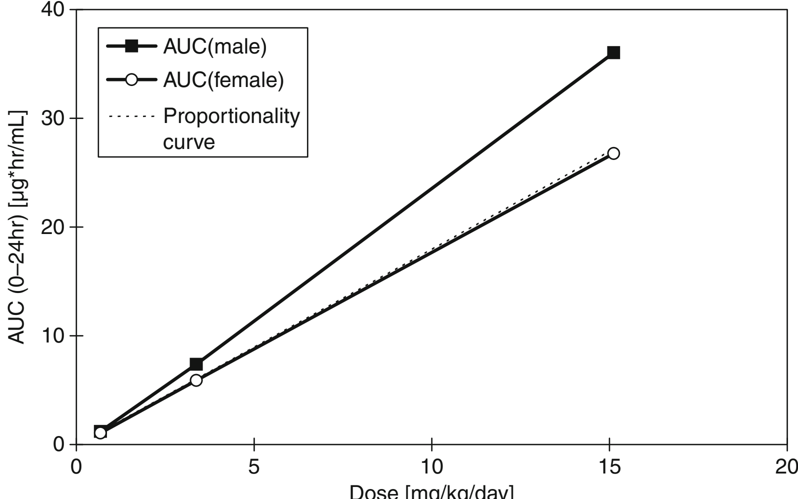

Fig. 33.1 Proportional dose dependency of AUC in an intravenous toxicity study in rat with the test compound A

33.5.1 Pharmacokinetic Profile of the Compound (Exposure)

For toxicokinetic purposes, it is usually sufficient to describe the systemic burden in plasma or serum of the test species with the test compound and/or its metabolites. The area under the matrix-level concentration-time curve (AUC) and/or the measurement of matrix concentrations at the expected peak-concentration time C_{max}, or at some other selected time (For example C (24 h) as trough value) $C_{(time)}$, is the most commonly used parameters. According to the supplementary notes in ICH Guidance Toxicokinetics 1994 for a profile (e.g., 4–8), matrix samples during a dosing interval should be taken to make an estimate of C_{max} and/or $C_{(time)}$ and area under matrix concentration time curve (AUC).

33.5.2 Dose Dependency of AUC and C_{max}

According to the ICH Guidance Toxicokinetics 1994, it is one of the primary objectives of toxicokinetics to describe the systemic exposure achieved in animals and its relationship to dose level.

At pharmacological and clinical doses, it can be generally assumed that most of the drugs show linear pharmacokinetics. Linear pharmacokinetics is given when exposure (AUC) is proportional to dose and principal pharmacokinetic parameters like bioavailability, elimination rate, volume of distribution, and clearance are independent on dose. For toxicokinetic studies, however, nonlinear pharmacokinetics is much more frequent than linear pharmacokinetics. This is mainly due to the fact that at very high doses, most systems in the body are likely to be stressed and, possibly, saturated to some degree. Thus, additional to the dose proportional increase of exposure (Fig. 33.1) and a less than proportional increase (Fig. 33.2) and a more than proportional increase (Fig. 33.3) is very frequently observed. For a less than proportional increase of exposure, a saturation of absorption processes or a concentration dependent change of volume of distribution should be considered as a potential cause. For a more than proportional increase of exposure saturation of metabolic elimination pathways, saturation of renal of biliary excretion of parent compound or a concentration dependent change of volume of distribution should be considered as a potential cause.

33.5.3 Chances of Exposure During the Course of the Toxicity Study

According to the ICH Guidance Toxicokinetics 1994, the description of the relationship of exposure to the time course of the toxicity study belongs to the primary objective of toxicokinetics. This objective may

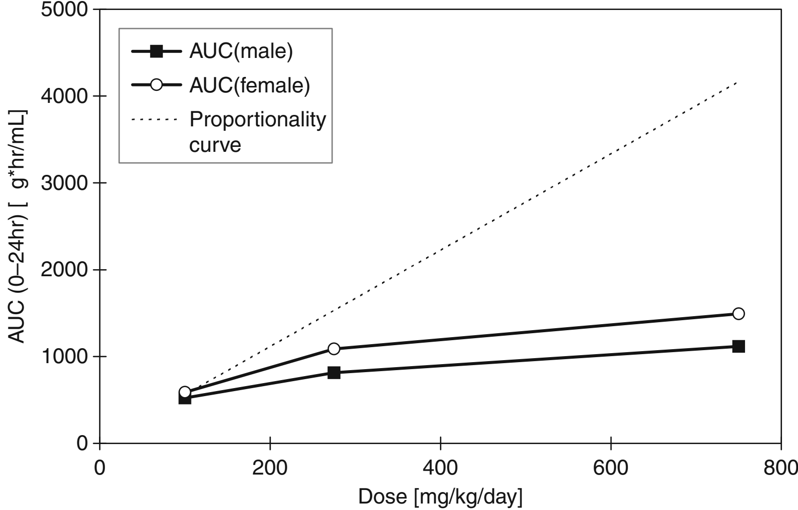

Fig. 33.2 Less than proportional dose dependency of AUC in an oral toxicity study in rat with the test compound B

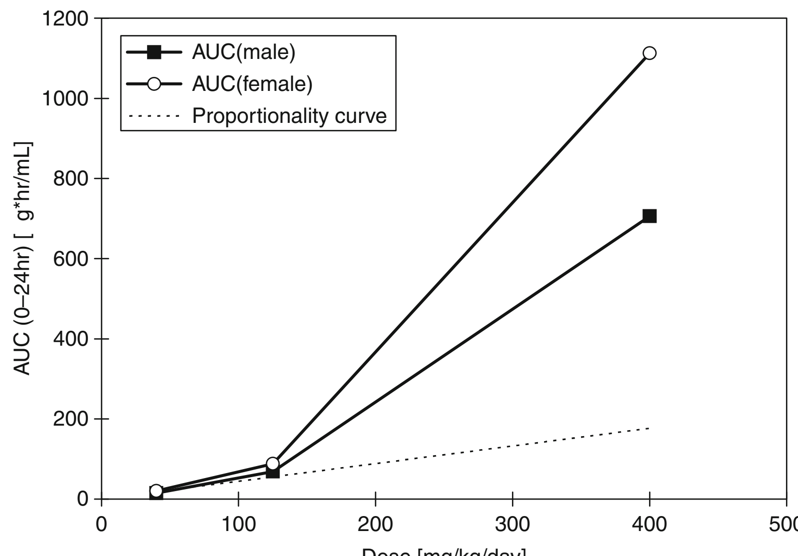

Fig. 33.3 More than proportional dose dependency of AUC in an oral toxicity study in dog with the test compound C

be achieved by derivation of pharmacokinetic parameters from measurements made at appropriate time points during the course of the individual studies. In the short-term studies (1 month or shorter), day1 and a day at the end of the toxicity study may be appropriate sampling days. In the long-term studies, day1, a day after one-third of the study duration, and a day at the end of the toxicity study may be appropriate sampling days. Increasing exposure may occur during the course of a study for those compounds, which have a particularly long plasma half-life. Conversely, unexpectedly low exposure may occur during a study as a result of auto-induction of metabolizing enzymes. However, other facts can also play a role in changes of exposure during the course of the study. Very often, rats and mice were used in an age at which they are not sexually matured, and during the study, the sexual maturation with their known impact on the rate and extent on metabolism takes place in the first 2 months. The harm of elimination pathways (e.g., nephro- or hepatoxicity) by the test compound can be another reason for changes in exposure. A more trivial

reason as the aging or the change of the administered batch with impact on bioavailability should also be considered.

33.5.4 Gender Differences

According to the ICH Guidance Toxicokinetics 1994, it is normal to estimate exposure in animals of both genders unless some justification can be made for not so doing. For evaluation, both genders should be evaluated separately. The assessment of exposure data of the two genders can be performed just by calculation of the ratio of AUC and C_{max} and elimination half-life in males and females. However, additional factors such as, for example, size of the investigated groups (with respect to random variation) and sexual maturity have to be considered. As a rule of thumb, it can be stated that in rodents, a gender difference is quite usual, when metabolism is involved as major elimination pathway, whereas in nonrodents, distinct gender difference is rather seldom.

33.6 Practical Examples

33.6.1 HPLC UV Assay

PURPOSE AND RATIONALE

Levels of drug and/or its metabolite have to be determined in plasma samples collected during the course of a toxicity study in order to evaluate the toxicokinetics of that compound. The UV absorption properties of the compound are used to determine the compound of interest. Since many of the endogenous compounds also show absorption in that wavelength range, a tailored sample work-up has to provide additional selectivity for the compound of interest. In addition, the plasma proteins have to be removed by the work-up in order to avoid blocking of the HPLC columns. Three principles are generally applied to remove the proteins from the sample: Protein precipitation, liquid/liquid extraction and liquid/solid extraction.

PROCEDURE

A typical method using liquid/liquid extraction was described by Shum et al. (1994) for the determination of an ACAT inhibitor in rat plasma. Internal standard, 1 mL water and 1 mL of n-pentane were added to 0.25 mL volume of plasma. After shaking for 15 min and centrifugation for 15 min at approx. 1200 g, the upper organic phase was transferred and evaporated. The residue was reconstituted in 200 μL of mobile phase, and 100 μL was injected onto the HPLC column for analysis. The HPLC system consisted of a Bio_Sil ODS-5S column (150 × 4 mm; 5 μm particle size) and a UV detector operating at 250 nm. The mobile phase consisted of 55 % acetonitrile, 27 % methanol, and 18% water. The flow rate was 1.9 mL/min. The column temperature was ambient temperature.

EVALUATION

For calibration, a set of eight standards was prepared by fortifying blank plasma with concentrations ranging from 60 ng/mL to 8000 ng/mL. In addition, three sets of quality control samples are prepared of low, medium and high concentration within the range of standards. From the response of the eight standards a calibration curve is determined using the least-square linear regression using a weighting factor of 1/concentration squared. The response is generally the peak height or peak area ratio of analyte/internal standard.

MODIFICATIONS OF THE METHOD

For sample preparation, protein precipitation or solid phase extraction or any combination of the different principles can also be applied. Kim et al. (2002) described a simple toxicokinetic assay for a prodrug and its two consecutively hydrolyzed active antifungal compounds. A 0.2 mL aliquot of dog plasma was added to 0.6 mL methanol containing the internal standard compound in a 2 mL microcentrifuge tube. The tubes were vortexed at high speed and centrifuged at 4500 g for 5 min. The supernatant was transferred into a new tube and stored for a minimum of 12 h at −20 °C to complete the precipitation. The samples were again vortexed and centrifuged. 200 μL of the supernatant were injected onto the HPLC column. In order to cover all three analytes and the internal standard in a reasonable HPLC-run time, a gradient elution on an Ultrasphere ODS column was applied instead of isocratic elution.

An appropriate tool to enhance the selectivity and the feasibility of the work-up procedure using liquid/liquid extraction is the subsequent back extraction into aqueous phase. For example, Los et al. (1996) described a toxicokinetic assay for diltiazem and its two metabolites. To 0.2 mL rat plasma, internal standard solution and a pH 7.3 phosphate buffer and methyl-t-butyl ether were added. The analytes were extracted into the organic phase. The organic phase was transferred and the analytes back-extracted into 250 μL of 0.05 M phosphoric acid. The phosphoric acid was modified with 100 μL acetonitrile before injection onto HPLC.

Kawauchi et al. (2001) described a toxicokinetic assay for a thymidin phosphorylase inhibitor. This compound was water-soluble and not extracted with organic solvents. Protein precipitation failed also due to the appearance of a lot of interfering peaks. Therefore, solid-phase extraction on a strong cation exchange sorbent (= RPS) was used for sample preparation. To 0.1 ml of plasma 50 μL of internal standard solution and 0.7 mL of 0.01 M HCl were added and mixed. The mixed sample was loaded 5 onto a Bond Elut PRS column (1 cc/100 mg) set up at a Vac Elut SPS 24 (Varian) that prior to the sample loading had been conditioned with 1 ml of methanol, and then with 1 ml of water. After passing the sample, the column was washed with 1 ml of water and then with 1 ml of methanol. The eluate was collected with 2 ml of 2 % ammonia solution - methanol in a glass test tube, and dried under a stream of N gas at 37 °C. The residue was reconstituted in 0.2 ml of 10 mM acetate buffer (pH 4.3), and a 60 ml aliquot was injected onto the HPLC column. The HPLC system consisted of a Mightsil RP-18 column (150 × 4.6 mm; 5 μm particle size) and a UV detector operating at 276 nm. The mobile phase consisted of 9 % acetonitrile and 91 % 7 mM sodium 1-hexanesulfonate in 10 mM acetate buffer (pH 4.3). The flow rate was 1.0 mL/min.

CRITICAL ASSESSMENT OF THE METHODS

The described methods are typical HPLC UV assays for drug level determination for toxicokinetic purposes. However, the conditions of sample preparation, the choice of the internal standard substance, the choice of the HPLC stationary and mobile phase and the wavelength of the UV detector have to be adjusted specifically to the properties of the analytes. Particularly, the lipophilicity, the pKa value, and the pH stability of the analytes have to be considered. Regarding selectivity and sensitivity of the assay, HPLC UV assays are not the cutting edge technology. However, in most cases the sensitivity is adequate, since doses, and concomitantly the drug levels, are usually quite high in toxicity studies. A very important aspect for assays used in toxicokinetics is huge range of drug concentration, which can be expected due to very different doses. Therefore, an optimal assay should have a large dynamic range, in order to avoid time consuming and error prone dilution procedures. The assay in plasma described by Shum et al. (1994) was validated from 0.06 to 8 μg/mL (dynamic range of 133), the assay described by Kim et al. (2002) was validated from 0.05 to 50 μg/mL (dynamic range of 1000), the assay described by Los et al. (1996) was validated from 0.01 to 5 μg/mL (dynamic range of 400) and the assay described by Kawauchi et al. (2001) was validated from 0.05 to 40 μg/mL (dynamic range of 800).

33.6.2 Fluorescence Assay for Analytes with Native Fluorescence

PURPOSE AND RATIONALE

Levels of drug and/or its metabolite have to be determined in plasma samples collected during the course of a toxicity study in order to evaluate the toxicokinetics of that compound. The native fluorescence of the compound is used, to determine the compound with a relatively high sensitivity and selectivity.

PROCEDURE

A typical method was described by Kim et al. (1999). for the determination of a dopamine D receptor antagonist in rat plasma. 0.2 mL volume of plasma was diluted with 1.5 mL of 0.25 M potassium phosphate buffer, pH 8, followed by the addition of 20 μL of the internal standard (1000 ng/mL in methanol), which was a methyl analog of the analyte. The diluted sample was slowly applied on a 1 mL disposable ethyl cartridge which had been successively prewashed with 2 mL of methanol, 1 mL of acetonitrile, 1 mL of water and 1 mL of 0.25 M phosphate buffer, pH 8, using a vacuum manifold. The loaded cartridge was washed with 2 mL of water, then dried by airflow through under vacuum for 5 min. The analyte was eluted from the cartridge with 2 × 0.6 mL of methyl-t-butyl ether (saturated with water and containing 8 % triethylamine). The eluate was evaporated to dryness under nitrogen. The residue was dissolved in 0.4 mL of mobile phase and a 90 μL aliquot was injected onto the HPLC column. The HPLC system consisted of a YMC basic column (150 × 4.6 mm; 5 μm particle size) and a fluorescence detector. The detector was set at an excitation wavelength of 260 nm and an emission wavelength of 400 nm. The mobile phase consisted of 35 % acetonitrile and 65 % 0.05 M ammonium acetate. The flow rate was 1 mL/min. The column temperature was ambient temperature.

EVALUATION

For calibration, a set of five standards is prepared by fortifying blank plasma with concentrations ranging from 5 ng/mL to 100 ng/mL. In addition, three sets of quality control samples are prepared of low, medium and high concentration within the range of standards. From the response of the five standards a calibration curve is determined using the least-square linear regression with or without weighting factor. The response is generally the peak height or peak area ratio of analyte/internal standard.

MODIFICATIONS OF THE METHOD

For sample preparation, protein precipitation or liquid/liquid extraction can also be applied instead of solid phase extraction. Gluth et al. (1988) described for a toxicokinetic assay for Sotalol a threefold combination of these principles. A protein precipitation using 5 M perchloric acid was followed by a liquid/liquid extraction into a mixture of n-pentanol-chloroform 1/3 at pH 9. Thereafter, the organic phase was transferred to another glass tube and the analyte back extracted into 0.05 M sulfuric acid.

For the case that two analytes with quite different native fluorescence and different concentration ranges have to be determined, Chollet et al. (1998) describe an elegant solution. They developed a gradient elution program which generated an elution order suitable for an automated wavelength change in respect to reliable peak integration. The carboxylate and lactone form of Irinotecan and its metabolite were detected at λ_{ex} = 362 nm/λ_{em} = 425 nm and λ_{ex} = 375 nm/ λ_{em} = 560 nm, respectively.

CRITICAL ASSESSMENT OF THE METHODS

The described method is a typical HPLC fluorescence assay for drug level determination for toxicokinetic purposes. However, the conditions of sample extraction, the choice of the internal standard substance, the choice of the HPLC stationary and mobile phase and the combination of excitation and emission wavelength has to be adjusted specifically to the properties of the analytes. Particularly, the lipophilicity, the pKa value and the pH stability of the analytes have to be considered.

Regarding selectivity and sensitivity of the assay, HPLC fluorescence assays are clearly preferable to UV assays, however a prerequisite is the native fluorescence of the analytes. A very important aspect for assays used in toxicokinetics is a huge range of drug

concentration, which can be expected due to very different doses. Therefore, an optimal assay should have a large dynamic range, in order to avoid time consuming and error prone dilution procedures. The assay in plasma described by Kim et al. (1999) was validated from 5 to 100 ng/mL (dynamic range of 20), the assay in plasma described by Gluth et al. (1988) was validated from 50 to 1500 ng/mL (dynamic range of 30) and the assay in urine was validated from 2 to 100 μg/mL (dynamic range of 50).

33.6.2.1 HPLC DBS MS/MS Assay

PURPOSE AND RATIONALE

Levels of drug and/or its metabolite can be determined in blood samples instead of plasma samples collected during the course of a toxicity study in order to evaluate the toxicokinetics of that compound. The currently most versatile approach to perform a drug level determination in blood is the bioanalysis in dried blood spots (DBS) followed by quantification using the LC–MS/MS technique. This approach requires very low blood volumes and has consequently the potential to significantly reduce the number of animals required in a toxicokinetic study. Typical animal numbers required using dried blood spot samples were compared with animal numbers required when generating toxicokinetic data from plasma samples by Burnett (2011).

PROCEDURE

A typical procedure using dried blood spots combined with HPLC-MS/MS was described by Barfield et al. (2008) for the quantification of acetaminophen in dog blood. Replicate (n = 3 for each time point) 0.15-mL volume aliquots from each plasma sample were spotted onto FTA® Elute blood spot cards (supplied by Whatman, Sanford, USA) and allowed to dry at room temperature for 2 h. These were stored and shipped at room temperature in a sealed plastic bag (Fisher, Loughborough, UK) containing a sachet of desiccant (Sud-Chemie, Northwich, UK). For DBS analyses, a 3-mm-diameter disk was punched from the center of the DBS into a clean tube. Methanol (0.1 mL) containing internal standard ($[^2H_4]$-acetaminophen) laws was added and the tube vortex was mixed for approximately 30 s. The tube was centrifuged for 5 min at 3000x g and the supernatant transferred to a clean tube and a portion injected onto the HPLC-MS/MS system.

The HPLC-MS/MS system consisted of a CTC HTS PAL autosampler (Presearch, Hitchin, UK) with fast wash, an Agilent 1,100 binary pump (Palo Alto, CA, USA) with integrated column oven and divert valve, and a Polaris Amide C18, 3 μm, 50 mm × 3.2 mm i.d, HPLC column (Varian Limited, Oxford, UK). The post column flow was diverted to waste for first 0.5 min of each chromatographic run. During this time, flow (0.25 mL/min, methanol:water (1:1, v/v)) was provided to the MS by a Knauer pump (Presearch, Hitchin, UK). The chromatographic separation was achieved using a solvent gradient employing the mobile phase 10-mM ammonium formate containing 0.3% ammonia (A) and methanol (B). Following sample injection (3μL), the mobile phase was held at 98% A for 0.2 min. A ballistic gradient at 5% A for 0.3 min was followed by an isocratic period at 5% for 0.8 min. The mobile phase was then returned to 98% A by 0.9 min and was held at this composition until 1.5 min, before the injection of the next sample. The flow rate was 1 mL/min; the column was maintained at 40°C. The HPLC effluent was split approximately 1:3 before entering the ion source. MS detection was performed on a Sciex API-3000 (Applied Biosystems/MDS Sciex, Canada) equipped with a TurboIonspray™ ion source. The source temperature was 450°C with a turbo gas flow of 7 L/min (N_2) and a nebulizer gas setting of 10 (N_2). The curtain gas and collision gas settings were 10 and 6, respectively (both N_2). The characteristic precursor $[M + H]^+$ to product ions transitions, m/z 152 → 110 for acetaminophen and 156 → 114 for the internal standard respectively, was used as selected reaction monitoring transitions. A dwell time of 200 ms was used for both transitions. The pause time was 5 ms.

EVALUATION

For calibration, a set of eight standards were prepared fresh on the day of analysis by diluting the appropriate working solutions with blank whole dog blood to target concentrations ranging from 0.1–50 μg/mL. In addition, sets of quality control samples were prepared within the range of standards. When required, the DBS QCs were stored at room temperature in a sealed plastic bag containing desiccant until analysis. A calibration plot of analyte/internal standard peak area ratio versus the nominal concentration of acetaminophen was constructed, and a weighted $1/x^2$ linear regression was applied to the data.

MODIFICATION OF THE METHOD

One of the main considerations before starting the in-life phase of a safety study is confirmation of the type of DBS card to be used for sample collection. This requires some bioanalytical development and/or validation work to have been carried out in advance. Burnett (2011) has described in detail card selection and sample spotting considerations.

CRITICAL ASSESSMENT OF THE METHODS

Beharry (2010) from UK MHRA stated: "Dried blood spots is clearly a technique that falls into the remit of the replacement, refinement and reduction of animals in research (3Rs), which is fully supported by the MHRA." Given that this is a "relatively" new technique, it will be necessary to provide adequate details of analytical methods used, and these should conform to the requirements set out in ICH S3A.

Timmerman (2011) have outlined in a white paper the intensive discussion within the European Bioanalysis Forum (EBF) concerning the validation requirements needed to generate robust and reproducible concentration data from DBS experiments. They identified and evaluated the validation requirements needed in addition or in excess of the method validation practices established for liquid assays. In consequence, that means that the validation efforts using DBS are considerably higher.

34.1 Introduction

The protein binding plays an important role in the pharmacokinetics and pharmacodynamics of a drug. Plasma binding can also be viewed as a circulating site of storage, releasing the drug to tissue with higher affinity. Only the unbound drug is thought to be able to diffuse across membranes and to interact with an effector site to produce a therapeutic response.

The extent of protein binding in the plasma or tissues controls the volume of distribution and affects both hepatic and renal clearance. The volume of distribution (V) depends on the fraction unbound in plasma (f_u), the fraction unbound in tissue (f_{uT}), the volume of tissue (V_T), and the volume of plasma (V_P) by the equation:

$$V = [f_u/f_{uT}]V_T + V_P$$

For all drugs with a volume of distribution value >30 L, changes in f_u therefore translate directly into changes in V (Rowland and Tozer 1995). According to their incidence on drug distribution, two types of drug plasma binding can be distinguished. It can be restrictive, when the quantitative distribution of the drug is limited, respectively vice versa nonrestrictive, when the distribution is not limited. A restrictive binding is characterized by blood concentrations higher than tissue concentrations. Large volumes of distribution values indicate a nonrestrictive plasma binding, especially if the binding capacity of some tissues is greater than that of the circulating protein and the greatest part of the applied dose penetrates into tissues (Urien et al. 2001).

The influences of plasma binding on drug elimination may be best understood by consideration of clearance.

H.G. Vogel et al. (eds.), *Drug Discovery and Evaluation: Safety and Pharmacokinetic Assays*,
DOI 10.1007/978-3-642-25240-2_39, © Springer-Verlag Berlin Heidelberg 2013

All organ clearance models incorporate a protein-binding term. For example, the conversion of the intrinsic clearance (CL_{int}) to the hepatic clearance (CL_{hep}) involves the use of equations describing the well-stirred and parallel tube models of hepatic clearance (Pang and Rowland 1977; Wilkinson and Shand 1975).

$$CL_{hep} = \frac{Q^{*}fu^{*}CL_{int}}{Q + fu^{*}CL_{int}} \text{(Well − stirred model)} \quad (34.1)$$

$$CL_{hep} = Q^{*}\left(1 - e\frac{-CL_{int}{}^{*}fu}{Q}\right) \text{(Parallel tube model)} \quad (34.2)$$

Q: hepatic blood flow

Taking into consideration that (hepatic) clearance is a product of (hepatic) blood flow and (hepatic) extraction ratio of the drug ($CL_{hep} = Q_{hep}{*}E_{hep}$), two types of elimination can be distinguished. For very highly extracted drugs E_{hep} approaches the factor 1. As the product $CL_{int}{*}f_u$ for these drugs is greater than Q, CL_{hep} approaches Q. Under this perfusion rate-limited condition, changes in fu have only small influence on the hepatic clearance. Conversely, the impact of the unbound fraction on the clearance is higher for drug with a small hepatic extraction ratio (Rowland and Tozer 1995).

Only the unbound fraction in plasma is filtered in the kidney. Therefore, the rate of filtration is the product of glomerular filtration rate and unbound plasma concentration. For a drug which is only filtered and all filtered drug is excreted into the urine, the renal clearance (CL_R) is the rate of filtration product:

$$CL_R = f_u{}^{*}GFR \quad (34.3)$$

The binding to plasma or subcellular liver fraction can be taken into account for the prediction of human pharmacokinetic parameters either from preclinical and/or in vitro metabolism data (Obach et al. 1997; Mahmood 2000). Obach (1999) showed by comparison the in vivo investigated clearance values and clearance values projected from in vitro intrinsic clearance data of 29 drugs that the inclusion of blood and liver microsomes binding values gave the best agreement.

The unbound fraction of the drug can be included for the calculation of the safety margin, based on the exposure of the drug from toxicological results in animal and the expected exposure in the first human study.

The binding of a drug, hence its amount of unbound fraction, can be changed by co-medication of another drug. The bound fraction of the primary drug is displaced by the secondary drug, which shows a higher affinity to the protein. The increase of free fraction can cause an increase of pharmacological effects, side effects, or/and toxicological effects. The quantitative and clinical importance of the drug-drug interaction from plasma protein binding depends on the total amount of the initial drug in the body that is bound to plasma before displacement, the extent of displacement, the extent of binding to tissue structures, and the apparent volume of distribution. However, the importance of displacement has been controversial and discussed by several authors. Rolan (1994), Sansom and Evans (1995), and Benet and Hoener (2002) have presented theoretic arguments about the limited cases when drug interaction has been regarded as significant. Rolan has shown with several examples that drug interactions, which have been attributed to plasma protein binding displacement, can be explained by other mechanism (e.g., inhibition of metabolism). He suggests an algorithm to determine the clinical significance of potential PPB displacement interactions. An interaction is likely and a clinical study should be performed to quantify the effects, if the drug of interest has a plasma protein binding above 90%, a narrow therapeutic index, the hepatic extraction ratio is high, and the drug is given intravenously.

The plasma protein profiles in humans are influenced by age, gender, and disease (Verbeeck et al. 1984; Grainger-Rousseau et al. 1989). Elderly tend to have decreased plasma protein concentrations. Disease may cause hypoalbuminemia as found in patients with burns, cancer, cardiac failure, cystic fibrosis, enteropathy, inflammations, liver impairment, malabsorption, nephrotic syndrome, renal failure, sepsis, and trauma. In acute renal failure the concentration of total plasma concentration, particularly of albumin, is significantly reduced (by approximately 25%). Significant changes in plasma composition have been observed in pregnancy and in neonates (Notarianni 1990). Pregnancy results in decreased drug-protein binding to albumin. Fetal albumin present in newborn

infants has less binding affinity for acidic drugs. Thus, free drug concentrations in neonates are higher than those observed in children or adults.

The PPB of racemic drugs is potentially stereoselective, as a consequence of chiral discriminative properties of the binding sites of the protein fractions. However, the limited available data on the binding of enantiomers indicate the differences are small (Pacifici and Viani 1992). The concentrations of total protein, albumin, and α-acid glycoprotein in plasma differ slightly between human and animal species (Davies and Morris 1993). Interspecies differences in the stereoselectivity of protein binding have been reported for various drugs (Lima 1988; Lin et al. 1990, 1991).

Beside the measurement in whole plasma, the PPB can be characterized according to the participated proteins. It may involve, in the simplest case one, or even several proteins. The most frequent situation is that of a drug-albumin complex since albumin is the protein having the highest concentration in plasma. It is by far the most important drug carrier. The plasma level of albumin in a healthy adult is 35–50 g/L (Rowland and Tozer 1995), with a mean value of 41.8 g/L (Davies and Morris 1993). It is mainly involved in acidic drug binding and has three major drug binding sites. Noncarboxylic acids (e.g., endol derivates) bind to site I that is also known as the warfarin site. Site II binds carboxylic acids through hydrophobic forces and is also selective for benzodiazepine and indole compounds (Fehske et al. 1981). Site III is specific for cardenolides and biliary acids (Kragh-Hansen et al. 1985; Kragh-Hansen 1990). Oral anticoagulants, oral hypoglycaemics and nonsteroidal anti-inflammatory drugs (NSAIDs) are examples of drugs that are extensively bound to albumin with a fraction unbound less than 10% and sometimes less than 1%.

The second main plasma protein fraction is α_1-acid glycoprotein. The normal plasma levels are 0.4–1.0 g/L (Rowland and Tozer 1995). As the protein contains an anionic charge, it attracts basic molecules (Muller 1989; Kremer et al. 1988). Drugs with high affinity to α_1-acid glycoprotein include synthetic opioids (e.g., fentanyl, methadone), antiarrhythmic agents (e.g., lidocaine, disopyramide) and tricyclic antidepressants (Jack 1992). Plasma concentrations of α_1-acid glycoprotein increase in the presence of stress, inflammation, malignancy, myocardial infarction, and various hematology disorders.

Other blood components, such as erythrocytes, lipoproteins, and α-, β- and γ-globulins, and tissue proteins, are also capable of drug-protein interactions.

The addition of anticoagulants to the plasma can alter the PPB and should be evaluated prior. Hence, the binding is determined in plasma (e.g., of human) collected using potassium EDTA, sodium citrate, and lithium heparin anticoagulants and compared against serum binding. The effect of an anticoagulant is considered acceptable, if the ratio of the free fraction in plasma to serum is within 0.8 and 1.25.

The affinity of drugs to proteins can be pH dependent. Hence, it is necessary to control the pH of the plasma prior. The pH value can be adjusted to an appropriate standard value (pH 7.4) by introducing carbon oxide or nitrogen gas. Also the stability of the drug in the matrix (e.g., plasma) should be verified prior to the assay. For instable compounds, the degradation (e.g., esterase) can be avoided by addition of appropriate inhibitor (e.g., sodium fluoride).

34.2 General Considerations

From the great variety of methods for the determination of protein binding three separation methods, equilibrium dialysis (ED), ultra filtration (UF), and ultracentrifugation (UC), and a non-conventional method with the binding to immobilized proteins has been chosen. The first methods are undoubtedly the most widely used because of their simplicity and general applicability to many different systems. Other methods, for example, size-exclusion chromatography, capillary electrophoresis, or spectroscopic methods, have been not described. Oravcová et al. (1995) gives a comprehensive review and comparison for these applications.

The methods, described in this chapter, are for the determination of adherent protein binding, which is reversible. Irreversible covalent binding (e.g., caused by reactive intermediates) has not been considered.

34.3 Analytics

The applied analytical method depends on the binding assay used, and on the phase of drug development when the protein binding is performed respectively, on the availability of radiolabelled substance.

Generally the highest purity of the compound is preferred, to avoid interferences with contaminants or degradation products.

In the stage of drug discovery, LC/MS-MS analytics is the method of choice to quantify the unbound drug concentration. The sensitivity can be increased by the use of radiolabelled substance. But, the radiochemical purity, isotope decay, if not ^{14}C-label is used; as well a sufficient specific activity must be taken into consideration (Wright et al. 1996). The concentrations of radioactivity in bound and unbound fraction are measured by liquid scintillation counting. The use of radiolabelled material allows easy examination of the potential of adsorption. However, the identity of the drug in unbound fraction should additionally be verified by HPLC-radiometry detection. In the early phase of drug discovery, high-throughput screening assays with 96 well plates, and fluorescence or UV readers are employed.

34.4 Evaluation of Binding Data

In characterizing the protein binding, several parameters of a drug can be experimentally determined—the unbound plasma concentration (c_u), the bound plasma concentration (c_b), the fraction bound (f_b), and the fraction unbound f_u. The determination can be performed at one defined concentration (e.g., 10 μM) or within a range including the pharmacological and toxicological relevant concentrations.

Additionally, the equilibrium association constant (K_A), equilibrium dissociation constant (K_D), and the number of protein binding per sites per class of binding site (n) are results of interest (Wright et al. 1996).

The drug protein association can be schematically represented as:

$$c_u + P \xleftrightarrow{K_A} c_b$$

P: protein concentration

whereas K_A is defined as $[c_b]/[c_u]^*[P]$, and $K_A = 1/K_D$

The equilibrium association constant K_A, or the corresponding dissociation constant (K_D) provides information on the affinity or the strength of the drug-protein association. A highly protein bound drug will typically have a K_A value ranging from 10^5 to 10^7 L/mol, and a drug with low to moderate protein binding will usually have a K_A value ranging from 10^2 to 10^4 L/mol (Wright et al. 1996).

Derivation of the second order equation for protein interactions yields an equation that describes c_b as a function of c_u:

$$c_b = \frac{n^*P^*K_A}{1 + K_A{}^*c_u} \quad (34.4)$$

This equation describes the bound drug concentrations as a function of unbound drug concentrations. A binding system with a single class of non-saturable binding sites can be described by:

$$c_b = n^*P^*K_A{}^*c_u \quad (34.5)$$

If the binding system consists of two classes of binding site, it is characterized by Eq. 34.6:

$$c_b = \frac{n_1{}^*P_1{}^*K_{A_1}}{1 + K_{A_1}{}^*c_u} + \frac{n_2{}^*P_2{}^*K_{A_2}}{1 + K_{A_2}{}^*c_u} \quad (34.6)$$

34.4.1 Graphical Methods

The graphical methods for the estimation of the protein binding parameters are limited to protein systems, which have only one class of binding sites. If the protein concentration P is known, the product n^*K_A can be calculated by using Eq. 34.4. The slope of the regression line is equal to $n^*K_A{}^*P$.

For saturable binding, the following graphical methods can be used after rearrangement and linearization of Eq. 34.5:

The Double–Reciprocal Plot (Fig. 34.1):

$$\frac{1}{v} = \frac{1}{n^*K_A{}^*c_u} + \frac{1}{n} \quad (34.7)$$

$$\text{Where} \quad v = \frac{c_b}{P} \quad (34.8)$$

The Scatchard Plot (Fig. 34.2):

$$\frac{v}{c_u} = n^*K_A - v^*K_A \quad (34.9)$$

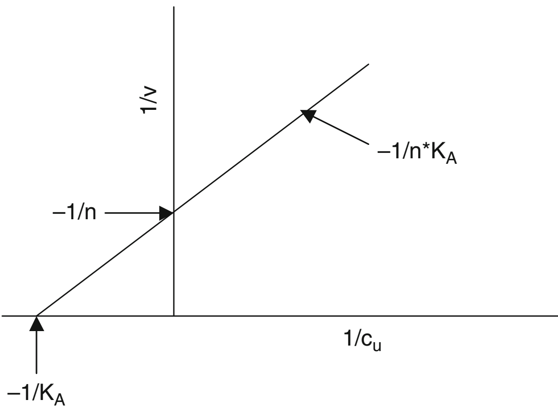

Fig. 34.1 Double reciprocal plot. The y-intercept is 1/n and the x-intercept is—$1/K_A$

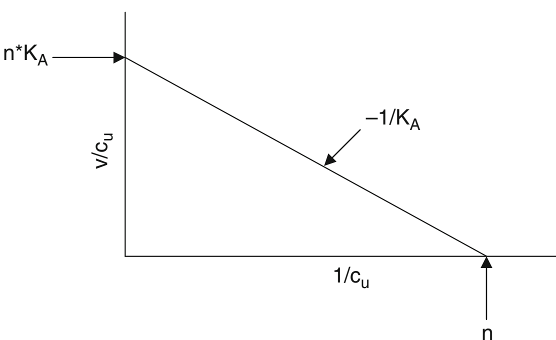

Fig. 34.2 Scatchard plot. The y-intercept is $n{*}K_A$ and the x-intercept is n. The slope is—K_A (Scatchard 1949)

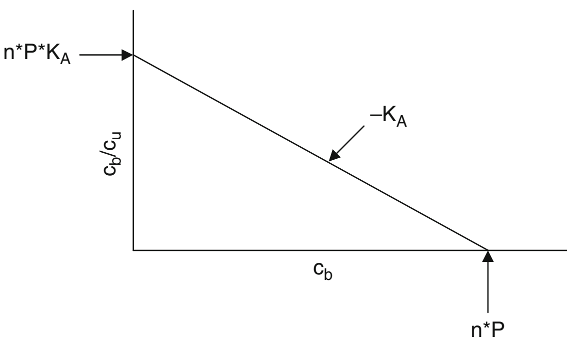

Fig. 34.3 Rosenthal plot. The y-intercept is $n{*}P{*}K_A$, the x-intercept n*P and the slope—K_A

$$\text{Where } v = \frac{c_b}{P} \tag{34.10}$$

The Rosenthal Plot (Fig. 34.3):
This modified Scatchard Plot is used if the protein concentration is unknown (Rosenthal 1967).

$$\frac{c_b}{c_u} = n^*K_A{}^*P - c_b{}^*K_A \tag{34.11}$$

34.5 Ultrafiltration

PURPOSE AND RATIONALE

The ultrafiltration (UF) with semipermeable, size-exclusion membranes produces a separation of the free drug from macromolecules by employing a pressure gradient, which forces small molecules through the membrane. UF can either be used in an individual filtration unit or in a 96 well plate format system.

34.5.1 Conventional Ultrafiltration (Individual Devices)

34.5.1.1 Equipment and Material

- Plasma pool of different species.
- Stock solution of the drug prepared in an appropriate organic solvent (e.g., 10 mM, DMSO).
- Phosphate buffered saline pH 7.4 (0.1 M phosphate buffer/0.09 M NaCl).
- Calibrated pH Meter.
- Nitrogen gas and carbon dioxide gas.
- Glass wool for lab purpose.
- 1.5 mL microcentrifuge tubes.
- Thermostatized centrifuge with fixes angle rotor (angle of inclination 33°) (e.g., Hettich Rotixa RP 001260, Tuttlingen, Germany).
- Disposable individual ultrafiltration unit (e.g., Centrifree Micropartition System No. 4104, Millipore, Bedford, MA, USA). It consists of two compartments—the sample reservoir and filtrate cup. A hydrophilic ultrafiltration membrane with a defined molecular cutoff (30 kDa) separates them.
- Single pipettes.

PROCEDURE

1. The frozen plasma is slowly thawed in cold water, or overnight in the refrigerator and filtered over glass wool. Protein binding of some drug is pH dependent. Therefore, the pH value of the freshly thawed plasma has to be adjusted to pH 7.3–7.4 by CO_2 or N_2. In the lab, carbon dioxide gas may be released by vaporizing small quantities of dry ice in an Erlenmeyer flask with plastic tube and small pipette for the introduction of the gas. Due to the strong pH lowering effect of the gas, the CO_2 should be introduced carefully and in small quantities. If the pH value falls below pH 7.3–7.4, it can be re-adjusted by degassing with nitrogen.
2. Aliquots of the stock solution diluted to 10 μM are added to 1 mL of pH-adjusted plasma, protein fraction, or buffer. The amount of organic content should not exceed more than 2% of the initial spiked plasma. Higher content could adversely interfere with protein binding.
3. The spiked sample (1 mL) is immediately placed in the ultrafiltration unit. Closing the sample reservoir with a provided cap before the centrifugation can prevent changes of the pH during the determination.

4. The sample is filtered through the membrane by centrifugation in a fixed angle rotor at 1,000–2,000 *g*. The flow rate depends on the protein concentration in the sample, which can differ between the species, the starting volume, the relative centrifugal forces, the rotor type, and the temperature. For the determination of the protein binding, the volume of the obtained filtrate should be a fifth (approx. 200 μL) of the initial volume of sample. Hence, for each matrix, the centrifuge time has to be determined beforehand.
5. In parallel, the nonspecific adsorption has to be investigated by using physiological PBS buffer or recommended, protein free serum filtrate.
6. The concentration of the free drug (c_u) in the ultrafiltrates or the concentration of bound fraction (c_b) in the retentate can be quantified by LC-MS/MS by means of a calibration curve. If radiolabelled substrate has been applied, liquid scintillation counting can be employed.

Complementary to the simple adsorption test, the mass balance of the separation could be investigated. This method is more accurate to determine the loss of free drug, which may occur due to variations in sample preparations methods, nonspecific protein binding, and to metabolism. The latter may also be tested in separate stability tests in plasma or applied matrix.

The mass balance is calculated by determining volumes by gravimetric and drug concentrations in both the retentate and ultrafiltrate.

34.5.2 Automated Ultrafiltration in a 96 Well Plate System

34.5.2.1 Equipment and Material

- Plasma pool of different species.
- Stock solution of radiolabelled or non-radiolabelled drug prepared in an appropriate organic solvent (e.g., 10 mM, DMSO).
- Phosphate buffered saline (PBS), pH 7.4 (0.1 M phosphate buffer/0.09 M NaCl).
- Calibrated pH Meter with one bar measuring chain.
- Pure nitrogen (N_2) and carbon dioxide (CO_2). In the lab, carbon dioxide gas may be released by vaporizing small quantities of dry ice in an Erlenmeyer flask with stopcock, plastic tube, and small pipette for the introduction of the gas.
- Incubator.
- 96 well plate mixer.
- Centrifuge with swinging bucket rotor and sealed microtiter plate carriers.
- Liquid Scintillation Counter (LSC) or LC/MS-MS - equipment.
- MultiScreen Filter Assembly with Ultracel-PPB™ Membrane No. MAPPB1010 (Millipore Corp—Bedford, MA, USA).
- Single and multichannel pipetters.
- Non-sterile troughs.
- Microplate 96 deep-well (2 mL/well).
- 15 mL graduated centrifuge tubes.
- 1.5 mL microcentrifuge tubes.

PROCEDURE

1. Adjusting the pH of the plasma.
   The frozen plasma is slowly thawed in cold water, or overnight in the refrigerator and filtered over glass wool. Protein binding of some drugs is pH dependent. Therefore, the pH value of the freshly thawed plasma has to be adjusted to pH 7.3–7.4 by CO_2 or N_2. Due to the strong pH lowering effect of the gas, the CO_2 should be introduced carefully and in small quantities. If the pH value falls below pH 7.3–7.4, it can be re-adjusted by degassing with N_2.
2. Using a 1.5 mL microcentrifuge tube, prepare a 0.5 mM solution of each drug in PBS.
3. Add 80 μL of the drug solution to 7.92 mL of plasma or plasma fraction in a 15 mL centrifuge tube for a final test solution concentration of 5 μM.
4. Mix and incubate at 37°C for 60 min.
5. Transfer 300 μL/well of each plasma/drug mixture to one column of each of two Multi-Screen plates with Ultracel-PPB fitted with receiver plates. Cover the assemblies with sealed plate covers or the supplied extended centrifugal covers.
6. Centrifuge at 2,000 *g* (37°C) for 45 min.
7. Remove a 25 μL aliquot of the retentate volume (for purposes of determining the mass balance) and a 25 μL aliquot of the filtrate volume (for purposes of determining the concentration of free drug). It is possible that a concentrated protein layer forms on the membrane during filtration, so care should be taken to thoroughly mix the retentate prior to removing the aliquot.
8. The filtrate remaining in the receiver plate is then analyzed for volume determination using either spectrophotometry by determining the dilution

factor of a known aliquot of a chromophore added to the filtrate, or spectrophotometry by using the near infrared (NIR) absorption of water according to standard protocols, or gravimetric determination (Millipore Application Note AN1733EN00).

9. 25 µL of each sample or standard dilution is either analyzed by LC/MS-MS or LSC. The analytical method depends on the use of radiolabelled or non-radiolabelled drug. For good quantitative analysis, four to six point standard curves are generated.
10. Concentrations are determined for filtrates, retentates, controls, and standard dilutions.

EVALUATION

Final results are given as percentile fraction unbound (f_u) of percentile fraction bound (f_b) for a defined concentration.

$$f_u[\%] = \frac{c_u}{c_{initial}} * 100\% \quad (34.12)$$

$$f_{bd}[\%] = f_u[\%] - 100\% \quad (34.13)$$

c_u: concentration in ultrafiltrate [µM or µg/mL]
$c_{initial}$: concentration added [µM or µg/mL]

The fraction of nonspecific adsorption (f_{ads}) is calculated as:

$$f_{ads}[\%] = \frac{\text{conc.in filtrat of adsorption test}}{c_{initial}} * 100\% \quad (34.14)$$

Determination of Mass Balance (MB):

$$MB[\%] = \frac{c_u{}^* V_u + c_{ret.}{}^* V_{ret.}}{c_{initial}{}^* V_{initial}} * 100\% \quad (34.15)$$

V_u: Volume of ultrafiltrate [mL]
V_{ret}: Volume of retentate [mL]
$V_{initial}$: Initial volume [mL]
$c_{ret.}$: Concentration in retentate [µM or µg/mL]

As well, the evaluation of equilibrium association constant (K_A) and the determination of the number of protein binding per sites per class of binding site (n) is possible, if different concentrations of the drug are applied (see Sect. 34.4).

CRITICAL ASSESSMENT OF THE METHOD

Advantages

- Rapid, efficient, and simple technique
- Commercially available kits
- Lack of sample dilution and volume shifts
- No requirement of a nonphysiological buffer
- Applicable for plasma and plasma fraction as well for other different types of biological matrices, including tissue homogenates
- If automated 96 well plate ultrafiltration system is used, high throughput with sample handling by robotic system

Disadvantages

- Potential of nonspecific binding (NSB) to filter membrane or plastic devices. Low recovery from either protein-filtrate or buffer indicates adsorptive losses and/or membrane rejection.
- Leakage of bound drug through membrane.
- Deviation of the drug protein binding equilibrium because of the change in the protein concentration, especially in case of high binding drugs. The concentration unbound may remain constant even though the proteins became concentrated in the upper reservoir as the amount of plasma water increases in the ultrafiltrate (Judd and Pesce 1982; Withlam and Brown 1981).

Ultrafiltration has been used to determine the protein bound fraction of many drugs, such as methadone (Wilkins et al. 1997), phenylacetate and phenylbutyrate (Boudoulas et al. 1996), etoposide (Robieux et al. 1997), doxorubin and vincristine (Mayer and St-Onge 1995), disopyramide (Echize et al. 1995), and ketamine and its active metabolites (Hijazi and Boulieu 2002). Schuhmacher et al. (2000) have shown the applicability for the determination of erythrocyte/plasma distribution. The method of UF has been applied in the measurement of free unaltered thyroxin or after displacement by salicylate as well after displacement by heparin in healthy people and in patients with non-thyroidal somatic illness (Faber et al. 1993). The protein binding of tritium labeled, anti-diabetic repaglinide and its displacement by warfarin, furosemide, tolbutamide, diazepam, glibenclamide, and nicardipine were determined by ultrafiltration (Plum et al. 2000).

The reliability and applicability of the UF has been done in comparison to the classical method of equilibrium dialysis for several drugs, like thiopental (Christensen et al. 1980), disopyramide (Norris et al. 1982), and valproic acid (Barre et al. 1985).

Although different filter material procedures were applied in these studies, the comparison gave comparable values for the free fraction of the drug for total concentrations between the two methods. Beside its use in in vitro assay, this method is widely applied for routine free drug monitoring of ex vivo PPB in clinical laboratories.

The implementation of new materials for filter membrane and plastics (e.g., polypropylene with PTFE) for the ultrafiltration units has diminished the disadvantages of nonspecific binding (NSB) and the break trough of protein, respectively protein bound drug. Eight radiolabelled drugs (Taxol, Digoxin, Prednisone, Testosterone, Warfarin, Propranolol, Methotrexate, Ibuprofen, and Mannitol) were analyzed for their drug recovery The applied Ultracel YM membrane with a nominal molecular weight limit of 10 K Da exhibits less than 2% NSB and >99.5% retention of serum proteins. (Millipore, Application Note AN1735EN00). With the improvement in the devices, the determination of the nonspecific binding of new drug by recovery experiment is recommended and taken into account by a correction factor, if necessary.

MODIFICATION OF THE METHOD

Pretreatment of the filter membrane (regenerated cellulose, Molecular cut off 10 KDa) with 5% Tween 80 or benzalkonium chloride showed significantly less nonspecific binding for compounds that had a tendency toward high membrane binding (Lee et al. 2003).

With rising temperature the drug binding decreases. The determination can be performed either at room temperature (approx. 22°C) or under more physiologically condition at 37°C. The chosen temperature should be maintained in the plasma sample, and during the separation by pre-warming the rotor or using a heated centrifuge.

The UF can either performed in a single ultrafilter unit or in a 96 well plate ultrafiltration system, latter in a semiautomatic high-throughput determination with sampling handling by a robotic system (Fung et al. 2003; Jordan et al. 2000).

34.6 Equilibrium Dialysis

PURPOSE AND RATIONALE

The equilibrium dialysis (ED) is based on the establishment of an equilibrium state between a protein compartment and buffer compartment, separated by a membrane, which is permeable only for a low-molecular weight ligand. Although there is no "standard method" for binding measurement, ED is often regarded as the "reference method" for the determination of drug-protein-binding profile (Oravcová et al. 1995).

34.6.1 Equilibrium Dialysis (Individual Device)

34.6.1.1 Equipment and Material

- Fresh or frozen heparinized plasma of different species (pool), collected from fasted animals and humans. If frozen plasma is used, the pH value has to be adjusted (see adjustment of pH at Sect. 34. 5).
- Stock solution of the radiolabelled, respectively non-radiolabelled drug prepared in an appropriate organic solvent (e.g., 10 mM ethanol).
- Phosphate buffered saline pH 7.4 (0.1 M phosphate buffer/0.09 M NaCl).
- Equilibrium dialysis apparatus, for example, variable speed dialyser Dianorm-4 (Dianorm, Munich, Germany). The dialyser is equipped with 1 mL macro cells (4.5 cm working surface area) and cellulose dialysis membrane (63 mm diameter, molecular cutoff weight 10 KDa). The apparatus is placed in a water bath with a circulating system to obtain a constant temperature of 37°C in the system.

PROCEDURE

1. Preconditioning of Membrane
   Prior to dialysis, the membranes are preconditioned by soaking in water for 15 min, followed by soaking in PBS for 30 min. The cells are filled at ambient temperature, and when fully loaded, the Dianorm apparatus is placed in a water bath at 37°C and started at 12 rpm.
2. Determination of the time to equilibrium (ET)
   The ET is determined by dialyzing freshly spiked plasma containing the high (10 μg/mL) and intermediate (0.05 μg/mL) test concentrations against PBS. At time points 1, 2, 3, 4, and 6 h of dialysis, a small sample (50 μL) of plasma and PBS is removed from each cell and the concentration is analyzed by LSC or LC/MS-MS. The optimal ET is then determined.
3. Equilibrium Dialysis
   The ED is performed for five test concentrations (0.01, 0.05, 0.1, 1, and 10 μg/mL) for each of the test plasma samples against PBS. At each concentration, four cells, each containing 1 ml of spiked plasma and PBS, are prepared for each plasma type. At the time when the equilibrium is reached (e.g., 4 h), which was determined in the preliminary test, the dialysis is stopped. Aliquots of 200 μL plasma sample or PBS buffer are taken from each cell. To determine the concentration bound in plasma (c_{bd}) or the free or unbound fraction (c_u) in the buffer, the samples are analyzed by LC/MS-MS of LSC. The analytical method depends on the use of unlabelled or radiolabelled substance. The initial concentrations (c_{inital}) of each spiked plasma (aliquots of 200 μL) can also be determined.

EVALUATION

Final results are given as percentile fraction unbound (f_u) or percentile fraction bound (f_b) for a defined concentration.

$$f_u[\%] = \frac{c_u}{c_{initial}} * 100\% \qquad (34.16)$$

or if c_{intial} is not determined:

$$f_u[\%] = \frac{c_u}{c_u + c_{bd}} * 100\% \qquad (34.17)$$

$$f_b[\%] = \frac{c_{bd}}{c_{initial}} * 100\% \qquad (34.18)$$

$$f_b[\%] = f_u[\%] - 100\% \qquad (34.19)$$

c_u: concentration in buffer [μM or μg/mL]
$c_u + c_b$: concentration in plasma [μM or μg/mL]
$c_{initial}$: concentration added [μM or μg/mL]

If different concentrations are applied, the evaluation of equilibrium association constant (K_A) and the determination of the number of protein sites (n) are possible (see Sect. 34.4).

CRITICAL ASSESSMENT OF THE METHOD

Advantages

- Easy to set up and to use
- Temperature controlled

Disadvantages

- Long time to reach equilibrium, up to 24 h, potential degradation of test substance as a result of thermal or metabolic instability in plasma.
- Volume shift (Tozer et al. 1983)
- Donnan effects (Hindering of the passage of free ligand) (Mapleson 1987).
- Nonspecific adsorption to dialysis apparatus and membrane (Henricsson 1987; Henry and Mitchell 1981).
- Overestimation of the free fraction resulting from slight leakage of protein (or fragments of it) into the dialysate. The absence of protein in the dialysate should be verified by protein assay (Bowers et al. 1984).
- pH shift during ED due to continuous loss of CO_2, need of adjustment, and control (Brørs and Jacobsen 1985).
- High consumption of plasma.

34.6.2 24-Multiwell Plate Equilibrium Dialysis

34.6.2.1 Equipment and Material

– Freshly or frozen heparinized plasma of different species (pool), collected from fasted animals and humans. If frozen plasma is used, the pH value has to be adjusted (see adjustment of pH at Sect. 34. 5).
– Stock solution of the radiolabelled, or non-radiolabelled drug is prepared in an appropriate organic solvent (e.g., 10 mM ethanol).
– Phosphate buffered saline pH 7.4 (0.1 M phosphate buffer/0.09 M NaCl).
– Incubator.
– Plate shaker (orbital or reciprocating).
– Disposable 24-well BD Gentest™ Serum Binding System with 24 well dialysis insert, containing individual Spectrapor 2 membranes and 24 well BD Falcon™ Microplate (BD Biosciences, Bedford, MA, USA, Cat. No. 453700).
– Single and multichannel pipetters.
– Liquid Scintillation Counter (LSC) or LC/MS-MS-equipment.

PROCEDURE

1. Preconditioning of Membrane
   The plate is soaked for 20 min in deionized water thereafter in 30% absolute alcohol: deionized water. Then the plate is washed with water and soaked for 20 min in PBS used for the dialysis experiment.

Test well:	Bottom chamber: serum protein spiked with test compound
	Top chamber: PBS buffer only
Control well:	Bottom chamber: test compound in PBS buffer
	Top chamber: PBS buffer only

2. The bottom chamber is loaded with 742.5 μL of plasma/serum protein for the test well, and PBS buffer for the control wells. To both 7.5 μL of 100× concentrated compound (solved in DMSO) is added. To both top chamber of control and test well 250 μL of PBS buffer is added.
3. The plate is shaken for 20 h on medium setting: The shaker is placed in humidified incubator to reduce evaporation.
4. Aliquots (100 μL) from the upper chamber of the control and test wells are removed.
5. The concentration of test compound in the upper chamber of the test well ($c_{test\ well\ upper}$) and the concentration of compound in the upper chamber of the control well ($c_{control\ well\ upper}$) are analyzed by LC/MS-MS or LSC.
6. Alternatively, plasma protein binding can be determined without using a control well by comparing the concentration of compound in the upper

chamber ($c_{control\ well\ upper}$) to the total concentration (sum of $c_{control\ well\ upper} + c_{control\ well\ lower}$). This approach conserves test compound, but requires an analytical technique that can measure the concentration of compound in high protein samples (plasma).

EVALUATION

Final results are given as percentile fraction unbound (f_u) or percentile fraction bound (f_b) for a defined concentration.

$$f_u[\%] = \frac{c_{(test\ well)}}{c_{(control\ well)}} * 100\% \tag{34.20}$$

Or (for single well approach, if control well is not applied):

$$f_u[\%] = \frac{c_{(test\ well\ upper\ chamber)}}{c_{(test\ well\ upper\ chamber)} + c_{(test\ well\ lower\ chamber)}} * 100\% \tag{34.21}$$

$$f_b[\%] = f_u[\%] - 100\% \tag{34.22}$$

Also evaluation of equilibrium association constant (K_A) and the number of protein binding per sites per class of binding site (n) is possible if different concentration are applied (see Sect. 34.4).

CRITICAL ASSESSMENT OF THE METHOD

Advantages

- Commercial available disposable 24-well system
- Easy to set and use
- High-throughput compatible with robotic systems
- Temperature controlled

Disadvantages

- Long time to reach equilibrium, up to 24 h and more
- Volume shift (Tozer et al. 1983)
- Donnan effects (Hindering of the passage of free ligand) (Mapleson 1987)
- Nonspecific adsorption to dialysis apparatus and membrane (Henricsson 1987; Henry and Mitchell 1981)
- Overestimation of the free fraction as result from slight leakage of protein (or fragments of it) into the dialysate, the absence of protein in the dialysate should be verified by protein assay (Bowers et al. 1984)
- pH labiality during ED due to continuous loss of CO_2 (Brørs and Jacobsen 1985)
- Potential degradation of test substance as a result of thermal or metabolic instability in plasma

MODIFICATION OF THE METHOD

An alternative ED method in 96 well plate format has been reported by Kariv et al. (2000). The authors used a disposable equilibrium dialyser with a 10 KDa ultrathin membrane, co-developed with Amika Corp. (Columbia, MD, USA). The binding of three well-studied drugs, propranolol, paroxetine, and losartan with low, medium, high binding properties, respectively, was tested to validate the method. The data of free fraction correlated with the published values determined by conventional ED.

The vertical design of 96 well dialysis block of Banker et al. (2003) allows the robotic system the access to the sample and dialysate site. The dialysis block with partially separated bars is reusable. The validity of the system was tested with ten different standard compounds, in comparison to standard ED, and literature data.

To equalize the osmotic pressure and therefore to attenuate the volume shift, dextran 2.5% (w/v) was added to the dialysate (Lima et al. 1983). However, this approach is inconvenient for high throughput. That the test compounds show no affinity to dextran has to be proven in an additional experiment.

Plum et al. (1999) showed the applicability of a step-wise ED for the plasma binding determination of the two strong adhesive ^{125}I-labeled proteins insulin aspart and insulin detemir.

34.7 Ultracentrifugation

PURPOSE AND RATIONALE

The ultracentrifugation (UC) method achieves separation of free and protein bound drugs by centrifugation of the sample in a tube without a membrane. It makes use of the fact that sedimentation of solutes depends upon their molecular weight. For the first time Steinberg and Schachman (1966) demonstrated theoretically and practically the potential of the method.

PROCEDURE

34.7.1 Equipment and Material

– Freshly or frozen heparinized plasma of different species (pool), collected from fasted animals and humans. If frozen plasma is used, the pH value has to be adjusted (see adjustment of pH at Sect. 34. 5).
– Stock solution of the radiolabelled, or non-radiolabelled drug prepared in an appropriate organic solvent (e.g., 10 mM ethanol).
– Centrifuge tubes (e.g., Ultra Clear tubes, Beckmann, Palo Alto, CA).
– Ultracentrifuge (e.g., Airfuge Beckmann, Palo Alto, CA).
– Single pipettes.
– Liquid Scintillation Counter (LSC) or LC/MS-MS-equipment.

PROCEDURE

1. Plasma samples are spiked with labeled or unlabeled drug to give specific concentrations (ranging from pharmacological to toxicological relevant concentrations). An aliquot (200 μL) is either transferred to LSC or LC/MS-MS to quantify the initial concentration (c_{intial}).
2. The centrifuge tubes are filled with identical volume (200 μL) of spiked plasma and loaded into the rotor of the ultracentrifuge. The cooled sample is centrifuged for 4 h at an air pressure of 30 psi and 150,000× g. The sample is cooled during and after the centrifugation to 4°C to avoid thermodynamic interferences. The time needed to obtain a "protein free" top layer should be determined in a series of preliminary experiments. Therefore, the centrifuge is loaded with a spiked plasma sample. The samples are spun at 150,000× g and the Airfuge stopped at different time intervals. An aliquot of 20 μL top layer is removed and the concentration is measured. The time where the concentration is constant is chosen for the experiment.
3. From the supernatant consecutive aliquots of 20 μL are taken without disturbing the remaining plasma sample. The concentrations of the top layers are quantified in the same manner like c_{intial} by means of a calibration curve.

EVALUATION

After the measurement of the concentration of the individual consecutive aliquots, the mean ($c_{supernatant}$) of the constant values is chosen. A significant higher amount in the first aliquot indicates a binding to lipoproteins.

Final results are given as percentile fraction unbound (f_u) or percentile fraction bound (f_b) for a defined concentration.

$$f_u[\%] = \frac{c_{(supernatant)}}{c_{(intial)}} * 100\% \qquad (34.23)$$

$$f_b[\%] = f_u[\%] - 100\% \qquad (34.24)$$

CRITICAL ASSESSMENT OF THE METHOD

34.7.1.1 Advantages

• Alternative method to ultrafiltration and equilibrium dialysis

- Elimination of the problems associated with free membrane effects like fewer nonspecific binding (NSB)
- No dilution of the sample, native status of plasma

34.7.1.2 Disadvantages

- High cost of ultracentrifuge.
- Time consuming (up to 18–24 h centrifugation time).
- Limited number of sample can be spun simultaneously.
- Intricate manual process, no automation applicable.
- Interferences according to sedimentation, thermal back diffusion, viscosity, and floating of lipoprotein in the supernatant fluid.
- Self-sedimentation of the test compound with molecular weight >300 Da.

Ultracentrifugation (UC) is an alternative to both equilibrium dialysis and ultrafiltration and enables the separation of the free and protein fraction in a more physiological environment. The UC is a method of choice for compound with a high affinity to nonspecific binding. It eliminates the problems associated with free membrane effects. Without the necessity to add a buffer system, a dilution observed at the equilibrium dialysis is avoided.

However several comparative studies showed quantitative discrepancies between the results obtained by UC compared to ultrafiltration, or equilibrium dialysis (Barre et al. 1985; Kurz et al. 1977). Verbeeck and Cardinal (1985) investigated the plasma protein binding of phenytoin, salicylic acid, propranolol, phetidine, and chlorpromazine using UC. The binding data was comparable to those obtained by equilibrium dialysis, except for chlorpromazine. The latter has been explained by the author in relation to the binding of the compound to a very low-density lipoprotein fraction, which floats after the centrifugation step. A micro scale UC was evaluated by Nakai et al. (2003). It showed a good correlation of the protein binding of ten compounds, with reported values determined by ultrafiltration and equilibrium dialysis.

MODIFICATION OF THE METHOD

Depending on the available ultracentrifuge different relative centrifugation forces have been used, ranging from 120,000 *g* up to 436,000 *g* (Nakai et al. 2003). Depending on the affinity of the test substrate for nonspecific binding, different material of ultracentrifuge tubes can be applied.

34.8 Binding on Silica Beads Immobilized Protein Fraction

PURPOSE AND RATIONALE

This method is based on the affinity of the new chemical entity to a membrane, consisting of human serum albumin immobilized on Transil® beads. The silica beads are coated with egg yolk phosphatidylcholine and are commercially available under the trademark Transil® from Nimbus (Nimbus, Leipzig, Germany).

PROCEDURE

34.8.1 Equipment and Material

- Stock solution of drug prepared in an appropriate organic solvent, diluted to appropriate concentration (e.g., 10 µg/mL). The amount of the solubility modifier should be below 5% in the final concentration.
- Transil® "Ready to go plates" for 10 compounds per plate; for high precision assay, order no.: SP200096 (Nimbus Biotechnology, Leipzig, Germany).
- UV translucent plate (suitable for UV measurement above 250 nm).
- Multichannel pipette.
- UV plate reader and/or LC/MS-MS (needed for quantification of UV-inactive compounds).
- Centrifuge with rotor for 96 well plate or vacuum filtration device.

PROCEDURE

1. The plates are delivered in frozen state filled with a total volume of 270 μL of buffer for control well (column 1 and 7) and 270 μL of buffer/varying amounts of Transil for sample well. The plates are slowly defrosted immediately before measurement.
2. To each well (control and sample) 30 μL of compound solution has to be added. If UV spectroscopy method is used for quantification the wells H7–H12 have to use a reference sample to account for the absorbance of the UV plate (not necessary for LC/MS-MS).
3. Resuspend the liquid at least three to six times by swirling the beads around using a multichannel pipette to ensure complete mixing of the compound and the beads.
4. Separate the unbound fraction by short low speed centrifugation (15 min/10,000 *g*). Alternatively a vacuum filtration with collector plate can be applied.
5. Transfer a fixed volume (100 μL) of the filtrate into a UV translucent plate
6. UV plate reader and/or LC/MS-MS determines the concentrations of the unbound fraction at varying HSA concentration.

EVALUATION

The data is transferred into an excel workbook supplied by Nimbus to conveniently calculate the dissociation constant (K_D).

In the high affinity assay for each compound, five assay points are generated and evaluated via a Scatchard type analysis using a linearized binding equation.

Rearrangement of

$$c_b = \frac{n^* P^* K_A}{1 + K_A * c_u} \text{ with } K_A = 1/K_D \tag{34.25}$$

leads to the dissociation constant (K_D)

$$K_D = c_u{}^* \frac{1 - \frac{c_b}{P}}{\frac{c_b}{P}} \tag{34.26}$$

With the assumption $c_{protein} >> c_b$ simplifies Eq. 34.24 to:

$$K_D = \frac{P^* c_u}{c_{intial} - c_u} \tag{34.27}$$

This condition is valid for compounds with low and medium affinity and also for compound concentrations larger than the protein concentration. Otherwise Eq. 34.24 has to be used, where the total compound concentration $c_{initial}$ has to be determined.

The bound fraction f_b is calculated by Eq. 34.26:

$$f_b = \frac{c_b}{c_{intial}} = 1 - \frac{1}{\frac{1+P}{K_D}} \tag{34.28}$$

P: Concentration of the protein in the blood. For HSA it is usually 40 g/L, corresponding to 588 μM.

CRITICAL ASSESSMENT OF THE METHOD

34.8.1.1 Advantages

- Fast and easy, high-throughput assay, applicable to a robotic systems in 96 or 386 well plate format
- Simple quantification by hints of UV plate reader, MS measurement is only needed for UV-inactive compounds
- “Ready to go plates” are commercially available
- Determination of dissociation constant K_D and fraction bound
- Small amount of compound is needed
- Low influence of nonspecific binding for the determination of K_D

34.8.1.2 Disadvantages

- Only applicable to determine the binding to human serum albumin
- For UV-inactive compounds LC/MS-MS is needed, which diminishes the throughput

MODIFICATION OF THE METHOD

Schumacher et al. (2004) published a method, where Transil® beads in suspension have been used for the determination of protein binding in diluted plasma and plasma/erythrocyte distribution for strongly bound compounds. For HTS of the method 96 well plates with removable glass inserts filled with Transil suspension were applied. On comparison with the classical methods, ultrafiltration and equilibrium dialysis showed for eight compounds comparable precision and accuracy of the binding parameters.

35.1 In Situ-Perfused Isolated Intestinal Segments and Bile Secretion in Anesthetized Rats

PURPOSE AND RATIONALE

The gut technique of in situ-perfused isolated intestinal segments in rats is used to determine the rates of intestinal absorption or intestinal secretion of a candidate compound, as well as in combination with a bile fistula to detect the hepatobiliary elimination of a candidate compound. By perfusion of different intestinal segments (duodenum, proximal and distal part of the jejunum, and ileum), the site of intestinal absorption or secretion of a candidate compound can be determined.

PROCEDURE

In general, rats are fasted overnight and are anesthetized with an intraperitoneal injection of 20 mg/kg ketamine plus 60 mg/kg pentobarbital sodium, and anesthesia is maintained by an s.c. infusion of pentobarbital sodium at a rate of 20 mg/kg/h for the desired length of the perfusion experiment. Animals are laparotomized by a median incision, and the common bile duct is cannulated with a polyethylene (PE) 10 catheter. Duodenum, or jejunal segments, or the ileum are cannulated for single pass perfusion or recirculated perfusion. After flushing the lumen of the respective intestinal segment with 40 ml of medium, perfusion is performed in situ at a very low continuous flow rate of 0.5 ml/min, ensuring a minimal perfusion pressure. The candidate compound is added to the perfusion medium at an appropriate concentration to reach detectable compound levels in blood (plasma) and bile. Body temperature

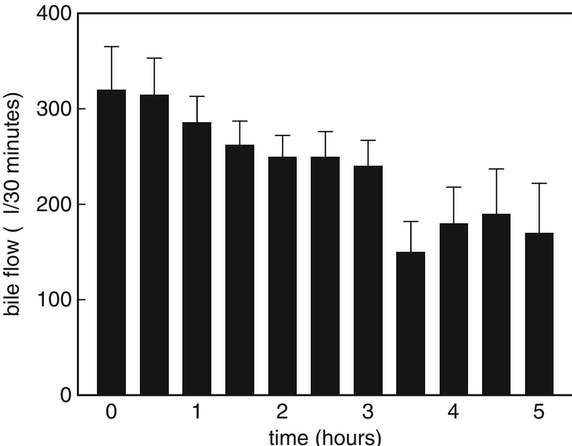

Fig. 35.1 Representative time course of bile flow in anesthetized rats with separate drainage of the bile. Values are mean ± SEM, $n = 4$

and perfusion medium are maintained at 37°C. Bile aliquots are collected at 10- to 30-min intervals. Blood samples (100 µl) are collected from the jugular vein every 30 min in EDTA tubes. At the end of the perfusion experiment, the livers are removed from all animals, total weight is determined, and the livers are immediately frozen for determination of tissue level of the compound in liquid nitrogen and then stored at −20°C until analysis. For analysis of tissue levels of the candidate compound, the frozen livers are homogenized in water (1 g tissue in 1 ml water (or solvent to extract the candidate compound from the tissue)) using an ULTRA-TURRAX. A continuous bile flow throughout the experiment is the best measure of the functional integrity of the organ (typically bile flow is shown in Fig. 35.1). Animals with an initial bile flow below 100 µl/30 min should be excluded from the final evaluation of the data.

EVALUATION

The concentrations of the compound are determined using appropriate analytical methods for the respective candidate compound in the perfusate at the end of the perfusion experiment, plasma, bile, and hepatic tissue. From the data, the site of intestinal absorption using different perfused intestinal segments in separate experiments as well as the degree of hepatobiliary elimination can be estimated.

Appropriate analytical methods with sufficient sensitivity are used for detection of the candidate compound in the perfusate, plasma, bile, and liver tissue. From the total amount of the candidate compound in the perfusate of the respective intestinal segment at the end of the perfusion experiment in relation to the total added amount of compound at time 0, the total enteral absorption rate can be estimated. The decline in the concentration of the candidate compound in the perfusate is a measure of the enteral absorption, uptake, metabolism, and elimination of the compound by the liver. The concentration in the plasma is a measure of the bioavailability. The appearance of the candidate compound in the bile is a measure of the hepatobiliary elimination of the compound. The tissue level of the candidate compound is a measure of the uptake and accumulation of the candidate compound in the liver. Ideally the analytical method for the detection of the candidate compound included also the detections of known metabolites of the candidate compound in plasma, bile, and liver tissue.

In addition, the total hepatobiliary elimination of the candidate compound (sum of all collecting intervals (concentration × secreted volume per collecting interval)) can be calculated.

MODIFICATIONS OF THE METHOD

Various modifications are reported with respect to the animal species used as well as to the experimental setup (single pass or recirculated intestinal perfusion) and the site of blood collection, e.g., mesenteric vessels (DeGraw and Anderson 2004) or the portal veins (Gan et al. 2002) for estimation of the intestinal absorption rate when comparing the compound levels achieved in the mesenteric or portal veins and the concentrations in peripheral veins for estimation of systemic availability of the candidate compound. This method is widely used in rats, but also other animal species can be used and are reported, e.g., rabbits (Sawchuk and Awni 1986; Riad and Sawchuk 1991) and ferrets (Wang et al. 1993).

This method is often used for investigation of intestinal absorption of nutrients by using radioactive tracers (e.g., cholesterol, glucose) and their interference with the candidate compound (Arts et al. 2004). In addition, the secretion of the candidate compound into the intestine can be studied by peripheral administration of the compound into a peripheral vein and subsequent determination of the appearance of the

candidate compound in the intestinal perfusate (Merino et al. 2003; Berggren et al. 2004). Also variations are reported using chronically isolated intestinal loops in rats (Poelma et al. 1992).

CRITICAL ASSESSMENT OF THE METHOD

During anesthesia, intestinal motility is dramatically reduced, which secondarily might influence the intestinal absorption of the candidate compound. Bile flow is relatively constant during the first 2–3 h but declined during prolonged anesthesia (Fig. 35.1) due to the interruption of the enterohepatic circulation of bile acids.

35.2 Isolated Perfused Livers

PURPOSE AND RATIONALE

Isolated perfused rat livers are used for physiological and pharmacological purposes to study intermediary metabolism of carbohydrates and lipids (e.g., gluconeogenesis, glycogenolysis, ketogenesis). This isolated organ preparation with separated cannulated bile duct can ideally be used for investigations of pharmacokinetic and of drug metabolism by elucidation of hepatic uptake and drug metabolic stability and its hepatobiliary elimination. The advantage of this perfused organ preparation over isolated hepatocytes is the maintained architecture of the hepatic structure (perivenous–periportal orientation).

PROCEDURE

Rats with a body weight between 250 and 300 g are anesthetized with 20 mg/kg ketamine plus pentobarbital sodium (60 mg/kg i.p.). The liver is exposed by longitudinal midline and transverse subcostal incisions, and the bile duct is cannulated as well as the portal vein with a venous cannula. The liver is immediately infused via the portal vein at 37°C with oxygenated saline containing heparin (70 units/ml). The vena cava caudalis is opened to allow a continuous flow of the saline/heparin solution for about 2 min. Then the liver is transferred into a heated (37°C) perfusion chamber and perfused via the portal vein in a recirculating manner at a constant flow rate of 35 ml/min with continuously oxygenated Krebs-Ringer bicarbonate buffer (100 ml total volume). The buffer consists of 137 mM NaCl, 2.7 mM KCl, 11.9 mM $NaHCO_3$, 0.72 mM NaH_2PO_4, 1.8 mM $CaCl_2$, and 0.5 mM $MgCl_2$ with 10 mM glucose, and is supplemented with 30% (v/v) washed bovine erythrocytes and 1.6% (w/v) bovine serum albumin. Experiments are routinely carried out on four livers simultaneously, and they are perfused for 2 h as total perfusion time for each liver.

The candidate compound is added to the perfusate before the isolated liver is transferred to the perfusion setup. After 5 min recirculation in the system without

the organ, a sample of the perfusate is collected for determination of the starting concentration of the candidate compound (value at time 0). Then the isolated liver is connected to the perfusion chamber, and subsequently samples of the perfusate are taken in 10- to 15-min intervals as well as bile samples are taken in 15-min intervals for the determination of compound levels. The volume of excreted bile per 30 min is determined gravimetrically (difference between tube weight without and with bile per collection period) with the assumption that 1 g is equivalent to 1 ml of bile. If radioactive-labeled candidate compounds are used, the intervals for bile collection can be much shorter (1–2 min). The liver is perfused for 2 h, and at the end of the perfusion experiment, the liver is removed and immediately frozen for determination of tissue level of the compound in liquid nitrogen and later on stored at $-20°C$ until analysis. For analysis of tissue levels of the candidate compound, the frozen livers are homogenized in water (1 g tissue in 1 ml water (or solvent to extract the candidate compound from the tissue)) using an ULTRA-TURRAX.

Samples for determination of lactate dehydrogenase (LDH) activity are taken every 30 min, and they are a measure for the viability and integrity of the isolated organ. A continuous bile flow throughout the perfusion time is the best measure of the functional integrity of the organ (typically bile flow of four livers is shown in Fig. 35.2). Isolated livers without bile flow should be excluded from the final evaluation of the data.

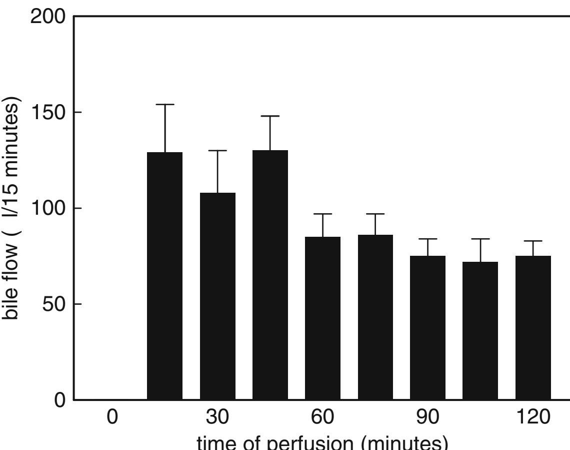

Fig. 35.2 Representative time course of bile flow of isolated perfused rat livers. Values are mean ± SEM, $n = 4$

EVALUATION

Compound levels in samples of the perfusate and bile are measured using appropriate analytical methods for detection of the candidate compound. The decline in the concentrations of the compound in the perfusate is a measure of the uptake, metabolism, and elimination of the compound by the liver. The appearance of the candidate compound in the bile is a measure of the hepatobiliary elimination of the compound. The tissue level of the candidate compound is a measure for the uptake and accumulation of the candidate compound in the liver. Ideally the analytical method for the detection of the candidate compound included also the detections of known metabolites of the candidate compound in perfusate and bile.

From the total amount of the candidate compound and metabolites in the perfusate (100 ml) at the end of the perfusion experiment (after 2 h) in relation to the total added amount of compound at time 0, the total uptake into the liver can be calculated. In addition, the total hepatobiliary elimination of the candidate compound (sum of all collecting intervals (concentration × secreted volume per collecting interval)) can be calculated. From these values together with the remaining tissue concentration, a balance calculation can be set up, and the proportion of compound metabolism can be estimated. Representative data are shown for a candidate compound with a high first pass effect in Fig. 35.3.

MODIFICATIONS OF THE METHOD

This method has been widely used for studying carbohydrate and lipid intermediary metabolism (Herling et al. 1998) as well as drug metabolism (Milne et al. 1997, 2000; Vuppugalla and Mehvar 2004). Many variations have been reported predominantly with respect to the animal species used. Chaib et al. (2004) compared isolated perfused livers of rats with those of guinea pigs. den Butter et al. (1994) used livers from rabbits. Further modifications are related to the direction of perfusion via hepatic artery or portal vein or both simultaneously or in connection with the isolated jointly perfused small intestine (Stumpel and Jungermann 1997; Stumpel et al. 2000) as well as the continuous perfusion in a recirculated (see above) or open (nonrecirculated) manner (Lopez et al. 1998).

CRITICAL ASSESSMENT OF THE METHOD

Using an erythrocyte-containing medium for perfusion, one has to take into account the putative

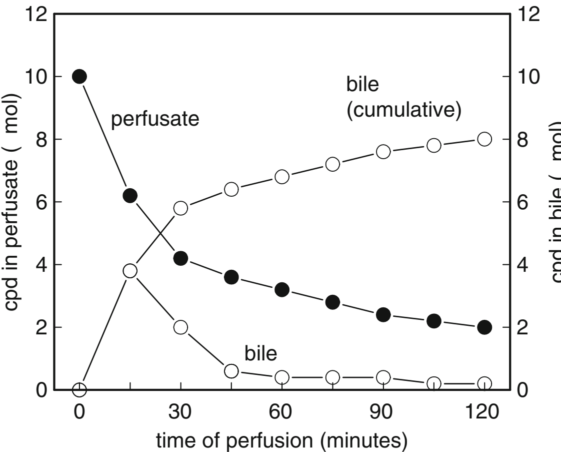

Fig. 35.3 Example for the time course of a compound with a high first pass effect. The values for the perfusate represent the total amount of compound in the total volume of perfusate (100 ml; nmol/ml × 100). The values for the bile represent the total excreted amount of compound in the bile per sampling period of 15 min (μmol/ml × bile volume per 15 min) and were expressed as the values measured per sampling interval and as cumulative excreted into the bile

involvement of the erythrocytes themselves with respect to uptake of the candidate compound. Therefore, not only the erythrocyte-free perfusate but also the erythrocyte fraction should be included in the analysis of the candidate compound, separately. In our hands, the model of isolated perfused liver is metabolically active for up to 3 h, and during this time, no decline in hepatic metabolic activity becomes obvious. However, bile flow declined during the perfusion experiments. Therefore, our total perfusion time of isolated livers in our standard experimental setup is limited to 2 h. The tissue level of the candidate compound analyzed after 2 h in the liver is a measure for the total amount of compound in the whole organ. This does not necessarily mean the presence of the candidate compound in hepatocytes but additionally in the capillary and biliary space of the liver.

35.3 Isolated Perfused Kidneys

PURPOSE AND RATIONALE

Isolated perfused rat kidneys are used for physiological and pharmacological purposes to study overall renal functions. For pharmacokinetic purposes, this preparation is used to study renal excretion profiles of the candidate compound and/or its metabolites.

PROCEDURE

Karpf et al. (2003) used isolated kidney from rats. Rats are anesthetized with an intraperitoneal injection of 20 mg/kg ketamine plus 60 mg/kg sodium pentobarbitone before surgery. The isolated kidneys are perfused in a recirculating manner in a thermostatically controlled cabinet maintained at 37°C. An erythrocyte-free modified Krebs-Henseleit bicarbonate buffer solution containing bovine serum albumin, glycine, L-cysteine, L-glutamic acid, and glucose in a reservoir is pumped through the kidney via an in-line filter

(8 μm), a membrane oxygenator, glass bubble trap, flow meter, and finally a glass arterial cannula inserted into the renal artery, and returned to the reservoir. Throughout the perfusion, carbogen is supplied to the membrane oxygenator to maintain a constant concentration of oxygen in the perfusate at a value greater than 0.6 mM, and the pH was maintained at 7.4. The viability of the kidney is monitored by measuring glomerular filtration rate (GFR) and the reabsorption of water, sodium, and glucose. The organs are considered viable if the respective values are greater than 0.4 mL/min, 75%, 95%, and 99%, respectively.

Urine is collected over successive 10-min intervals (10–20, 20–30, 30–40, 40–50, 50–60, 60–70, 70–80, and 80–90 min) from the start of the perfusion; samples of the perfusate are collected from the reservoir at the midpoint times of these intervals.

EVALUATION

Compound levels in samples of the perfusate and urine are measured using appropriate analytical methods for detection of compound levels. The decline in the concentrations of the candidate compound in the perfusate is a measure of the uptake, metabolism, and elimination of the compound by the kidney. The appearance of the candidate compound in the urine is a measure of the renal elimination (glomerular excretion and tubular secretion) of the compound. Ideally the analytical method for the detection of the candidate compound included also the detections of known metabolites of the compound in perfusate and urine.

MODIFICATIONS OF THE METHOD

Wang et al. (2004a, b) used isolated kidneys from rats after removal from anesthetized (sodium pentobarbitone (60 mg/kg)) animals. Briefly, a midline laparotomy incision was made from pelvis to sternum on the animal. Next, the right ureter was ligated immediately proximal to the bladder. A solution of mannitol (150 mg) and heparin (100 U) in 1 ml normal saline was injected into the penile vein. The right ureter was then cannulated by the introduction of a cannula consisting of a 200-mm length of tubing (od = 0.61 mm, ID = 0.28 mm, Paton Scientific, Victor Harbour, Australia). The area around the anastomosis of the superior mesenteric artery, renal artery, and aorta was cleared of connective tissue and loose ligatures placed around the superior mesenteric artery and renal artery. After removing the capsule of the kidney, a right-angled glass cannula was inserted into the superior mesenteric artery via a small incision and passed proximally along the superior mesenteric artery, across the aorta and into the renal artery where it was tied in place. Perfusate flow was commenced immediately. The cannulated kidney was then excised from the body of the rat and suspended within a thermostatically controlled cabinet at 34-37°C. The recirculating perfusion medium (160 ml) was pumped at approximately 36 ml/min, which maintained renal artery perfusion pressure at 110 ± 25 mmHg, which was monitored by a manometer, corrected for the intrinsic pressure of the apparatus. The functional viability of each kidney was assessed by the glomerular filtration rate (GFR), which was determined as the renal clearance of [^{14}C]-inulin, urine flow, and the percentage tubular reabsorption of water, glucose, and sodium.

Urine samples were collected in 10-min intervals over the 10- to 130-min period after the bolus. Urine volume was measured gravimetrically in preweighed collection vials. Perfusate samples were collected from the reservoir at the midpoint of each urine collection interval; appropriate amounts of perfusate and of urine were taken for further analysis.

CRITICAL ASSESSMENT OF THE METHOD

The isolated perfused kidney technique has been used for decades to investigate aspects of renal physiology, pharmacology, and pharmacokinetics. The model used most extensively is the isolated perfused rat kidney continuously perfused with medium containing electrolytes, glucose, amino acids, and the oncotic agents, bovine serum albumin (BSA) or dextran. The oncotic agents included in perfusate create "physiological" colloid osmotic pressure, which is one of the key factors to regulate glomerular filtration rate (GFR), tubular reabsorption of water and sodium, and water content in kidney interstitial tissue. BSA is the oncotic agent used most commonly in the isolated perfused rat kidney and affords reasonably stable isolated perfused kidney function. Perfusate BSA concentrations used in the past have varied from 20 to 80 g/l. Generally, the higher the BSA concentration in perfusate, the higher the extent of reabsorption of water and sodium, but at the expense of lower GFR and urine flow rate. Thus, it is necessary for investigators to weigh the balance between GFR and the extent of reabsorption of water and sodium. Practically, 60–65 g/l BSA in perfusate has been used by most investigators employing the isolated perfused kidney.

Distribution of drugs across barriers plays a predominant role in the processes of absorption (A), distribution (D), and excretion (E) and is thus a major determinant of a drugs pharmacokinetic profile. The barrier at the site of absorption is in most cases built by the enterocytes of the small intestine (see Chap. 29 "Absorption: In Vivo Tests (Radiolabeled)"). Apart from lung, heart, muscle, and brain, the main target organs are kidney and liver which are also the major elimination pathways of drugs. Cell membranes of liver hepatocytes and kidney cells have to be passed in these cases. The brain plays a special role in the distribution of drugs because drugs normally should not enter the central nervous system to avoid severe adverse effects. It is, therefore, protected by the very tight blood–brain barrier. However, when the target is located in the brain, the drug needs to cross this barrier. Meanwhile, there exist several in vitro systems to study drug permeation across this special blood–brain barrier (Sect. 36.1). They cover primary cultures of brain endothelial cells in monoculture or as coculture with astrocytes or pericytes (Sect. 36.1.1), immortalized endothelial cell lines from different species (Sect. 36.1.2), and surrogate models (Sect. 36.1.3).

Over the recent years, many membrane transporters have been cloned, characterized, and localized in cell membranes of different tissues. In numerous in vivo and in vitro studies, membrane transporters mainly expressed in epithelial of the intestine, liver, and kidney and in the endothelium of the blood–brain barrier show clinically relevant interaction with drugs and/or their metabolites. Therefore, they can play an important role in modulating drug absorption, distribution, and elimination.

Membrane transporters can be classified into two major groups: the solute carrier (SLC) transporter family and the ATP-binding cassette (ABC) transporter family (HUGO Gene Nomenclature Committee http://www.gene.ucl.ac.uk/nomenclature/).

The SLC family consists of 51 gene subfamilies with 378 family members, including ion-coupled transporters, facilitated transporters, and exchangers (http://www.bioparadigms.org). SLC transporters mediate the uptake of substrates, including organic anions and cations, peptides, amino acids, bile salts, and nucleosides into the cell. These transporters accept not only physiological or endogenous substrates but also xenobiotics, including drugs and/or their metabolites, and are therefore referred to as drug transporters. Members of the SLC families are the sodium bile salt cotransporters (ASBT, NTCP), oligopeptide transporters (PEPTs), organic anion transporting polypeptides (OATPs) organic anion as well as organic cation transporters (OATs, OCTs, and OCTNs), and multidrug and toxin extrusion proteins (MATEs).

In the ABC-transporter family, 49 genes have been identified and classified into seven subfamilies, including the widely studied P-glycoprotein (MDR1, Pgp), multidrug resistance proteins (MRPs), breast cancer-related protein (BCRP), and the bile-salt export pump (BSEP). ABC transporters mediate the transport of substrates across the cell membrane against their concentration gradient. The energy required for this process is derived from ATP hydrolysis.

Table 36.1 summarizes for in vitro studies the most important drug transporters, their expression profile, well-established probe substrates, and inhibitors. Some of them are defined by the International Transporter Consortium (ITC; *Nature Reviews* Drug Discov. 9, 215–236, from March 2010) as clinically relevant transporters. The ITC members comprising scientists from the industries, Food and Drug Administration (FDA), and universities justify their selection on practical consideration and on clinical evidence that these transporters influence, drug absorption, drug disposition, side effects, and/or drug–drug interactions (DDIs).

In May 2010, the European Medicines Agency (EMA) recommends in their draft guidance that new drug candidates should be evaluated as substrates and inhibitors of drug transporters to assess the potential for clinical drug–drug interactions (Table 36.1).

Therefore, consideration must be given to the role of drug transporters in the absorption (e.g., intestinal Pgp and BCRP), distribution (Pgp in the blood–brain barrier and OATPs for hepatocytes uptake), and excretion (OATs and OCTs for renal elimination) of a new drug candidate in development. Based on the current knowledge, decision trees recommended by the ITC whitepaper can be used for planning and implementing drug transporter studies during the drug development (*Nature Reviews* Drug Discov. 9, 215–236, from March 2010). Examples of clinical transporter study design and in vitro/in vivo correlations for transporters are summarized by Eisenblaetter T. and Weitz D. (Drug discovery and evaluation: *Methods in Clinical Pharmacology* Springer Verlag 2011). Another aspect that demands careful consideration is that by knowing

Table 36.1 Basic characteristics of relevant uptake and efflux transporters

Gene	Transporter	Organ expression	Substrates	Inhibitors
SLC-transporter family				
SLC10A1	NTCP	Liver, pancreas	Estrone-3-sulfate, taurocholate, BSP	Cyclosporine, furosemide
SLC10A2	ASBT	Ileum, kidney	Taurocholate	BSP, cyclosporin A
SLC15A1	PEPT1	Kidney, intestine	Cephalexin, enalapril, cefadroxil, dipeptides, tripeptides	Glycyl-proline
SLC15A2	PEPT2	Kidney, brain, lung	Cephalexin, enalapril, cefadroxil, dipeptides, tripeptides	Zofenopril, fosinopril
SLCO1A2	OATP1A2	Kidney, brain, liver	Statins, estrone-3-sulfate, DHEAS, fexofenadine	Rifampicin, ritonavir
SLCO1B1	OATP1B1$^{FDA/EMA}$	Liver	BSP, statins, estrone-3-sulfate, valsartan	Rifampicin, ritonavir
SLCO1B3	OATP1B3$^{FDA/EMA}$	Liver	BSP, statins, cholecystokinin 8, estradiol-17-β-glucuronide	Rifampicin, ritonavir
SLCO2B1	OATP2B1	Liver, intestine, placenta	BSP, statins, estrone-3-sulfate	Rifampicin, cyclosporine
SLC22A1	OCT1^{EMA}	Liver	TEA, MPP, metformin	Quinine, quinidine
SLC22A2	OCT2$^{FDA/EMA}$	Kidney, brain	TEA, MPP, metformin	Tetrabutylammonium, cimetidine
SLC22A3	OCT3	Liver, kidney, heart, placenta, lung, brain, skeletal muscle	TEA, MPP, metformin	Corticosterone, quinidine
SLC22A4	OCTN1	Kidney, liver, brain, intestine, lung, heart, placenta, etc.	TEA, ergothioneine	Verapamil
SLC22A5	OCTN2	Kidney, liver, intestine, lung, heart, skeletal muscle, etc.	Carnitine	Verapamil
SLC22A6	OAT1$^{FDA/EMA}$	Kidney, brain, placenta	PAH, cidofovir, adefovir	Probenecid, glibenclamide
SLC22A7	OAT2	Liver, kidney	cGMP	Indomethacin, bumetanide
SLC22A8	OAT3$^{FDA/EMA}$	Kidney, brain, skeletal muscle	Estrone sulfate, DHEAS, furosemide, bumetanide	Probenecid, indomethacin
SLC22A11	OAT4	Kidney, placenta	Estrone sulfate, DHEAS, methotrexate, bumetanide	BSP, probenecid
SLC47A1	MATE1	Kidney, liver	MPP, TEA	Quinidine, cimetidine
SLC47A2	MATE2	Kidney, intestine, testis	MPP, TEA	Cimitidine, quinidine
ABC-transporter family				
ABCB1	MDR1$^{FDA/EMA}$	Intestine, kidney, liver, brain	Digoxin, loperamide, doxorubicin	Cyclosporine A, quinidine
ABCB4	MDR3	Liver	Digoxin, paclitaxel, vinblastine	Cyclosporine, verapamil
ABCB11	BSEP ^{EMA}	Liver	Taurocholate, pravastatin	Cyclosporine A, rifampicin
ABCC1	MRP1	Lung, placenta, testis, kidney, skeletal muscle	Estradiol-17-β-glucuronide, estrone-3-sulfate	Cyclosporine A
ABCC2	MRP2	Liver, kidney, intestine	Glutathione, methotrexate, valsartan	Cyclosporine A, delaviridine
ABCC3	MRP3	Liver, intestine	Estradiol-17-β-glucuronide, methotrexate, fexofenadine	Delaviridine, efavirenz
ABCC4	MRP4	Kidney, liver, brain	Adefovir, DHEAS, furosemide, methotrexate, cAMP, cGMP	Celecoxib, diclofenac
ABCG2	BCRP$^{FDA/EMA}$	Intestine, kidney, liver, brain, placenta	Methotrexate, mitoxantrone, statins, imatinib, irinotecan	Fumitremorgin C

BSP bromosulfophthalein, *DHEAS* dehydroepiandrosteron sulfate, *MPP* methylphenylpyridinium, *PAH para*-aminohippurate, *TEA* tetraethylammonium; FDA/EMA indicated transporters are defined as clinically relevant from ITC or EMA

the substrate specificity and the expression profile of each transporter, efficient drug delivery to, or exclusion from, the target organs can be accomplished by appropriately modifying the structure of the drug.

To study these drug transporter interactions, in vitro systems expressing single transporters (Sects. 36.2 and 36.3) or transporter combinations (Sect. 36.4) can successfully be used. Drug uptake mediated by SLC transporters (Sect. 36.2) can be measured by using transfected eukaryotic cells like HEK, CHO (Sect. 36.2.1), or injected oocytes (Sect. 36.2.2). Drug efflux processes mediated by ABC transporters (Sect. 36.3) are investigated using membrane vesicles from either eukaryotic cell lines like HEK, CHO, MDCK (Sect. 36.3.1), or insect cells (Sect. 36.3.2). By using double-transfected MDCK cells, drug uptake and efflux (Sect. 36.4) can be measured in one single setup (Sect. 36.4.1). For liver-specific drug transport, sandwich-cultured hepatocytes can be used (Sect. 36.4.2).

36.1 Blood–Brain Barrier (BBB)

36.1.1 Primary Cultures of Brain Capillary Endothelial Cells

36.1.1.1 Primary Cultures of Porcine Brain Microvascular Endothelial Cells

PURPOSE AND RATIONALE

Franke et al. (1999) have described an in vitro model for screening of drug entry into the brain using primary cultures of porcine brain capillary endothelial cells (PBCECs). By using serum-free culture conditions, transport studies are highly reproducible, and sample analysis (HPLC, LC-MS) is facilitated.

PROCEDURE

Porcine brain microvessel endothelial cells are prepared following a method of Bowman et al. (1983) using modifications described by Tewes et al. (1997) and Franke et al. (2000). Hemispheres of porcine brains of freshly slaughtered animals (female, about 6 months) are collected in ice-cold ethanol (70 % v/v) and stored in PBS (4°C; containing penicillin/streptomycin (200 U/ml each)) for transport and during the preparation procedure. After flaming the hemisphere shortly, the meninges and adhering larger vessels are completely removed. Secretory brain areas are dissected, and the remaining cerebral gray and white matter is homogenized mechanically. The homogenate is supplemented with preparation medium (Earle's Medium M199 containing 0.7 mM L-glutamine, 1% (v/v) penicillin/streptomycin (10 mg/ml) and 1% (v/v) gentamicin (10 mg/ml)) to a final volume of 50 ml per brain hemisphere, and 1% (w/v) dry powdered unspecific protease/dispase II (Sigma) is added for an incubation period of 2 h at 37°C with magnetic stirring. One hundred and fifty milliliters of 18% (w/v) dextran solution per 100 ml of digested homogenate is then added, shaked, and spinned with 6,800 × g for 10 min at 4°C. After dextran density gradient centrifugation, capillary fragments are obtained as pellet and are resuspended in culture medium. This microvessel-fragment suspension is filtered through a nylon mesh (180 μm pore size) and then triturated up and down 3–5 times in a 10-ml pipette with the pipette tip placed directly onto the bottom of a petri dish. For the second digestion, the suspension is incubated with 0.1% (w/v) collagenase/dispase (Boehringer) in 10-ml plating medium (preparation medium + 10% (v/v) ox serum) per brain equivalent for 1 h at 37°C using a flask with hanging stirrer. A discontinuous Percoll gradient is prepared from 15 ml Percoll solution ($\delta = 1.07$ g/ml) and 20 ml Percoll solution ($\delta = 1.03$ g/ml). Ten milliliters of the cell suspension is placed onto the top of the gradient and centrifuged in a swing-out bucket rotor ($1,250 \times g$, 10 min, room temperature). Released endothelial cells are collected from the interface of the gradient and washed with an excess of plating medium (110 × g, 10 min, room temperature). The cells are resuspended very gently in plating medium and seeded onto collagen-coated culture surfaces (seeding density: 450 cm^2 per brain). Cultures are kept at 37°C in a humidified atmosphere with 5% CO_2. Twenty-four hours after initial plating, cells are washed with PBS containing Ca^{2+} (0.9 mM) and Mg^{2+} (0.5 mM) and supplied with culture medium (plating medium without gentamicin). For further purification and to obtain a homogenous monolayer, primary cultures of PBCEC are subcultured at second day of culture by gentle trypsination (1:250 trypsin solution in PBS) at room temperature. The displacement of endothelial cells is followed with a reverse phase-contrast microscope and stopped by addition of ox serum when the majority of endothelial cells are removed from the culture surface. The cells are collected and centrifuged with $110 \times g$ for 10 min at room temperature and plated in culture

medium with a density of 30,000 cells/cm^2 on rat tail collagen-coated Transwell™ or Transwell-Clear™ filter inserts (24 mm diameter, 0.4 mm pore size, Corning Costar). Medium volumes are 1.5 ml apical and 2.5 ml basolateral. On the second day after passage, the culture medium is replaced by a serum-free assay medium (DME/Ham's F12; 1:1) containing 550 nM hydrocortisone. Within 2–4 days after this medium exchange, the PBCEC have built up a very tight monolayer and are ready for BBB in vitro–transport experiments.

Coating with Rat-Tail Collagen

Collagen fibers are collected as described by Bornstein (1958). Fibers of each tail are incubated in 50 ml 0.1% (v/v) acetic acid at 4°C for 24 h. Centrifugation for 2 h at 5,000 × g separates the fiber residues from solubilized collagen which is aspirated. Total protein content of the collagen solution is determined and adjusted to 0.1 mg/ml. Transwell™ or Transwell-Clear™ filters are coated by adding 100 µl of rat-tail collagen solution per filter and allowed to dry for at least 2 days at 37°C. No further washing steps are occurred (Franke et al. 1999).

Transport Measurements

Directly prior to the experiment, the quality, that means the tightness, of the PBCEC monolayer is assessed by determination of the transendothelial electrical resistance (TEER) of each filter. TEER measurements can be easily performed with the ENDOHM-24™ chamber and the EVOHM™ voltometer (World Precision Instruments, Inc.). The resistance data, expressed in Ω, are multiplied with the filter surface (4.52 cm^2), corrected for blank filter resistance, and expressed in Ω × cm^2.

To measure the transport of drugs across the BBB in vitro, 2.5 µCi of ^{3}H-labeled drug and ^{14}C-sucrose are applied to each Transwell (in case of ^{14}C-labeled substances, permeability studies are performed with ^{3}H-sucrose). This concentration is high enough to ensure sufficient excess to neglect the decrease of tracer in the donor (apical) compartment during the experiments. Volumes of 1.5 ml in the donor (apical) and 2.5 ml in the acceptor (basolateral) compartment avoid hydrostatic pressure. After addition of the radiolabeled compound, samples of 50 µl are taken in duplicate from the basolateral acceptor compartment each 20 min and replaced by 100 µl of fresh assay medium. Cells are kept under culture conditions during the whole transport experiment. Radioactivity is measured after addition of liquid scintillation cocktail in a counter.

Uptake Experiments

To determine the uptake of test substances, filters are gently washed 90 min after drug application with PBS, and cells are solubilized with a solution containing 0.1 M NaOH, 1% (w/v) sodium dodecyl sulfate, and 2% (w/v) Na_2CO_3. Radioactivity of the solubilized cells is counted and compared with the radioactivity of the medium in the donor compartment at 90 min.

Calculation of Permeability Coefficients

Following the majority of publications, permeability coefficients can be calculated according to Pardridge et al. (1990). The permeability coefficient of the endothelial cell layer P_e is calculated as follows:

$$1/P_e = 1/P_t + 1/P_f$$

(P_t permeability coefficient of the total system and P_f permeability coefficient of the cell-free filter)

$$P[cm/s] = (cpm_t{}^a \times volume^d\left[cm^3\right])/(\Delta t[s] \times filter - area\left[cm^2\right] \times cpm_0{}^d)$$

($cpm_t{}^a$ total radioactivity in the acceptor compartment after t seconds; $cpm_0{}^d$ total radioactivity added at time 0 to the donor compartment; Δt time measured in seconds; filter-area here 4.52 cm^2; volume^d here 1.5 ml)

EVALUATION

Under these culture and assay conditions, PBCEC displayed sucrose permeabilities as low as 2×10^{-7} cm/s. This tightness becomes close to in vivo permeabilities of 3×10^{-8} cm/s (Ohno et al. 1978) and 1.2×10^{-7} cm/s (Levin 1980). Data are expressed as mean±standard deviation ($n = 3$–6).

CRITICAL ASSESSMENT OF THE METHOD

The absence of serum and presence of hydrocortisone in this in vitro model ensure the appropriate differentiation of brain endothelial cells with a characteristic BBB phenotype including (a) impermeable intercellular tight junctions (Nitz et al. 2001, 2003; Eisenblatter et al. 2001); (b) low pinocytotic activity;

(c) expression of specific transporters like SGLT1 (Elfeber et al. 2004), neutral amino acid transporter, P-glycoprotein (Eisenblatter et al. 2003), ABCG2 (Eisenblatter and Galla 2002), and the transferrin, scavenger, and LDL receptors (Hoheisel et al. 1997); (d) expression of specific enzymes like γ-GT (Mischeck et al. 1989) and alkaline phosphatase (Meyer et al. 1990); and (e) an efficient endothelial barrier function with low paracellular permeability (Hoheisel et al. 1998, Franke et al. 1999, 2000; Nitz et al. 2003).

As described before, TEER measurements can be performed with the ENDOHM-24^{TM} chamber and the EVOHM^{TM} voltometer. Use of the STX-2 "chopstick" electrodes (World Precision Instruments, Inc,) leads to inaccurate data and cannot be recommended for TEER measurements. Very much in favor is a technique called impedance spectroscopy (Wegener et al. 1999).

MODIFICATION OF THE METHOD

Prof. H-J Galla (University of Muenster, Germany) has already established an in vitro BBB model with murine brain capillary endothelial cells based on this procedure (not yet published). Thus, this procedure might easily be adapted to brain endothelial cells of other relevant species in drug discovery like rat, dog, and rabbit.

Wegener J, Zink S, Rosen P, Galla H (1999) Use of electrochemical impedance measurements to monitor beta-adrenergic stimulation of bovine aortic endothelial cells. Pflugers Arch 437:925–934

EXAMPLES

The industrial application of ranking of CNS penetration was nicely shown by Lohmann et al. (2002). In this work, different in vitro assays were evaluated in order to predict the BBB permeability.

36.1.2 Cocultures of Bovine Brain Microvascular Endothelial Cells and Rat Astrocytes

PURPOSE AND RATIONALE

The passage of substances across the blood–brain barrier (BBB) is regulated in the cerebral capillaries,

which possess certain distinct different morphological and enzymatic properties compared with the capillaries of other organs. To provide an in vitro system with the functional characteristics of a BBB, Cecchelli et al. (1999) developed an in vitro system with cloned bovine brain capillary endothelial cells on one side of a filter and rat astrocytes on the other side which is described in detail below. Recently, Kroll et al. (2009) confirmed in a coculture model of porcine brain cerebral endothelial cells together with astrocytes that if astrocytes are able to contact the endothelial cells, they induce in concert with external factors like glucocorticoids the BBB function in vitro.

PROCEDURE

The cloning of endothelial cell islands is purchased according to Meresse et al. (1989). In brief, microvessels are isolated by mechanical homogenization from one cerebral hemisphere and then seeded onto dishes coated with an extracellular matrix secreted by bovine corneal endothelial cells. Only capillaries adhere on the extracellular matrix, whereas arterioles and venules can easily be discarded. Five days after seeding, the first endothelial cells migrate out of the capillaries and start to form microcolonies. When the colonies are sufficiently large, the five largest islands are trypsinized and seeded onto 35-mm-diameter gelatin-coated dishes (one clone per dish) in the presence of Dulbecco's modified Eagle's medium supplemented with 15% calf serum, 2 mM glutamine, 50 μg/ml gentamicin, 2.5 μg/ml amphotericin B, and basic fibroblast growth factor (bFGF, 1 ng/ml added every other day). Endothelial cells from one 35-mm diameter dish are then harvested and seeded onto 60-mm diameter gelatin-coated dishes. After 6–8 days, confluent cells are subcultured at the split ratio of 1:20. Cells at the third passage are stored in liquid nitrogen.

For experiments, cells are rapidly thawed at 37°C and seeded onto two 60-mm diameter gelatin-coated dishes. Once they reach confluence, cells are subcultured up to passage eight. The life span of the endothelial cell cultures is about 50 cumulative population doublings. At each passage, the cells are seeded in stock gelatin-coated dishes and on microporous membranes. At this stage, care needs to be given in selecting the matrix on the microporous membrane which will support cell attachment, growth, and differentiation. Different cell culture inserts and coatings have been evaluated by Cecchelli et al. (1999), and they found self-made rat-tail collagen on Millicell-CM inserts (Millipore, 0.4 μm pore size, 30 mm diameter) to give well-organized and confluent monolayers with typical junctions between them.

36.1.2.1 Preparation of Rat Astrocytes

Primary cultures of astrocytes are made from newborn rat cerebral cortex according to Dehouck et al. (1990). The meninges are cleaned off, and the brain tissue is forced gently through a nylon sieve. DMEM supplemented with 10% fetal calf serum, 2 mM glutamine, and 50 μg/ml of gentamicin is used for the dissociation of cerebral tissue and development of astrocytes.

36.1.3 Cocultures of Bovine Brain Capillary Endothelial Cells (BBCECs) and Astrocytes

Astrocytes are plated at a concentration of 2.5×10^5 cells/ml on the bottom side using the filter upside down. After 8 days, filters are properly positioned, and the medium is changed twice a week. Three weeks after seeding, cultures of astrocytes become stabilized. Then, frozen BBCECs are recultured on a 60-mm-diameter gelatin-coated dish. Confluent cells are trypsinized and plated on the upper side of the filters at a concentration of 4×10^5 cells. The medium used for the coculture is DMEM supplemented with 15% calf serum, 2 mM glutamine, 50 μg/ml of gentamicin, and 1 ng/ml of bovine fibroblast growth factor added every other day. Under these conditions, BBCECs form a confluent monolayer in 8 days (Dehouck et al. 1990).

EVALUATION

Cecchelli et al. (1999) compared the extraction ratios in vivo to the permeability of the in vitro model and showed a strong correlation between both values.

CRITICAL ASSESSMENT OF THE METHOD

The relative ease with which such cocultures can be produced in large quantities facilitates the screening of new CNS drugs. This model provides an easier, reproducible, and mass-production method to study the blood–brain barrier in vitro.

Using this model, one has to consider that two different species are used and that cow is a species not typically used in pharmaceutical development. Species differences according to transporter expression and lipid membrane composition have to be taken into account.

Most of the laboratories use enzymatic digestion to isolate endothelial cells (see Sect. 36.1.1.1). Often, cells of capillary, arteriolar, and venular origin as well as pericytes lead to a heterogenous mixture of these different cellular types. The subculture technique enables to circumvent the limitations of primary cultures and to provide large quantities of these monolayers. Endothelial cells can be cultured from passage three after thawing to passage seven, each passage generating at least 75 cocultures.

A complete characterization is summarized by Dehouck et al. (1990).

MODIFICATION OF THE METHOD

Instead of using cocultures with rat astrocytes, some laboratories are also using astrocytic conditioned medium in order to reinduce blood–brain barrier properties (Dehouck et al. 1994). They have found that induction does not require direct cell–cell interactions.

EXAMPLES

Cocultures of bovine capillary endothelial cells and astrocytes can be used to study the permeability of drugs (Dehouck et al. 1990). Culture plate inserts are set into six-well plates with 2 ml of buffer added to the upper chamber and 2 ml added to the plate coating the inserts. Radiolabeled compounds are added to the upper chamber, and 100 μl is removed from the lower chamber at various times. The radioactivity can be determined, and the permeability can be calculated. Using such techniques, ranking of CNS drugs concerning their permeability into the brain can be achieved.

36.1.4 Cocultures of Porcine Brain Capillary Endothelial Cells and Pericytes

PURPOSE AND RATIONALE

The blood–brain barrier (BBB) comprises the cerebral microvascular endothelium, pericytes, and astrocytes, which are connected by the extracellular matrix. The basis of the barrier function is the formation of complex tight junctions between adjacent endothelial cells which seal the paracellular pathway for various substances from the blood into the brain tissue (Abott et al. 2010). The induction of the BBB phenotype by astrocytes was well described in the past decades and is summarized in chapter "Cocultures of Bovine Brain Mircovascular Endothelial Cells and Rat Astrocytes." Recently, more and more functions of pericytes, like their contribution to angiogenesis and their role in various pathological conditions like brain tumorgenesis, multiple sclerosis, Alzheimer's disease, diabetic retinopathy, and prolonged oxygen deprivation are discovered. Thanabalasundaram et al. (2011a) first described that the impact of pericytes on the brain endothelial barrier integrity depends critically on the pericyte differentiation stage and established a species-consistent coculture model of primary porcine brain capillary endothelial cells (PBCECs) and porcine brain capillary pericytes (PBCPs). The new coculture model is described below and allows the examination of pericytes on pharmacological, transport, migration, and metabolic activity of the BBB (Thanabalasundaram et al. 2011a).

PROCEDURE

36.1.4.1 Preparation and Cultivation of PBCECs and PBCPs

PBCECs are isolated and cultured as described in chapter "Primary Cultures of Porcine Brain Microvascular Endothelial Cells." Briefly, cerebra of freshly slaughtered adult pigs are mechanically homogenized and stepwise digested by two proteases, followed by further purification steps. Twenty-four hours after initial plating, the cells are washed with phosphate-buffered saline (PBS) containing 1 mM Ca^{2+} and 0.5 mM Mg^{2+}. Puromycin (2.5 μg/ml) is used to remove pericytes according to Perriere et al. (2005). PBCECs are subcultured by fractionated trypsinization 2 days later to reduce contamination by other cells and then cryoconserved as described by Kroll et al. (2009).

PBCPs are obtained from PBCEC preparations which are not treated with puromycin. Since pericytes attach more firmly to the culture substrate than PBCEC, selective trypsinization of PBCEC yields pure PBCP cultures which are grown 14 days in pericyte medium (Dulbecco's modified Eagle's medium Ham's F-12, 2 mM L-glutamine, 100 μg/ml gentamicin, 100 U/ml penicillin and 100 μg/ml streptomycin, and 10% (v/v) NCS) before they are cryoconserved (Thanabalasundaram et al. 2011b). Pericytes are characterized by their branched morphology; large size; positive immunostaining for α-smooth muscle actin (α-SMA), desmin, Thy 1.1, and NG-2 proteoglycan; and negative staining for factor-VIII-related antigen and glial fibrillary acidic protein (GFAP).

36.1.4.2 Differentiation Procedure of PBCPs

PBCPs are seeded on collagen G-coated culture flasks (25 cm, 75,000 cells per flask) or on 96-well plates in pericyte medium. After 2 days, the medium is exchanged with serum-free pericyte medium containing 20 ng/ml bFGF (basic fibroblast growth factor) or 4 ng/ml TGFβ (transforming growth factor β). The differentiation medium is renewed with fresh medium 2 days later. The morphological analysis and the Western blot analysis of total protein and cell culture supernatant are carried out after 5 days treatment with the corresponding differentiation medium. Furthermore, it is recommended to verify the relative proliferation of the differentiation stage by a cell proliferation assay like the MTS-based assay.

36.1.4.3 Coculture Model of PBCECs and PBCPs

The pericytes are seeded (5,000 cells/filter) with pericyte medium on the basolateral (bottom) compartment of rat tail collagen (0.54 mg/ml) coated 12-well Transwell® filter inserts (Corning; 1.12 cm growth area, 0.4 μm pore size) (Thanabalasundaram et al. 2011a). The PBCPs are cultivated for 2 days in serum containing pericyte medium. Then, the cells are treated with the corresponding serum-free differentiation medium (20 ng/ml bFGF or 4 ng/ml TGFβ) for 5 days, and the medium is renewed after 2 days. After the differentiation step, the filter inserts are washed twice with serum-free pericyte medium to remove bFGF or TGFβ. Afterward, the PBCECs are seeded in excess (250,000 cells/filter) in plating medium on the apical (upper) compartment. The basolateral compartment contained serum-free pericyte medium. In order to induce the development of the PBCEC barrier integrity, the medium of the apical and basolateral compartment is exchanged 2 days later with fresh serum-free medium. After additional 2 days, the barrier integrity reaches the maximum TEER values, and experiments can be performed. The reference filters without PBCPs are treated according to the coculture procedure first with pericyte medium and then with the corresponding differentiation medium. After washing twice with serum-free pericyte medium, PBCECs are cultured on the apical compartment of the control filter inserts. The basolateral side refers to the brain side where the interaction by secreted signaling molecules of both cell types can be analyzed.

A very detailed description of the new coculture model including supplier information is provided in Thanabalasundaram et al. (2011b).

EVALUATION

Thanabalasundaram et al. (2011a) characterized the differentiation of PBCPs in vitro by analysis of morphological changes, cell proliferation assays, Western blot analysis, immunocytochemistry, and transendothelial electrical resistance (TEER) measurements. They identified two distinct differentiation stages of the primary pericytes in vitro. TGFβ-treated cells developed larger processes and enlarged cell bodies, whereas bFGF-treated pericytes formed shorter processes and smaller cell bodies. α-SMA and actin expression was increased while desmin,

vimentin, and nestin expression was decreased in TGFβ-treated cells when compared to bFGF-treated PBCPs. bFGF-treated PBCPs displayed a higher relative proliferation rate than TGFβ-differentiated PBCPs. In addition, the permeability factors VEGF, MMP-2, and MMP-9 were higher secreted by the α-SMA-positive phenotype, indicating a proangiogenic role of this TGFβ-induced pericyte differentiation stage. The TEER measurement of the barrier integrity of cocultured porcine brain capillary endothelial cells revealed that bFGF-pretreated α-SMA-negative pericytes stabilize the barrier integrity while α-SMA-positive pericytes differentiated by TGFβ decrease the barrier integrity.

CRITICAL ASSESSMENT OF THE METHOD

Due to the fact that pericytes are located next to the endothelial cells and release a large number of endothelial permeability regulating signaling molecules, their impact on the BBB integrity is of great interest. Pericytes are characterized by pluripotent differentiation characteristics, and thus, it remains complicated to analyze their impact on the BBB integrity both in vivo and in vitro. Whereas Nakagawa et al. (2007) revealed a barrier integrity increasing effect of pericytes in a primary rat cell in vitro coculture model, Thanabalasundaram et al. (2010) previously identified that primary porcine pericytes decrease the endothelial barrier integrity by secretion of the permeability factors VEGF, MMP-2, and MMP-9. In their recent assessment, Thanabalasundaram et al. (2011a) could show that different culture conditions can trigger pericyte differentiation in vitro and that the impact on BBB integrity depends on their differentiation status.

MODIFICATION OF THE METHOD

Instead of porcine-derived brain capillary endothelial cells and pericytes, the coculture model might also be established with cells derived from other species like rat (Nakagawa et al. 2007).

EXAMPLES

Cocultures of porcine capillary endothelial cells and porcine pericytes can be used to study the impact of pericyte-derived extracellular matrix proteins on the endothelial cell monolayer integrity (Thanabalasundaram et al. 2011b) and can provide new insights into the regulation of the BBB integrity by pericytes which will further improve the understanding of the physiological and pathological conditions like angiogenesis, tumorgenesis, multiple sclerosis, and Alzheimer's disease.

36.1.5 Immortalized Cell Lines

36.1.5.1 Immortalized Human Cerebromicrovascular Endothelial Cells

PURPOSE AND RATIONALE

Primary cultures of cerebromicrovascular endothelial cells (CECs) derived from rat, bovine, porcine, mouse, and human can rapidly loose key phenotypic markers of the blood–brain barrier (BBB) and undergo cellular senescence after a limited number of divisions in vitro. Furthermore, expression of BBB markers varies considerably among BCEC obtained from different species. These issues, compounded with the problems associated with very limited availability of human brain biopsies, small initial yield of cells, and short proliferative life span of human cells, greatly restrict

the utility of primary human BCEC as a reliable in vitro BBB model. Therefore, Muruganandam et al. (1997) developed an immortalized human cerebromicrovascular endothelial cell line as an in vitro model of the human blood–brain barrier.

PROCEDURE

Human CECs are isolated by using a modification of the procedure described by Gerhart et al. (1988). Briefly, the brain samples are excised surgically from patients treated with idiopathic epilepsy (Stanimirovic et al. 1996) and cleaned of meninges, surface vessels, and cortical gray matter. The tissue is minced and homogenized and passed once though 350-μm and twice through 112-μm mesh nylon nets. The filtrate is then centrifuged at 1,000 × *g* for 10 min, and the pellet is resuspended in 20% dextran (mol wt. 70,000) and again centrifuged at 3,000 × *g* for 15 min. The microvessels and capillaries contained in the pellet are collected on a 20-μm nylon mesh, dislodged, and exposed to 1 mg/ml type IV collagenase for 15 min at 37°C. The dissociated microvessels are collected by centrifugation and resuspended in growth media containing 65% medium M199 (Earles's salts, 25 mM HEPES, 4.35 g/l sodium bicarbonate, and 3 mM L-glutamine), 10% fetal bovine serum, 5% human serum, 20% murine melanoma cell-conditioned media (mouse melanoma, Cloudman S91, clone M-3, melanin-producing cells), 5 μg/ml of insulin, 5 μg/ml transferrin, 5 ng/ml selenium, and 10 μg/ml endothelial cell growth supplement (ECGS). Dissociated microvessels are seeded in 0.5% gelatin-coated plastic tissue culture dishes and maintained at 37°C in an atmosphere of 5% CO_2 in air. Endothelial cell colonies emerging from attached microvessels at days 4–5 after seeding are isolated using cloning rings; two or three of these cloned colonies are pooled and grown to confluence (10–14 days). The cells are further propagated at 1:3 split ratio every 7–10 days (Muruganandam et al. (1997): human cerebromicrovascular endothelial cells (HCECs).

Transfection of Human CEC with pSV3-Neoplasmid

Human CECs are transfected with the pSV3-neoplasmid encoding for the SV40 large T antigen and the neomycin resistance gene by using a calcium phosphate coprecipitation method (Graham et al. 1973). Transfection solution containing 2.5 M $CaCl_2$ (65 μl), 30 μg of pSV3-neo DNA, 500 μl HBSS buffer (275 mM NaCl, 10 mM KCl, 1.5 mM Na_2HPO_4, 4.2 mM HEPES, 11 mM dextrose; pH 7.19), and 400 μl water is vortexed briefly and allowed to precipitate for 30 min at room temperature. Human BCECs grown to near confluence in 100 mm dishes are exposed to the transfection solution for 6 h at 37°C. After removing the transfection solution, the cells are subjected to a short (90 s) glycerol shock (20% v/v) and washed with HEPES buffer, pH 7.1. Fresh growth media is added, and the cells are allowed to grow for 48 h at 37°C. Transfected cell cultures are then split (1:3) and seeded in the media containing the neomycin analog G418 (400 μg/ml). Cell colonies that survive 72 h of G418 treatment are isolated using cloning rings and passaged three times in G418-containing medium. The colonies that yielded cultures with cobblestone morphology should be used for initial genotypic and phenotypic analyses. They are called SV-HCEC.

Transport Studies

The barrier-like properties of SV-HCEC are developed in cells grown on a 0.5% gelatin-coated Falcon tissue culture insert (1 μm pore size; 0.83 cm^2 surface area) in 1 ml growth medium. The bottom chamber of the insert assembly contains 2 ml of growth medium either alone or supplemented with the fetal human astrocyte (FHAS)-conditioned medium in a 1:1 (v/v) ratio. The FHAS-conditioned medium is obtained by incubating confluent FHAS in serum-free M199 for 72 h. The transendothelial electrical resistance (TEER) of the endothelial cell monolayers can be measured with the ENDOHM-24™ chamber voltometer (World Precision Instruments, Inc.). Paracellular passage of ^{3}H-sucrose (2 μCi/ml) and ^{14}C-inulin (0.5 μCi/ml) across triplicate SV-HCEC monolayers and across the 0.5% gelatin-coated inserts without cells is determined from clearance values (Pardridge et al. 1990). Samples are collected from the bottom chambers every 15-min over 120-min period. Clearance volume [μl] was calculated as:

$$CL[\mu l] = (C_b \times V_b)/C_a,$$

where C_b is the basolateral tracer concentration, V_b the volume of the basolateral (lower) chamber, and C_a is the initial apical tracer concentration. The slopes of the clearance curves for membranes alone (PS_m) and membranes with cell monolayers (PS_{m+e}) are calculated using linear regression analysis to give

PS [μl/min]. The PS_e value for the SV-HCEC monolayer is calculated from:

$$1/PS_e = 1/PS_{m+e} - 1/PS_m.$$

The permeability coefficient P_e [cm/min] for the endothelial monolayer is derived by dividing PS_e by surface area (0.83 cm^2) of the membranes.

EVALUATION

Permeability coefficients for paracellular diffusion of ^3H-sucrose and ^{14}C-inulin across monolayers of HCEC and immortalized SV-HCEC and transendothelial resistances have been compared to human lung microvascular endothelial cells to evaluate the BBB phenotype of the cerebromicrovascular endothelial cell cultures (Muruganandam et al. 1997).

CRITICAL ASSESSMENT OF THE METHOD

Immortalization of especially human cerebromicrovascular endothelial cells is an invaluable tool for identifying specific aspects of the human BBB physiology and to analyze drug penetration into the human CNS. Nevertheless, D. Stanimirovic uses in all her following publications the primary cultures of HCEC and not the immortal cell line SV-HCEC to study transporter and receptor expression at the human BBB and to investigate the complicated brain inflammation processes. Possibly, the phenotype of HCEC is not retained in the Simian virus 40 large tumor antigen-transfected SV-HCEC cell line. One should probably think of a milder immortalization method when developing an immortalized human brain capillary endothelial cell line.

MODIFICATION OF THE METHOD

Rat brain capillary endothelial cells have been immortalized by the entire E1A region of adenovirus 2 by Roux et al. (1994) which was used for a number of cell types without oncogenic transformation. Bovine umbilical vein endothelial cells have been immortalized by transfection with an expression vector containing the human papillomavirus type 16 E6E7 oncogenes (Cajero-Juarez et al. 2002).

EXAMPLES

Human CEC cultured on filter inserts can be used to measure brain penetration of drugs to make in vitro–in vivo correlations. They can further be used to study, for example, brain inflammation that has been implicated in the development of brain edema and secondary brain damage in ischemia and trauma. Zhang et al. (2000) have studied leukocyte infiltration across the blood–brain barrier and could show the expression of adhesion molecules and leukocyte chemoattractants under ischemia in vitro conditions.

36.1.6 Immortalized Rat Brain Microvascular Endothelial Cells

PURPOSE AND RATIONALE

To overcome the large variability in the starting material and the rapid senescence observed after passages of pure cerebromicrovascular endothelial cells from primary cultures, Roux et al. (1994) produced an immortalized cellular clone displaying a stable, nontransformed phenotype. The aim was to constitute a valuable

in vitro model of the rat blood–brain barrier in order to make mechanistic studies and to avoid pharmaceutical drug screening for CNS penetration in vivo.

PROCEDURE

Primary cultures of rat brain microvessel endothelial cells are prepared according to the method of Bowman et al. (1982) and Roux et al. (1989). Briefly, two brains from 3-month-old Sprague Dawley rats are removed, cleaned of meninges and white matter, minced, and incubated for 1 h at 37°C in 25 ml of minimal essential medium (MEM) containing 1 mg/ml collagenase/dispase, 1% bovine serum albumin (BSA), and 15 mM Hepes, pH 7.4. After enzymatic treatment, brain tissue is suspended in 20 ml medium containing 25% BSA. Microvessels are pelleted by centrifugation at 1,000×*g* for 10 min to eliminate contaminating cells and debris, passed through a 120-μm nylon mesh, and incubated in 10 ml MEM containing 1 mg/ml collagenase/dispase for 3 h. Clumps of cells are layered over 7 ml Percoll gradients prepared by centrifuging 50% isotonic Percoll at 25,000×*g* for 1 h. The band containing mainly endothelial cells is removed and seeded onto extracellular matrix (ECM)-coated dishes (Gospodarowicz et al. 1986). Cultures are maintained in Alpha MEM/Ham's F10 (1:1) supplemented with 10 mM Hepes, 2 mM glutamine, 100 μg/ml gentamicin, 20% heat-inactivated, rat plasma-derived serum, and 1 ng/ml basic fibroblast growth factor, in humidified 5% CO_2/95% air at 37°C. After 3 days, contaminating pericytes surrounding endothelial cell colonies are removed with a modified glass Pasteur pipette. Experiments can be performed on confluent once-passaged 3-week-old cultures (Regina et al. 2001).

36.1.6.1 Transfection of Rat Brain Capillary Endothelial Cells

The plasmid pE1A-neo carries the entire E1A region of adenovirus 2 and the neo gene for resistance to the aminoglycoside G418 (Roux et al. 1994). Transfection is carried out using the calcium phosphate precipitation procedure. Endothelial cells are transfected 24 h after the second passage, at ~50 % confluence, with 1–10 μg plasmid DNA. After 3 h in the presence of DNA, cells are submitted to a 2-min DMSO (10%) shock, then rinsed and refed with complete medium. They are trypsinized 25 h later and seeded at various densities in 6-cm dishes in complete medium supplemented with 300 μg/ml G418. The selective medium is changed every 3–4 days. The clones appear ~2 weeks later; they are individually trypsinized within cloning cylinders and transferred into collagen-coated 24-well plates. For experiments, immortalized rat brain microvessel endothelial cells are plated on rat tail collagen I-coated plates and maintained in a-MEM/Ham's F10 (1:1 v/v) with Glutamax containing 10% heat-inactivated FCS, 300 μg/ml Geneticin (G418), and 1 ng/ml basic fibroblast growth factor (bFGF) in humidified 5% CO_2/95% air at 37°C.

36.1.6.2 Induction of BBB Phenotype by Astrocyte-Conditioned Medium (ACM)

For endothelial cell treatment, the medium is changed to a 1:1 (v/v) mixture of standard endothelial cell culture medium and ACM (Regina et al. 2001). ACM is obtained by incubating 3–5-week-old confluent astrocytes for 48 h in serum-free medium supplemented with 2 mM glutamine and 100 μg/ml gentamicin. Primary cultures of astrocytes are prepared from the cerebral cortex of three newborn rats. After removing meninges, the brain tissue is forced gently through a nylon sieve. Astrocytes are plated at a concentration of 1.2×10^5 cells/ml in 75-cm^2 flasks in αMEM/Ham's F10 (1:1 v/v) with Glutamax™ containing 10% FCS and 100 μg/ml gentamicin. Two weeks after seeding, astrocytes are purified by overnight shaking at 37°C and treated with cytosyl arabinoside and 3-estermethylleucine according to the method of Meyer et al. (1989). Three weeks after seeding, astrocytes are used for preparation of ACM.

EVALUATION

The BBB model system of RBE4 cells (Roux et al. 1994) is used in many publications to study brain transport (carnitine: Mroczkowska et al. 2000; P-glycoprotein and Mrp1: Begley et al. 1996 and Regina et al. 1998) as well as drug-metabolizing enzyme activities (Chat et al. 1998).

CRITICAL ASSESSMENT OF THE METHOD

Immortalization of brain capillary endothelial cells is a difficult process, and phenotype characterization must be performed very carefully and always in comparison to primary cultured cells. However, an immortal cell line promises higher reproducibility of results, easier handling, and finally to be less time-, material-, and labor consuming.

MODIFICATION OF THE METHOD

Another immortalized rat brain capillary endothelial cell line is used in some labs, called GPNT. This cell line is obtained from GP8 cell line (Greenwood et al. 1996) by re-transfection with the plasmid pcDNA3-RSV and repeated limiting dilution cloning of the parent line (GPNT: GP8 and the French Company NeuroTech SA). GPNT cells are repeatedly treated with 5 μg/ml puromycin. They are plated on collagen I-coated plates and grown in a-MEM/Ham's F-10 (1:1) containing 10% heat-inactivated fetal calf serum, 0.5 ng/ml basic fibroblast growth factor, 5 μg/ml transferring, 5 μg/ml insulin, 5 ng/ml selenium, and 5 μg/ml puromycin, in humidified 5% CO_2/95% air at 37°C (Theron et al. 2003). P-glycoprotein expression can selectively be increased by repeated puromycin treatment (Demeuse et al. 2004).

EXAMPLES

Begley et al. (1996) demonstrated the use of RBE4 cells for the assessment of P-glycoprotein activity at the blood–brain barrier. They showed that cellular accumulation of ^{3}H-colchicine and ^{3}H-vinblastine is enhanced in the presence of azidothymidine, chlorpromazine, verapamil, cyclosporine A, and PSC833. Vinblastine uptake was measured in RBE4 cells grown on collagen-coated 24- or 48-well plates. Cells were washed several times with DMEM containing 0.1% BSA and then incubated with 200 nM ^{3}H-vinblastine alone or together with 50 μM of the inhibitors. At several time points (15, 30, 60, and 90 min), the incubation medium was aspirated, and the cells washed with ice-cold medium and then solubilized in 1 N NaOH containing 0.1% SDS. Solubilized cells were pipetted into vials containing scintillation liquid for β-scintillation counting.

36.1.7 A Surrogate BBB Model: MDCK-MDR1 Cells

PURPOSE AND RATIONALE

Early assessment of the ability of a drug candidate to penetrate the CNS is critical during the drug discovery selection process, especially for therapeutic indications that require delivery to a CNS site of action. Equally important is the ability to design drugs for

non-CNS indications that have minimal brain penetration to avoid undesirable CNS side effects. In vitro BBB models using primary and immortalized brain capillary endothelial cells are described in the previous chapters. The Madine Darby canine kidney (MDCK) cell line is increasingly used as a substitute for the more labor-intensive in vitro BBB models in passive permeability and membrane transport studies.

PROCEDURE

Multidrug resistance-transfected MDCK type II (MDR1-MDCKII) cells were firstly described by Evers et al. (1997). They are maintained in minimum essential medium (MEM) containing 10% FBS and 2 mM L-glutamine and are cultured at 37°C in an atmosphere of 5% CO_2 and 95% relative humidity. Cells are passaged at 80–90% confluence (every 3–4 days) at a ratio 1:10 using trypsin-EDTA solution according to Irvine et al. (1998). They are grown in the absence of any selection agent to maintain Pgp (MDR1) expression (Mahar Doan et al. 2002). For transport studies, cells are seeded onto polycarbonate Transwell filter membranes at a density of 300,000 cells/cm^2. MDCK monolayers are washed and fed with fresh medium 1 h post-seeding and again 24 h post-seeding, and monolayers are ready for studies 3 days later.

36.1.7.1 Permeability Studies

Drugs are tested at 10 μM concentration and in two directions (apical to basolateral (a-b) and basolateral to apical (b-a)). Monolayer efflux studies are conducted at 37°C in a humidified incubator with shaking (90 rpm) for 60 min. Transendothelial electrical resistance is measured with an Endohm Meter (World Precision Instruments, New Haven, CT). Reference drugs for paracellular transport (^{14}C-mannitol), transcellular transport (^{3}H-propranolol), and Pgp efflux (amprenavir) should be included in each experiment. Concentrations of ^{14}C-mannitol and ^{3}H-propranolol are measured by liquid scintillation counting. Amprenavir is analyzed by cassette LC/MS/MS analysis along with the test drugs.

36.1.7.2 Calculations

The apparent permeability (P_{app}) is calculated with the equation:

$$P_{app}[nm/s] = 1/(S \times C_0) \times (dQ/dt),$$

where S = membrane surface area, C_0 = donor concentration at time 0, and dQ/dt = amount of drug transported per time. A ratio of the b-a and a-b P_{app} value is calculated. Involvement of a Pgp-mediated efflux mechanism is concluded if the b-a/a-b ratio is >1.5 (Mahar Doan et al. 2002).

EVALUATION

Mahar Doan et al. (2002) used the assay to classify 93 CNS and non-CNS drugs. The CNS set of drugs had a sevenfold lower incidence of passive permeability values <150 nm/s compared with the non-CNS set. The majority of drugs (72%) were not Pgp substrates. The CNS drug set had a threefold lower incidence of Pgp-mediated efflux than the non-CNS drug set. For CNS delivery, they concluded that drugs should ideally have an in vitro passive permeability >150 nm/s and not be a good (b-a/a-b ratio <2.5) Pgp substrate.

CRITICAL ASSESSMENT OF THE METHOD

The MDR1-MDCK transport assay was evaluated by Polli et al. (2001). The scientist compared the Pgp transport assay with the calcein-AM and ATPase assays. They tested 66 compounds and yielded two categories of compounds. Category I (n = 35) exhibited concordance across the assays. Category II (n = 31) revealed differences among the assays that related to the apparent permeability (P_{app}) of the compounds. Within category II, two groups are discerned based on the absence (group IIA, nontransported substrates) or presence (group IIB, transported substrates) of monolayer efflux. Detection of efflux (group IIB) is associated with compounds having low/moderate P_{app} values (mean = 16.6 nm/s), whereas inability to detect efflux (group IIA) is associated with compounds having high P_{app} values (mean = 535 nm/s). The calcein-AM and ATPase assays revealed Pgp interactions for highly permeable group IIA compounds but are less responsive than monolayer efflux for low/moderate P_{app} compounds of group IIB. All assays detect substrates across a broad range of P_{app}, but the efflux assay is more prone to fail at high P_{app}, whereas the calcein-AM and ATPase assays are more prone to fail at low P_{app}. When P_{app} is low, efflux is a greater factor in the disposition of Pgp substrates. The MDR1-MDCK assay is more reliable at low/moderate P_{app} and is therefore the method of choice for evaluating drug candidates despite its much lower throughput and more complicated read out.

However, the user needs to take into account that MDCK cells are derived from kidney. Thus, kidney-specific transporters are expressed which do not play any role at the BBB. Furthermore, membrane composition is distinct in epithelial cell type (MDCK) and endothelial cells lining the brain capillaries influencing membrane partitioning of drug candidates.

MODIFICATION OF THE METHOD

To confirm that drugs are Pgp substrates, drugs can also be tested in the presence of a specific Pgp inhibitor, for example, 2 μM GF120918 (Polli et al. 2001). Inclusion of a Pgp inhibitor reduces the b-a/a-b ratio to ~1 for Pgp substrates.

Polli JW, Wring SA, Humphreys JE, Huang L, Morgan JB, Webster LO, Serabjit-Singh CS (2001) Rational use of in vitro P-glycoprotein assays in drug discovery. J Pharmacol Exp Ther 299:620–628

EXAMPLES

As written earlier, Mahar Doan et al. (2002) demonstrated in a very convincing paper the use of MDCK-MDR1 cell line to classify CNS and non-CNS drugs. They investigated 93 drugs and found that a drug should ideally have an in vitro passive permeability >150 nm/s and not be a good (B-A/A-B ratio < 2.5) Pgp substrate for CNS delivery. Together with physical chemical properties like molecular weight, solute McGowen volume, solute dipolarity/polarizability, hydrogen bond acidity and basiscity, and charges and number of aromatic rings, a good prediction of a drugs permeability into the CNS should be possible. In 2004 (Gombar et al. 2004), they published a first quantitative structure–activity relationship (QSAR) model predicting Pgp substrates that takes into account the ability to partition into membranes, molecular bulk, and the counts and electrotopological values of certain isolated and bonded hydrides. The training set consisted of 95 compounds classified as substrates or nonsubstrates based on the results from MDR1-MDCK efflux assays (Mahar Doan et al. 2002). The model fit the data with sensitivity of 100% and specificity of 91% in the jackknifed cross-validation test. A prediction accuracy of 86% was obtained on a test set of 58 compounds.

36.2 Drug Uptake by SLC Transporters

36.2.1 Drug Transport Mediated by SLC Transporters Using Eukaryotic Cells

PURPOSE AND RATIONALE

Endogenous compounds like bilirubin, bile salts, steroid conjugates, thyroid hormones, prostaglandins, purine metabolites, as well as pharmaceutical drugs are taken up from the blood into the liver and into kidney proximal tubule epithelia in order to be eliminated from the body. In the liver, several compounds are metabolized and excreted into bile or through the sinusoidal membrane of the hepatocytes back into the blood for renal elimination. Hepatic uptake transporters like OATP1B1, OATP1B3, OATP2B1, OAT2, OCT1, and NTCP are involved in liver uptake processes, while MATE1 is involved in the canalicular secretion of several substrates. The renal elimination is mediated by the basolateral uptake transporters OAT1, OAT2, OAT3, OCT2, and OATP4C1 and luminal secretion into primary urine by OAT4, MATE1, and MATE2.

Eukaryotic cell lines expressing single uptake transporters at high expression levels are convenient to study uptake of endogenous compounds or pharmaceutical drugs.

PROCEDURE

36.2.1.1 Cell Culture and Cell Lines

HEK293 (human embryonic kidney) cells are cultured in minimum essential medium supplemented with 10% fetal bovine serum, 100 U/ml penicillin, and 100 μg/ml streptomycin at 37°C, 95% humidity, and 5% CO_2.

HEK293 cells can be stably transfected by the polybrene (hexadimethrine bromide) method (Brewer 1994) or by using the Flp-In expression system (Invitrogen). Briefly, exponential growing Flp-In HEK293 cells are incubated in a 6-well plate with 0.35 μg expression vector containing the transporter gene, 3 μg pOG44 vector (Ratio 1:9), and with 10 μl Lipofectamine in serum-free medium for 5 h under normal culture conditions. Then, cells are grown overnight in fresh medium and transferred to a 10-cm petri dish before starting selection with G418 or hygromycin, depending on the expression vector. After 2–3 weeks of antibiotic selection, single colonies can be transferred into 96-well plates and cultivated for verification.

36.2.1.2 Uptake Studies in Cell Monolayers

For uptake experiments according to Bakhiya et al. (2006), cells are seeded in 24-well plates (coated with 0.1 mg/ml poly-D-lysine) at a density of 2×10^5 cells/well in cell culture medium. Experiments will be conducted 2–3 days after cell seeding. Before starting the uptake experiments, cells are washed with an appropriate uptake buffer, for example, HBSS solution (130 mM NaCl, 4 mM KCl, 1 mM NaH_2PO_4, 1 mM $MgSO_4$, 1 mM $CaCl_2$, 18 mM glucose, and 20 mM HEPES, pH 7.4). The uptake assay is performed at 37°C and is started by the addition of 200 μl uptake buffer containing ^3H- or ^{14}C-labeled substrate to the cells. Unlabeled substrate is added to give the desired final concentration. For inhibition studies, inhibitors are included in the uptake buffer. For termination of the transport, solution is sucked off, and 0.5 ml ice-cold PBS buffer is immediately added into the wells. Cells are subsequently washed three times with PBS buffer, lysed with 0.5 ml of 1 N NaOH, and neutralized with 0.5 ml of 1 N HCl. The ^3H or ^{14}C content is assayed by liquid scintillation counting. The net uptake rates are calculated by subtracting values obtained with HEK cells from those obtained with transporter transfected HEK cells.

EVALUATION

36.2.1.3 Verification of the Test System

- Stably transfected cell line: Expression should be verified by immunoblotting and/or immunofluorescence microscopy and/or on mRNA level by real time PCR.
- At least 1.5-fold uptake of a substrate in stably transfected compared to empty vector cells.
- Time dependency experiments with time points between 0.5 and 30 min help to find the optimal time point, which is in the linear range of the time curve.
- Determination of K_m values of well-known substrates.
- Inhibition studies with known inhibitors (IC_{50} values).
- Protein concentrations are determined by using standard protocols like the Bradford method.

36.2.1.4 Procedure for Analyses of a Test Compound

See Fig. 36.1.

CRITICAL ASSESSMENT OF THE METHOD

Advantages

- The eukaryotic cell lines expressing single uptake transporters at high expression levels.
- Low background activity.
- High-throughput screening.
- Radioactive-labeled substrates are preferred for uptake assays because of the high sensitivity and easy quantification.
- Opportunity for multiple transfection of cells (see Sect. 36.4.1).

Disadvantages

- Direct comparison to in vivo data is difficult.

MODIFICATION OF THE METHOD

- Uptake experiments are also performed in other plate formats, for example, 96-well or 6-well plates. The seeding density is depending on the plate format and the time point of experiment (1–3 days after seeding).
- Alternatively, CHO (Chinese hamster ovarian) cells can be used instead of HEK293 cells.
- Another possibility with lower sensitivity and variety of substrates is the measurement of fluorescent substrates like 6-carboxyfluorescein (which is a substrate for OATs) or the time-consuming analyses by LC/MS.
- Services for interaction studies with uptake transporters are offered by PortaCellTec biosciences (www.portacelltec.de).

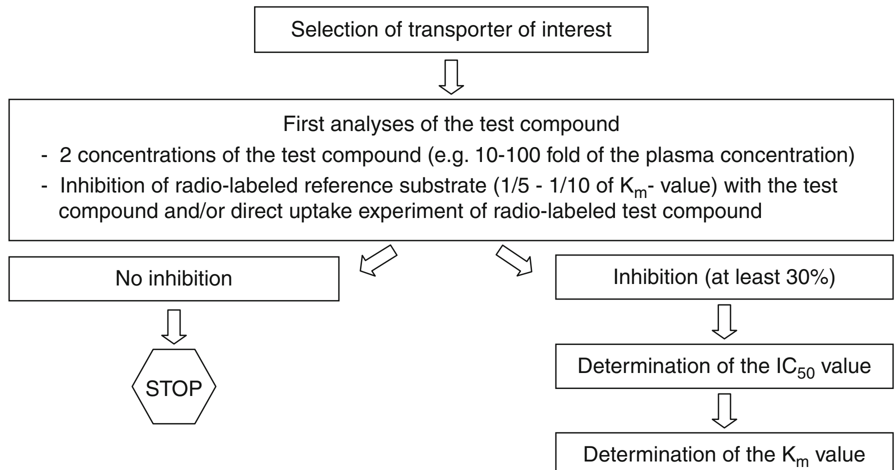

Fig. 36.1 Procedure for analysis of a test compound

36.2.1.5 Uptake in Suspension Cells

Due to high background binding of some radiolabeled substrates (e.g., ^{3}H-bilirubin) to poly-D-lysine-coated plastic dishes, uptake of these compounds into transfected cells is measured in cell suspension (Cui et al. 2001). For uptake assays, cells are detached from culture flasks by knocking, washed twice with uptake buffer, and resuspended in uptake buffer at a density of 3×10^6 cells/ml. ^{3}H-Bilirubin is diluted with human serum albumin in uptake buffer (75,000–100,000 dpm/ml). Unlabeled bilirubin is added to give the desired final concentrations. Uptake is started by mixing 1 ml of cell suspension with 1 ml bilirubin/albumin solution to give a final radioactivity of 37,500–50,000 dm/ml and stopped at different time points by centrifugation of the mixture at 13,000 rpm for 10 s. Cell pellets are washed twice with 1 ml of uptake buffer containing HSA and lysed in 2 ml of 0.2% SDS in water. Aliquots (300 µl) of the lysate are counted for radioactivity. To determine the nonspecific binding of ^{3}H-bilirubin, cells are incubated with ^{3}H-bilirubin in the presence of HSA for 1 min at 4°C. Cell-associated radioactivity measured under these conditions is used as a blank and subtracted from all other values.

36.2.1.6 Uptake in Hepatocytes by Silicon Oil Technique

According to Sugiyama 2008 for uptake assays, hepatocytes are diluted with ice-cold Krebs-Henseleit buffer at a concentration of 1–2 $\times 10^6$ viable cells/ml.

Glass round-bottom centrifuge tubes are prechilled at 4°C, and 160 µl of cell suspension is added to each tube. The cell suspension is warmed in a water bath at 37°C for 3 min. To initiate cellular uptake, 160 µl substrate solution (37°C) is added to the cell suspension. When cells are sampled at 30 s, 2 min, and 5 min, an aliquot of 80 µl of the hepatocyte suspension is obtained at each time point and loaded into a sampling tube containing 100 µl of the oil mixture (46.8 g silicon oil (Sigma-Aldrich) and 8.6 g mineral oil (Sigma); final density: 1.015) and 50 µl 2 N NaOH to separate the hepatocytes from the incubation medium. The sampling tube is then centrifuged at $10{,}000 \times g$ for 10 s using a benchtop centrifuge. During the process, hepatocytes pass through the oil layer into alkaline solution, and the incubation medium remains above the oil layer. After centrifugation, the sample tube is incubated overnight at room temperature to enable complete lyses of the cells in NaOH phase. The sampling tube is (alternatively, after freezing) cut at the middle of the oil layer, and the upper and lower phases are transferred in two separate scintillation vials. The lower phase containing the lysed cells are neutralized with 50 µl of 2 N HCl. Radioactivity is measured using liquid scintillation counting.

J Pharmacol Exp Ther 311:228–236

EXAMPLES

36.2.2 Example for OATs

The OATs play an important role in the secretion of several loop diuretics (e.g., torasemide). Torasemide and its metabolite are secreted through the sinusoidal membrane of the hepatocytes into the blood. The renal elimination is mediated by active uptake from the blood by OAT1 and OAT3 into proximal tubule cells followed by an OAT4-mediated efflux into the primary urine. In stably transfected HEK293 cells, Hagos et al. (2007) determined K_i values for torasemide and its metabolites using [^{3}H] PAH and [^{3}H] estrone sulfate as substrates. For example, the K_i values for torasemide were determined by Dixon plot analyses with 55 μM for OAT1, 90 μM for OAT3, and 47 μM for OAT4.

36.2.3 Example for OATPs

Coadministration of statins and fibrates is associated with an increased risk for myopathy, which may be due in part to a pharmacokinetic interaction. In case of the drug–drug interaction between cerivastatin and gemfibrozil, involvement of both metabolism and transporters is discussed. Shitara et al. (2004) have presented the interaction of gemfibrozil and gemfibrozil-glucuronide on the ^{14}C-cerivastatin uptake by the liver-specific OATP1B1 (OATP2) uptake transporter. Using transfected MDCK cells, they showed that gemfibrozil and gemfibrozil-glucuronide significantly inhibited the OATP1B1-mediated uptake of cerivastatin with IC_{50} values of 72 and 24 μM, respectively. These IC_{50} values of gemfibrozil and gemfibrozil-glucuronide were lower than their total plasma concentrations. However, because of the high plasma protein binding, the unbound concentrations of gemfibrozil and gemfibrozil-glucuronide were at most 0.97 and 2.3 μM, respectively, that is, less than the IC_{50} values obtained in the presented study. Because only unbound drugs interact with transporters, these results suggest that it is unlikely to cause the reported serious drug–drug interaction between cerivastatin and gemfibrozil. However, it is likely that gemfibrozil or its glucuronide inhibits the metabolism of cerivastatin in the liver because they are actively transported to the liver and accumulate there (Sallustio et al. 1996). The estimated unbound concentration in the liver of gemfibrozil-glucuronide is about 90 μM (Shitara et al. 2004).

36.2.4 Drug Transport Mediated by SLC Transporters Using *Xenopus laevis* Oocytes

PURPOSE AND RATIONALE

Transporters of the SLC family are responsible for the uptake of endogenous compounds or pharmaceutical drugs into the liver and kidney. To study liver- or kidney-specific uptake of such compounds, oocytes expressing single uptake transporters at a very high expression level are a widely used technology. The large size (~1 mm) of the oocytes facilitates the injection of cRNA, which is translated efficiently and results in a high number of transporters in the plasma membrane.

PROCEDURE

Xenopus laevis frogs can be purchased from different suppliers, for example, Nasco (www.enasco.com) or Xenopus Express (www.xenopus.com).

The procedure described is based on the references Vavricka et al. (2002), Hagenbuch et al. (1990), and Kullak-Ublick et al. (1995). In vitro synthesis of SLC transporter complementary RNA (cRNA) can be performed according to Kullak-Ublick et al. (1995) using T7 RNA polymerase (alternatively: T3 or SP6;

Promega Corp, Madison, WI). *Xenopus laevis* oocytes are prepared according to Hagenbuch et al. (1990): Frogs are anesthetized by immersion for 15 min in a 0.17% solution of ethyl m-aminobenzoate (MS-222). Oocytes are removed (Colman 1984) and incubated at room temperature for 3 h in Ca^{2+}-free OR-2 solution (82 mM NaCl, 2.5 mM KCl, 1.0 mM $MgCl_2$, 5 mM HEPES, pH 7.6) supplemented with 2 mg/ml collagenase (Sigma type I) and 10 units/ml penicillin and 10 μg/ml streptomycin. They are then washed in modified Barth's solution consisting of 88 mM NaCl, 1 mM KCl, 2.4 mM $NaHCO_3$, 15 mM HEPES-NaOH (pH 7.6), 0.3 mM $Ca(NO_3)_2 \times 4H_2O$, 0.41 mM $CaCl_2 \times 6H_2O$, and 0.82 mM $MgSO_4 \times 7H_2O$ and containing 10 units/ml penicillin and 10 μg/ml streptomycin. Stage V and VI oocytes are selected. After an overnight incubation at 18°C modified Barth's solution, healthy oocytes are injected with 5 up to 23 ng of cRNA, cultured for 3 days in a medium containing 88 mM NaCl, 2.4 mM $NaHCO_3$, 1 mM KCl, 0.3 mM $Ca(NO_3)_2$, 0.41 mM $CaCl_2$, 0.82 mM $MgSO_4$, 0.05 mg/ml gentamicin, and 15 mM HEPES (pH 7.6) and washed once with sodium-free buffer consisting of 100 mM choline chloride, 2 mM KCl, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 10 mM HEPES (pH 7.5), trace amounts of radiolabeled substrate ^{3}H-BSP or ^{3}H-rifampicin, and appropriated substrate and inhibitor concentrations. Water-injected oocytes are used as controls for unspecific substrate uptake. After an incubation period of 20 min, the uptake experiment is stopped by adding 6 ml of ice-cold solution consisting of sodium-free choline buffer and 1 mM unlabeled substrate. Oocytes are washed twice with 6 ml ice-cold stop solution. Each oocyte is dissolved in 0.5 ml of 10% sodium dodecyl sulfate and 5 ml scintillation fluid, and the oocyte associated radioactivity is determined.

EVALUATION
