Diseases Spread by Food and Water

Typhoid Fever

Pavani Kalluri Ram • Eric D. Mintz

Typhoid fever is an acute, life-threatening, febrile illness caused by the bacterium *Salmonella* subspecies *enterica* serotype Typhi. Because humans are the only known natural host for *Salmonella* Typhi, fecal-oral transmission through contaminated food and water is the most common mode of infection. In the United States, about 300 cases are reported each year, and the majority of these are acquired while traveling internationally.^{1,2,3}

Bacteriology

Salmonella Typhi, like other *Salmonella*, is a gram-negative, flagellated, non-lactose-fermenting bacillus. It is identified by its biochemical properties and somatic (O) and flagellar (H) antigens. Most freshly isolated strains have a capsular (Vi) antigen.⁴ In the Kauffman-White schema, *Salmonella* Typhi is a member of *Salmonella* group D, characterized by O antigens 9 and 12, and a single flagellar antigen (H). The organism survives well in water and sewage, but is readily killed by pasteurization.⁵

In studies of volunteers, ingesting as few as 10⁵ bacteria has caused clinical illness in a few, and ingestion of 10⁶ organisms results in 50% of subjects becoming ill.⁷ Incubation periods have been as short as 3 days and as long as 56 days; a higher inoculum is associated with shorter incubation periods. The median incubation period for a dose of 10⁵ organisms was 9 days, for 10⁶ organisms 7 days, and for 10⁸ organisms 5 days.⁷ Partial immunity follows clinical illness, but reinfection and illness can still occur after a large oral dose. Antibody titers are not correlated with resistance to reinfection or occurrence of relapse.

Clinical Characteristics

Typhoid fever has an insidious onset characterized by fever, headache, constipation, malaise, chills, and myalgia.^{4,5} Many patients cough for the first few days of illness, and some report sore throat or joint pain. Splenomegaly, leukopenia, and abdominal distention and tenderness

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

are generally present. Early in the illness, small, discrete, rose-colored spots caused by bacterial emboli in the skin capillaries may appear on the trunk. Diarrhea is uncommon, and vomiting is not usually severe. In children, the disease presentation is often atypical, and respiratory symptoms and diarrhea are often present.⁶ Complications of typhoid fever include confusion, delirium, intestinal perforation, and death. Chronic carriage of *Salmonella* Typhi, defined as fecal shedding of the organism for greater than one year after acute illness, occurs in 1–4% of patients.^{5,9}

Diagnosis

The most commonly used methods of diagnosis are blood culture and serologic assays. The sensitivity of a single blood culture has been estimated at about 50%.⁸ *Salmonella* Typhi is most frequently isolated from blood during the first week of illness, but it can also be isolated during the second and third weeks of illness, during the first week of antimicrobial therapy, and during clinical relapse. Fecal cultures are positive in approximately half the cases during the first week of fever, but the largest number of positive stool cultures is detected during the second and third weeks of disease. Bone marrow cultures are frequently positive (90% of cases) and are more likely to yield *Salmonella* Typhi than are cultures from any other site, especially when the patient has already received antimicrobial therapy.⁸ Organisms can also be isolated from duodenal aspirates, rose spots, and infrequently from urine cultures.^{8,10}

Serologic responses to O, H, and Vi antigens usually occur by the end of the first week of typhoid fever. The Widal test, which measures antibody responses to O and H antigens, can suggest the diagnosis, but the results are not definitive and must be interpreted with care since titers may be elevated in a number of other infections. High-titer, single-serum specimens from adults in areas of endemic disease have little diagnostic value. Even when paired sera are used, the results must be interpreted in light of the patient's history of typhoid immunization and previous illness, the stage of the illness when the first serum specimen was obtained, the use of early antimicrobial therapy, and the reagents used.¹¹ Several rapid serodiagnostic assays are commercially available; their cost limits their utility in typhoid-endemic areas.¹² Serodiagnostic methods may facilitate initial clinical management

of patients with suspected typhoid fever; however, they do not allow for examination of antimicrobial resistance patterns since the pathogen is not isolated.

Treatment

Effective antimicrobial therapy reduces morbidity and mortality from typhoid fever. Without therapy, the acute illness may last for 3–4 weeks and death rates range between 12% and 30%.^{5,10} With appropriate treatment, clinical symptoms subside within two days and fever recedes within five days. In the United States, mortality is approximately 1%.^{2,3} Relapses, characterized by a less severe but otherwise typical illness, occur in 10–20% of patients with typhoid fever, usually after an afebrile period of 1–2 weeks. Relapses may occur despite appropriate antimicrobial therapy.⁵

Complications of typhoid fever are less likely if effective antimicrobial therapy is begun early. Organisms resistant to antimicrobial agents, including amoxicillin, trimethoprim-sulfamethoxazole, and chloramphenicol, have increasingly been reported from numerous countries, including the United States.^{2,13,16} Determining antimicrobial resistance patterns is essential in recommending appropriate treatment. Fluoroquinolones and third-generation cephalosporins remain the best choice for empiric treatment of typhoid fever, although quinolone resistance is on the rise, particularly in strains circulating in South and Southeast Asia.^{14–17}

Carriers

Following treated or untreated infection, carriage of *Salmonella* Typhi in the stool often persists for 1–2 months. The likelihood of a chronic carrier state is related to age at onset of disease and gender, and ultimately to predisposing conditions such as gall bladder disease. Women are three times more likely than men to become chronic carriers. Chronic carriage (13.3%) is more common among women whose illness occurs when they are over 40 years of age, in contrast to men or women whose illness occurs when they are under 20 years of age (0.3%).⁸ Antimicrobial treatment of typhoid fever may not significantly decrease the occurrence of chronic fecal carriage. Chronic carriers are at risk for cancer of the gall bladder, and therefore termination of the carrier state through antimicrobial therapy is recommended for clinical and public health reasons.^{18,19} Urinary excretion is common in the first months after illness, but chronic urinary carriage is usually associated with preexisting pathologic changes in the kidneys or bladder, such as occur in patients with schistosomiasis and in the elderly.

Antibody to the Vi antigen is often present in high titers in serum samples from persons who are chronic carriers and can be used as a screening test for identification of chronic carriers in certain high-risk groups and during investigation of sporadic cases and outbreaks.^{20–23}

Elimination of a chronic carrier state is achievable in most cases with fluoroquinolone therapy.²⁴ Cure rates between 78% and 93% have been reported in four small series of between 10 and 23 chronic carriers who received 2–4 weeks of oral fluoroquinolone treatment.²⁴

In some patients with chronic gallbladder or urinary tract disease, antimicrobial agents alone may be ineffective, and surgery may be necessary.

Occurrence

Typhoid fever occurs worldwide but incidence varies widely according to geographic region, seasonality, and vehicles of infection. An estimated 21 million cases of typhoid fever and 200,000 deaths occur annually worldwide.²⁵ The annual incidence in high-burden areas, such as South and Southeast Asia, is estimated to be greater than 100 cases per 100,000 persons.²⁵ Recent population-based incidence data from India demonstrate that children under age five years are at increased risk for typhoid fever, when compared with school-aged children and adults.²⁶

Transmission

Since *Salmonella* Typhi has no known animal reservoir other than humans, isolated cases and outbreaks must originate from a human infection. Most typhoid outbreaks are traced to ingestion of food or water contaminated with human waste. Poorly functioning municipal water supply systems have been efficient vehicles of typhoid fever transmission and continue to contribute to large outbreaks of typhoid fever in urban areas.^{27,28} Studies of endemic typhoid fever transmission have implicated street-vended foods and raw or poorly cooked shellfish.^{29,30}

In the United States, about 75% of typhoid fever cases occur among persons returning from foreign travel, particularly to South and Southeast Asia, Africa, and Latin America.³ Occasionally, large foodborne outbreaks occur in the United States, frequently due to contamination by asymptomatic food handlers who are chronic carriers, and sometimes to imported food.^{31–33}

Prevention

Vaccines against typhoid fever have been available for more than 80 years.³⁴ Studies of volunteers have shown that vaccine-induced immunity is protective (65–70% effective) against low-to-moderate infecting doses but, like natural immunity, it provides little protection against very large challenge doses.⁷ Two vaccines are licensed for use in the United States (Table 13-1). The oral vaccine, a live, attenuated *Salmonella* Typhi strain (Ty21a), which lacks the enzyme UDP-galactose-4-epimerase23, and the single-dose parenteral vaccine (ViCPS), a polysaccharide formula based on purified Vi antigen, are equally effective and rarely cause adverse reactions.^{3,35}

The inactivated typhoid vaccine, a parenteral formulation manufactured by Wyeth Ayerst, has been discontinued and is no longer available in the United States.

Microbiology laboratory workers are at risk for typhoid fever and should be vaccinated if they anticipate contact with specimens from patients with typhoid fever or with isolates of *Salmonella* Typhi.

TABLE 13-1. TYPHOID FEVER VACCINATION

Vaccine Name	How Given	Number of Doses Necessary	Time Between Doses	Total Time Needed to Set Aside for Vaccination	Minimum Age for Vaccination	Booster Needed Every
Ty21a (Vivotif Bema, Swiss Serum and Vaccine Institute)	1 capsule by mouth	4	48 hours	2 weeks	6 years	5 years
ViCPS (Typhim Vi, Sanofi Pasteur MSD)	Injection	1	—	1 week	2 years	2 years

Travel-associated typhoid fever is largely preventable. Vaccination against typhoid fever is recommended for travelers visiting countries with endemic disease.³⁵ Travelers are also encouraged to take routine precautions in selecting and preparing foods and beverages: cooked foods should be eaten hot, raw fruits and vegetables should be peeled by the traveler, and only low-risk beverages should be consumed, such as hot drinks, carbonated beverages without ice, and water that has been boiled or chemically disinfected.

Shigellosis

Anna Bowen • Eric D. Mintz

Shigella is the third most common bacterial etiology of diarrhea in the United States, causing more than 163 million cases of diarrhea in developing countries each year.^{1,2} “Bacillary dysentery,” a term used to describe a diarrheal illness with fever, abdominal pain, and blood and pus (leukocytes) in the stool, is often used to refer to shigellosis. Lack of safe piped water and sewage disposal, poor personal hygiene, and crowding underlie epidemics of dysentery caused by *Shigella* species. Although improvements in water and sewage infrastructure have reduced the risk for epidemic shigellosis in the United States, outbreaks continue to occur among young children in daycare, people in the military, displaced persons, and crowded urban and rural poor populations, and sporadic disease is not uncommon.²

Bacteriology

The shigellae are a fairly homogeneous group of aerobic, nonmotile, non-lactose-fermenting, gram-negative bacilli. The four major *Shigella* subgroups are differentiated by their ability to ferment D-mannitol and their antigenic properties. *Shigella dysenteriae* (group A) has 15 serotypes; type 1 (the Shiga bacillus) remains a cause of epidemic severe dysentery in the developing world. *Shigella flexneri* (group B) has 8 serotypes, some of which are subdivided. *Shigella boydii* (group C) is divided into 20 serotypes, and *Shigella sonnei* (group D) has only 1 serotype. New serotypes continue to be identified.

A number of factors contribute to *Shigella* virulence. For example, the shigellae do not bind to host cells efficiently. However, after they are engulfed by intestinal macrophages and dendritic cells, they can lyse phagocytic vacuoles and spread intra- and intercellularly.³ Also, Shiga toxin-producing genes are encoded in a highly conserved defective lambdoid prophage in the chromosome of *S. dysenteriae* type 1 and rarely, that of *S. sonnei*.⁴ Thirdly, Shiga toxins appear to be associated with the development of hemolytic uremic syndrome and central nervous system complications. Finally, *Shigella* can easily acquire antibiotic resistance genes through plasmids, transposons, or clonal spread. This, in combination with antibiotic misuse, has resulted in a dramatic increase in antimicrobial resistance in recent years. Resistance of *Shigella* to ampicillin, tetracycline, and trimethoprim-sulfamethoxazole has been reported worldwide; ciprofloxacin resistance is also becoming increasingly important.^{5–8} In the United States, *Shigella* isolates remain sensitive to nalidixic acid, ciprofloxacin, and ceftriaxone despite rising resistance to other antimicrobials.⁹

Clinical Characteristics

Although asymptomatic infection is possible, shigellosis often begins with fever, abdominal pain, and watery diarrhea without blood. At

As noted in industrialized countries in the early twentieth century, dramatic reductions in typhoid fever incidence can be accomplished with the implementation and maintenance of chlorinated municipal water supplies and sanitation with sewage collection and treatment.^{36,37} Providing these basic services to the underserved population of 1–2 billion people would be a major step towards the eradication of this disease.³⁸

this stage, the diarrhea is difficult to distinguish from that caused by other agents. Following invasion of the colonic mucosa, stools often become bloody, mucoid, and scant. Large bowel microabscesses and ulcers may form, and the patient may suffer from urgency and tenesmus. Infection with *S. sonnei* typically causes milder illness than infection with the other *Shigella* subgroups; illness associated with *S. dysenteriae* type 1 is often severe. The usual incubation period is about 48 hours, but it ranges from less than 12 hours to 6 days. Symptoms generally last 1 week. Case fatality rates vary from 0.4% among all ages in the United States, to 13.9% among infants hospitalized in the developing world; overall, children under the age of five years suffer the greatest mortality rates.^{2,10} Prolonged carriage is uncommon in healthy people, but carriage for more than one year has been reported.¹¹ With each subsequent infection by the same serotype, clinical illness becomes milder or absent, perhaps because of local gut immunity.

Extraintestinal manifestations of *Shigella* infections, although rare, also can be important. Convulsions may occur in children, often in association with fever or metabolic derangements.^{12–14} Reactive arthritis is a late complication of between 1.5% and 7% of adults with *Shigella* infection.^{15–17} It may be associated with *S. flexneri*, *S. sonnei*, or *S. dysenteriae*, and is especially common among persons with the genetic marker HLA-B27.^{17–19} Hemolytic uremic syndrome can occur after *S. dysenteriae* type 1 infection, especially in children, and may be associated with antibiotic treatment of a resistant infection.^{20–22}

Diagnosis and Treatment

Isolation of *Shigella* organisms from the blood is rare. However, many *Shigella* organisms are present in the intestinal mucus or feces during the first several days of the illness. When feces are alkaline, the bacilli may survive for days, whereas in acidic stools they remain viable for only a few hours. Therefore, if direct inoculation of culture media is not possible, placing fecal material or rectal swabs in Cary-Blair transport medium is suggested. The organism is isolated on routine enteric media; so-called “*Salmonella-Shigella*” agar is actually inhibitory to some *Shigellae*.²³ Commercially available antisera may be used for grouping and typing.

Without a positive culture, diagnosis is often difficult. In a study of Bolivian children, crying during defecation, temperature above 38.4°C, five or more stools per 24 hours, and more than 50 leukocytes per high-power field on microscopic fecal examination were associated with *Shigella* infection.²⁴

Treatment with appropriate antimicrobial agents reduces the duration of symptoms and the excretion of shigellae.^{25–27} However, the high prevalence of antibiotic resistance complicates selection of antimicrobial treatments. Monitoring local antimicrobial resistance

patterns in a community with endemic disease can help guide the selection of effective agents with which to begin therapy. Although the World Health Organization recommends ciprofloxacin as a first-line agent in the treatment of *Shigella* among all age groups, the drug is not currently labeled for this use in children in the United States.^{28,29} Further, it remains unclear whether there exists an association between antimicrobial treatment and hemolytic uremic syndrome among persons infected with Shiga toxin-producing organisms.^{22,30} Since the illness caused by *S. sonnei*, the predominant strain in the United States, is often mild and self-limited, reserving antimicrobial treatment for very ill and high-risk persons may delay the emergence of resistant strains and reduce medication adverse events.³¹

Transmission

The primary reservoir for *Shigella* organisms is humans, although *Shigellae* occasionally infect other primates. A small inoculum (10–200 organisms) is sufficient to cause infection.³² As a result, approximately 80% of *Shigella* infections occur through person-to-person spread.³³ Persons who excrete the organism asymptotically are less likely than clinically ill persons to transmit infection.³⁴ Shigellosis outbreaks in day care centers, which are the most common setting for outbreaks in the United States, may be associated with preparation of food by workers who also changed diapers, provision of group transportation to young children, access to non-chlorinated water play areas,³⁷ and high child-to-toilet ratios.³⁵ Secondary attack rates are high in homes of preschool children with clinical shigellosis.^{36,37} Other groups with an increased risk of shigellosis in the United States include persons in custodial institutions, where personal hygiene is difficult to maintain;^{27,38} observant Jews;^{2,39} travelers;⁴⁰ homosexual men;^{41,42} and those in homes with inadequate water for handwashing. Although Native Americans historically have suffered elevated rates of shigellosis, this pattern appears to be changing.^{1,43}

Outbreaks are infrequently caused by contaminated food.^{44,45} However, large-scale outbreaks associated with ill food handlers have occurred.^{46–48} Drinking or swimming in contaminated water has also led to outbreaks.^{49,50}

Occurrence

In the United States, shigellosis is becoming less common. In 2003, there were four cases of *Shigella* infection per 100,000 persons, 47% less than a decade earlier.^{1,51} The relative proportions of isolates due to *S. sonnei*, *S. flexneri*, *S. boydii*, and *S. dysenteriae* were 80.2%, 14.4%, 1.1%, and 0.4% in 2003; the remaining 4% of isolates were of unknown subgroup.⁵¹ The highest attack rates are among children 1–4 years of age, with a peak in 2-year-olds. Nearly all infections in

the preschool age group are due to *S. sonnei*.⁵¹ More *Shigella* infections occur among females than males between ages 10 to 29 and 60 to 79 years. The excess cases are mainly due to *S. sonnei*, perhaps because women are more likely to be primary caretakers of young children at these ages. Meanwhile, a greater number of *Shigella* infections occur in men between the ages of 30 and 49 years; the excess cases are predominantly due to *S. flexneri*, and may be the result of adult male homosexual practices.^{41,51} Infections with *S. dysenteriae* in the United States generally result from importation of this infection by adults returning from overseas travel.⁴⁰ Infections with all four *Shigella* subgroups are most common in the late summer.^{1,51}

In developing areas of the world, however, the epidemiology of *Shigella* differs. There, the predominant subgroup is *S. flexneri* (60%), followed by *S. sonnei* (15%), *S. dysenteriae* (6%), and *S. boydii* (6%), and the seasonality of *Shigella* infection varies.² Epidemics of multiply drug-resistant *S. dysenteriae* type 1 infections with considerable mortality may also occur in developing areas, most notably in recent years in Africa.^{31,52–54}

Prevention and Control

Shigella infections are least common in communities and institutions where treated water is readily available and used frequently for hand washing and where an adequate system exists for disposal of human wastes. Hand washing is an effective control measure even in areas with poor sanitation.⁵⁵ Protected food supplies and adequate refrigeration are important for reducing the risk of common source infection. Efforts to develop *Shigella* vaccines have been complicated by the vast number of antigenically distinct serotypes.^{2,8,56}

Once begun, outbreaks of shigellosis are difficult to control.^{57,58} Interrupting the fecal-oral transmission cycle is the key objective, and hand washing with soap and running water is the most effective intervention.^{35,55} Additionally, efforts have included isolation of patients, improved sanitation, antimicrobial treatment of ill persons and occasionally those with asymptomatic infection, and, rarely, prophylactic treatment of all members of a household or closed institution. Cohorting persons who no longer have diarrhea in a separate room with a separate toilet and dedicated staff could be a key element in controlling day care and institutional outbreaks.²⁷ This practice is preferable to barring clinically recovered but still infectious children from the day care center because it does not encourage parents to send their children to other facilities without reporting the antecedent infection.⁵⁸ Attempts to control outbreaks with antimicrobial agents may be compromised, particularly among children, by the development of antimicrobial-resistant strains. Therefore, control of outbreaks requires unflagging insistence on handwashing—with supervision, if required.

Cholera

Margaret Kosek • Robert E. Black

Cholera, an acute infection of the small intestine by *Vibrio cholerae*, is manifested as profuse watery diarrhea. It has been known and feared for centuries because of its propensity to occur in epidemics, resulting in high mortality and social disruption.

Agent and Pathogenesis

Vibrio cholerae is a small, curved, motile aerobic gram-negative organism best identified by inoculating stool onto thiosulfate-citrate-bile salts-sucrose (TCBS) agar ideally with pre-enrichment

in alkaline peptone water. On TCBS agar *V. cholerae* are easily recognized as large yellow colonies with slightly raised centers on a blue-green medium. The isolate is classically identified further on the basis of serological, biochemical, hemagglutination and hemolysis reactions, phage-typing, and polymyxin B testing. More recently DNA-based typing strategies have been used in addition to these methods.¹

Vibrio cholerae is classified principally by serogroup based on the somatic O antigen. Although over 150 serogroups exist, only two (1 and 139) have been shown to cause widespread epidemic and

pandemic disease, produce classical cholera toxin (CT), and result in the most severe classical manifestation of disease, cholera gravis. The other *V. cholerae* serogroups—referred to as non-agglutinating *V. cholerae* or non-O1 non-O139 *V. cholerae*—may be isolated from persons with sporadic cases of acute watery diarrhea and even in small diarrhea epidemics,² but they have not occurred in pandemics, they do not produce CT, and these infections rarely if ever result in cholera gravis. Non-O1 non-O139 strains also may rarely cause extraintestinal infections such as cellulitis or sepsis, especially in individuals with preexisting liver disease.

V. cholerae O1 and O139 are further classified into three serotypes—Ogawa, Inaba, and Hikojima—based on three somatic, or O antigens. *V. cholerae* O1, but not O139, can be divided into two biotypes, classical and El Tor. *V. cholerae* O1 and O139 produce CT, a highly potent protein enterotoxin that increases the activity of adenylate cyclase in the intestinal mucosa, resulting in increased levels of cyclic 3', 5' adenosine monophosphate (cAMP). This in turn leads to inhibition of sodium chloride absorption by villus cells and secretion of chloride and bicarbonate by secretory cells in the crypts of Lieberkuhn. The bacteria do not invade or structurally damage the intestinal mucosa.

History

Cholera has probably afflicted humankind since prehistoric times but was not clearly distinguished from other diarrheal illness in ancient medical writings. As a result, the ancestral home of the cholera vibrio is unclear, although Portuguese explorers' descriptions of diarrhea epidemics in India from the late fifteenth century suggest that the Bengal region of India and Bangladesh has been a continuous endemic region for cholera.³

The worldwide spread of cholera began in 1817, and by 1823 the first pandemic of cholera had spread from the Ganges River delta to much of Asia and Africa. During the nineteenth century, cholera repeatedly spread along routes of trade and travel from India to Europe, Africa, and North America. Five periods of pandemic spread occurred before 1900: from 1817 to 1823; from 1826 to 1837; from 1846 to 1862; from 1864 to 1875; and from 1887 to 1896. John Snow's observations on the waterborne transmission of cholera were from the third and fourth pandemics and Robert Koch's accurate description of the cholera bacillus was made during the fifth pandemic. In each country involved, thousands were affected, with case-to-fatality rates often approaching 50%.

The sixth pandemic (1902 to 1923) also involved severe epidemics, especially in Asia, but outbreaks in Africa and Europe were more limited than in previous pandemics, and the Western Hemisphere was not involved. The sixth pandemic and presumably the previous pandemics were due to the classic biotype of *V. cholerae*. This biotype decreased in frequency of isolation in the 1960s and has largely disappeared except in Bangladesh, where it reemerged in epidemic form in 1982.⁴

The seventh pandemic, which still continues, is generally considered to have started in 1961. The causative agent of this pandemic was first isolated in 1905 by Gotchlich from pilgrims returning from Mecca at the El Tor quarantine camp in Egypt. Although this organism was initially considered nonpathogenic, outbreaks of severe disease between 1937 and 1958 confirmed its ability to cause epidemics.⁵ An outbreak caused by *V. cholerae* biotype El Tor in Sulawesi in 1961 was the beginning of the seventh pandemic. From there it quickly spread to Java, Sarawak, Borneo, the Philippines, and most of Southeast Asia. Between 1963 and 1969, this organism continued its spread across the Asian mainland. The El Tor biotype eventually replaced classic *V. cholerae* in Asia. In 1970, the pandemic continued its westward progression and involved the Middle East and the Soviet Union, and resulted in serious outbreaks in Spain, Portugal, and Italy. From 1970 to the present, nearly all countries in Africa have been involved with cholera outbreaks, and there was a recrudescence in 1991 when 20 countries were affected.

North America had no indigenous cases of cholera in this century until a single case was detected in Texas in 1973. In August 1978, a case in Louisiana led to an investigation that ultimately detected infection in 11 persons.⁶ In this outbreak, *V. cholerae* El Tor serotype

Inaba was recovered from sewage and canal water and from crabs, which were implicated as the vehicle of infection. In 1981, cholera was found in two residents of the Gulf Coast of Texas and another 16 persons on an oil rig in the gulf near Texas. Investigations of these outbreaks determined that they were due to the same unique strain of *V. cholerae* that apparently persisted in the environment.⁷ This observation and other evidence have led to the conclusion that cholera is indigenous to the Gulf Coast area of the United States, where the organism has a persistent environmental reservoir. Other than in the United States, no recent cases of cholera were recognized in any country of North, Central, or South America until 1983 when a U.S. tourist apparently became infected with *V. cholerae* while visiting the Caribbean coast of Mexico and developed cholera after returning home. The strain causing this infection was the same as the U.S. Gulf Coast strains, suggesting that the environmental reservoir may also run south around the Gulf of Mexico.⁸ It appears that Australia also has a similar environmental reservoir, in this case freshwater rivers instead of brackish water of the Gulf estuaries, resulting in a small number of cases or small outbreaks.

Latin America was spared from cholera epidemics since the end of the last century until early 1991 when cholera appeared in Peru.⁹ The outbreak, which began in a number of cities along a 900-km coastal area, subsequently spread throughout Peru, with more than a half million cases reported in 1991–1992. The source of the initial contamination is unknown, but subsequent transmission was shown to be related to both water and foods.^{9,10} Cholera spread rapidly throughout Latin America, with Bolivia, Brazil, Colombia, Ecuador, El Salvador, Guatemala, and Mexico each reporting more than 10000 cases between 1991 and 1993.¹¹ In countries other than Peru, where cities were the major focus of the epidemic, rural areas were more affected than urban areas; native cultures appear to have been at especially high risk. Although about 7000 deaths were reported due to cholera between 1991 and 1993, the case-to-fatality rate was less than 1%, probably reflecting the effectiveness of rehydration therapy available in large cities where most cases were reported. Case-to-fatality rates were notably higher, reaching 10% in rural areas in populations with more limited access to adequately trained health-care providers.¹²

All epidemic cholera in previous pandemics had been due to *V. cholerae* serotype O1, although other strains appear to have caused sporadic cases. In October 1992, cases of cholera associated with a *V. cholerae* strain that did not agglutinate with O1 antisera were reported from Madras, India, and subsequently other cities in southern and eastern India and Bangladesh.⁹ This strain, ultimately designated serotype O139, caused epidemic disease throughout Bangladesh, and cases occurred in Malaysia, Nepal, Pakistan, and Thailand. After the initial outbreaks, the rates of disease have decreased in Bangladesh, but the strain persists along with *V. cholerae* O1. Since this outbreak, molecular analysis has clearly demonstrated that serotype O139 arose from the O1 El Tor strain that caused the seventh pandemic following the horizontal transfer of DNA. This transfer resulted in the deletion of a 22 kb DNA fragment which coded for the O1 antigen and its replacement with a DNA segment most likely derived from *V. cholerae* O22.¹³ Regardless of genetic origins, the emergence of cholera O139 has demonstrated the potential for strains other than serotype O1 to cause epidemic cholera.

Ecology of Disease

Over the last few years it has become clear that *V. cholerae*, including the pandemic strains O1 and O139, are able to multiply and maintain stable populations in brackish waters independently of human behavior. Cholera is not likely to be able to be eradicated.

Ecological changes, such as elevated sea-surface temperatures have been shown to be highly associated with the presence of cholera in water samples and seasonal outbreaks and the re-emergence of cholera in Peru¹⁴ and time series analysis of historic data.¹⁵ Biofilms have also shown to have an important role in the environmental stability and perseverance of *V. cholerae* populations.¹⁶ Most interestingly, the equilibrium of *V. cholerae* O1 and O139 and their phages appeared to predict fluctuations in the incidence of cholera over a three-year period in Bangladesh. Periods between epidemics were

characterized by water samples with evidence of phages but no viable *V. cholerae*. The number of viable bacteria and the absence of phages increased during epidemic periods and an increase in phages preceded the end of a transmission period of a phage-sensitive cholera strain.^{17,18} If confirmed, these findings would offer an important explanation for seasonal and temporal changes in the occurrence of cholera cases. The ability to monitor the environment and predict cholera outbreaks has a potentially important role in decreasing disease burden. Reliable prediction strategies would allow for improved timeliness of disease control measures (such as point of source water treatment or reinforcement of quality control measures in municipal water supplies, logistic measures to ensure the availability of adequate amounts of ORS, intravenous fluids, and reinforcement of staff training in non-endemic areas).

Transmission Dynamics

The extent of spread of cholera during the seventh pandemic has been facilitated by human transportation, likely in the ballasts of ships that take up water with *V. cholerae* associated with plankton and copepods in one port and then release it in distant ports as well as with human carriers.

Since the investigations of John Snow and the waterborne epidemic in Hamburg in 1892, water has been considered an important vehicle in the transmission of cholera. Water is probably the primary vehicle of infection in endemic areas such as Bangladesh.¹⁹ Even in this setting, however, the exposures are varied and complex. Epidemiologic studies in rural Bangladesh have failed to demonstrate lower cholera infection rates in persons taking drinking water from bacteriologically safe tube wells than in persons drinking contaminated surface water. This unexpected finding has led to the speculation, supported by several studies, that the protection afforded by drinking better-quality water may be overwhelmed by frequent exposure to polluted surface water through bathing, food preparation, and utensil washing.²⁰ Avoidance of tube well water by children, who have a high incidence of cholera, may also contribute to the apparent lack of protection noted in these areas when such safe drinking water was provided.

In endemic areas, outbreaks can sometimes be related to a common food source. In addition, contaminated foods have been the source of explosive outbreaks in newly infected areas. During the seventh pandemic, careful epidemiologic investigation of outbreaks has frequently led to the identification of a responsible food item. These have included mussels in Italy (1973), salted fish in Guam (1974), raw cockles and commercially bottled water in Portugal (1974), raw shellfish in the Gilbert Islands (1977), and inadequately steamed crabs in Louisiana (1978). Non-seafood items that have been implicated include millet gruel in Mali (1984), leftover cooked rice in Guinea (1986), raw pork in Thailand (1987), and frozen coconut milk in Maryland (1991). In Latin America seafood, cooked rice, raw vegetables and fruit, and street vendor food were implicated in transmission (1991). The commonly implicated shellfish either come from polluted water or are “freshened” with contaminated water before being sold. In arid inland areas of Africa that should be hostile to marine vibrios the organism seems to survive better than predicted. Person-to-person transmission can occur under special circumstances, but are not an important route of transmission as the infectious dose of cholera is very high.

Susceptibility and Immunity

Several biological factors have been shown to modify the incidence and severity of disease following exposure to *V. cholerae*. It has long been noted that patients with achlorhydria (post-gastrectomy or from auto-immune disease) were severely affected with cholera and acquired the disease more frequently than normal hosts. More recently severity of cholera has been linked to *H. pylori* infection with the likely mechanism being the development of hypochlorhydria secondary to chronic atrophic gastritis of the gastric portion (acid-secreting region) of the stomach.²¹ For reasons that remain unclear, the risk of developing severe cholera is much greater in

patients with blood group O. Breast-feeding does not prevent infection but does offer important protection against the development of clinical disease. Prior infection is highly protective²² and there is significant cross-protection between Inaba and Ogawa serotypes with the greatest protection observed when the initial infection is serotype Inaba. Initial infection with El Tor biotypes has a more limited cross-protection.

Lower socioeconomic groups have a higher incidence of cholera for a variety of reasons: (a) occupational exposures (e.g., boatmen in several areas have a high incidence of cholera, probably because they often drink raw river water or eat seafood); (b) unsanitary conditions in low-income housing areas, primarily reflected in inadequate sewage disposal and contaminated water sources; and (c) high population density in low-income areas, increasing the risk of introduction of *V. cholerae* and possibly enhancing transmission of the organism after it has been introduced. Once illness occurs they are also more likely to encounter barriers to care and are at a greater risk of mortality.

Clinical Presentation

The clinical spectrum of cholera is broad, ranging from asymptomatic infection to cholera gravis, which may be fatal in a few hours. The majority of patients are asymptomatic or mildly symptomatic. In patients with moderate to severe disease, the incubation period of 24–48 hours is followed by an abrupt onset of watery, generally painless diarrhea. Vomiting often follows the diarrhea in the early stages of illness.

In severe cases, the loss of diarrheal stool can be extreme and rapidly reach 1 L/hr. The symptoms of severe dehydration seen in cholera gravis can be appreciated from a description written in 1831:

[Its victims] were in a manner stricken down at once, and exhibited more the appearances of a corpse than a living being; with the eyes sunk in the sockets, the skin dark as if from nitrate of silver, the toes and fingers shriveled, and the tendons standing out like rigid cords along the limbs; while the very breath was cold, and the pulse scarcely to be felt.²³ The stool of patients with severe cholera is characteristic. It is a clear nonoffensive, sometimes fishy-smelling, fluid containing flakes of mucus. This characteristic appearance has resulted in the descriptive term “rice water stool.”

The symptoms and signs of cholera are entirely due to the loss of large volumes of isotonic fluid and resultant depletion of intravascular and extracellular fluid, metabolic acidosis, and hypokalemia. In addition to the diarrhea and vomiting, symptoms include lightheadedness, anxiety, thirst, and abdominal and muscle cramps. Signs include cyanosis, tachycardia, hypotension, tachypnea, and loss of skin turgor. In those who survive, the disease subsides spontaneously in 2–7 days. Excretion of the organism may continue for days and occasionally weeks after recovery from the illness; a chronic gallbladder carrier state is rare. The severity of illness caused by classic and El Tor *V. cholerae* differs greatly. In classic cholera, about 60% of infections are inapparent but 20% of infected persons have severe cholera requiring hospitalization. In El Tor cholera, 80% of infections are inapparent and fewer than 3% are severe. This milder disease has important public health implications, because for each severe case many more undetected infections are present in the community.

Treatment

Therapy has improved dramatically during the last 20 years, so that with prompt treatment few persons die of cholera regardless of severity in areas where properly trained medical staff is available. Optimal therapy requires aggressive rehydration therapy, management of electrolyte deficits, and the institution of antibiotic therapy to which the isolate is susceptible. If this treatment is instituted effectively, mortality will be predictably less than 1%.

Underhydration is a frequent error in therapy in centers without experience in the treatment of cholera.²⁴ If possible, patients should be weighed at treatment centers. A severely dehydrated adult will

require 10% of their total bodyweight in appropriate rehydration fluids over 2–4 hours in addition to the replacement of ongoing losses. Indeed, by the time dehydration is clinically apparent, the patient will require 5% of their body weight in replacement fluids. Intravenous therapy is necessary for patients in shock, in states of diminished consciousness, or with persistent vomiting and for those with an exceptionally high rate of stool output (over 750 mL/hr in adults). In these settings, the rapid administration of a large volume of fluid may be life-saving. But even in these patients, concurrent oral therapy should be instituted as soon as it is feasible in order to aid in the adequate and safe replacement of potassium. Since glucose-facilitated sodium absorption is not disturbed in cholera, all but the most severe disease can be treated with oral administration of glucose (or even sucrose) electrolyte solution. The preferred oral solution is reduced osmolarity (245 mOsm/L) ORS²⁵ and contains (in milliequivalents or millimoles per liter) sodium 75, potassium 20, chloride 65, citrate 10, and glucose 75. If pre-prepared sachets are not available 1 L of potable water should be mixed with 2.6 g sodium chloride, 2.9 g sodium trisodium citrate, 1.5 g potassium chloride, and 13.5 g glucose. This oral therapy has great importance, because in many areas where cholera occurs, a sufficient supply of intravenous fluid is too expensive or too difficult to obtain. The ingredients for oral rehydration can be readily packaged, transported, and reconstituted on site. In the absence of any immediately available method of prevention in many areas of the world affected by cholera, this simplified treatment is critically important.

In general, treatment should be given in treatment centers to ensure the adequate replacement of liquid lost and educational campaigns should motivate populations to seek care in health centers. In retrospective studies, delays in seeking or reaching health centers is consistently shown to be a risk factor for death despite the use of ORS packets or sugar salt solutions in the home. The volumes of liquid lost in moderate and severe cases greatly exceed what people, without significant encouragement, spontaneously ingest or administer to family members.^{12,26,27}

The duration of diarrhea, the volume of diarrhea, and the persistence of the organism can be reduced by antibiotic therapy.²⁸ Tetracycline has traditionally been the drug of choice in all ages. However, the emergence of *V. cholerae* strains resistant to multiple antibiotics, including tetracycline, in East Africa and Asia complicates antimicrobial therapy. Quinolones (Ciprofloxacin and Norfloxacin) have also been used successfully in adults, but antibiotic resistance limits their use in India and Bangladesh, and their use in children is not generally recommended. Most recently, single dose azithromycin has been shown to be effective in the treatment and is also safe in pediatric populations.

Prevention

The provision of safe water and adequate disposal of excreta would reduce the high rate of cholera and other diarrheal diseases in developing countries and be the most effective form of primary prevention of cholera. Traditionally, secondary prevention has been the major form of public health activity relating to limiting the number of cases and death from cholera. The practice of disease surveillance began with cholera; today, surveillance still constitutes the basis of an adequate public health response to cholera. Surveillance should include the registration of cases of acute watery diarrhea in individuals over the age of five, and microbiologic testing of isolates in a subset of such patients in places where facilities are available. Sudden increases in acute watery diarrhea in adults should prompt the expanded testing of samples, and the transport of samples from areas where microbiologic testing is not available to appropriate regional and national diagnostic centers. Communities at risk may also be identified by culturing water from the sewage system.²⁹ Cholera outbreaks require significant logistic activity, and disease control and treatment will be optimized only when notification has allowed for the reinforcement of health-care systems and an increased public awareness of the disease.

When an epidemic has been confirmed, mass media messages can have an important role in limiting the spread of diseases and case

fatality. The population should be made aware of the potential severity of disease and be educated on how to chlorinate or filter water in areas where a secure water source is not available and consume only well-cooked shellfish. Recently it has been shown that in an endemic area, the filtering of water through a folded sari can reduce the case load of cholera by nearly 50%, a disease measure that could be rapidly adopted in outbreaks in many areas.³⁰ Public health messages should also include the importance of seeking medical care rapidly at the onset of disease and identify local treatment centers as delay in reaching treatment centers greatly increases the risk of death in cholera patients.

The public health response should rapidly be mobilized to coordinate international agencies, non-governmental organizations, and national resources to meet the logistical needs of the outbreak which will rapidly overwhelm health systems. Health-care providers should have training reinforced to ensure for adequate case management and shifted to the most affected areas and public buildings should be made available for use as rehydration centers. Antibiotic prophylaxis for family members of persons with cholera decreases the risk of disease.³¹ However, community or regional prophylaxis should be discouraged as it promotes the development of drug resistance as was the case in a large program in Ecuador.³² Furthermore, the number of individuals needed to treat to prevent a case or death is far too large to make such a strategy practical. The use of repressives such as quarantine should be strongly discouraged because they are ineffective and will predictably inhibit case reporting.

Three licensed cholera vaccines exist. The first is a parenteral whole-cell killed vaccine which confers short-term protection of 50% for five months, has significant side effects, and does not prevent asymptomatic carriage and has little role in the prevention and control of cholera. The second vaccine is the B-subunit whole-cell killed vaccine (BS/WCV: Dukoral) which is administered orally in two doses 1–6 weeks apart. When used in Bangladesh, this vaccine conferred 58% protection against symptomatic carriage and was effective for both classical and El Tor biotypes over a one-year follow-up period but did not provide protection to children under the age of five. At five years of follow-up, vaccine efficacy was still 50%.³³ When used in Mozambique where HIV is highly endemic, the vaccine provided 78% protection against the disease and the vaccine protection was also noted in the under age five category.³⁴ The increased efficacy may be partially explained by differences in follow-up; data from Mozambique was reported at six months of follow-up. In Peru, the same vaccine was not shown to have a significant protective effect after two doses, but after three doses (the 3rd at 10 months) it was found to have a protective efficacy of 61% against the disease and a protective efficacy of 82% against the severe disease.³⁵ There is now good evidence that this vaccine confers herd immunity in an endemic setting.³⁶ This vaccine has been recommended for use by the World Health Organization for refugee populations in Africa where at least one descriptive study appears to demonstrate utility³⁷ and several studies have demonstrated feasibility. Its use in endemic settings and outbreaks is less well defined. A similar vaccine is produced and administered at \$0.89 a dose in Vietnam, the only country where a cholera vaccine is being used to control disease in an endemic setting.³⁸

The third vaccine is CVD103-HgR (Orochol), a live O1 Inaba strain genetically modified to disable the A (active) portion of the cholera toxin which is given as a single oral dose. It had excellent results in volunteer studies,³⁹ but when used in a single dose in an endemic area in Indonesia it had no significant protective effect.⁴⁰ The same one dose regime had a protective effect of 79% when used in Micronesia during a cholera outbreak.⁴¹ Further studies will be required to determine its utility. Other vaccine candidates include Peru-15, a unlicensed genetically modified O1 El Tor Inaba strain that when given in a single dose has excellent immunogenicity and early efficacy studies⁴² and is currently undergoing further evaluation. Currently, vaccination with BS-WC is the best empirically supported vaccine option that can be recommended in outbreaks and likely has a potential role in highly endemic conditions when cost per dose falls below \$1.00.⁴³

Escherichia coli Diarrhea

Margaret Kosek • Robert E. Black

Escherichia coli is a gram-negative bacillus that is part of the normal intestinal flora of humans and animals, but a small subset of the isolates known collectively as diarrheagenic or enterovirulent *E. coli* are an important cause of enteric illness worldwide. The five principal categories of enterovirulent *E. coli* are enterotoxigenic (ETEC), enteropathogenic (EPEC), enterohemorrhagic (EHEC), enteroaggregative (EAEC), and enteroinvasive *E. coli* (EIEC). The relative importance of each of these pathotypes in both global and regional burden of disease estimates is an evolving area of knowledge as new diagnostic techniques developed over the last few years have allowed for expanded testing of isolates.

E. coli can be typed biochemically, serologically, and by using molecular typing strategies most notably pulsed field gel electrophoresis. Serotyping has remained the predominant form of typing used for epidemiologic investigations. Enterovirulent *E. coli* falls within a relatively limited number of the numerous definable serotypes, with some overlap between enterovirulent pathotypes, most notably between enteropathogenic *E. coli* and enterohemorrhagic *E. coli*. The serotypes are described by letter and number on the basis of three antigenic groups: O lipopolysaccharide (173 groups described), K capsular (80 groups described), and H flagellar (56 groups described). A standard presentation of an outbreak isolate is therefore *E. coli* O111:K58:H12.

▶ ENTEROTOXIGENIC ESCHERICHIA COLI

In the late 1960s, it was first recognized that some *E. coli* strains produced enterotoxins that caused diarrhea in many animals and in humans. Research in the following decade led to the recognition that these organisms are a major cause of diarrhea in developing countries where it is estimated it causes 14% of diarrhea in community based studies.¹ The illness caused by enterotoxigenic *E. coli* ranges from mild diarrhea to a dehydrating cholera-like illness but is usually characterized by watery, nonbloody diarrhea lasting from 1 day to 7 days and little or no dehydration. Replacement of water and electrolytes by either the oral or the parenteral route is the only treatment usually required.

Enterotoxigenic *E. coli* organisms are now known to produce two plasmid-mediated enterotoxins: one heat labile (LT) and the other heat stable (ST). The heat-labile toxin is structurally similar to cholera toxin and causes loss of fluid and electrolytes in the intestine as a result of adenylate cyclase stimulation. The heat-stable toxin acts in a similar way through stimulation of guanylate cyclase.² The relative frequency with which *E. coli* produces the heat-labile toxin, the heat-stable toxin, or both varies in different regions of the world. Analysis of *E. coli* from various areas suggests that strains producing both toxins are largely restricted to a small number of serotypes. The ability to produce only heat-stable toxin or only heat-labile toxin seems to occur in a broader range of serotypes. Colonization factors, also plasmid mediated, appear to be essential for the *E. coli* to establish itself in the small intestine and are the target of vaccine development for ETEC.^{3,4}

Transmission of enterotoxigenic *E. coli* is thought to be primarily through water and food. Water was the vehicle for an outbreak in a national park in the United States.⁵ Food-borne outbreaks have also been reported in a hospital nursery and on a cruise ship, and enterotoxigenic organisms have been isolated from foods in Bangladesh and the United States. Rarely, person-to-person transmission occurs, particularly in hospital nurseries.

▶ ENTEROPATHOGENIC ESCHERICHIA COLI

Nursery epidemics of watery diarrhea associated with *E. coli* were first reported in the 1940s; and although nursery epidemics associated with EPEC have decreased in the United States in recent years they continue to be reported in other countries, such as the United Kingdom and Finland. EPEC is an important cause of morbidity and mortality in children under the age of five living in developing countries where it is estimated that it causes 8.8% of all episodes of diarrhea at the community level and 15.6% of diarrhea in hospitalized children.¹

EPEC adheres to the intestinal mucosa and injects an array of virulence proteins into the enterocyte. Prominent among the injected proteins is Tir, which working with other bacterial proteins pirates cellular cytoskeletal elements to aid pathogen-host binding. This process compromises enterocyte structure and increases the permeability of intercellular tight junctions.⁶ The result is a characteristic lesion of microvillus destruction called the attaching and effacing lesion. EPEC causes a profuse watery diarrhea with a prolonged clinical course and has had notably high mortality rates in several outbreaks. The degree of intestinal inflammation as measured by the presence of fecal leucocytes is variable. The higher isolation rate of EPEC in hospitalized children as opposed to ambulatory children also speaks to the relative severity of EPEC diarrhea when compared with other common enteropathogens.

EPEC has multiple animal reservoirs including cattle and dogs which appear to be important in disease transmission,^{7,8} although it would appear that food and water contaminated with human feces is the predominant route of transmission. Despite the detail in which the pathogenesis of this organism has been studied as a prototype pathogen of type III secretion systems, vaccine development efforts for this important cause of morbidity and mortality lags notably behind that of other important enteropathogens with similar disease burdens.

▶ ENTEROHEMORRHAGIC ESCHERICHIA COLI

In 1982, two outbreaks of illness characterized by severe abdominal cramps, grossly bloody diarrhea, and little or no fever were associated with a rare serotype of *E. coli* (O157:H7).⁹ Since this time, multiple other outbreaks in industrialized countries have occurred with this and other strains of the pathotype of *E. coli* known as EHEC. EHEC adheres to enterocytes and injects similar pathogenic proteins into host enterocytes as EPEC. However, the characteristics of clinical disease are a result of the secretion of one or more toxins that are highly similar to Shiga toxin produced by *Shigella dysenteriae* type 1. These toxins, Shiga-like toxin I (SLT-I) and Shiga-like toxin II (SLT-II) are the pathogenic factors responsible for the development of bloody diarrhea and later thrombotic complications of the disease, hemolytic-uremic syndrome, and thrombotic thrombocytopenic purpura. There is evidence that infections with certain serotypes of EHEC are more likely to produce hemolytic uremic syndrome than others and that infections with strains of EHEC that produce SLT-II are more likely to be complicated by hemolytic uremic syndrome than infections with EHEC strains producing SLT-I.¹⁰⁻¹²

In the United States, most outbreaks have been caused by foods of bovine origin, especially ground beef; however, outbreaks have also been related to unchlorinated water, unpasteurized apple juice contaminated with bovine feces, and raw vegetables, among other vehicles. Person-to-person transmission has been the mode in a number of outbreaks among children in day care centers, elderly adults in nursing homes, and in institutions for the mentally disabled. While this organism is not part

of the normal bowel flora, asymptomatic infections can occur and contribute to spread. An animal reservoir in cattle is also important in its epidemiology. While the disease is much publicized because of its severity and occurrence in more developed countries, it is an extremely infrequent cause of diarrhea and dysentery in the developing world, which points to compromised sanitary practices at large scale food processing plants as the dominant route of disease transmission.

There is no proven specific therapy for disease due to enterohemorrhagic *E. coli*; indeed there is evidence that suggests antibiotic therapy increases the risk for the subsequent development of hemolytic-uremic syndrome,¹³ although there is controversy on this point.¹⁴ Prevention is a challenge and must encompass control measures in farming, cattle raising, and animal slaughtering and processing, as well as thorough cooking or pasteurization of beef, milk, apple juice and vegetables, chlorination of water, and hygienic practices to reduce person-to-person spread. Surveillance for this organism and prompt epidemiologic investigation can also help to limit the scope of outbreaks. Vaccination of cattle against type III secretion proteins Esps and Tir decreases the percent of animals shedding the bacteria, the bacterial load in positive animals, and the duration of EHEC shedding and may be a tenable strategy to decrease the risk of human disease following further testing.¹⁵

► ENTEROINVASIVE *ESCHERICHIA COLI*

In 1971, an outbreak of disease caused by enteroinvasive *E. coli* involved almost 400 persons in the United States. This outbreak was caused by imported French cheese contaminated with *E. coli* O124:B17.¹⁶ These *E. coli* organisms cause a dysenteric diarrheal illness with tenesmus, fever, abdominal cramps, and bloody stools. The *E. coli* strains associated with this illness possess of the same virulence plasmid present in *Shigella* species which contains pathogenic factors that allow organisms to invade the intestinal mucosa and produce a clinical syndrome indistinguishable from that of shigellosis.

The global importance of enteroinvasive *E. coli* organisms as a cause of disease is quite limited, and it is estimated that it causes 0–2% of all cases of diarrhea detected at the community level in developing countries and likely a small minority of the total global burden of dysenteric diarrhea.^{17–20} However, in cases or outbreaks of dysentery that are culture negative for *Shigella*, diagnostic tests for EIEC should be performed.

► ENTEROAGGREGATIVE *ESCHERICHIA COLI*

Enteroggregative *E. coli* have a “stacked brick” pattern of adherence to tissue culture cells and glass slides. The pathogenesis of EAEC is less clear than that of other enterovirulent pathotypes, although multiple pathogenic factors have been described. The extent of intestinal inflammation present is dependent on a pro-inflammatory flagellin.²¹ These organisms have variably been associated with acute diarrhea,^{20,22,23} but convincingly with persistent diarrhea,^{24,25} in children of developing countries. They are consistently found to be important in diarrhea in AIDS patients²⁶ and travelers.^{27,28}

Illness associated with these organisms is characterized by fever and malaise, and by vomiting and diarrhea with fecal mucus but not gross blood. Control measures, as for other forms of *E. coli*-associated diarrhea, consist of limiting fecal-oral transmission. Because of the association of contaminated water and food with occurrence of this disease, avoidance of fecally contaminated water and attention to hygienic food handling help prevent illness.

► OTHER ENTEROVIRULENT *E. COLI*

Diffusely adherent *E. coli* (DEAC) is so named for its adherence pattern in cell cultures. It appears to be diarrheagenic in some, but not all, contexts,^{29–31} which may be in part due to the difficulties in a clear identification of isolates in different laboratories. Cytotoxic distending

toxin producing-*E. coli* have been described,³² but the presence of the toxin in many serotypes and pathotypes (predominantly those of EPEC)³³ make it hard to delineate the epidemiology and public health importance of strains producing this toxin. It seems likely that in the future new pathotypes of *E. coli* will continue to be described.

► TRAVELERS' DIARRHEA

Travelers' diarrhea, or “tourista,” commonly affects travelers within 1–2 weeks after they arrive in a foreign country, particularly a developing country. The illness usually consists of watery diarrhea with abdominal cramps; vomiting and high fever are unusual. The diarrhea lasts from 1 day to 7 days and is self-limited in most cases.

Diarrhea in travelers may be caused by a variety of bacteria (such as shigellae, campylobacter, and vibrios), viruses (such as calicivirus and rotavirus), and parasites (such as *Giardia lamblia* and *Entamoeba histolytica*). Enterovirulent *E. coli* strains appear to cause most cases, however with ETEC being the primary disease agent in most series although EAEC is also common.^{34,35} Travelers apparently acquire the *E. coli* from fecally contaminated water or food, such as salads containing raw vegetables.

Travelers should be advised to avoid water and ice of dubious safety, uncooked foods, and partially cooked shellfish and meats. Perishable or cooked foods that have been left at room temperature should also be avoided. Raw fruits the traveler peels are generally safe, but raw leafy vegetables (if consumed at all) should be disinfected in chlorine solution. Drinking water may be purified by boiling or by adding 2–4 drops of 5% chlorine bleach or 5–10 drops of 2% tincture of iodine per quart of water 30 minutes before drinking. Carbonated drinks may be considered safe, but noncarbonated drinks should be avoided.

Daily prophylaxis with doxycycline or trimethoprim-sulfamethoxazole prevents most travelers' diarrhea, primarily by preventing infection with enterotoxigenic *E. coli*. Norfloxacin is also effective in preventing travelers' diarrhea. The antibiotics, however, may have side effects and may promote the emergence of bacteria with multiple drug resistance. Prophylactic use of antibiotics is not generally recommended, but might be considered if disruption of travel plans would cause severe problems. Probiotics, which is the use of live bacteria such as lactobacillus, have not been shown to prevent travelers' diarrhea.³⁶

Iodochlorhydroxyquin (Entero-Vioform) should not be used in therapy for diarrhea; it is of dubious value and is dangerous (associated with subacute myeloptic neuropathy). Limited studies have shown little or no value in using most antidiarrheal agents, such as kaolin-pectin to treat diarrheal illness. Preparations containing bismuth subsalicylate (e.g., Pepto-Bismol), however, may reduce gastrointestinal fluid loss. Antimotility agents shorten the course of diarrhea when used in clinical trials in combination with antibiotics, however data associating the use of antimotility agents with protracted illness and carriage of shigellosis, another frequent agent of travelers' diarrhea, makes their widespread use ill-advised. Multiple studies with trimethoprim-sulfamethoxazole, fluoroquinolones (ciprofloxacin, norfloxacin, and levofloxacin), azithromycin, and rifaximin indicate that antibiotic treatment of travelers' diarrhea decreases the duration of illness generally by 1–2 days. Generally, empiric therapy for travelers' diarrhea is dispensed in travel clinics in the United States and prescriptions are primarily guided by the regional antimicrobial susceptibility patterns of ETEC and Campylobacter from the programmed destination. Although replacement of stool fluid and electrolyte losses during enterotoxigenic *E. coli* diarrhea is usually sufficient, as in cholera, antibiotic therapy may be indicated for persons with particularly severe diarrhea or those with cardiac, renal, or other diseases, in whom management of fluid and electrolyte imbalance is difficult.³⁷ Some other types of diarrhea occurring in travelers such as shigellosis, giardiasis, and amebiasis may require more specific antimicrobial treatment.

Yersiniosis

M. Patricia Quinlisk

Although they were first described in 1934, it is over the past 30 years that *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*, as well as the non-*Yersinia enterocolitica* species, have been increasingly recognized as significant pathogens.

Clinical Characteristics

Two-thirds of acute *Yersinia* infections present as enterocolitis and are characterized by a febrile diarrhea with abdominal pain. The diarrhea can be bloody, especially in children less than five years old. In older children and adolescents, acute infection more often presents as an acute mesenteric lymphadenitis with leukocytosis, which can be clinically indistinguishable from acute appendicitis and may result in unnecessary laparotomies. The non-*Y. enterocolitica* species are as likely to cause gastroenteritis, but are more commonly seen in older age groups.¹

Incubation period is typically 3–7 days, usually under 10 days. While most *Yersinia* infections are self-limited, they may trigger autoimmune diseases, and some persons, particularly adults, can develop postinfectious complications of reactive polyarthritis or erythema nodosum. These symptoms usually occur within 2 to 20 days, with the onset of fever and abdominal pain and usually resolve within one month. Less frequently reported manifestations are exudative pharyngitis, septicemia, and abscesses. *Y. pseudotuberculosis* infection has also been associated with Izumi fever, Kawasaki disease, and scarlet fever-like disease, and septicemia has been reported in a variety of immunocompromised patients.^{2–5} Non-*Yersinia enterocolitica* species were found to cause approximately 20% of *Yersinia* infections in one study in the United States.¹ *Yersinia enterocolitica* sepsis has been reported after blood transfusion from asymptomatic and mildly symptomatic donors.⁶

Convalescent carriage of *Yersinia* is common and can be prolonged, but secondary spread is rare. There is increasing evidence that chronic complaints may not be uncommon following *Yersinia* infection.^{7,8}

Bacteriology

Yersinia enterocolitica can be isolated using routine techniques for stool cultures; however, the colonies are small after 24 hours and can be easily overgrown. Most laboratories in the United States culture specifically for *Y. enterocolitica* only on request because it is not cost-effective to routinely include selective media for this low-prevalence organism. The use of selective media like cefsulodin irgasan novobiocin (CIN) with incubation at lower than usual temperatures increases the probability of isolating of *Yersinia* species (including nonpathogenic strains) and may be of particular use in persons with low numbers of organisms in their stool, such as convalescent patients. *Yersinia* spp can be isolated from blood using standard blood culture media. Serologic tests (agglutination tests or enzyme-linked immunosorbent assays) and PCR tests can be useful for diagnosis, particularly in culture-negative cases, but availability is limited.

More than 50 serotypes of *Y. enterocolitica* have been described; serotypes O3, O8, and O9 are most frequently associated

with human illness. Although type O8 has been associated with most of the U.S. outbreaks in the past, O3 became more common in the 1990s.⁹ Isolates in Europe are usually types O3 or O9. Approximately 80% of *Y. pseudotuberculosis* infections are caused by O-group I strains.

Epidemiology

Yersinia enterocolitica has been only infrequently isolated as a cause of gastroenteritis in the United States, Africa, Asia, and South America. However, in parts of northern Europe, Japan, and Canada it may be as common or more common than other enteric pathogens, such as *Shigella* or *Salmonella*. In some countries, such as Japan and Russia, *Y. pseudotuberculosis* is the most prevalent *Yersinia* species. Most cases occur in the cold months, and although susceptibility is general, children are more likely to be infected.

A wide variety of animals have been found to be asymptotically infected with *Y. enterocolitica*, including domestic dogs, cats, sheep, cattle, and pigs. Although this bacterium has been isolated from a variety of foods, most of these isolates are nonpathogenic. In northern Europe, this bacterium is frequently found in the pharynx of pigs, with many of the strains isolated from raw pork and pork products being pathogenic. These foods have often been implicated as a source of human disease.¹⁰ Since this organism grows at 4°C, raw or partly cooked refrigerated meats may play a major role in sporadic cases as well as in outbreaks.¹¹ In the United States, illness in black infants has been associated with pork chitterlings (intestines) being prepared in the infant's home.¹² Outbreaks have also been associated with ingestion of milk, contaminated tofu, and bean sprouts prepared in unchlorinated well water. Cases have also been associated with ill pets. Few cases have been associated with water even though this organism has been found in rivers, lakes, and drinking water. Secondary cases are rare, but nosocomial and intrafamilial transmission have been reported. It is estimated that the dose needed for infection may be as high as 10⁹.

Y. pseudotuberculosis is widespread and can be found in many animal species, especially rodents and other small mammals.

Prevention

In the United States, these organisms do not appear to play a major role in gastroenteritis, however, their incidence and prevalence are probably underestimated. Several suggestions have been made to prevent and control these infections: (a) during the butchering of pigs, steps should be taken to prevent contamination of the pork with the bacteria in the pharynx (irradiation would also reduce the number of bacteria); (b) pork should be used promptly to minimize the time kept at refrigerator temperatures; (c) all meat should be properly cooked prior to consumption; (d) hands should be washed well after handling raw meat/intestines; (e) cross-contamination should be prevented; (f) steps should be taken to minimize the possibility of milk being contaminated after pasteurization; and (g) prospective blood donors with recent history of gastroenteritis should be deferred and/or blood handling practices should be modified.¹³

Legionellosis

Matthew R. Moore • Barry S. Fields

► INTRODUCTION

Legionellosis comprises two distinct clinical syndromes with different pathophysiologic mechanisms. Legionnaires' disease refers to the syndrome of community-acquired or health-care-associated pneumonia named for the 1976 outbreak among American Legionnaires in Philadelphia¹ that ultimately led to the discovery of the pathogen.^{2,3} Pontiac fever refers to the self-limited illness originally described after an outbreak of influenza-like illness at a health department in Michigan.⁴ Since these seminal public health events were first described more than 25 years ago, much has been learned about the bacterium, its environmental reservoirs, and the epidemiology of the syndromes it causes. While *Legionellae* are ubiquitous in freshwater environments, and likely have been for centuries, it is their unique growth requirements in the environment coupled with the advent of human technology favoring complex water systems that has led to the designation of legionellosis as an emerging infectious disease in the late twentieth century.

Microbiology

Bacteria of the genus *Legionella* are gram-negative, aerobic, and rod-shaped. The bacterial cells are 0.3–0.9 μm by 1–20 μm and motile, with one or more polar or lateral flagella.⁵ Currently, there are 49 species comprising 71 distinct serogroups in the genus *Legionella*.^{6–8} One species, *Legionella pneumophila*, causes approximately 90% of all reported cases of legionellosis in the United States. This figure may be inflated, as most diagnostic tests are specific to *L. pneumophila*. Approximately half of the 49 species of *Legionellae* have been associated with human disease, and it is likely that many of the rest can cause disease under appropriate conditions.

Legionellae use amino acids as their carbon and energy sources and do not oxidize or ferment carbohydrates.⁹ The bacteria can be grown in the laboratory on buffered charcoal yeast extract agar. This is a complex medium supplemented with soluble iron and the amino acid cysteine. These fastidious growth requirements are the result of the bacteria's existence as a facultative intracellular parasite of eukaryotic cells. *Legionellae* multiply intracellularly in freshwater protozoa in the environment and in monocytes and alveolar macrophages of humans.⁹ Infection of both of these hosts is accomplished utilizing a type IVB secretion system composed of 25 genes.¹⁰ This type IV secretion system delivers substrates that allow the bacteria to subvert host cell processes for its own propagation. *Legionellae* survive in aquatic and, possibly, some moist soil environments as intracellular parasites of free-living protozoa.^{11,12}

Water is the major reservoir for *Legionellae*, and the bacteria are found in freshwater environments worldwide.¹³ *Legionellae* have been detected in as many as 40% of freshwater environments by culture and up to 80% of freshwater sites tested by PCR.⁷ Several outbreaks of legionellosis have been associated with construction; it was originally believed that the bacteria could survive and be transmitted to humans via soil. However, *Legionellae* do not survive in dry environments, and these outbreaks are more likely the result of massive descalement of plumbing systems due to changes in water pressure during construction.^{14,15} A single exception to this observation is *Legionella longbeachae*, a frequent isolate from potting soil.¹⁶ This species is the leading cause of legionellosis in Australia and occurs in gardeners and those exposed to commercial potting soil.¹⁷ The first U.S. cases of *L. longbeachae* infection associated with potting soil were reported in 2000.¹⁸

Legionella pneumophila multiplies at temperatures between 25°C and 42°C, with an optimal growth temperature of 35°C.¹⁴ Most

cases of legionellosis can be traced to man-made aquatic environments where the water temperature is higher than ambient temperature. Thermally altered aquatic environments can shift the balance between protozoa and bacteria, resulting in rapid multiplication of *Legionellae*, which can translate into human disease.

Clinical Presentation, Diagnosis, and Treatment

Legionnaires' disease, like other forms of community-acquired pneumonia, typically presents with fever, cough, and pleuritic chest pain combined with radiographic evidence of pneumonia. Other signs, symptoms, and laboratory findings, such as confusion, diarrhea, and hyponatremia, have been associated with the classical presentation of the disease;¹ however, these manifestations do not distinguish pneumonia caused by *Legionella* from pneumonia caused by other etiologies (e.g., *Streptococcus pneumoniae*). Therefore, laboratory confirmation is required to make the diagnosis.⁷ Many patients with Legionnaires' disease have underlying lung disease (e.g., chronic obstructive pulmonary disease), immunosuppression (e.g., malignancy), or other comorbidities such as renal disease.¹⁹ Because of the interaction between this relatively virulent pathogen and the susceptible host, Legionnaires' disease patients are often quite ill upon presentation, and all require antimicrobial chemotherapy for recovery, and even then, the case-fatality rate can approach 35%.^{1,20,21}

Pontiac fever is thought to have an entirely different pathogenesis that does not rely upon actual infection of the host. Instead, the nonspecific symptoms of fever, headache, and malaise probably result from the inflammatory response of the host to large quantities of *Legionella* that have died in response to acutely unfavorable environmental conditions or to strains that are incapable of multiplication in the tissues of the exposed individuals. Endotoxin released by dead or nonmultiplying *Legionellae* may play an important role in the pathogenesis.^{22,23} Recovery of the organism is rare in patients with Pontiac fever, and laboratory confirmation is not required to make the diagnosis; the clinical presentation coupled with an appropriate epidemiologic setting—for example, an outbreak associated with recovery of *Legionella* from a whirlpool spa—is sufficient. Patients with Pontiac fever can present with other symptoms (e.g., myalgias, abdominal pain) as well, but ultimately the clinical course is self-limited and unaffected by antimicrobial therapy. Persons of any age can develop Pontiac fever 12–72 hours after exposure to an appropriate source and, in contrast to Legionnaires' disease, the case-fatality ratio is zero.

Legionella infections that do not fit the clinical syndromes of Legionnaires' disease or Pontiac fever have also been reported and include endocarditis, peritonitis, and skin and soft-tissue infections.²⁴

The performance characteristics of available diagnostic tests for Legionnaires' disease have been well characterized (Table 13-2). Culture of respiratory specimens has long been considered the "gold standard" because it allows one to characterize fully a clinical isolate in terms of species and serogroup. In addition, isolates from patients can be compared to those from the environment using a variety of molecular techniques.^{25,26} However, culture of respiratory specimens for all bacterial causes of pneumonia generally has become less common in recent years.²⁷ *Legionella* urinary antigen testing has become increasingly popular because the test is easy to perform and reliable.²⁰

Treatment for Legionnaires' disease should be instituted as soon as the diagnosis is suspected.²⁸ Agents shown to be effective against *Legionella* in vitro include macrolides, fluoroquinolones, and tetracyclines. Current recommendations advocate for treatment with

TABLE 13-2. PERFORMANCE CHARACTERISTICS OF DIAGNOSTIC TESTS FOR LEGIONNAIRES' DISEASE

Test	Sensitivity	Specificity	Comments
Culture	Variable	100%	<ul style="list-style-type: none"> • Detects all <i>Legionella</i> • Provides isolates for molecular comparison to environmental isolates • Requires ≥ 5 days for growth • Requires substantial laboratory expertise
Urinary antigen	60–80%	>99%	<ul style="list-style-type: none"> • Rapid, easy to perform • Only detects <i>Legionella pneumophila</i> serogroup 1 • Does not provide an isolate for comparison to environmental isolates
Serology	70–80%	>90%	<ul style="list-style-type: none"> • Paired sera required • Seroconversion can require up to 2 months, so results not useful for clinical decision-making
Direct fluorescent antigen	25–75%	95%	<ul style="list-style-type: none"> • Highly variable sensitivity • Performance dependent on individual laboratory • Only detects <i>Legionella pneumophila</i>

azithromycin or a respiratory fluoroquinolone, such as levofloxacin, moxifloxacin, or gatifloxacin.^{29,30}

Transmission

Inhalation of *Legionellae* in aerosolized droplets is the primary means of transmission for legionellosis.³¹ These aerosolized droplets must be of a respirable size (1–5 μm). No person-to-person transmission of Legionnaires' disease has been documented. A number of devices have been implicated as sources of aerosol transmission of *Legionellae*. These sources are associated with both potable and non-potable water. Sources producing aerosols of contaminated potable water include showers, faucets, and respiratory therapy equipment.^{32,33} Sources utilizing non-potable water include cooling towers, heated spas, decorative fountains, humidifiers, ultrasonic mist machines, and industrial manufacturing systems.^{21,34–37} The role of home humidifiers in sporadic cases of Legionnaires' disease is unknown. Ducts and vents of air-conditioning systems can be conduits for passage of aerosol-containing *Legionella* organisms from nearby contaminated cooling towers. Most studies have indicated that aerosol from contaminated cooling towers can transmit disease within a limited range (<200 m); however, in certain circumstances, cooling towers may transmit *Legionella* to persons over long distances.³⁸ Air-conditioning systems based on direct exchange of heat from refrigerant to air, without use of water evaporation (such as window and most other home air-conditioning units and automobile air-conditioners), are not intrinsically capable of transmitting disease. Legionellosis resulting from aspiration of upper respiratory secretions or gastric contents may occur among certain hospitalized patients.³⁹ Transmission of extrapulmonary *L. dumoffii* infection by direct inoculation of surgical wounds with colonized tap water during bathing or dressing changes has been reported.⁴⁰ Meaningful identification of sources of transmission requires a multidisciplinary approach including epidemiology, molecular epidemiology, and microbiological techniques such as water and, occasionally, air sampling.

Surveillance

Like other types of infectious disease surveillance, surveillance for legionellosis is dependent upon a clinician suspecting the diagnosis, ordering appropriate diagnostic testing, and reporting the results to appropriate public health authorities. National surveillance for legionellosis in the United States is conducted through two systems. The National Notifiable Diseases Surveillance System (NNDSS) collects information from state health departments on individual cases of legionellosis, along with more than 50 other infectious diseases. Each case report includes basic information, such as age, state of residence, and date of the report.⁴¹ The second system is a paper-based, voluntary reporting system that captures information on hospital and travel exposures, as well as the method of diagnosis. The combination of these two systems has shown that the case-fatality rate for Legionnaires' disease declined from 34% to 12% between 1980 and 1998.²⁰ When compared with 8000 to 18,000 hospitalized Legionnaires' disease cases estimated to occur each year, approximately 3% of all sporadic community-acquired cases are actually reported.⁴²

Surveillance for travel-associated Legionnaires' disease poses a special challenge, as case-patients associated with a particular point-source often return home before they are diagnosed. When travelers originate from the same state or region, local surveillance can often link these cases together to identify the outbreak.^{43,44} However, when travelers converge on a single location from many different regions or countries, individual local health authorities are less likely to identify more than one case, and are therefore less likely to detect the outbreak.^{45,46} Recognition of this issue has led to great improvements in surveillance for travel-associated Legionnaires' disease in Europe.⁴⁷

Control and Prevention

Outbreak Investigations. Investigations of outbreaks of legionellosis can be challenging, depending on the setting and the timeliness of reporting. Health-care-associated outbreaks are typically investigated by individual health-care facilities, with or without the assistance of local or state health departments. Investigations of community-wide outbreaks can be especially arduous, as the source of the outbreak can evade detection for weeks or months.^{21,48} Because of the ubiquity of *Legionella* in the environment, it is difficult to interpret the results of cultures from numerous environmental sources. Therefore, most authorities recommend using a careful, systematic epidemiologic investigation⁴⁹ to guide environmental sampling. The incubation period in most outbreaks has been reported to be 2–10 days. However, in a recent large outbreak associated with a contaminated whirlpool spa, 16% of cases were exposed more than 10 days before symptom onset, suggesting that the incubation period should be extended to 2 weeks.²¹ The attack rate, even in well-described outbreak settings, is usually less than 5%, so that case-finding is often a labor-intensive part of any Legionnaires' disease outbreak investigation. Outbreaks of Pontiac fever are typically explosive, affecting more than 80% of persons exposed.

Investigation of Individual Cases. Investigating individual community-acquired cases of legionellosis is difficult because most people residing in countries where the disease occurs have multiple exposures to the organism during any given two-week period. Culturing environmental sources for *Legionella* is labor intensive and expensive, but some countries have adopted recommendations for investigations of individual cases that cannot be linked to hospitals, travel, or other community-acquired cases.⁵⁰ Individual cases of health-care-associated legionellosis, especially when the incubation period falls entirely within a given hospitalization, always warrant further investigation.^{51,52}

Guidelines for Control in Special Settings. Practical information concerning treatment processes that effectively control *Legionellae* is limited, making it difficult to offer many specific recommendations. Various biocides and alternative disinfection methods, such as heat

eradication, ultraviolet irradiation, ionization, and ozonation, have been tested to determine their abilities to kill *Legionellae*; however, results obtained in these types of laboratory studies often fail to translate into effective prevention protocols.⁷ Several countries have produced guidelines or codes of practice relating to the control of *Legionellae*; however, research to substantiate these practices is scarce, and the prevailing rationale for these recommendations is almost entirely empirical.⁵³

Currently there are 13 U.S. guidelines for the prevention and control of legionellosis. Federal guidelines include four from the Centers for Disease Control and Prevention (CDC) for various health-care settings^{54–56} and cruise ships,⁵⁷ and one from the Occupational Safety and Health Administration (OSHA).⁵⁸ There are three state and local guidelines from Maryland,⁵⁹ Texas,⁶⁰ and Allegheny County, Pennsylvania.⁶¹ Professional societies and organizations have produced five guidelines. These come from the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE),⁶² the American Society for Testing of Materials (ASTM) International,⁶³ the Association of Water Technologies (AWT),⁶⁴ the Cooling Technology Institute (CTI),⁶⁵ and the Joint Commission on Accreditation of Health Care Organizations (JCAHO).⁶⁶ Most of these documents contain recommendations for routine maintenance and emergency disinfection of building water systems, also known as secondary prevention. These prevention measures include maintenance of temperatures for hot and cold water systems and documentation of specific concentrations of biocide. Virtually all guidelines that address secondary prevention agree that repeated follow-up cultures are critical to assess the effectiveness of interventions.

Recommendations aimed at primary prevention, that is, before a case has been identified in association with a particular water system, are more controversial. The controversy is especially prevalent in health-care settings where large numbers of patients are at increased risk of acquiring legionellosis. Arguments in favor of routine environmental sampling include the idea that positive cultures will lead to increased vigilance among clinicians and that negative cultures indicate minimal risk of nosocomial disease. Arguments against routine environmental sampling include a lack of a clear relationship between environmental culture results and transmission, difficulties in interpreting the results of routine sampling performed

using different methods in different laboratories, and the fact that many other factors, such as host susceptibility, means of transmission, and strain virulence, influence risk of disease. Until definitive studies resolve this controversy, it is important to emphasize that all of the current guidelines that address environmental sampling in health-care settings agree that some sort of risk assessment is warranted as a means of determining whether to conduct environmental culturing,^{55,60} how often to conduct it,⁵⁹ or how to respond to environmental cultures that yield *Legionella*.⁶¹

Prevention of Community-Acquired Legionnaires' Disease.

While most efforts to prevent Legionnaires' disease have been focused on hospitals, it is estimated that 65% of cases are community-acquired.²⁰ However, there are no community-based interventions that have been shown to prevent legionellosis. *Legionellae* are difficult to detect in water treatment plants and municipal water supplies because of the lower temperatures of these waters. *Legionellae* are more frequently detected and present in higher concentrations in warm or thermally altered environments.⁶⁷ Because *Legionella* infection can be acquired from a variety of man-made community-based settings, including residential hot water systems,^{68,69} community-wide strategies are needed to reduce risk. One approach taken by the Health and Safety Executive of the United Kingdom is to develop guidelines for control of *Legionella* in all workplaces in the country.⁷⁰

Another approach considers modes of residual disinfection other than chlorine. Recent legislation in the United States requires that all public water systems reduce levels of trihalomethanes, byproducts of chlorine disinfection that have been linked to various malignancies.⁷¹ While individual municipalities can choose from a variety of approaches to achieve this goal, one common method involves the use of monochloramine as a residual disinfectant. In 1990, approximately 25% of municipal water systems in the United States used monochloramine.⁷² The use of monochloramine in communities holds promise because hospitals that are served by monochloramine-treated systems appear to be less likely to have outbreak-associated or sporadic cases of Legionnaires' disease.^{73,74} These data, along with in vitro data supporting the positive effects of monochloramine on biofilm-associated *Legionella*,^{75,76} provide some hope for a community-wide intervention to prevent Legionnaires' disease.

Amebiasis and Amebic Meningoencephalitis

William Stauffer

► AMEBIASIS

Although there are many species of amoeba that infect humans, the term "amebiasis" generally refers to human infection by the enteric protozoan *Entamoeba histolytica*. *E. histolytica* and nonpathogenic *Entamoeba dispar*, morphologically identical, infect 10% of the earth's population, with the percent being higher in poor developing areas. *E. histolytica* is estimated to be the third leading parasitic cause of death worldwide.¹ Infection with *E. histolytica* or *E. dispar* readily follows ingestion of the cyst form; however, only approximately 10% of those infected with *E. histolytica* manifest the symptoms of invasive amebiasis, colitis, and liver abscess. *E. dispar* infections are always asymptomatic. Recognition of amebic infection requires knowledge of the epidemiology of the parasite, the varied clinical presentations, and the available diagnostic methods. Therapy for amebiasis requires use of multiple antiparasitic drugs that act against amebae in the bowel lumen or invading host tissues. Prevention of amebic infection depends on adequate sanitation with availability of

safe water supplies and avoidance of direct fecal-oral contamination among family members or sexual partners.

Life Cycle and Epidemiology

Infection is contracted by ingestion of the cyst form, which by virtue of its chitinous cell wall resists desiccation in the environment and destruction by stomach acid. Cysts contain one to four nuclei; encystation occurs in the small bowel, and the trophozoite form proceeds downstream to colonize the colon. Encystment of trophozoites followed by fecal excretion of cysts completes the life cycle; trophozoites rapidly disintegrate in the environment and if immediately ingested would most likely be killed by the acid pH of the stomach.

Risk factors for acquisition of *E. histolytica* infection and increased susceptibility to aggressive invasive amebiasis are summarized in Table 13-3. Infection is most prevalent in developing areas of the world such as Mexico, Africa, India, Southeast Asian, and South America. In developed countries, amebic infection and disease are concentrated in high-risk groups, such as those with prior exposure to

TABLE 13-3. EPIDEMIOLOGIC RISK FACTORS THAT APPARENTLY PREDISPOSE TO ENTAMOEBIA HISTOLYTICA INFECTION AND INCREASED SEVERITY OF DISEASE**■ Increased Prevalence**

Lower socioeconomic status in endemic area, including crowding and lack of indoor plumbing
 Immigrants from endemic area
 Institutionalized population, especially mentally retarded
 Communal living
 Promiscuous homosexual men

■ Increased Severity

Children, especially neonates
 Pregnancy and postpartum states
 Corticosteroid use
 Malignancy
 Malnutrition

an endemic environment or those more likely to have direct fecal-oral contamination because of unhygienic living conditions or sexual practices.

Until recently studies demonstrating prevalence of disease have been flawed by failing to distinguish *E. histolytica* from *E. dispar*. However, more recent studies have begun to elucidate the true prevalence of disease. A key study investigating immunity to disease in Bangladesh enrolled 230 Bangladeshi children (age 2–5 years) in a two-year observational study. Over the duration of the study, 55% of children acquired *E. histolytica* infection in this impoverished population. Of these, infected children, 80% remained asymptomatic while 20% had an associated diarrhea with 4% of these meeting the definition of amoebic colitis. It was also interesting to note that 17% of infected children acquired an additional *E. histolytica* infection during the 2-year study. These second infections were felt to be due to a genetically distinct strain as determined by polymerase chain reaction (PCR) for the serine-rich *E. histolytica* protein.²

Although little has been published from Africa distinguishing *E. histolytica* and *E. dispar*, it is clear that it is a prevalent disease in many areas of Africa. One thorough prevalence study was conducted by Heckendorn et al. in 967 school children in Cote d'Ivoire where an overall prevalence of *E. histolytica* was low at 0.83%, while *E. dispar* infected 15% of the children.³ Low *E. histolytica* prevalence compared to a higher *E. dispar* was attributed to variation in stool culture yield. Two studies in Egypt found very high rates of *E. histolytica*. The first demonstrated point prevalence rates exceeding 20% for both *E. histolytica* and *E. dispar*.⁴ The second study enrolled 84 persons with acute diarrhea and found that 57% of patients with acute diarrhea (compared to 21% of controls) had positive stool antigen tests for *E. histolytica*.⁵ In South Africa, studies in children found that the prevalence varied by community with children living in areas with better water supply harbored both *E. dispar* and *E. histolytica* (2%), while those in the rural setting with less sanitation harbored only *E. dispar* but at a very high rate (>50%).⁶

Another cross-sectional survey of children in Ecuador found asymptomatic *E. histolytica* in only 7 of 178 children. However, it was interesting to note that more than 64% of children showed high serotiters implying current or recent infection with *E. histolytica*.⁷ This high seroprevalence corresponds to another recent sero-survey conducted in Mexico.⁸ Further, this study summarized some of the difficulties in conducting prevalence studies as it revealed very non-concordant results between some previously well validated tests; two antigen detection assays (the Prospect *Entamoeba histolytica* Microplate Assay and the *Entamoeba histolytica* II Assay), several methods of direct microscopic exam, in vitro culture, starch gel isoenzyme electrophoresis, and serologic analysis by three separate

methods. This paper revisited the question of what should be considered an adequate screening test (sensitive, specific, inexpensive), and what should be considered the true “gold standard” in investigating individuals for *E. histolytica* and *E. dispar*.

A related question arises frequently in clinical practice in low prevalence areas who receive large numbers of immigrants and refugees from high prevalence areas. Most medical screening protocols in the United States for immigrants and refugees arriving from the developing world suggest three ova and parasite examinations (O&P's) be routinely collected.⁹ This screening is conducted to enhance the individuals health by treating intestinal parasitic infections, as well as to protect the public health of the community. *Entamoeba* specifically is known to spread within families, institutions, (i.e., day cares) and occasionally may cause epidemics. Despite these recommendations it is known that stool O&P's are relatively insensitive and they are unable to distinguish the *E. histolytica* from *E. dispar*. It remains to be determined if in addition to the stool O&P examination other diagnostic screening examinations (i.e., stool antigen testing) would be a sensitive, specific and cost-effective in addition to the routine medical screening of immigrants and refugees.

E. histolytica is one of the treatable causes of diarrhea in patients with the acquired immunodeficiency syndrome (AIDS).¹⁰ However, although documented to slightly increase risk of invasive disease,¹¹ the immune dysfunction seems to exert little influence over disease manifestation, and this organism does not act as an opportunistic infection.¹² Severe invasive amebiasis with increased mortality has been reported in the very young, during pregnancy, in association with corticosteroid administration, and in malnourished individuals. A careful epidemiological history is essential for recognition of amebic disease.

Pathogenesis and Host Immune Response

The low frequency of invasive clinical disease complicating widespread *E. histolytica* infection appears to be due to the existence of distinct pathogenic and nonpathogenic species (*histolytica* and *dispar*, respectively)^{13,14} and a complex interplay between parasite and host factors that regulate expression of invasive pathogenic activities. Isoenzyme analysis of *E. histolytica* isolates was first used to demonstrate electrophoretic patterns uniquely associated with invasive amebiasis or asymptomatic noninvasive infection.¹⁵ Asymptomatic intestinal infection with *E. histolytica* does occur and is distinguished from *E. dispar* infection by the presence of serum antiamebic antibodies during pathogenic infection.¹⁶ In addition, serum antigenemia occurs during *E. histolytica* and not *E. dispar* infection.¹⁷ Mucosal antiamebic IgA responses are more prominent in infection with *E. histolytica* than with *E. dispar*.¹⁸

Pathogenesis of invasive amebiasis requires adherence of amebae to the colonic mucus blanket, disruption of the colonic epithelial barrier, parasite attachment to and lysis of host epithelial and acute inflammatory cells, and resistance of trophozoites to host humoral and cell-mediated immune defense mechanisms present in tissues.¹⁹ Amebic adherence to colonic mucins is mediated by a surface lectin inhibitable by galactose or *N*-acetyl-D-galactosamine (Gal/GalNAc); binding of this Gal/GalNAc-inhibitable adherence lectin to cell surface carbohydrates is required for *E. histolytica* cytolytic activity. Amebic proteinases can degrade epithelial basement membranes and cell-anchoring proteins, disrupting epithelial cell layers. Amebae lyse responding host neutrophils, resulting in release of neutrophil nonoxidant constituents that are toxic to host tissues. *E. histolytica* cytolytic activity is apparently regulated by a parasitic protein kinase C enzyme, involves amebic phospholipase A enzyme and acid pH vesicles, and results from an irreversible toxic increase in target cell free intracellular calcium ion concentration, possibly mediated by an amebic pore-forming protein.²⁰ The amebic pore-forming protein has been well-defined, bearing genetic homology to bee venom proteins such as mellitin; it apparently mediates the parasite's host defense against ingested bacteria.²¹ Purified pore-forming protein can lyse nucleated cells in vitro, but may not be directly involved in amebic cytolysis of human cells. Invasive *E. histolytica* trophozoites are

resistant to the lytic effects of complement, despite their activation of both alternative and classic pathways. This is apparently due to an inhibitory binding effect of the lectin-heavy subunits, preventing formation of lytic complement complexes.²² In a nonimmune host, *E. histolytica* trophozoites are capable of killing host lymphocytes and macrophages.

In humans, asymptomatic *E. histolytica* infection is generally self-limited ending within 8–12 months of infection; whether this results from a specific host mucosal immune response or is associated with brief immunity to subsequent intestinal infection is unknown. In contrast, cure of invasive amebiasis in humans or experimental animals is followed by resistance to a recurrence of invasive amebic disease. This is apparently due to development of an amebicidal cell-mediated immune response, although antibodies that block the amebic adherence lectin are also present in the serum and mucosal secretions of immune individuals.²⁰ Immunization of experimental animals with total amebic protein, purified Gal/GalNAc-inhibitable adherence lectin, and a 52-kDa recombinant lectin subunit provides effective immunity against liver abscess through amebicidal cell-mediated mechanisms.

Clinical Characteristics

The clinical syndromes associated with *E. histolytica* infection are listed in Table 13-4. As discussed, up to 90% of individuals infected with *E. histolytica* are asymptomatic and without evidence of ill health related to the parasite. Many infected persons have nonspecific gastrointestinal symptoms, such as abdominal pain, bloating, or watery diarrhea, but are without evidence of invasive disease. Although the reason for their complaints may not be clear or detectable, their amebic infection should be eradicated. Amebic dysentery has a subacute onset over days to weeks and is manifest as abdominal pain and bloody diarrhea; only a minority of patients are febrile.²³ Stool almost uniformly contain occult blood; despite the inflammatory nature of the lesion, fecal leukocytes may not be present because the trophozoites can lyse neutrophils. The differential diagnosis includes invasive bacterial causes of colitis such as *Campylobacter*, *Shigella*, and *Salmonella* infection, toxin-mediated *Clostridium difficile* colitis or invasive *Escherichia coli* infection (i.e., *Enterohemorrhagic E. coli*).

Amebic colitis may be fulminate, especially in the high-risk groups summarized in Table 13-3, with high fever, peritonitis, and colonic perforation resulting in a high mortality. Conversion of amebic dysentery to toxic megacolon is clearly associated with corticosteroid administration which may result from the misdiagnosis of amebic

colitis as idiopathic inflammatory bowel disease. A chronic nondysenteric syndrome is characterized by intermittent bouts of inflammatory diarrhea over a period of years. These patients have invasive amebic colitis that can be diagnosed by biopsy and the presence of serum antiamebic antibodies, yet their disease is frequently mistaken for idiopathic ulcerative colitis.²⁴ Ameboma is a chronic segmental lesion, usually in the cecum or ascending colon, that is characterized by abdominal pain and mass and is often confused with colonic carcinoma. Perianal ulcerative amebic lesions may develop in patients with skin maceration caused by diarrhea; squamous epithelium is usually resistant to amebic invasion.

Extraintestinal disease is overwhelmingly manifest as liver abscess and its spread to contiguous body spaces. Common symptoms of amebic liver abscess are acute right upper quadrant pain and fever, necessitating differentiation from biliary tract disease. Alternatively, liver abscess may become symptomatic over a period of weeks with pain and weight loss but without fever, a presentation more suggestive of abdominal malignancy.²⁵ Knowledge of epidemiological risk factors and early use of hepatic imaging are essential for diagnosis. The risk of amebic liver abscess manifesting in patients returning from an endemic area is greatest in the first three months and rarely, if ever, is observed after six months. Occasionally an amebic liver abscess, especially an abscess of the left lobe, which may be less symptomatic, ruptures into the peritoneum. The liver abscess can also penetrate through the diaphragm into the pleural space, resulting in an empyema. Extension of a left lobe abscess into the pericardium is a rare but often fatal complication. Lung and brain abscesses are rare examples of hematogenous dissemination; amebiasis of the penis and of the uterine cervix has been reported.

Diagnosis

Asymptomatic amebic infection is frequently encountered when individuals receive screening for parasites by stool ova and parasite examination (stool O&P) as occurs in the United States during new refugee medical screening. Many amebic species may be encountered although most are considered non-pathogenic (i.e., *Entamoeba coli*, *E. hartmanni*, *E. polecki*) and are simply a marker of fecal-oral contamination. Quadrinucleated cysts or trophozoites are encountered in about 1–3% of newly arriving refugees depending on the population screened. As previously mentioned, these quadrinucleated cysts cannot be morphologically distinguished from the more common *E. dispar*, or another more unusual species, *E. moshkovski*. In addition, unless the trophozoite has ingested RBC's it too is indistinguishable from the more common non-pathogenic *E. dispar* infection. In these cases, there is currently commercially available stool antigen testing which can distinguish the species and should be used before initiating treatment.

The occurrence of invasive colitis is indicated by the finding of trophozoites (often containing ingested erythrocytes) in stool, a positive serological test for antiamebic antibodies, and the presence of ulcerative mucosal lesions observed by lower gastrointestinal endoscopy.²⁶ In this setting, amebic antigen stool testing should be positive for *E. histolytica*, however, when not readily available, at least three separate stool samples should be examined using permanently stained slides. Colonoscopy with biopsy is highly sensitive and definitive although caution must be used in this approach in severely ill patients as the intestinal mucosa may be fragile and perforation may result from this invasive procedure. Serological tests for *E. histolytica* become positive within one week of disease onset and are usually positive at the time of presentation. It should be noted that prior to the diagnosis of idiopathic inflammatory bowel disease and the corresponding commencement of corticosteroid therapy, any patient with an epidemiological risk of *E. histolytica* should have a documented negative antiamebic antibody.

Patients with a clinical syndrome and epidemiological risk factors consistent with amebic liver abscess should immediately undergo ultrasonography to look for a nonhomogeneous defect in the liver or evidence of biliary tract disease. Ultrasonography is highly sensitive, noninvasive, and relatively inexpensive; computed tomography (CT)

TABLE 13-4. CLINICAL SYNDROMES ASSOCIATED WITH ENTAMOEBIA HISTOLYTICA INFECTION

and magnetic resonance imaging are not more specific and are only slightly more sensitive.²⁷ Amebic liver abscess is difficult to distinguish from bacterial liver abscess or hepatoma by imaging, but usually a correct clinical diagnosis is possible. Amebic liver abscess may occur at any age in persons who do not have the risk factors commonly associated with pyogenic abscess or hepatoma; however, if amebic serological testing is unavailable, ultrasonography or CT-guided fine-needle aspiration can be helpful. A negative Gram's stain and culture for bacteria helps establish the diagnosis; in amebic abscesses, a yellow proteinous debris without white blood cells is found. Trophozoites are not usually seen in the abscess aspirate, since they commonly reside in tissue only at the lesion's periphery. Virtually all persons with amebic liver abscess develop serum antiamebic antibodies but often not until the seventh day of symptoms.²⁵ Thus an initial negative serological test for *E. histolytica* can be misleading early in the course of the abscess. *E. histolytica* trophozoites or cysts can be found in the stool of only a small number of patients with amebic liver abscess.

Treatment

Therapy for *E. histolytica* infection is complicated by the necessity for different agents to treat intraluminal and tissue infestation. Tables 13-5 and 13-6 summarize the drugs in use, their respective sites of activity, and recommendations for drug dosage, and duration of therapy. In a nonendemic area, most experts would treat asymptomatic cyst passers after the diagnosis of *E. histolytica* has been confirmed by stool antigen testing. However, in a highly endemic area, asymptomatic infection should rarely be treated due to the difficulty in distinguishing *E. histolytica* and the much more common non-pathogenic *E. dispar*. Diloxanide furoate is highly efficacious and relatively nontoxic; unfortunately, in the United States this drug is available only from the Centers for Disease Control Drug Service in Atlanta.²⁸ Paromomycin is a nonabsorbable aminoglycoside that is efficacious and often better tolerated than the combination of tetracycline and diiodohydroxyquin.²⁹ Iodoquinol is also available in the United States but demands a longer, three-week course of therapy. A new broad spectrum well tolerated and safe anti-parasitic agent, nitazoxanide, has shown preliminary evidence of effectiveness and is currently under investigation.³⁰

The nitroimidazoles are the drugs of choice for treatment of invasive amebiasis; metronidazole is the only one available in the United States. In the regimens outlined in Table 13-6, metronidazole is highly effective in treating amebic colitis or liver abscess; however, treatment with an intraluminal agent should follow to ensure that intestinal infection is eradicated. Use of metronidazole may be limited by side effects such as nausea and vomiting. In addition, there are

TABLE 13-6. THERAPEUTIC REGIMENS FOR TREATMENT OF AMEBIASIS*

■ Cyst Passers

Diloxanide furoate 500 mg tid × 10 d
Paromomycin 30 mg/kg/d in 3 divided doses × 5–10 d
Tetracycline 250 mg qid × 10 d, then diiodohydroxyquin 650 mg tid × 20 d
Metronidazole 750 mg tid × 10 d

■ Invasive Rectocolitis

Metronidazole 750 mg tid × 5–10 d or 2.4 gr qd × 2–3 d or 50 mg/kg × 1 dose plus diloxanide furoate or paromomycin
Tetracycline 250 mg qid × 15 d plus chloroquine [base] 600 mg, 300 mg, then 150 mg tid × 14 d
Dehydroemetine 1–1.5 mg/kg/d × 5 d plus diloxanide furoate or paromomycin

■ Liver Abscess

Metronidazole 750 mg tid × 5–10 d or 2.4 mg qd × 1–2 d plus diloxanide furoate or paromomycin
Dehydroemetine 1–1.5 mg/kg/d × 5 d plus diloxanide furoate or paromomycin
Chloroquine [base] 600 mg qd × 2 d, 300 mg base qd × 2–3 w (can be added to other regimens)

*All dosages are for oral administration except that of dehydroemetine, which is given intramuscularly; metronidazole can be given intravenously. Source: Reproduced with permission from Mandell GL, Douglas RG Jr, Bennett JF, eds. *Principles and Practice of Infectious Diseases*, 3rd ed. New York: Churchill Livingstone, 1989.

concerns regarding carcinogenesis and teratogenesis when used in pregnant women. Long-term clinical follow-up has not indicated a carcinogenic effect of metronidazole, but if possible the drug should be avoided during pregnancy. The emetines are second-line agents rarely used in the United States. Adding these cardiotoxic agents to metronidazole has not been found to enhance clinical outcome. Patients with amebic liver abscess respond to metronidazole with gradual defervescence and decreased symptoms over a 3- to 5-day period. Progression of symptoms during therapy or failure of metronidazole treatment is an indication for drainage of the liver abscess by needle aspiration and continued treatment with metronidazole.³¹ Open surgical drainage or addition of emetine therapy usually is not indicated but may be considered particularly when other therapies are not tolerated or contraindicated. Some authorities routinely add chloroquine to metronidazole in treatment of liver abscess, although there are no studies that support this practice.

Prevention

Prevention of *E. histolytica* infection rests on availability of safe water supplies, adequate disposal of fecal material, and avoidance of practices that promote direct fecal-oral contamination. Boiling of water is the only certain means of killing *E. histolytica* cysts; use of halide tablets is generally inadequate. No vaccine or reasonable form of chemoprophylaxis is available; however, recent research on pathogenesis and host immunity has suggested that numerous amebic proteins are viable candidates for vaccine development. In fact, several laboratories are actively pursuing the development of a human vaccine.

▶ AMEBIC MENINGOENCEPHALITIS

Amebic meningoencephalitis is a rare clinical syndrome caused by acquisition of free-living amebae from the environment. *Naegleria fowleri* causes a primary amebic meningoencephalitis (PAM) in otherwise healthy individuals; infection with *Acanthamoeba* spp. is manifest as a subacute granulomatous amebic encephalitis (GAE) in patients already having serious underlying diseases. The diagnostician must be familiar with the epidemiology and clinical manifestations of amebic meningoencephalitis to avoid overlooking this infection in

the differential diagnosis of patients at risk, despite the low frequency of occurrence. Diagnosis ultimately rests on finding the amebae in cerebrospinal fluid or brain tissue. Unfortunately, treatment is usually ineffective for either syndrome. Frequently the diagnosis is not made until postmortem examination.

Life Cycle and Epidemiology

N. fowleri can exist in a trophozoite or a flagellate form; cell division is restricted to trophozoites. The organism grows best at higher temperatures (46°C) and is acquired from fresh water.³² Encystment does occur and allows prolonged survival of the parasite at low temperatures. PAM is a rare disease despite the frequent occurrence of warm fresh water exposure during swimming, diving, or boating. The disease occurs in all areas of the world, especially in tropical regions.

Acanthamoebae exist in only the trophozoite and cyst forms, grow best at normal ambient temperatures (25–35°C), and may be transmitted by an airborne or a droplet route.³³ As with *Naegleria*, despite frequent exposure to the *Acanthamoeba* species, *A. culbertsoni*, *A. polyphaga*, and *A. rhysodes*, GAE is found mainly in individuals with serious underlying conditions such as diabetes mellitus, AIDS, or recent organ transplantation.

Pathogenesis and Host Immune Response

N. fowleri apparently enters the central nervous system by penetrating the nasal mucosa and cribriform plate. Trophozoites can be found in nerves and perivascular spaces.³³ Amebic cell lytic activity has been demonstrated in vitro. Invasion of gray matter results in purulent meningitis. Trophozoites are susceptible to complement-mediated lysis, which is potentiated by agglutinating antibody to *N. fowleri*. Humoral and cell-mediated immunity limit the occurrence of PAM despite the ubiquitous exposure to this parasite.

In GAE, granulomatous lesions can occur throughout the central nervous system, suggesting a hematogenous route of dissemination. Further evidence for this route of spread is the frequent occurrence of skin lesions before spread to the nervous system and other organ systems. *Acanthamoeba* can be differentiated from *Naegleria* by the presence of cysts in tissue. The opportunistic nature of *Acanthamoeba* infection suggests that cell-mediated mechanisms are important in resistance to disease; however, GAE in immunologically competent hosts has been reported.

Clinical Characteristics

PAM is often first manifest as alterations in taste or smell, followed by abrupt onset of headache, fever, and meningismus.^{32,33} A fulminate illness ensues with depressed mental status and focal neurologic signs ending in death within one week. Other than the olfactory involvement in PAM, the disease is difficult to distinguish from community-acquired bacterial meningitis.

GAE is a subacute disease that becomes manifest over a period of weeks with focal neurologic signs, mental status changes, seizures, headache, and fever.³⁴ The occurrence of nodular or ulcerative skin lesions containing *Acanthamoeba* can be helpful in establishing the diagnosis. Most patients do not have meningismus, and the disease must be differentiated from brain abscess or other opportunistic infection such as toxoplasmosis.

Diagnosis

PAM is characterized by a neutrophilic cerebrospinal fluid (CSF) pleocytosis, elevated protein levels in the CSF, and hypoglycorrhachia are not uncommon. A Gram stain of CSF negative for bacteria and an India ink test negative for cryptococcal disease in a young healthy person should suggest the need to examine the CSF for motile *N. fowleri* trophozoites, which are 10–30 µm in diameter. In contrast, in GAE, amebae are not found in the CSF, and brain biopsy is necessary for diagnosis. CT scans of the brain reveal nonspecific findings in PAM but may show focal lucencies in GAE.³⁵ In GAE, the CSF undergoes nonspecific changes such as lymphocytic pleocytosis and alterations in protein and glucose levels. A biopsy specimen should be obtained from any suspect skin lesion and examined for *Acanthamoeba*. Although several biochemical markers in the CSF have been investigated, due to the rarity of the disorder the test performance characteristics (i.e., sensitivity, specificity) are unknown and these tests are generally only available from research laboratories. A recent study found an indirect immunofluorescence antibody (IFA) specific for *Balamuthia mandrillaris* was positive in 7 of 7 patients with fatal encephalitis.³⁶

Treatment

No effective treatment for amebic meningoencephalitis has been established. Known survivors of PAM were treated with systemic and intrathecal amphotericin B.²⁷ One patient also received systemic rifampin, sulfisoxazole, and miconazole by the intravenous and intrathecal routes. Successful therapy for GAE also is undetermined; *Acanthamoeba* is generally susceptible in vitro to ketoconazole, miconazole, 5-flucytosine, and pentamidine, although isolates vary substantially,³⁷ systemic and intrathecal miconazole, and rifampin and sulfisoxazole. If GAE is diagnosed, in vitro susceptibility should be studied, and therapy with the above agents and amphotericin B considered.

Prevention

PAM and GAE are such rare infections that, in general, preventive measures are unnecessary. A small risk of PAM may be associated with repeated episodes of having water forced into the nose under pressure, as in diving or waterskiing in warm freshwater lakes. However, the level of risk is impossible to define. Opportunistic infections other than GAE are more common and of paramount importance in immunocompromised individuals.

Giardiasis

Mary E. Wilson

Giardia lamblia is a flagellated protozoan that causes subacute or chronic diarrheal disease in humans. Giardiasis occurs worldwide, particularly where people do not adhere strictly to good hygienic standards. In the United States, giardiasis has been documented as a cause of waterborne outbreaks, epidemics in day care centers, and sporadic disease of overseas travelers, family members, and campers or hikers who ingest untreated surface water. The disease can be associated with acute or chronic malabsorption and may be a cause of failure to thrive in children.

The *Giardia* spp are classified in six species. These are further divided into Assemblages (A, B, C, E, F) that correspond to proposed distinct species of the parasite *G. duodenalis*. Assemblages A and B have been documented using PCR of stool specimens to cause human disease.¹ Assemblages B, C, E, and F have been proposed to contain the species *G. enterica*, *G. canis*, *G. bovis*, and *G. cati*, respectively.^{1,2}

Life Cycle

The life cycle of *G. lamblia* includes two stages: the cyst and the trophozoite. Giardiasis is acquired by ingestion of the dormant cyst from contaminated environmental sources. The parasite excysts while passing through the acidic stomach environment, and out of each cyst emerge two trophozoites that colonize the proximal portion of the small intestine. As the parasite passes through to the proximal colon, it encysts and undergoes one cell division before it is passed in the stool. Trophozoites are fragile motile forms with four pairs of flagellae, a ventral surface disc involved in attachment to intestinal mucosa, central axonemes, and two nuclei, which give the parasite a face-like appearance. Cysts are oval and thin-walled with four nuclei. During severe bouts of diarrhea, both stages of the parasite can be seen in fresh stool specimens because of rapid transit of bowel contents. Often, however, only cysts are detected in stool samples.

Several aspects of the parasite's life cycle are important determinants in the epidemiology of the disease. First, *G. lamblia* cysts are immediately infectious for humans when passed in the stool, allowing person-to-person transmission of infection in settings of frequent interpersonal contact. This accounts for epidemic outbreaks in day care centers and institutions and for transfer of infection between family members. Second, the infectious dose is low, between 10 and 100 cysts, facilitating a high transmission rate. Third, *Giardia* cysts can survive for long periods in the environment, up to 16 days at 8°C, so that waterborne spread of infection or spread by fomites is possible. Fourth, most infected patients are asymptomatic carriers, providing a large reservoir of infection in some populations.³ In combination, these factors produce efficient fecal-oral spread of the organism, particularly where hygienic practices are poor.

HUMAN DISEASE

Pathogenesis and Clinical Characteristics

The spectrum of *Giardia* infection includes asymptomatic cyst passage; subacute, noninflammatory, usually self-limited diarrhea; allergic symptoms; failure to thrive in children; and a chronic diarrheal syndrome with malabsorption and weight loss.³ Whether the variable manifestations are due to host and/or parasite genetic variability is not established. The incubation period is 1–2 weeks, after which typical symptoms of abdominal bloating, flatulence, eructation, crampy abdominal pain, malaise, and greasy foul-smelling diarrhea may develop. Tenesmus, vomiting, and fever are less common, and leukocytes are generally absent from the stool. The symptoms are often present for a prolonged period, averaging 17 days in one study, and approximately half of patients have a significant weight loss of approximately 10 lbs. Laboratory examinations may reveal increased fecal fat content, as well as impaired absorption of D-xylose, lactose, and vitamin B₁₂. Protein-losing enteropathy and vitamin A deficiency have also been documented.⁴

The mechanism through which *Giardia* spp cause diarrhea is not entirely known. Theories that the parasite acts as a barrier to absorption are not compatible with the parasite's low infectious dose. Histological studies can show flattening of intestinal villi and varying degrees of cellular infiltration. According to one study, these changes relate to symptoms and are reversible with eradication of the organism. However, not all human biopsies show similar pathology, and there must be more to the pathogenesis.³ Assays of brush-border disaccharidases show deficient levels in patients with giardiasis, leading to theories that enzymatic deficiencies, abnormal lipolysis, and other factors may contribute to the pathogenesis of disease.⁴

Host immune responses provide partial protection against giardiasis. This has been established in animal models, but appears relevant during human disease since many adults residing in endemic regions appear less susceptible to symptomatic disease than do children or visitors. The factors needed for protection of mouse models include IL-6 and mast cells. Innate immune anti-giardial defense mechanisms include antimicrobial peptides defensin and lactoferrin

released from Paneth cells. It has not been established whether IL-8, reactive oxygen species or nitric oxide are important for defense. Mice deficient in T cells do not control *G. lamblia* or *G. muris* infections, and the requirement seems to be for CD4+ cells.³

Humans infected with *Giardia* spp produce antibodies specific for the parasite in mucous and serum.³ Individuals with common variable immunodeficiency and children with X-linked agammaglobulinemia are more susceptible to giardiasis than healthy individuals, underscoring the importance of humoral responses in clearance of infection. Serum IgM and IgG antibodies to *G. lamblia* antigens develop during giardiasis, but the most important isotype appears to be IgA secreted locally in the gut. IgA is not in itself cytotoxic for the parasite, and IgA-mediated protection likely occurs by preventing trophozoite adherence to gut endothelium.⁵

Factors in human breast milk provide partial protection against giardiasis in children. The level of secretory IgA in breast milk correlates with protection of African children against infection,⁶ and of Mexican children against symptomatic disease.⁷ Additionally, fatty acids and peptides derived from lactoferrin⁸ are cytotoxic for the organisms.

A major target antigen for the humoral immune response belongs to a heterogeneous set of variant-specific surface proteins (called VSPs) on the surface of *G. lamblia* trophozoites.^{3,9} These molecules range from 30 kDa to 200 kDa in size, but they share a conserved cysteine-rich motif and a 34-amino acid homologous peptide at their C termini. Host antibody responses are largely targeted toward variable and semi conserved portions of the VSP proteins, but not to the 34-amino acid conserved C-terminal peptide. There is evidence that parasites can "switch" between VSP types, raising the possibility that humoral responses to one VSP induces expression of a distinct VSP.¹⁰ Other targets of humoral immunity include cytoskeletal proteins (α - and β - tubulins, α - and β -giardin), or metabolic enzymes (arginine deiminase, ornithine carbamoyl transferase, α -enolase).³

Diagnosis

Methods available for diagnosis of giardiasis include microscopic examination of stool samples for ova and parasites, microscopic examination after staining with fluorescent antibodies to *G. lamblia* and *Cryptosporidium*, and enzyme-linked immunosorbent assay (ELISA) examination of the stool for a 65-kDa *G. lamblia* antigen. All are comparable in cost. The sensitivity of microscopic examination increases from 50% to 70% on one stool sample to more than 90% after three examinations and offers the advantage that other pathogens can also be detected. When *G. lamblia* is the primary diagnostic consideration, however, such as in individuals who obtained their exposure through day care centers or by hiking in endemic regions of the United States, specific examination for *G. lamblia* may be in order. In such a setting, an immunofluorescence assay has 55–100% sensitivity and 99.8–100% specificity, and has the advantage that another cause of chronic diarrhea, *Cryptosporidium*, can also be detected. Stool ELISA is 91–97% sensitive and has 98–99.8% sensitivity and is quicker to perform. Several alternate ELISA and indirect fluorescent antibody (IFA) detection kits are available. The sensitivity of any of the above tests increases with repeated examinations.^{5,11,12}

Although stool examinations are almost always adequate for diagnosis of symptomatic giardiasis, other methods allow examination of duodenal contents for the organism. A weighted-string capsule entails microscopic examination of mucus from the duodenum without an invasive test, although this is less sensitive than upper endoscopy. The latter method with aspiration of duodenal contents and/or small bowel biopsy can also be used to detect *G. lamblia* and simultaneously examine for other causes of chronic malabsorption (e.g., bacterial overgrowth, sprue). The systemic IgG response to *Giardia* spp. remains positive for a long period after infection, and as such serology is of limited use for diagnosis of individual cases.

Methods for epidemiological studies include techniques to identify isolates in animals/specimens, and methods to identify cysts in environmental samples. DNA-based methods for diagnosis, often involving PCR of specimens, are used primarily for epidemiological

studies and are likely to assume higher importance in the future.¹³ Techniques for detecting *Giardia* spp cysts in water samples are complicated and involve steps of concentration, purification, and detection.¹⁴ Purification methods include the use of antibody-coated beads, with detection by immuno-epifluorescence.¹⁴

Treatment

The two main treatment regimens for giardiasis include metronidazole 250 mg tid for 5–7 days, and Nitazoxanide 500 mg bid for 3 days.¹⁵ Tinidazole, a nitroimidazole and structural analog of metronidazole, is as effective as metronidazole in a single dose of 2 grams orally. In comparisons of single dose regimens, however, tinidazole is more effective.¹⁶ Alternates include furazolidone 100 mg qid for 7–10 days (80% efficacy). Paromomycin, a non-absorbed aminoglycoside with about 60–70% efficacy against giardiasis, may have a therapeutic role if treatment during pregnancy cannot be postponed.¹⁵

Epidemiology

Transmission of giardiasis occurs by the fecal-oral route, either through direct contact with an infected individual or indirectly by ingestion of contaminated water or food. *Giardia* infection is more common in young children than adults in the United States, probably both because of their poorer hygienic practices, and in highly endemic situations due to their less mature immune systems. Risk factors for sporadic giardiasis in the United Kingdom are contact with recreational water and especially swallowing water while swimming, drinking treated tap water, and eating lettuce.¹⁷

Prevalence rates for the organism vary widely depending on location. In the United States, 3.9% of stool specimens submitted for examination have contained the organism. The prevalence of *Giardia* among 1- to 3-year-olds in Washington State was 7.1%. The prevalence of cyst carriage in day care centers ranges from 0–50% at different centers, with many children remaining asymptomatic.¹⁸ Children in Queensland, Australia, were found to harbor the organism in 5.7% and 2.1% of random stool samples from households serviced by septic tanks or city sewage lines, respectively.¹⁹ In South Australia, 2.1% of 100 adults undergoing upper endoscopy and 9% of 200 adults in Pakistan were positive for *G. lamblia*.^{20,21} The annual incidence of symptomatic disease has been reported as 9.8, 11.6, and 45.7 per 100,000 population in Minnesota, Colorado, and Vermont, respectively.²² Prevalence rates were higher in developing countries, estimated at 19.4% in Zimbabwe and 42% in rural Egypt.²³ Surveillance of travelers to eastern Europe revealed that 22.8% of 1419 tourists were ill with giardiasis and that infection was strongly associated with consumption of tap water in Leningrad.²⁴

Cases of giardiasis can be divided into those occurring sporadically and those associated with outbreaks. The former group includes travelers to countries where the organism is endemic and hikers or campers who ingest untreated surface water in areas where the streams and lakes are contaminated, such as Minnesota or Colorado. The presence of the organism in HIV-positive men does not correlate well with symptomatic disease and there does not seem to be an increase in symptomatic giardiasis in the AIDS population.⁵ Finally, up to 50% of children who attend day care centers pass *Giardia* cysts, and rates of giardiasis among household contacts of infected children range from 12% to 27%.

Outbreaks of Giardiasis

Large outbreaks of giardiasis have resulted from contamination of municipal water supplies with human waste. *Giardia* was the most common etiologic agent of waterborne infection between 1979 and 1988, and between 1992 and 1997 the annual incidence in the United States was estimated at 2.5 million cases per year.¹⁴ One such outbreak, affecting 11.3% of 1094 skiers, occurred in an Aspen ski resort during the 1965–1966 season when well water was contaminated with leaking sewage.²⁵ A large outbreak in Rome, New York, possibly due to contamination of the water supply with human waste from

settlements in the watershed area, affected 10.6% of the population (5300 persons).²⁶

Several waterborne outbreaks were not proven to be caused by human waste contamination, however. A Camas, Washington outbreak was traced to the city water supply, and cysts were found in three beavers in the watershed area for the water system, raising the hypothesis that the outbreak might be a zoonosis.²⁷ During another outbreak in Pittsfield, Massachusetts, *Giardia* cysts were found in one of three city reservoirs, and again the surrounding area contained *Giardia*-positive animals that may have been the source.²⁸ Although chlorine is sufficient to kill *Giardia* cysts in the laboratory, other factors such as temperature, pH, and contact time with chlorine may result in less than optimal killing of cysts in water treatment systems that use chlorination alone. Thus, of 21,990 cases of waterborne giardiasis caused by contaminated surface water sources in the United States between 1965 and 1984, 10.1% were due to cross-contamination of water supplies with sewage lines and 54.6% of cases (56% of outbreaks) occurred in water sources treated with chlorination alone. In contrast, only 33.8% of cases (21% of outbreaks) were associated with water supplies that had also undergone filtration. Thus, systems that include a filtration step as well as chlorination seem to be most effective in eliminating the organism.^{1,25}

Giardia has been the cause of 9% of outbreaks in the United States due to exposure to treated recreational water, and 4% of cases due to exposure to untreated recreational water since 1971.²⁹ Outbreaks of symptomatic giardiasis in day care centers have affected between 17% and 47% of the children attending. In general, ambulatory diapered children harbor the organism most frequently.³⁰ Several recurrent outbreaks have been documented, sometimes despite extensive efforts to improve personal and environmental hygiene among children and staff.³¹ One study documented that 16% of asymptomatic children harbored *G. lamblia* cysts, although no caregivers were infected other than those whose children were also infected. Thus fastidious hygiene can prevent infection of workers, but children and family members are still at risk. In the same study, *G. lamblia* cysts were recovered from chairs and tables in day care centers, indicating a possible route of transfer of cysts between the children.¹⁸ Other situations that have facilitated outbreaks of giardiasis include a contaminated cistern providing water to several families and a swimming pool contaminated by feces of a mentally retarded child.

Food-borne outbreaks of giardiasis have occurred when food was mixed by the bare hands of an individual carrying *G. lamblia* cysts.¹⁴ Examples include an outbreak at a party associated with consumption of fruit salad prepared by a woman with an infected infant and pet rabbit. Another outbreak occurred due to raw vegetables prepared by a *Giardia*-infected cafeteria worker.¹⁴ *Giardia* cysts are frequently found in sewage and surface waters, although it is not clear how many belong to strains that infect humans.¹⁴

Reservoir Hosts

Humans are the main reservoir for *Giardia duodenalis*; thus giardiasis is often a cosmopolitan disease. However, several animal hosts also harbor the organism. Whether these constitute a reservoir for human outbreaks is controversial. Cattle can acquire infection with *Giardia* Assemblage E (also called *G. bovis*). Domestic dogs can be infected with Assemblage C (*G. canis*) and the human Assemblages A or B, raising the (unproven) potential for dog-to-human transmission.¹³ Molecular studies suggested that cattle may not be a significant source of human infections.¹⁴ Cysts resembling *G. duodenalis* have been found in beavers, muskrats, cows, goats, and sheep. However, there is little evidence that wildlife can serve as a reservoir for human infection.¹³ Indeed, there is stronger evidence that beavers acquire *G. duodenalis* of human origin than vice versa.³² Surveys have identified personal hygiene and sanitation rather than zoonotic exposure as the major risk for giardiasis.² There is a need for use of molecular methods to genotype *Giardia* isolates, in order to better track transmission from animals to humans or/and vice versa. The recent sequencing of the *Giardia* genome may facilitate these goals.³³

Control Measures

Control measures for giardiasis include identification and treatment of colonized or infected individuals and screening of their household members for cyst passage. Treatment of water supplies by both chlorination and filtration is most effective for clearing the organism. In addition, water supplies should be routinely screened for coliform bacteria and turbidity to monitor for contamination with sewage or

other sources. Food-borne outbreaks can be prevented by heating at 71.7°C for 15 seconds, freezing at -18°C for 1 hour, or UV light exposure (2–3 mJ/cm²). Treatment of asymptomatic cyst passers is desirable due to the possibility that they will develop symptoms or that they will pass the infection to family members. However, in situations where the infection is highly endemic, such as in most developing countries and in some day care centers, this may not be practical. In these situations, the question of treatment must be individualized.

Dracunculiasis

Donald R. Hopkins

► INTRODUCTION

Dracunculiasis (Guinea worm disease), caused by infection with the parasite *Dracunculus medinensis*, has affected humans for centuries. Definitive evidence of the disease has been found in the 3000-year old mummy of an Egyptian girl. The ancient practice of “treating” the infection by slowly wrapping the emerging adult worm around a stick or twig is thought by some medical historians to have been the inspiration for the caduceus and the Staff of Aesculapius -symbols of the healing arts. Although dracunculiasis is not usually fatal, it causes enormous socioeconomic damage in affected rural populations, which is the main reason why this disease is now being eradicated.

The Parasite and Its Life Cycle

People are infected with *D. medinensis* when they drink water from contaminated ponds or step wells in which larvae of the parasite are found in tiny water fleas (copepods). When gastric juices kill the copepods, the larvae escape to migrate through the wall of the stomach into the abdominal cavity. Three or four months later, the parasites mate, after which the male worms die, and the female worms continue to grow. Approximately one year after the infection begins, adult female worms measuring about 1-m long migrate toward the skin, often on a lower limb, and produce a painful blister. When the blister ruptures, usually upon immersion of the affected limb in water, the gravid female worm, which resembles an ivory-colored strand of spaghetti, spews hundreds of thousands of larvae into the water. Diminishing numbers of larvae are spilled into the water by the same worm over the next several days as the wound is reimmersed in water.

Only immature larvae that are eaten by a receptive species of copepod within a few days of being released into the water survive. In the copepod, they undergo two moults within about 2 weeks, after which they are infective to humans who drink water containing the infected copepod. The larvae themselves are too small to be seen by the naked eye, but copepods are barely visible as moving specks if such water is held up to the light in a glass or jar. There is no known animal reservoir of *D. medinensis*.

Clinical Disease, Diagnosis, and Treatment

Infections are asymptomatic during most of the year-long incubation period. Shortly before a worm emerges, patients may experience non-specific fever, nausea, or aching, but often the first sign of infection is a painful blister or appearance of the worm under the skin. No inflammatory reaction to the worm is apparent before the blister appears, but thereafter white blood cells surround the body of the emerging worm and create resistance to its removal. Although most victims suffer only one worm that usually emerges through the skin on the lower leg, ankle, or foot, this parasite may emerge from any part of the body, and some especially unfortunate persons have had

more than a dozen worms emerge at the same time. Diagnosis is facilitated by the striking appearance of such a worm emerging through the skin, since no other infection of humans manifests that way. Often the ulcer surrounding an emerging worm becomes secondarily infected with various bacteria, which sometimes results in fatal complications such as tetanus. Most commonly, the emerging worm and associated pain incapacitate infected people for periods averaging 2 months. An estimated one-half of 1% of victims are permanently crippled each year as a result of infections or secondary complications which involve a major joint such as the knee or ankle. People do not become immune to reinfection.

At best, modern medicine can offer infected persons only relief from pain and secondary infections by providing analgesics and antibiotics when indicated, cleaning wounds, and applying topical antiseptics. Providing tetanus immunization is also advisable. Some anthelmintics such as niridazole, thiabendazole and metronidazole may facilitate removal of the worm by reducing associated inflammation. Physical removal of the worm by slowly wrapping it around a stick over several days or weeks, or surgical removal of an accessible worm can shorten the duration of suffering. Great care must be taken, however, to avoid breaking the worm, since withdrawal of a broken worm into the body spills larvae in the tissues and causes a severe inflammatory reaction. Dead worms may be absorbed by the body or they may calcify, producing unusual patterns on x-ray.

Epidemiology and Prevention

Because they drink larger amounts of water, working aged adults, especially farmers, are most affected by dracunculiasis. In endemic areas, many children are unable to attend school at certain times of the year because they can't walk due to dracunculiasis. Sometimes more than half of a village's population may be affected at the same time. Depending on the local ecology, the peak transmission season, when the disease is most prevalent, often coincides with the planting or harvest season. Because of the association with contaminated surface sources of drinking water, most affected areas are remote rural villages with poor inhabitants, but distribution of the disease in a given country is usually sporadic. In recent years, the infection has occurred in India, Pakistan, Yemen, and 17 countries in sub-Saharan Africa. About 3.5 million persons were estimated to be infected in 1986.

Incapacitation of farmers, mothers, and school children in large numbers, for periods averaging about 8 weeks, during the harvest or planting season, year after year, is devastating in affected communities. As a result, dracunculiasis has significant adverse effects on agricultural production, school attendance, and on the care and nutrition of uninfected infants, in addition to its direct adverse effects on the health of those who are infected. Thus the combined socio-economic impact of dracunculiasis greatly exceeds what one might otherwise expect of a disease that is not usually fatal.

While there is no curative treatment for dracunculiasis, there are several ways to prevent the disease. Providing a safe source of drinking water such as from a borehole well which cannot be contaminated by persons with emerging Guinea worms, is the preferred preventive measure, since it also helps prevent other waterborne diseases and may reduce the time and energy required to collect water for household use. But providing borehole wells is relatively expensive and slow.

The intervention used most commonly in recent years has been to teach villagers to filter their drinking water through a finely woven cloth to remove the copepods. Educating persons at risk to understand that the infection comes from their drinking water is another intervention. Demonstrating copepods swimming in their drinking water is particularly effective in convincing villagers of the connection between Guinea worm disease and their drinking water. Corollary teaching of villagers not to enter drinking water sources when a worm is emerging from their body helps reduce contamination of the water. Although boiling of the water kills copepods and Guinea worm larvae as well as other undesirable pathogens, most villagers at risk of dracunculiasis are too poor to afford enough fuel to boil their drinking water regularly.

Applying temephos (Abate larvicide) to ponds at four-week intervals during the transmission season is an effective means of vector control (by killing the copepods) which may also be used in some circumstances. At the recommended concentration of one part per million, Abate larvicide is tasteless, colorless, odorless, does not harm fish or plant life, and it has a wide margin of safety for humans.

The Eradication Campaign

The international campaign to eradicate dracunculiasis was initiated at the Centers for Disease Control and Prevention in 1980, just before

the beginning of the International Drinking Water Supply and Sanitation Decade (1981–1990), which was sponsored by United Nations agencies and other development organizations. Although the Decade’s overall goal to provide safe drinking water to all deprived populations was not achieved, the backers of the Decade accepted eradication of dracunculiasis as one of the Decade’s sub-goals, and by the end of the “Water Decade,” half of the known infected countries (Yemen was only discovered to still have current cases in 1994) had established national Dracunculiasis Eradication Programs.

In 1988, African ministers of health resolved to eradicate dracunculiasis by the end of 1995. The same goal was endorsed by the World Health Assembly in 1989 and 1991, making dracunculiasis the next disease to be officially targeted by the World Health Organization for eradication, after smallpox. Although the strategy for eradication of dracunculiasis was at first based mainly on providing safe drinking water to affected populations, because of the slow pace and expense of that approach, primary emphasis later shifted to health education and use of cloth filters, with vector control by means of Abate larvicide employed in certain appropriate areas. After programs reduced dracunculiasis’ prevalence by over 80% using those village-based interventions, the eradication effort began stressing an even more intensive “case containment” strategy, which focuses on preventing transmission from each infected person.

About 16,000 cases of dracunculiasis were reported globally in 2006, from about 4000 villages (more than 23,000 villages were known to be endemic in 1993). Over 98% of the cases in 2006 were in Ghana and Sudan (Figure 13-1). This is a reduction of over 99% in the incidence of dracunculiasis from the estimated total of 3.5 million cases in 1986. Eleven of the 20 previously endemic countries (when the program began) have now eliminated the disease. Approximately

Figure 13-1. Distribution of 25,217 cases of dracunculiasis reported during 2006.

90% of the remaining cases outside of Sudan in 2004 were in Ghana, which reduced its cases from almost 180,000 reported in 1989 to 4134 cases reported in 2006, after a decade of stagnation. Sudan, which reduced its number of reported cases by more than 50% in 2003 and again in 2004, finally achieved a negotiated settlement of its 21-year-old civil war in January 2005, which resulted in increased cases in 2006 as the program gained access to new areas.

Thus dracunculiasis was not eradicated by the end of 1995 as targeted, but it is now well on the way to becoming extinct. In 2004, ministers of health of the remaining endemic countries and the World Health Assembly resolved to complete the eradication of dracunculiasis by 2009. WHO's International Commission for the Certification of Dracunculiasis Eradication has already certified 180 countries as free of dracunculiasis.

Human Enteric Coccidial Infections

Katharine Bar

Cryptosporidia, Isospora, and Cyclospora are important causes of diarrheal disease. They are transmitted via spores, enabling fecal-oral transmission in sporadic and epidemic patterns. They are worldwide pathogens, with increased prevalence in developing countries. In immunocompetent hosts, these coccidia cause a self-limited diarrheal syndrome; in immunosuppressed hosts they manifest with more severe and chronic symptoms, often with considerable morbidity and mortality.

These spore-forming protozoa are obligate intracellular pathogens with several similarities in their life cycle. Upon human ingestion of a small inoculum, infectious spores release sporozoites, which invade the enterocytes of the small intestines.¹ With infection, a local inflammatory reaction occurs causing blunting of intestinal villi.² A complex life cycle, consisting of both sexual and asexual stages, follows with eventual excretion of spores in the host's feces.

Clinical presentation varies depending on the individual's immune function; however the hallmark of disease is a self-limited diarrheal illness. Many individuals are asymptomatic. In those with symptoms, a 1- to 2-week incubation period leads to a 1- to 3-week syndrome of watery diarrhea, abdominal pain, and constitutional symptoms.³ The diarrhea can be profuse enough to be reminiscent of toxin-mediated disease, such as cholera; however no toxin has been identified.⁴ Infrequently, normal hosts experience a chronic or relapsing pattern of diarrhea.⁴ Immune activation conditions such as Guillain-Barre syndrome and reactive arthritis have been reported to follow infection.⁵ In normal hosts, infection can often be asymptomatic. In immunocompromised individuals, most commonly AIDS patients, disease is more severe. Often chronic in this population, diarrhea may be profound with malabsorption and weight loss that can be life-threatening.^{6,7} In AIDS patients with waning CD4 counts, the coccidia infect a wider range of tissues, extending from the small intestine to the stomach, colon, and extra-gastrointestinal structures.^{4,8}

Epidemiologically, these pathogens have several patterns. In the United States and Europe, the major modes of infection are in water- or food-borne outbreaks, in travelers returning from the developing world, and in immunocompromised hosts. In the developing world, these coccidia are more prevalent; most people are first infected as children. In developing countries, malnourished or HIV+ children suffer more severe cases of longer duration with high mortality and greater long-term sequelae from their coccidial infections.⁶ Immunocompetent adults in the developing world have some degree of protective immunity and experience few or no symptoms.² Throughout the world, immunocompromised individuals are more frequently infected and more seriously affected than their immunocompetent counterparts.

Cryptosporidia

Since first reported as a cause of death in AIDS patients in the early 1980s, Cryptosporidia have become well-recognized human

pathogens with special relevance in AIDS-related infections and outbreaks.³ Of the many identified Cryptosporidia species, two regularly infect humans: *C. parvum* and *C. hominis*. *C. hominis* was only recently (2002) differentiated as a separate species from *C. parvum* because of molecular and clinical differences.^{1,6,9} Notably, *C. parvum* has a significant animal reservoir, while *C. hominis* has adapted to specifically infect humans.

Unlike Cyclospora and Isospora, Cryptosporidia's oocysts are immediately infective upon passage from the gastrointestinal tract in the host's feces. Because its entire life cycle is completed within the host's gastrointestinal tract, autoinfection may occur, resulting in the persistent infections seen in AIDS patients.^{3,4} The oocysts are extremely hardy in the environment, surviving and remaining infectious in ambient temperatures for months outside the host.^{3,10} Because they are resistant to extremes of temperature, chlorination, and desiccation, standard sanitation mandates for water processing and food preparation are often ineffective in eradicating the oocysts.¹¹

The immediate infectivity, hardiness of the spores, and low infectious dose make Cryptosporidium highly transferable through water- and food-borne contamination, direct person-to-person spread, and exposure to certain animals. In United States, there have been several outbreaks from water and food contamination. The largest occurred in 1993, when a water treatment plant serving more than half of Milwaukee, Wisconsin was contaminated and approximately 400,000 people were infected.¹² Cryptosporidial outbreaks have also been traced to a variety of food products, as well as exposure to communal water sources such as swimming pools and water parks.⁴ Direct person-to-person transmission has been implicated in institutions such as childcare centers, nursing homes, and hospitals. While *C. hominis* has an anthroponotic cycle, *C. parvum* is transmitted when humans are in close contact with animals. Cattle and sheep are an important reservoir of cryptosporidia, and exposed agricultural workers have higher rates of infection and seropositivity to this species.^{4,13}

Cryptosporidia affect the developing world more extensively than the West. In worldwide surveys of seroprevalence, endemicity rises in less developed countries. In the United States, seropositivity in adults and children is estimated between 25% and 35%, whereas it is about 50% in regions of China, and almost 100% in some urban Brazilian slums.^{2,11} In terms of clinical disease, approximately 2% of diarrheal syndromes in immunocompetent adults in developed countries are due to Cryptosporidia, whereas the rate is three times greater, at 6%, in developing countries.^{4,2} In AIDS patients with diarrhea, Cryptosporidia accounts for approximately 14% of cases in developed and 24% in developing countries.⁴

Despite recent advances, treatment of Cryptosporidium remains a dilemma. Nitazoxanide has been shown to be effective for the treatment of Cryptosporidial infections in immunocompetent adults and children over one year of age.^{14,15} In immunocompromised patients, however, results have been mixed, with demonstrated benefit in only

the mildly immunocompromised. In advanced AIDS, where disease is of the greatest burden, immune reconstitution remains the only demonstrated mode of cure. An antiretroviral therapy regimen that includes a protease inhibitor (versus a non-nucleoside reverse transcriptase inhibitor) is recommended, as protease inhibitors have demonstrated a direct toxic effect on Cryptosporidia.^{14,16,17,18}

Prevention is important, but challenging, with Cryptosporidia. The oocysts are ubiquitous and may survive even the most stringent water treatment programs. Improvements in water quality in developing regions, however, could reduce the burden of organisms in water sources and lower the risk of infection. In those immunocompromised patients at greater risk, aggressive personal measures may reduce risk of infection. Fastidious hygiene, avoidance of animal feces, and avoidance or treatment of public water by boiling for one minute or using a small-bore filter may be advocated. In health-care settings, standard precautions for patients with infectious diarrhea apply.³

Isospora

Contrary to Cryptosporidia, Isospora's oocysts are passed from its hosts in an unsporulated, dormant, form. In ambient conditions, these oocysts sporulate (becoming infective) within three days. Isospora infects only humans and is likely spread exclusively through fecal-oral transmission. It has worldwide distribution, with greater prevalence in tropical and sub-tropical areas, especially urban areas in Southeast Asia, Africa and parts of South America.¹⁹ In immunocompetent hosts, it causes a syndrome of diarrhea and peripheral eosinophilia. In developing countries throughout the world, Isospora are responsible for between 10% and 20% of chronic diarrhea.²⁰ As with the other enteric protozoa, Isospora often causes more serious disease in immunocompromised hosts. In the early 1980s, Isospora comprised approximately 2–3% of AIDS-defining illness in the United States. With the widespread use of trimethoprim-sulfamethoxazole for pneumocystis prophylaxis, it now represents less than 0.01%.²⁰ Accordingly, trimethoprim-sulfamethoxazole effectively treats Isospora, with several second-line agents also available. Prevention is important, especially in developing countries, with increased water sanitation and hygiene practices emphasized.

Cyclospora

Cyclospora were first detected in Papua New Guinea in 1977. It is now recognized as a worldwide cause of diarrhea with outbreak potential. Though postulated, an animal reservoir has not yet been identified. As with Isospora, immature oocysts are excreted through feces and require sporulation in the environment before becoming infective. In ambient temperatures, sporulation occurs in 1–2 weeks.²¹ Cold, heat, and desiccation can significantly delay sporulation and extreme conditions can prevent it. Cyclospora are ubiquitous throughout the world, with a cyclical incidence greatest in the spring and summer.^{21,22} Cyclospora are spread through fecal-oral transmission, and have been implicated in several outbreaks in the United States. Most notably, raspberries from Guatemala have caused outbreaks in North America over several different growing seasons. In 1996–1997, almost three thousand cases of cyclosporiasis were traced to Guatemalan raspberries, despite thorough attempts at disease eradication. Other fresh produce, such as basil and lettuce, and water contamination have also caused outbreaks.^{20,21} Cyclospora's clinical syndrome is similar to the other enteric protozoa, though in immunocompetent individuals it may be longer and have a cyclical pattern. Treatment and prevention are similar to Isospora.

Control of Infections in Institutions

Health Care-Associated Infections

R. Monina Klevens • Denise M. Cardo

► INTRODUCTION

Nosocomial or hospital-associated infections are adverse patient events that affect approximately 1.7 million persons and contribute to approximately 99,000 deaths annually in the United States.¹ The annual economic burden of these infections in the United States is estimated at \$6.7 billion per year, in 2002 prices.² Hospital-associated infections are one of the most common complications affecting hospitalized patients. One type of hospital-associated infection, surgical-wound infection, constitutes the second largest category of all hospital-associated adverse events, after drug-related events.³

During the past decade, health care in the United States has been increasingly delivered in a variety of settings, such as outpatient, long-term care, and home health settings. Invasive procedures are now frequently performed on an outpatient basis. Although the U.S. population has grown about 38% since the 1970s, the number of hospital admissions remains at 1975 levels (36.3 million in 2002 compared to 36.2 million in 1975); in contrast, the number of outpatient visits increased 2.5 times (to 640.5 million from 254.8 million).⁴ Further, the number of certified ambulatory surgical centers increased tenfold, from 336 in 1985 to 3371 in 2002. These changes result in an inpatient population that is more likely to have severe illnesses⁵ and be older.⁴

Because of the evolution in health care, the term “health care-associated infection” (HAI) has become more appropriate than “nosocomial infection,” since the latter is restricted to the hospital setting. Within hospitals, for many years, the highest rates of infections were observed in intensive care units (ICUs).^{6–8} However, recent studies have shown that procedures that pose a risk of infections (e.g., use of central venous catheters (CVC)) are also frequent outside ICUs. One study involving six medical centers revealed that 29% of 2459 patients had CVCs including 7–39% (mean 24%) of non-ICU patients.⁹

The epidemiology of HAI is best described in hospital ICUs and will be the focus of this chapter.

In general, HAIs are infections that are not present or incubating at the time of admission to the hospital or health-care facility.¹⁰ Infections are the most frequent adverse event in health care¹¹ and

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

occur at a rate of approximately 5–10 per hundred admissions.^{1,12} Many HAI are associated with an increased length of stay, prolonged therapy,^{13,14} and increased costs.¹⁵ Mortality is high: 26.6% of all deaths in a multihospital study were associated with an HAI.¹⁶ Among persons with a health care-associated bloodstream infection, the attributable mortality can be higher (35%).^{17–19}

Data from the Study on the Efficacy of Nosocomial Infection Control (SENIC) suggested that about a third of hospital-associated infections could have been prevented in the mid-1970s if effective infection control programs were in place;²⁰ however, a review of more recent studies suggests that preventability might range from 10% to 70% depending on the setting, the study methods, the baseline infection rates, and the type of HAI.²¹ Given the high cost of HAIs and increases in the costs of health care in the United States, there are strong financial incentives and benefits for hospitals to implement and maintain an effective infection control program.²²

► EPIDEMIOLOGY

General risk factors for HAI include factors related to the patient, the disease, and the management and treatment of the disease.²³ As in other settings, three elements are needed for transmission of infection in health care: a source of infection, a susceptible host, and a mode of transmission.²⁴ In health care, the source is frequently a human and less frequently the environment.²⁵ The host susceptibility varies and is influenced by characteristics such as age, nutritional status, comorbidities, and severity of underlying disease. Diagnostic procedures, various medical devices, and medical or surgical therapy may breach the normal host defenses and predispose to infections. Potent immunosuppressives, chemotherapy, and antibiotics may affect the host's normal colonizing flora, cause skin and mucosal membrane breakdown, and impair immune system function. Mode of transmission of organisms can be one of three primary routes: contact (direct or indirect), respiratory droplet, and air-borne.

Limiting potential for transmission requires various strategies. Prospective hospital surveillance may identify clusters of a particular type of infection or a specific infectious agent at an early stage. Importantly, investigation of the reservoirs of organisms and modes of transmission may allow effective interventions to be planned and implemented.²⁶ Appropriate use of diagnostic procedures, invasive

devices, and medical therapy, particularly antibiotics, may also decrease the likelihood of HAI. The hospital environment may be modified to prevent HAI; strategies to increase hand hygiene and other infection control approaches may be particularly beneficial.²⁷

Other factors associated with the occurrence of infections in health-care settings include the lack of adherence to infection control recommendations. Several factors related to the health-care system also play a role in the occurrence of HAIs. For example, the association of nursing staff shortages and increased rates of HAIs has been demonstrated in several outbreaks.²⁸ Infection rates differ considerably among hospitals, and measurement of HAI rates are a critical component of quality improvement.²⁹ Within an institution, rates vary by the type of ICU.³⁰ The ICU type is determined either by the disease condition of the patients or the type of specialty care provided.¹⁰

Infections by Site

The frequency of HAI also varies by body site and has changed over time. In the United States, in 2002, the most frequent HAIs overall were urinary tract infections (UTI) (32%), followed by surgical site infections (SSI) (22%), bloodstream infections (BSI) (14%), and pneumonia (15%).¹

Urinary Tract Infections

The greatest risk factor for UTIs is the use of urinary catheters,³¹ and utilization of urinary catheters is high in adult ICUs (from 56–85% of patient-days).³⁰ In medical ICUs, the mean rate of UTIs was 5.1 per 1000 catheter-days during 2002–2004;³⁰ catheter-related UTIs occur in about 13% of catheterized patients.³² The typical UTI prolongs hospital stay by an average of 1.2 days.³³ Urinary catheters might be needed for short or long term; the major indication for long-term use is urinary retention. Duration of catheterization is the most important risk factor for the development of catheter-associated bacteriuria.^{34,35}

Prevention of UTI starts with limiting the use of urinary catheters to necessary clinical indications and not for convenience of care.³⁶ Consideration of the risks and benefits of catheterization has led to development of more limited indications for its use. Alternative approaches to catheterization have included patient training and biofeedback, medications, surgery, and use of special clothes and pads. If a urinary catheter must be used, minimizing the duration of catheterization and maintaining a closed drainage system are recommended as measures to prevent bacteriuria. Aseptic technique is recommended during insertion, as is securing the catheter after insertion to prevent movement and urethral traction.³⁶ Several studies have demonstrated effectiveness of using urinary catheters impregnated with silver, in order to prevent UTI.^{37,38} The single measure most likely to prevent cross transmission of urinary pathogens is good hand hygiene after caring for each patient.^{39,40}

Four pathogens were each associated with at least 10% of the UTIs reported to NNIS from ICUs from 2000–2004: *Escherichia coli* (18%), *Candida albicans* (17%), *Enterococcus* spp. (13%), and *Pseudomonas aeruginosa* (11%). Other UTI pathogens reported to NNIS were associated with <10% of UTIs: *Klebsiella pneumoniae* (6%), *Enterobacter* spp. (4%), coagulase-negative staphylococci (3%), *Staphylococcus aureus* (2%), *Acinetobacter* spp. (1%), and *Serratia marcescens* (1%) (CDC unpublished data).

Surgical-Site Infections

SSIs constitute the second largest category of adverse events.³ SSIs result in increased morbidity, prolonged hospital stays, and increased direct costs.⁴¹ Rates of infection after surgery vary widely by surgical procedure,³⁰ and feedback of infection rates is helpful in preventing infections.²⁰ Among NNIS hospitals from January 1992–June 2004, the rate of SSI varied from a low of 1.8 per hundred procedures for certain surgeries of the musculoskeletal system to a high of 12.5 per hundred procedures for those of the head and neck.³⁰

Patient factors and factors associated with the wound affect the risk of infection. Adjustment for severity of risk of SSI rates requires the collection of additional information, such as wound classification (clean, clean-contaminated, contaminated, or dirty-infected), the physical status of the patient (using the American Society of Anesthesiology score ranging from 1 or healthy to 5 or moribund), and duration of the operative procedure.³⁰ In large part because use of laparoscopes was found to be associated with lower risk of SSI, the risk adjustment index incorporates a modification for laparoscope use.⁴² Most SSIs become evident after discharge,^{43,44} therefore post-discharge surveillance should be considered in institutions.

Guidelines for preventing SSIs have been developed by the Healthcare Infection Control Practices Advisory Committee (HIC-PAC);⁴⁵ general recommendations based on the strongest scientific evidence include postponing surgery until any remote site infections resolve, not removing hair preoperatively, administration of prophylactic antimicrobials only if necessary, administration of intravenous antimicrobials timed to ensure bactericidal levels from the time the incision is made to hours after the incision is closed.⁴⁵

The organisms associated with contamination of a surgical site vary by procedure, but overall, from 2000–2004 in NNIS hospitals, the pathogens most frequently associated with SSI were *S. aureus* (19%), *Enterococcus* spp. (16%), coagulase-negative staphylococci (13%), *P. aeruginosa* (9%), *Enterobacter* spp. (7%), *E. coli* (6%), and *C. albicans* (5%). Other pathogens were associated with ≤3% of SSI including *K. pneumoniae*, *S. marcescens*, and *Acinetobacter* spp.

Bloodstream Infections

An estimated one-half of all BSIs are health care-associated.⁴⁶ During 2002–2004 in NNIS hospitals, mean rates of central-line associated BSI ranged from 2.7 to 7.4 infections per 1000 catheter-days. The mean cost of a BSI is about \$35,000.⁴⁷ Mortality is high: an estimated 14% of hospital deaths may be associated with BSIs,⁴⁸ and the attributable mortality is about 23%.¹⁸ Among neonates in high-risk nurseries, the bloodstream is the most common site of HAI.^{12,49}

BSIs can be primary, when the isolation of a bacterial bloodstream pathogen occurs in the absence of an infection at another site, or secondary, when bacteria are isolated from the blood during an infection at another site with the same organism, for example, a UTI. Most primary BSIs are associated with the use of CVCs. Thus, prevention should include efforts to restrict use of catheters and remove catheters that are no longer necessary. For example, in dialysis patients, rates of BSI are lower among patients with fistula and graft vascular accesses compared to those with catheters.⁵⁰ Other important prevention recommendations are described in guidelines developed by HICPAC.⁵¹ These include training of health-care workers, hand hygiene, aseptic insertion technique, selection of catheter insertion site, and site care.

The pathogens associated with BSI have changed over time.⁵¹ For example, the frequency of BSI associated with coagulase-negative staphylococci in NNIS hospitals was 27% during 1986–1989 and 35% during 2000–2004. Two other pathogens were frequently associated with BSI during 2000–2004: *Enterococcus* spp. (15%) and *S. aureus* (14%). The frequency of BSI associated with antimicrobial-resistant organisms is increasing.⁵² To address this problem, the Centers for Disease Control and Prevention (CDC) launched a campaign to prevent antimicrobial resistance in health-care settings in 2002.⁵³ This campaign targets clinicians and focuses on four strategies: (a) prevent infections, (b) diagnose and treat infection effectively, (c) use antimicrobials wisely, and (d) prevent transmission (see resources section for more information).

Pneumonia

Pneumonia and lower respiratory infections are associated with significant morbidity, mortality, and costs.⁵⁴ The greatest risk factor for health care-associated pneumonia is the use of mechanical ventilation.⁵⁵ In the United States, ventilator-associated pneumonia (VAP) occurs at a mean rate ranging from 4.4 to 15.2 infections per

1000 ventilator-days in adult ICUs; in pediatric ICUs, the mean rate is lower (2.9 infections per 1000 ventilator-days).³⁰ Utilization of ventilators among patients reported to NNIS ranged from a mean of 25% to 71% during 2002–2004.³⁰ Attributable mortality of VAP ranges; in one community hospital it was 13%⁵⁶ but in special populations can be greater.⁵⁷

Multiple factors are associated with development of VAP and mortality. Risk factors for VAP include comorbid conditions such as burn, trauma, central nervous system disease, and cardiac and respiratory disease.⁵⁸ Strategies to prevent VAP and other acute respiratory infections were recently developed by HICPAC.⁵⁴ These include appropriate infection control of equipment and devices, hand hygiene, and standard precautions. The guidelines also address prevention of VAP and other infections outside of acute care hospitals; among these, vaccination is recommended for primary prevention of influenza.

Two pathogens were most frequently associated with VAP in NNIS hospitals during 2000–2004: *S. aureus* (26%) and *P. aeruginosa* (16%). Other pathogens were less frequent, including *Enterococcus* spp. (9%), *K. pneumoniae* (6%), *Acinetobacter* spp. (6%), *S. marcescens* (5%), *C. albicans* (4%), *E. coli* (4%), and *Haemophilus influenzae* (3%).

Other Health-Care Settings

With the delivery of health care expanding to a variety of settings outside of acute care hospitals, infection control programs will need to be developed and implemented in those settings.

Long-Term Care Facilities

In 2002, approximately 1.5 million persons 65 years of age and older resided in a nursing home.⁴ Care for elderly patients is complicated and HAIs are facilitated by the interaction of multiple risk factors, including age and its associated decrease in immunity;⁵⁹ multiple comorbidities, including cognitive impairment;⁶⁰ decreased functional status (e.g., urinary and fecal incontinence, immobility);⁶¹ long-term exposure to medical devices (e.g., urinary catheters); and an environment that supports opportunities for person-to-person transmission of pathogens during routine group activities such as dining, physical therapy, or recreational activities.

Outpatient Dialysis Centers

In 2003, there were over 250,000 chronic hemodialysis patients and about 4000 hemodialysis centers.⁶² Dialysis patients are at high risk for HAI for several reasons:⁶³ they require vascular access for prolonged periods for their hemodialysis; they are immunosuppressed and more susceptible to infection; they require frequent hospitalizations and surgery; and frequently have comorbidities.⁶² Antimicrobial resistance is an important issue for dialysis patients because they often receive antimicrobials including vancomycin; five of the first six patients with vancomycin intermediate or fully resistant *Staphylococcus aureus* were dialysis patients.⁶⁴ Vascular access is the strongest risk factor for infection; grafts and fistulas should be preferred over temporary and permanent catheters;⁵¹ other recommendations to prevent infections have been developed for peritoneal and hemodialysis patients.^{50,51,63,65} Primary prevention in the form of an *S. aureus* vaccine is uncertain.⁶⁶

Home Care and Other Outpatient Settings

Outpatient care is delivered in multiple settings, including outpatient clinics within hospitals, non-hospital-based physician and dentist offices, public health clinics, and ambulatory surgical centers. In 2002, about half of the U.S. population made at least one visit to a doctor's office or emergency room or had a home health-care visit.⁴ Of all surgical procedures in community hospitals in 2002, 63% were on outpatients compared with 16% on outpatients in 1980.⁴ In 2000, 1.3 million patients were enrolled in home care.⁴ Although patients receiving care in outpatient settings might not be more susceptible to HAI, invasive procedures in outpatient settings carry the

risk of infections. There are few data on HAI in outpatient settings; however, several outbreaks have been reported, usually related to breaks in basic infection control. Unsafe injection practices, reuse of syringes and needles, and contamination of multiple-dose medication vials have been associated with transmission of infections in outpatient settings.^{67–69} Intravenous infusion therapy has been identified as an important risk for infections in home care patients.⁷⁰

Antimicrobial Resistance and Emerging Infections

The frequency of HAI associated with resistant pathogens has increased substantially over the past decade. Resistant infections are frequently associated with increased mortality, morbidity, and costs;⁷¹ however, the factors contributing to increasing resistance are complex.⁷² To control resistance, a strategy is necessary that includes a monitoring system for antimicrobial use and associated outcomes, development of guidelines for control of antimicrobial use, and appropriate implementation of infection control.⁷³ During the last several decades, the prevalence of multi-drug-resistant organisms in the U.S. hospitals and medical centers has increased steadily. Methicillin-resistant *S. aureus* (MRSA), first recognized in the 1960s, became endemic in many hospitals during the 1990s. MRSA in NNIS hospitals increased from 29% of HAIs in ICUs in 1991⁷⁴ to 64% in 2004.^{30,75} Although resistance is a global problem, prevalence of resistance in HAIs appears to be highest in the United States.⁷⁶

In 1996, the first clinical isolate of *S. aureus* with reduced susceptibility to vancomycin was reported (VISA), and as of December 2004, 12 VISA infections had been confirmed in patients in the United States.⁷⁷ In June 2002, the first clinical isolate of vancomycin-resistant *S. aureus* (VRSA; vancomycin MIC greater than 32 µg per mL) was identified and by February 2005, two additional cases had been reported in the United States.^{78–80}

Infection control programs have been important in the control of emerging threats. Following the terrorist attacks on September 11, 2001, and the subsequent outbreaks of anthrax, health-care facilities developed plans to address bioterrorism preparedness and response. In 2003, health-care facilities were at the center of the severe acute respiratory syndrome (SARS) outbreak—a newly discovered respiratory disease caused by SARS-Corona virus that emerged in China and spread globally.⁸¹ The infection control issues to be addressed in response to natural or intentional infectious threats include preventing transmission among patients, health-care personnel, and visitors; identifying persons who may be infected or exposed; providing treatment and prophylaxis; protecting the environment; and providing appropriate staffing.

Components of Effective Infection Control Programs

A model infection control program, recommended by CDC, the American Hospital Association, and the Joint Commission on the Accreditation of Healthcare Organizations, was adopted in principle by many U.S. hospitals by the mid-1970s.⁸² CDC conducted the SENIC in the late 1970s to evaluate the effectiveness of hospital infection control programs.¹² This study demonstrated that hospitals with active surveillance and control programs had significantly fewer infections than did hospitals without such programs. The SENIC study also found that four elements were associated with effective programs:¹ an active infection surveillance system with reporting of results to staff members,² presence of vigorous control measures designed to eliminate recognized hazards,³ at least one full-time infection control practitioner for every 250 beds, and⁴ a physician on the staff knowledgeable about hospital-associated infections who took an active part in the infection control program.

Most infection control teams in the United States consist of a hospital epidemiologist and one or more infection control practitioners. The traditional duties of the infection control team include the collection and analysis of surveillance data, assisting in the development of infection control policies and procedures, and providing education and consultation to other hospital personnel. The team also

plays a critical role in advising the hospital's medical staff and administration about the clinical implications of patient-care practices, occupational infections, and quality improvement. Changes in the health-care delivery system and the emergence of new infections and bioterrorism added even more activities and responsibilities to the infection control team. A study using the Delphi method⁸³ examined infection control activities in 2001 and recommended a ratio of 0.8–1.0 ICP for every 100 occupied acute-care beds. However, despite the additional responsibilities, the ratio of one infection control practitioner for every 250 acute-care beds has continued in many health-care facilities in the United States since the 1976 SENIC project.

Surveillance

Surveillance is a first step in describing any public health event, and, in the area of HAI, implementation of surveillance is associated with a decline in infection rates in participating hospitals.⁸⁴ In the United States, methods for monitoring HAIs evolved from a hospital-wide system that counted the number of infections⁸⁵ to the application of standardized case definitions and methods that allow risk-adjusted comparisons today.⁸⁶ NNIS was an example of a hospital-based, systematic, voluntary, and confidential reporting system.^{11,87} Infection control practitioners are largely responsible for conducting surveillance activities in hospitals in addition to meeting many other demands, and resources are increasingly limited. Health-care surveillance systems are challenged to capture events associated not only with infections but also with medical errors, indicators for quality of patient care, and potential bioterrorism. Mandatory public reporting of HAI by health-care facilities has been enacted in several states. The perceived purpose of public reporting is to improve health-care quality through consumer choice; however, no data are available to support the effectiveness of public reporting. Although HICPAC has not recommended for or against public reporting, guidance from HICPAC includes the use of existing public health surveillance methods and feedback to health-care providers before public release of HAI data.⁸⁸

NNIS started in 1970 as a partnership between CDC and volunteer hospitals in the United States.⁸⁵ Through the partnership, protocols and definitions were developed, and prospective, hospital-wide surveillance for HAIs was initiated. In 1986, the focus of surveillance in NNIS shifted to patient-care areas with the highest infection rates and the collection of data that allowed risk adjustment and comparison of rates across hospitals.⁸⁵ The four components of NNIS were adult and pediatric ICU, high-risk nursery, surgical patient, and antimicrobial use and resistance.⁸⁹ A standard protocol was used for each component. The standardization of definitions and the collection of denominators such as days of device utilization or risk factors for SSI are necessary for comparisons across hospitals. A description of the NNIS system, definitions, and data collection forms are available.⁸⁹

Hospital participation in NNIS was restricted due to limitations in resources and an emphasis on larger hospitals; however, in 2005, NNIS integrates with dialysis and health-care worker surveillance into the National Health-care Safety Network (NHSN).⁹⁰ This change allows broader participation of hospitals and other health-care facilities over time and improves the utility of surveillance for prevention and quality improvement. An example of how the NHSN can support prevention efforts is through collection of process measures as performance indicators (e.g., the use of sterile barrier precautions during catheter insertion).⁵¹ Pilot testing is underway to determine whether feedback of information on process of care can increase adherence to recommended practices.

In the past few years, efforts to improve the efficiency of surveillance include the use of computer algorithms to identify patients likely to have an HAI.^{91,92} In addition, the sensitivity of SSI surveillance can be improved by using electronic data.⁹³ These practices standardize case finding and create efficiencies by targeting the review of medical records. CDC has explored simplification of HAI surveillance; one example is sampling for the number of days a catheter is used among patients to create an estimated denominator for BSI rates. Preliminary data suggest that counting patient-days and

estimating catheter-days from a sample of days or months is a promising approach that permits risk adjustment while potentially reducing the burden of collecting data on catheter-days.⁹⁰

Investigation of HAIs

Even in hospitals with exemplary infection control programs, epidemic and endemic infections continue to occur. Usually, an infection control committee oversees the HAI investigation activities of the hospital's infection control team. Occasionally, however, outside assistance is required from local or state health departments or the CDC. Most epidemiologic investigations are case-control studies, although other study designs, such as retrospective cohort or cross-sectional studies, can be useful.

Infection Control and Prevention

Preventing HAIs is an integral part of the national safety agenda in response to the Institute of Medicine's report *To Err Is Human: Building a Safer Health System*.⁹⁴ The systematic collection and analysis of data on HAIs have yielded critical, evidence-based information that can improve infection prevention and control. Data from the NNIS system have shown that during 1990–1999, risk-adjusted infection rates decreased for all three body sites (i.e., respiratory tract, urinary tract, and bloodstream) monitored in ICUs. BSI rates decreased substantially in medical ICUs (44%), coronary ICUs (43%), pediatric ICUs (32%), and surgical ICUs (31%).⁶

Data from the NNIS system have generally been used to motivate hospitals with higher than expected infection rates to strive for the relevant national benchmark rate.³⁰ However, with this approach, hospitals might not assess the preventability of infections unless the institution's rates are high or increasing. Several hospitals, however, are adopting "zero" preventable infections as a goal. Continuous quality improvement efforts, which focus on a continuous cycle of event tracking and process improvement, can be applied to reduce serious medication errors.¹¹ Most preventable HAIs are related to specific patient-care practices, and guidelines are available to minimize their infection risk.^{22,27,35,45,51,54} In addition, hospitals should develop and implement policies for isolation of patients with potentially communicable diseases, use of antimicrobial agents, and control of the hospital environment.

In the last few years, several new strategies have been developed and evaluated to improve prevention of HAIs. Advances in information technology have been adopted for use in health care, and several applications can help identify and prevent HAIs, including computerized decision support systems, personal digital assistants for data collection and management of patients, and web-based systems for education and training.⁹⁵ Another example is the improvement in strategies to prevent BSIs. Randomized, controlled trials have demonstrated that strategies such as preparing the skin with chlorhexidine antiseptic, using maximal sterile barrier precautions, and using a CVC with anti-infective properties can significantly reduce the risk of catheter-related infections.^{51,96} Since 2002, hand hygiene products such as alcohol-based rubs containing an emollient that do not require the use of water have been recommended in U.S. health-care facilities to improve adherence to hand hygiene. Adherence to recommended hand hygiene is the single most important practice to reduce the transmission of infectious diseases in health-care settings.²⁷

Despite advances in technology and several studies showing the efficacy of new strategies to prevent HAI, studies suggest that health-care worker adherence to recommended infection control practices varies widely, from 5% to 81%.²⁷ Improving adherence to infection control practices requires a multifaceted approach that incorporates continuous assessment of both the individual and the work environment.⁹⁷ Studies have shown that an educational program directed to nurses and physicians may significantly improve adherence to infection control practices and reduce the incidence of infections in specific units.⁹⁸ Once achieved, high levels of adherence need to be maintained for behaviors to become routine. Continued surveillance will help inform action, if necessary.

► RESOURCES FOR SURVEILLANCE AND CONTROL OF HAI

- Centers for Disease Control and Prevention: Rates of HAI, device utilization, resistant pathogens, and use of antimicrobials are published annually in the American Journal of Infection Control and are available from the CDC website (<http://www.cdc.gov/ncidod/hip/default.htm>). Guidelines for prevention and control of HAI are developed in partnership with HICPAC. The Campaign to Prevent Antimicrobial Resistance is a resource for health-care facilities to educate clinicians about a comprehensive strategy to prevent and control resistance. This campaign targets clinicians and focuses on four strategies: (a) prevent infections, (b) diagnose and treat infection effectively, (c) use antimicrobials wisely, and (d) prevent transmission. Within these four strategies, the campaign consists of multiple evidence-based 12-step programs targeted to clinicians who treat various specialty-specific patient populations (i.e., hospitalized adults, hospitalized children, surgical patients, patients in dialysis, and residents in long-term care) www.cdc.gov/drugresistance/healthcare. Guidance and educational materials for improving hand hygiene are also available (<http://www.cdc.gov/handhygiene/>). In addition, CDC provides technical assistance with outbreaks of HAI and protocols for monitoring and reporting VISA and MRSA.
- The Association for Professionals in Infection Control and Epidemiology (APIC; <http://www.apic.org/AM/Template.cfm?Section=Home>) and the Society for Healthcare Epidemiology in America (SHEA; <http://www.shea-online.org>) are professional organizations of persons working in health-care epidemiology and infection control. Both conduct training activities in infection control and surveillance for HAI.
- The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) requires that accredited hospitals have an active infection control program, an infection control committee, and specific written infection control policies and procedures for each of the hospital's departments. The JCAHO also requires written definitions of nosocomial infections, a system for reporting of infections, laboratory support for infection control, an active employee health program, and review of antibiotic use.
- The American Hospital Association's Committee on Infections within Hospitals has published guidelines for establishing infection control programs.
- State health departments and universities provide training courses and advice or assistance in conducting epidemiological investigations.

► ACKNOWLEDGMENTS

The authors acknowledge NNIS participants for their efforts to monitor and prevent healthcare-associated infections.

Diseases Transmitted Primarily by Arthropod Vectors

Viral Infections

Elizabeth A. Kleiner • Richard P. Wenzel

► INTRODUCTION TO ARBOVIRUSES

Arboviral, or arthropod-borne diseases are among the most important emerging infections. Arthropods, of the phylum Arthropoda, are invertebrates with a chitinous exoskeleton and internal hemocoel for blood meals. Mosquitoes, ticks, sand flies (phlebotomus) and midges serve as the primary arboviral vectors. The transmission by these vectors is biologic, rather than mechanical, in that true arboviruses replicate in arthropod tissues and salivary glands prior to transmission, rather than being simply carried by vectors.¹

Arboviruses produce a wide range of clinical manifestations. Primary hosts generally develop an asymptomatic viremia exemplifying a balanced host-parasite relationship. In non-susceptible hosts an abortive infection can occur in which there are no clinical manifestations or viremia, but serum antibodies can be detected.² Because of the individual variability within host species, severe or medically recognizable disease is often dependent on age and occurs in a small fraction of the total number of individuals infected. The disease patterns of arboviruses in clinically susceptible hosts provide a basis of classification and include the following: (a) acute central nervous system disease, including aseptic meningitis, encephalitis, or encephalomyelitis; (b) undifferentiated febrile illness that can occur with or without a rash; (c) fever and arthritis with or without a rash; and (d) hemorrhagic fever, a febrile systemic illness with hemorrhagic manifestations, cardiovascular instability and varying degrees of hepatic and renal insufficiency. Arthropod-borne hemorrhagic fevers, most of which produce the hemorrhagic fever syndrome, will be described in another chapter that includes non-arthropodborne (often rodent-associated) zoonotic disease.

► CLASSIFICATION OF ARBOVIRUSES

Arboviruses belong to a number of different taxonomic groups. The term arbovirus is a convenient, but imprecise, classification with different viral replication strategies and some viruses that are not transmitted by arthropods.¹ Of the more than 534 viruses listed in the *International Catalogue of Arboviruses*, only 134 have been shown to cause disease in humans; however, those that produce unusually severe disease or are of high incidence are much fewer.³ Most medically important arboviruses are included in the seven RNA virus

families of Togoviridae, Flaviviridae, Bunyaviridae, Reoviridae, Arenaviridae, Filoviridae and Rhabdoviridae⁴ (Table 15-1).

► EPIDEMIOLOGY OF ARBOVIRUSES

The distribution and incidence of arbovirus infections are affected by epidemiological, ecological, and biological factors including geophysical barriers, geographical distribution of hosts and vectors, climate, seasonal variations, the complexity of vector-host transmission cycles and viral recrudescence and survival mechanisms (Table 15-2).

Geographical Distribution

Geographical distribution may be physical or biological. Geophysical barriers such as a mountain range or body of water may limit vector and host distribution. However, there has been a resurgence and geographical spread of arboviruses due to changes in global demographics and modern transportation.⁵ Furthermore, expansion of global air travel and sea trade routes has provided mechanisms for viruses to break out of their natural habitats and become established in new locations providing permissive conditions for the occurrence of epidemics.

Biologic barriers that may limit the geographical distribution of arbovirus infections are determined by the presence or absence of susceptible vertebrate hosts and competent arthropod vectors. Viruses that utilize avian hosts tend to be more widely distributed than those viruses that utilize small terrestrial mammals with restricted territories and migration.⁶ Relative non-susceptibility of arthropod vectors or hosts to a particular virus also limits distribution. These biological factors are possible explanations for the absence of yellow fever epidemics in Ghana, despite the presence of the appropriate vector species and hosts.⁷ In developed countries improved sanitation, living conditions and lifestyle changes have significantly impacted the prevalence of vector-borne disease.⁸

Epidemiologic evaluations also show that the distribution of a virus may be much wider than that of the associated disease. Explanations for these discrepancies include the following: (a) the vector may have minimal interaction or be only weakly attracted to human hosts; (b) the virus may circulate only in remote, inaccessible areas rarely visited by humans or be under minimal medical surveillance; and (c) viral strains have reduced virulence in humans.⁹

TABLE 15-1. CLASSIFICATION OF MEDICALLY IMPORTANT ARBOVIRUSES

Family	Transmission	Host	Syndrome
Arenaviridae	Aerosolized	Rodents	Lymphocytic choriomeningitis
	Aerosolized	Rodents	Lassa fever
	Aerosolized	Rodents	South American Hemorrhagic Fevers: Machupo, Junin, Guanarito, Sabia
Bunyaviridae	Mosquitoes	Rodents	La Crosse encephalitis
	Mosquitoes	Rodents	California encephalitis

Seasonal Distribution and Chronology of Epidemics

Climate and seasonal variations play an important role in the epidemiology of arboviral infections due to the impact on vector density and activity. Seasonal variations typically correspond to vector breeding cycles and periods of peak population density.^{10,11} In temperate zones, vector density is highest from late spring through early fall. In tropical regions, the rainy seasons are associated with high vector density. Even with the same vector and hosts, the seasonal distribution of arboviral diseases may vary due to the duration of replication, viremia and incubation. The mosquito vector *Culex tarsalis* and birds serve as the respective vector and reservoir host for both Western equine encephalitis and St. Louis encephalitis. Western equine infections occur in early summer, but due to greater temperature dependence for replication and vector transmission, prolonged vector incubation and brief host viremia, St. Louis infections occur in late summer and fall.^{12,13}

► VARIABLES AFFECTING VECTOR-HOST TRANSMISSION CYCLES

Arboviral transmission cycles may be simple, involving only one host and one vector, such as dengue and yellow fever, or more complex with enzootic cycles, involving one or more vector species and

animal hosts. The viral susceptibility of the vector and host and the ability of the host to mount a viremic response are important determinants in arboviral transmission.

After ingestion of a blood meal from a viremic vertebrate, the vector develops a systemic infection that eventually affects the salivary glands. This period of vector viremia typically lasts 1–3 weeks and is called extrinsic incubation.² Upon completion of extrinsic incubation, an arthropod is capable of transmitting the virus to another susceptible vertebrate at the next blood meal. Therefore, the role of the vector is biological and dynamic, because active viral replication occurs within the vector providing a secondary reservoir for amplification for true arboviruses. The viral biology creates a highly efficient means for transmission: a small inoculum of virus into the arthropod vector can be greatly amplified.

Several factors related specifically to the vector, such as abundance, longevity and host preference, determine the rate of viral transmission and the risk of epidemics. Vector abundance depends on factors that affect breeding and survival. For example, climatic and environmental variations dramatically impact vector abundance accounting for many of the seasonal variations in arboviral infections. As an illustration, human and equine cases of Western equine encephalitis appear only when the density of *C. tarsalis* vectors reaches 3.2 adult females per light trap night.^{11,14} Yet extremely high vector densities may actually inhibit viral transmission due to host-avoidance behaviors or changes in host-selection patterns. Longevity is critical, since even a brief prolongation in vector lifespan may increase the proportion of the vector population capable of transmitting virus.¹⁵ The host preference of a vector species is also epidemiologically important, since vectors that are strongly attracted to reservoir hosts and are highly anthropophilic are ideal vectors. Host preferences may change during a season: the vectors of Western equine and St. Louis encephalitis viruses shift from predominant avian feeding in early summer to mammals, including humans, in late summer.⁶ This is ideally suited to viral amplification and often results in spillover to human populations.

Important Vectors: Mosquitoes and Ticks

Mosquitoes require aquatic habitats for oviposition (deposition or laying of eggs) and larval development. Suitable habitats that promote breeding vary by species, but are areas that hold standing water. Natural habitats include salt- and freshwater marshes, mangroves, swamps, lakes, ponds, streams, rain pools and tree holes. Man-made mosquito habitats include storm water control ditches, floodwaters, irrigation system runoff and man-made receptacles, such as discarded rubber tires.¹⁶ Viruses that utilize mosquito vectors adapted to habitats that are in close proximity to human populations tend to be responsible for the major epidemic diseases.

Most mosquito-borne arboviruses develop highly evolved and specialized relationships with vectors and hosts, thereby minimizing the jump to a new vector and reservoir host. However, there are a few examples of viruses that are transmitted by a wide array of taxonomically and ecologically different vectors.⁷

Ticks transmit the widest variety of pathogens of any blood-feeding arthropod. The two well established families of ticks include *Ixodidae*, hard ticks, and *Argasidae*, soft ticks. Both are important vectors of zoonoses and disease. Ticks have complicated life histories in order to optimize contact with susceptible hosts. During the larval, nymph and adult stages, the tick may seek a different host, which adds to the complexity of the transmission cycle. For example, *Dermacentor andersoni*, the hard tick vector for Colorado tick fever is a three-host tick, feeding on a different host during each life stage.¹⁷ Tick-borne infections tend to be endemic rather than epidemic due to lower vector densities and specialized and focal ecological niches.¹⁸

Some tick-borne viral populations may be amplified without the need for virus replication in the vertebrate host. For example, attached, infected ticks may transfer certain viruses, such as orthomyxoviruses, flaviviruses, and nairoviruses, directly to co-feeding uninfected ticks via the host's tissue lymphatics and macrophages without the need for vertebrate host viremia or viral replication.^{19,20}

TABLE 15-2. CHARACTERISTICS OF SELECTED ARBOVIRAL INFECTIONS

<i>Predominant Season</i>	<i>Syndrome and Pattern</i>	<i>Virus</i>	<i>Vector</i>	<i>Animal Hosts</i>	<i>Geographical Distribution</i>	<i>Incubation</i>	<i>Treatment</i>	<i>Vaccine</i>	<i>Laboratory Data</i>	<i>Differential Diagnosis (not all inclusive)</i>
March–November (peak April–June)	Encephalitis Endemic	Colorado Tick Fever	Tick	Mammals	Western United States and Canada	3–4 days	Supportive	N/A	Serology positive 10-14 days after symp- toms onset; PCR available	Other arboviral encephalitides, Ehrlichiosis, Lyme Disease, Q Fever, Rela- psing Fever, Rocky Moun- tain Spotted Fever, Tularemia
March–November (peak June–July)	Encephalitis Endemic	Tick-borne encephalitis	Tick	Mammals	Eurasia	7–14 days	Supportive	Not available in U.S.	Viral isolation from blood, CSF or tissue; Serological; IgM in CSF; PCR available	Other arboviral encephalitides, Ehrlichiosis, Lyme disease
April–September (peak July–August)	Encephalitis Endemic– Epidemic	Western equine encephalitis	Mosquito	Birds, horses	Americas	~7 days	Supportive	Inactivated equid vaccine	Viral isolation from CSF, blood or tissue; Serology; IgM in CSF; PCR available	Other arboviral encephalitides, Bartonellosis, Brain abscess, Cytomegalovirus, Herpes Simplex, Histoplasmosis, Leptospirosis, Lyme Disease, Malaria, Mycoplasma Infection, Naegleria Infection, Rheumatoid Arthritis, Stroke, Subarachnoid Hemorrhage, Systemic Lupus Erythematosus, Toxoplasmosis, Tuberculosis
April–December (peak August– September)	Encephalitis Endemic– Epidemic	West Nile virus	Mosquito	Wild birds	Americas, Eurasia, Africa, Middle East, Australia	2–15 days	Supportive	N/A	Culture from blood within 1st 2 weeks of infection; Serology; PCR available	Other arbovirus encephalitides, Enterovirus encephalitis, Herpes Simplex encephalitis, Meningitis (bacterial, tuberculous or fungal)

Important Hosts: Wild Birds, Rodents, and Domesticated Animals

Wild birds are important vertebrate hosts in the transmission cycles of most of the mosquito-borne arboviral disease, and some ground-dwelling birds may also play a role in tick-borne infections. Avian hosts play an important role in human infections due to large populations that are closely associated with humans and livestock. Due to migration patterns, avian hosts also assist in the transportation, dissemination and reintroduction of viruses over large geographical areas. During the spring and summer, nestling birds that are relatively defenseless against mosquito bites often support higher levels of viremia than adults and are considered important hosts for some viruses.^{21,22}

Birds generally develop viremia within 18–48 hours after inoculation by an infected arthropod. The viremia may last only 2–5 days or be prolonged depending on the specific viral species. Birds generally remain asymptomatic, and the viremia is followed by the appearance of specific antibodies. While most bird hosts are asymptomatic, outbreaks of arboviral disease have occurred. Significant avian mortality has also been noted in dead bird surveillance studies for West Nile Virus in the United States and Canada and may serve as a harbinger of human infections.^{22,23}

Rodents are the principal hosts for mosquito and tick-borne disease as well as viruses responsible for certain zoonotic hemorrhagic fevers. General characteristics of rodent hosts that affect viral transmission rates include high reproductive capacity and population turnover, limited movement and dispersal, and, often, specific requirements for habitat. These factors favor restricted viral transmission, although focal epidemics can occur. Rodents tend to be hosts for the larval and nymph stages of tick vectors, whereas the tick adult stage generally feed on large animals, including humans.¹⁷

Domestic animals are effective viremic hosts for a limited number of arboviruses. Domestic animal hosts not only serve as a source for amplification and vector feeding, but tend to show overt clinical manifestations of disease. Since viral amplification in livestock precedes spillover to human population, epizootic infections warn of an impending epidemic. Arboviral diseases of epidemiologic importance that affect domesticated animals include Venezuelan equine encephalomyelitis in *Equidae*, Rift Valley fever in sheep and cattle and Japanese encephalitis in swine.^{2,24} Unlike agents with rodent or avian hosts that have high reproductive potential, epizootics caused by these viruses often deplete the population of immunologically susceptible large animal hosts, so several more years may be required to attain susceptible host population densities allowing a high rate of viral transmission.

Viral Recrudescence and Survival Strategies

Virus survival is threatened during the winter and dry months when arthropod vector densities decrease and viral transmission and amplification is slowed or interrupted. Overwintering is an important concept in the epidemiology of vector-borne disease and includes known and speculative strategies for local survival or reintroduction. Overwintering may depend on the level of viral activity during the preceding summer and fall, accounting for arboviral outbreaks that commonly occur in two or more successive years. Strategies include hibernation, chronically infected reservoirs, transovarial infection and reintroduction.²⁵

Hibernation of arboviruses in the primary arthropod vector through adverse survival periods has been well documented in the nonpathogenic alphavirus Fort Morgan, which is transmitted and maintained by avian bedbugs, as well as for Colorado tick fever and tick-borne encephalitis viruses.^{26,27} Virus species persist in hibernating nymph and adult ticks. Hibernation as a survival strategy in mosquito vectors is less clear. The *Culex* genus hibernates in the adult stage, and midwinter isolation of the St. Louis virus in *C. pipiens* and Western equine virus in *C. tarsalis* has been reported. However, some studies have shown that female mosquitoes that have taken a blood meal in order to acquire viral infection appear physiologically poorly prepared for hibernation and rarely survive the winter.²⁸

Survival through chronically infected vertebrate reservoirs to span periods of vector hibernation has been speculated as a possible recrudescence strategy for arboviruses. This has been experimentally demonstrated in bats with St. Louis and Japanese encephalitis and in small mammals with tick-borne encephalitis and certain species of the California encephalitis group.² However, evidence of chronically infected animals that maintain arbovirus viremia in nature is lacking. Rodent-borne viruses such as the hantaviruses and arenaviruses are maintained in nature by chronic infections that are transmitted among rodents. Chronic shedding of virus in the urine by rodents harboring chronic infections also serves as an important mechanism of disease transmission to humans.²⁹

An alternative method for virus maintenance is transovarial transmission in an arthropod vector. This mechanism likely evolved due to limitations in the specific vector-host relationship of these viruses. Vertical transmission is a common strategy among members of the Bunyaviridae family.² The vertebrate hosts for these viruses are small forest rodents unsuited for dispersal or reintroduction of virus from afar; the vector *Aedes* only overwinters in the egg stage. This type of transmission is extremely efficient with successful transmission to 70–90% of the progeny of infected female *Aedes* mosquito. Up to one percent of collected mosquitoes hatched from overwintering ova are infected.³⁰ Evidence has now been obtained to show that a number of flaviviruses may be vertically transmitted by *Aedes*; although rates of inherited infection are often lower and require high rates of summertime amplification for successful survival of mosquito ova.³¹ Certain tick-borne infections are also transovarially transmitted within tick vectors.

Viruses can also be reintroduced to a habitat by migratory vertebrates. Transport of viruses over long distances by migratory birds has occasionally been documented, but it is generally not considered to be an important mechanism for the annual recrudescence of viral activity.

► SURVEILLANCE, PREVENTION, AND CONTROL OF ARBOVIRUS DISEASES

Systematic evaluation of biological and ecological factors that affect the dynamics of arbovirus transmission is necessary in order for surveillance programs to successfully anticipate outbreaks and intervene with preventive actions. Such efforts require coordinated efforts of health agencies from the local, state and federal level. While the specific sampling requirements vary based on local resources and population needs, most surveillance programs include monitoring of virus activity, vector population density, vertebrate host infections, human cases as well as landscape ecology, season, climate, and weather data.²⁴ In general, the transmission cycles of arbovirus require amplification and cumulative infection of vectors and vertebrate hosts before the virus can spillover into human populations. A proactive surveillance system will detect changes in vector and transmission cycles affecting enzootics that lead to epizootics or epidemics. Control measures should be initiated as soon as particular predictors exceed action thresholds, as dictated by historical data or experience.

Arbovirus surveillance programs use a variety of host species and vector sampling techniques. Mosquito surveillance involves identifying and mapping larval habitats and monitoring adult mosquito activity. Specific information on mosquito populations includes light trap indices, viral infection rates and changes in temporal and spatial patterns of vertebrate host infections. Monitoring infection rates in sentinel host species can be a practical and sensitive surveillance tool. There is no single sentinel host species that is effective in all areas. Sentinel species vary depending on location and include populations of wild birds, horses and small mammals such as rabbits, chipmunks, foxes, and rats. Accurate monitoring of these parameters provides an early warning of increased transmission that may constitute a risk to human populations.³² Local agencies should conduct surveys to gather data and information on various factors in order to design a surveillance system that fits local needs effectively and economically.

Suspected human cases should be reported to local and state health departments in order to initiate investigation and control measures as appropriate. For reporting purposes, clinical data must be collected to ensure that the case meets the criteria for the surveillance case definition as outlined by the Centers for Disease Control and Prevention 2004.³³ Suspected cases should be evaluated for exposure history and risk factors for illness. History should include recent travel to areas with known viral activity in mosquito populations, as well as peridomestic, neighborhood, occupational and recreational exposure risk that may promote exposure risk, such as empty tires and containers, outdoor activities and lack of air conditioning.

Increased or early arbovirus activity in animal populations, or reports of human cases may herald an impending outbreak in humans. Five risk categories developed by the Centers for Disease Control and Prevention define the probability of an outbreak and outline the recommended response.²⁴ Increased surveillance for human cases should be considered when an outbreak is suspected or anticipated. Strategies may include an increase in active or passive local hospital and clinic surveillance of specific syndromes, as well as alerting and educating local health-care workers of testing and reporting procedures. Such measures may increase the sensitivity of surveillance systems.

The prevention of epidemics may be achieved through vector management programs in conjunction with public health education. Vector control is most successfully applied to mosquito populations. Comprehensive and integrated mosquito management programs include source reduction, chemical control with resistance management and biological vector control.

Source reduction involves the elimination or reduction in mosquito larval breeding habitats. It is the most effective and economical method for long-term mosquito control in many regions. Methods of source reduction include education of property owners on how to minimize areas of standing water, regional water management programs, and sanitation projects. Effective elimination or reduction in breeding habitats can substantially reduce mosquito population densities and help to reduce the need for insecticides.

Chemical vector control methods include insecticides directed to either immature or adult stage mosquitoes. Insecticides are utilized when source reduction techniques have failed or are not feasible. Larviciding aims to control the immature stages localized to the breeding habitats in order to prevent maturation, dispersal and reproduction cycles. Applications can be limited to known mosquito breeding habitats and are therefore more target-specific. Adulticiding kills adult mosquitoes only and should only be used when surveillance indicates adult mosquito population posed a health risk to communities. Insecticide selection and timing of application are based on the specific distribution and behaviors of the target mosquito species and should coincide with high activity periods. Chemical control methods should be integrated with a resistance management program in order to prevent or delay the development of insecticide resistance in vector populations. Resistance management requires annual monitoring of target populations to track resistance patterns. This data facilitates the use of appropriate insecticides at the lowest effective concentrations.

Biologic control is an appealing technique given its vector-specificity. Biological control uses organisms and their by-products to control pests. Lavarious fish are the most commonly used agents in the biological control of mosquitoes, but other organisms such as predatory nematodes and mosquitoes are currently under investigation.

Public health education and behavioral change programs are essential in a comprehensive vector control program. Programs include information and strategies for mosquito avoidance and bite prevention. Interventions include use of diethyl-meta-toluamide (DEET)-based mosquito repellent, avoidance of outdoor activities from dusk until dawn and recognition of the signs and symptoms of arboviral diseases.

Prevention and control of arboviral disease has been augmented by the development of effective vaccines for both humans and some domesticated animals, especially equids. Effective vaccines have been developed for yellow fever, tick-borne encephalitis, Japanese encephalitis, Rift Valley fever, Crimean-Congo hemorrhagic fever, and the equine encephalitides. In the United States, only yellow fever

and Japanese encephalitis vaccines are licensed for human use.³⁴ Immunization of equines with Venezuelan, Western and Eastern encephalitis vaccination is widely practiced.³⁵ Immunization of wild animals is currently limited, but may be a practical approach in the future in certain regions. Postexposure prophylaxis with immune globulin has also been beneficial in certain arboviral diseases.

► DIAGNOSIS OF ARBOVIRAL DISEASES

Laboratory data aid in the diagnosis of individual cases and serve as a method to support surveillance by local and state health units. The choice of lab tests depends on the needs, approach, and surveillance philosophy of a particular health agency. Methods of viral identification include standard viral tube culture, direct or indirect demonstration of virus or viral antigens, detection of viral antibodies, or polymerase chain reaction to detect viral genomes.

Standard viral tube cultures may successfully isolate certain viruses from serum, cerebral spinal fluid, or tissue, but may require weeks for viral identification. Certain viruses are not readily recovered due to low viremic titers or short incubation periods. Furthermore, viral isolation may or may not indicate the true etiology of the disease, as some viruses are shed for months in asymptomatic or convalescent patients. Techniques include the inoculation of cell cultures to monitor for cytopathic effects and neutralization tests. These can be supplemented by the intracerebral inoculation of mice to observe for development of disease.³⁶

Serologic evidence of infection may involve either viral antigen or antibody detection. The most commonly used serological methods include direct and indirect fluorescent antibody (DFA, IFA) tests, hemagglutination inhibition (HI), complement-fixation (CF), neutralization (N), and Enzyme-Linked Immunosorbent Assay (ELISA) for the detection of antibody.³⁷ Antibody is generally not detectable until the end of the viremic phase. Detectable Immunoglobulin M (IgM) antibody usually appears shortly after the onset of illness and may persist for a few months. Detectable Immunoglobulin G (IgG) antibody appears shortly after IgM and contains antibody for neutralization. Detection of seroconversion from negative to positive results is conclusive evidence of recent infection if the appropriate testing method is applied in a timely manner. Paired sera should always be submitted for diagnosis of viral disease. The acute-phase serum should be obtained as early as possible in the clinical course followed by a convalescent-phase serum obtained two to four weeks later. Most convalescent sera samples are collected at three weeks, but in some infections causing encephalitis the titers are not elevated for 6–8 weeks. A four times or greater rise in antibody titer in paired serum samples collected 2–4 weeks apart is typically considered diagnostic for most viral diseases. The criteria for serological diagnosis are outlined in Table 15-3.³⁸ Due to the close antigenic relationships between viruses within specific genera, cross-reactions due to previous immunization or infections may interfere with assays. Studies have shown that individuals who have been vaccinated or recently infected with yellow fever, tick-borne encephalitis, or Japanese encephalitis may have a cross-reacting positive serologic test to one or more other flaviviruses that are not causing the current illness.

Recovery of virus and diagnosis of disease is enhanced with the use of the appropriate source of the specimen. In particular, evaluation of cerebral spinal fluid optimizes identification of arboviruses that cause encephalitis. For arboviral encephalitides, cerebral spinal fluid is typically normal appearing with protein that may range from 20 to greater than 200 with normal glucose levels. Pleocytosis is present with a lymphocytic predominance. IgM may be detected by ELISA in a single specimen of cerebral spinal fluid in less than one week and may persist for several weeks to months.

Polymerase chain reaction (PCR) is an extremely sensitive and specific diagnostic technique for detecting viral genome in a sample. PCR tests have been developed for Venezuelan equine, Western equine, Eastern equine, West Nile, Colorado tick fever and dengue viruses; however, such tests have not yet been validated for routine rapid identification in the clinical setting due to expense and high risk of contamination.³⁹

TABLE 15-3. GENERALLY ACCEPTED CRITERIA FOR THE SEROLOGICAL DIAGNOSIS³⁸

Confirmed Case	<ul style="list-style-type: none"> • A \geq 4-fold rise or fall in antibody titer in appropriately timed paired sera OR • Demonstration of virus-specific IgM antibodies in a single serum
Presumptive Case	<ul style="list-style-type: none"> • High antibody titers in a single convalescent serum OR • Stable high serum titers in paired sera obtained during convalescence OR • A case that is fatal 5 days or more after onset, with presence of detectable antibody in serum and postmortem findings consistent with the presumed infection
Inconclusive Case	<ul style="list-style-type: none"> • Antibody present but at titers that do not satisfy above criteria
Negative Case	<ul style="list-style-type: none"> • No antibodies, or stable minimally detectable titers in appropriately timed paired sera

► CLASSIFICATION OF ARBOVIRUSES BY PREDOMINANT DISEASE PATTERN

Viruses Causing Acute Central Nervous System Infections

Acute central nervous system manifestations of arboviruses include aseptic meningitis, encephalitis, and encephalomyelitis. Arboviral encephalitis is a seasonal disease that typically occurs in warmer months and months with increased rainfall. Vectors are primarily mosquitoes, but tick-borne encephalitis and Powassan fever represent two encephalitides that utilize tick vectors. Arboviruses that cause encephalitis currently represent a significant public health problem.

Infections are often subclinical. Symptomatic disease presents with a prodrome of nonspecific constitutional symptoms including fever, abdominal pain, sore throat, and respiratory symptoms. Headache, nuchal rigidity, photophobia, and vomiting may ensue. Altered mental status, lethargy, and increased somnolence leading to comatose signify more significant disease. Neurological manifestations also include tremor, cranial nerve palsies, hemiparesis, and seizure activity. Acute encephalitis may last for only a few days to several weeks. Full recovery may take weeks to months. Treatment involves supportive therapy. The primary prevention measure is vector control, although effective vaccinations are available for some viral diseases.

The equine encephalitides are important pathogens in the Western Hemisphere, whereas in North America, West Nile, St. Louis encephalitis, and La Crosse encephalitides pose the greatest public health threats.

California Encephalitis

The diverse California encephalitis virus group includes La Crosse, Snowshoe hare, Inkoo, Jamestown Canyon, Trivittatus, and California encephalitis. La Crosse virus is responsible for most human disease and is an important cause of endemic disease in Ohio, Minnesota, Wisconsin, Eastern Iowa, Illinois, and upstate New York. All serogroups employ the mosquito vector *Aedes* and mammals as the primary host. Transovarial transmission is a prominent feature in virus sustainability. Most cases occur from July through October.⁴⁰

The majority of cases are subclinical with encephalitis primarily recognized as a childhood disease. Manifestations include aseptic meningitis to severe and occasionally fatal encephalitis. Onset of neurologic disease is typically sudden, but may be preceded by a prodrome. Significant neurological dysfunction is common with up to 6–15% having residual neurologic sequelae. Of those individuals that present with seizures, 25% will have recurrent seizures.^{40–42} Treatment

is supportive for a 1- to 2-week acute phase during which time recurrent seizures, cerebral edema and syndrome of inappropriate antidiuretic hormone (SIADH) are important concerns. Ribavirin has been used in severe cases, but no clinical trials proving its efficacy exist.⁴¹

Eastern Equine Encephalitis

Eastern equine encephalitis (EEE) is widely distributed throughout the Americas and the Caribbean, although the epidemiology is best understood in North America. The mosquito *Culiseta melanura*, found in freshwater swamps, sustains the virus in wild birds. *C. melanura* rarely bites equines and humans; other mosquito vectors implicated in enzootic and epidemics include *Aedes sollicitans* and *Coquillettidia perturbans*.⁴³ The infections are typically recognized in July through September.

After a 1-week incubation period, the initial clinical manifestations consist of a prodrome with fever, headache, nausea, and vomiting. Approximately 2% of infected adults and 6% of children develop encephalitis. Neurological disease is severe with approximately 50% developing seizures or focal neurologic signs and 90% progressing to stupor. The case fatality rate in patients that develop neurological stigmata ranges from 30% to 50%, and death may be rapid within 3–5 days of disease onset. Even in survivors, complete recovery is uncommon. Sequelae include convulsions, paralysis, or mental retardation.⁴⁴ Therapy is supportive. Inactivated vaccines have been effective in horses and utilized in laboratory workers at high risk for exposure.⁴⁵

Japanese Encephalitis

Japanese encephalitis (JE) causes endemic and epidemic disease in parts of Asia. In the tropical regions of southern Thailand and Indonesia where JE is endemic, human infections are prevalent, but only sporadic disease occurs with no seasonal variation. Epidemic disease occurs in temperate regions in the late summer and fall primarily May through September. The principle vector for epidemic disease is the *Culex* mosquito, although some *Aedes* species are involved with specific species varying by region. *Culex tritaeniorhynchus*, which breeds in rice paddy habitats, is an important vector for human disease.^{46,47} Hosts include water birds and large mammals. In particular, swine have become an important amplifying host, given high viremic titers, proximity to human populations and high population turnover related to slaughtering. Intrauterine infection of swine with JE virus results in abortion and stillbirth. Scheduled breeding and vaccination to limit stillbirth are two strategies that have helped to decrease viral transmission from swine hosts.

Only about one in every 250 JE viral infections is symptomatic. Children and older persons are at higher risk for clinical infections. However, in endemic areas where the immunity is high, the disease primarily affects preschool children. Mild disease is typically undetected and includes aseptic meningitis and febrile illness with headache, which resolves within 5–7 days if there is no CNS involvement. Encephalitis due to JE tends to be more severe with seizures occurring in up to 85% of children and 10% of adults.⁴⁸ Other neurological sequelae include motor disturbances, parkinsonism, and psychiatric abnormalities. Mortality among hospitalized patients is as high as 30%, and approximately 50% of survivors have neurological sequelae. Treatment is supportive. Vaccination is indicated for summer travelers to rural Asia where the risk of disease is at least 0.5–2.1 per 10,000 per week. There is a 0.1–1% risk of late systemic or cutaneous allergic reaction that may be severe and occur within 1–9 days after immunization. Symptoms include pruritis, urticaria, and angioedema. Live attenuated vaccines are used in China, but are currently not approved for use in the United States.^{46,49}

Powassan Encephalitis

Powassan encephalitis is a rare cause of tick-borne encephalitis in eastern Canada and the United States. *Ixodes cookei* is the primary vector, although other species of *Ixodes* and *Dermacentor andersoni* are competent vectors. Hosts include small mammals such as squirrels

and woodchucks.⁵⁰ The incubation period can vary widely, but averages approximately one week. Human infection occurs from May through December after outdoor exposure to ticks. Asymptomatic infection is common. Encephalitis is severe with common long-term neurological sequelae; children are more commonly affected.⁵¹

St. Louis Encephalitis

St. Louis encephalitis (SLE) is widely distributed in North America. The life cycle includes wild birds and several species of *Culex* that vary by geography. Unlike other arboviral encephalitides, SLE rarely causes disease in horses. In the eastern United States, *C. pipiens* and *C. quinquefasciatus* are responsible for epidemics; these species breed in urban habitats such as stagnant water and sewage. Epidemics occur in approximately 10- to 20-year cycles and are associated with poor sanitary conditions and weather patterns. Although epidemics have been limited to a single year, successive annual outbreaks also occur related to successful overwintering strategies. *C. nigripalpus* is the principle vector in Florida where habitats include swamps and drainage ditches. In the western United States, *C. tarsalis* causes low-level endemic infection among rural residents where the mosquito breeds in irrigated farmland.⁵² SLE occurs in the summer months and peaks in August and September.

SLE is the second leading cause of epidemic viral encephalitis in the United States after West Nile virus. Overt clinical manifestations of disease are rare with older age being an important risk factor. Disease severity also increases with age.^{2,53} The spectrum of clinical illness includes mild disease, aseptic meningitis, or fatal meningoencephalitis occurring after a 4- to 21-day incubation period. Neurological symptoms have an abrupt onset often preceded by prodromal symptoms of fever, malaise, myalgias, and severe headache that may be associated with photophobia, nausea, and vomiting. Some patients may complain of respiratory and urinary symptoms.⁴² Tremor, nuchal rigidity, hyperreflexia, and myoclonus are common. More severe manifestations include cranial nerve palsies, hemiparesis, and convulsions. Hyponatremia due to syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has been documented in 30% of patients. The case fatality rate is higher in adults older than 60 years. Treatment is supportive and includes water restriction in cases with SIADH. No vaccine is available.

Tick-borne Encephalitis Virus Complex

Tick-borne encephalitis (TBE) is caused by a group of three viruses: Far Eastern subtype (formerly Russian spring-summer encephalitis); Siberian subtype (formerly Western Siberian); and Western European subtype (formerly Central European). Distribution is throughout Eurasia.⁵³ The principle vectors are *Ixodes* ticks, which can acquire infection through small mammal hosts or through vertical transmission. Large animals such as goats, sheep, cattle, and deer are also susceptible to infection and may shed virus in their milk. Human infections acquired from milk account for 8–25% of cases.⁵⁴ However, most human exposure occurs through work and recreational activities in areas with high tick populations.

The epidemiology and clinical features of the TBE vary by serotype. *Ixodes ricinus* is the primary vector for Western European subtype cases that typically occur between April and November with peak transmission rates in June and July.⁵³ Distribution of *I. ricinus* is primarily in Scandinavia and Greece. Western European subtype classically presents with a biphasic disease that starts with 3–4 days of a febrile-myalgia phase that remits and then recurs with the onset of meningeal signs. Central nervous system symptoms can range from aseptic meningitis, which is more common in younger patients, to severe encephalitis with coma, convulsions, and tremors that may last for 7–10 days. Most patients recover without significant deficits. *Ixodes persulcatus* in Eastern Europe, China, and northern Japan is the primary vector for the more virulent Far Eastern and Siberian subtypes. Peak transmission is early summer, although lower rates of disease also occur in late summer. Far Eastern encephalitis tends to be more abrupt in onset with more severe central nervous system symptoms to include a poliomyelitic form that starts with a prodrome and

then evolves into neck, shoulder, and extremity paralysis. Residual neurological deficits are more frequent.^{53,55} The Siberian subtype may develop into a chronic form with disease progression over months to years or onset of parkinsonism, progressive muscle atrophy, or dementia that occurs years after infection without any acute disease symptoms. Effective formalin-inactivated vaccines are available in Europe and Canada, but not in the United States. There are rare case reports of post-vaccination Gullain-Bare syndrome. Passive immunization with globulin may be used for post-tick bite prophylaxis, but no controlled data on efficacy are available.

Venezuelan Equine Encephalitis

There are six known types of Venezuelan equine encephalitis (VEE) that are further subdivided into antigenic variants. An important distinction in this group is between epizootic viruses (subtypes IAB and IC) and the enzootic viruses (subtypes ID through IF and Types II through VI). For the epizootic viruses, equine are the primary viremic host. The mosquito vectors include species from the *Aedes*, *Psorophora*, and *Mansonia* genera. Epizootic infections result in high titers of equine viremia and disease and that are associated with more severe human disease. Equine outbreaks precede human epidemics by several weeks. In enzootic subtypes the cycle involves small rodents and *Culex* mosquitoes. Enzootic infections may result in sporadic human disease, but are not pathogenic in horses. VEE is an important veterinary and public health problem in South and Central America, with historical epidemics in Texas and Florida.⁵⁶ VEE occurs in the summer when vector density is increased.

Most human infections are symptomatic. Symptoms occur after a 6-day incubation period and are mild and gripe-like, characterized by sudden onset of fevers, chills, headache, myalgias, and gastrointestinal symptoms. Pharyngitis is present in about 25% of cases.⁵⁷ The illness typically lasts 4–6 days but a small portion of cases develop a biphasic pattern with return of symptoms several days to a week later. Development of overt central nervous system symptoms is rare, occurring in less than 0.5% of adults and 4% of children. Long-term neurologic sequelae and death are rare. Therapy is supportive. Both attenuated live and inactivated equine vaccinations are available and have resulted in dramatic improvements in public health prevention.

West Nile Encephalitis

West Nile Virus (WNV) is one of the most widely distributed arboviruses with distribution through the Americas, Europe, Asia, Africa, Middle East, Australia, and the former Soviet Union. The first reported case in the United States was in 1999; in 2002 a multistate epidemic throughout the Midwest occurred and since that time cases of WNV have been reported in 48 states. It is now the leading cause of epidemic viral encephalitis in the United States.⁵⁸ The natural transmission cycle includes wild birds and *Culex* mosquitoes. Nearly all human infections are due to mosquitoes, but transmission has also been documented via transfused blood, transplanted organs, transplant, and percutaneous exposure.⁵⁹

WNV causes both sporadic cases as well as epidemics. Serologic surveys suggest that 80% of infections are completely asymptomatic and less than 1% present with neuroinvasive disease.⁶⁰ WNV is a frequent cause of febrile illness and a febrile-myalgic syndrome without central nervous system involvement. The febrile-myalgic syndrome is frequently accompanied by lymphadenopathy and a truncal maculopapular rash. Aseptic meningitis and encephalitis are more common among the elderly and may be associated with muscle weakness or flaccid paralysis. Treatment is supportive.

Western Equine Encephalitis

Western equine encephalitis (WEE) includes a group of closely related viruses found in North and South America. In the United States the virus cycle involves wild birds, especially house finches and house sparrows, in the spring and small mammals in midsummer through the vector *Culex tarsalis* mosquito. The shift in *C. tarsalis* feeding to mammals in midsummer coincides with equine and human infections.⁴³

Horses and humans do not develop sufficient viremia to infect mosquito vectors. Flooding, as in irrigation practices, or with heavy snowmelt promotes higher vector density and may precipitate summer outbreaks. The WEE viral transmission cycle is shared with the SLE virus in the western United States; while mixed WEE-SLE outbreaks have occurred, generally one virus predominates in a given year.

Encephalitis may occur after a 1-week incubation period. Most cases are abortive or very mild, although the development of clinical symptoms and severity of disease is increased in children. The ratio of inapparent infection to overt encephalitis is approximately 50:1 in children under the age of 5 years and more than 1000:1 in adults.² Initial symptoms include a prodrome of stiff neck, headache, backache, and vomiting. Restlessness, irritability, and neurologic sequelae such as seizures are more common in children. Therapy is supportive. Equine vaccination through the use of an inactivated vaccine has helped to reduce disease incidence.

Viruses Causing Undifferentiated Febrile Illness

Fever and myalgias are a common syndrome associated with arboviral infection. The syndrome begins with abrupt onset of fever, chills, malaise, and intense myalgias. Patients may complain of joint pain, but no true arthritis is detectable. Headache is common and may be severe and associated with photophobia, nausea, and vomiting. Some viruses may progress to aseptic meningitis. Other findings may include maculopapular rash, epistaxis, and pharyngitis. Complete recovery is the general rule, although prolonged asthenia has been reported particularly in cases of dengue fever and lymphocytic choriomeningitis. Treatment is supportive with the avoidance of aspirin due to its potential to exacerbate bleeding or induce Reye syndrome.

The most important viruses include Colorado tick fever, sand fly fever, and dengue fever. The differential diagnosis includes anicteric leptospirosis, other zoonotic viral infections, and rickettsial diseases.

Colorado Tick Fever

The epidemiology of Colorado tick fever corresponds to the distribution of the primary vector *Dermacentor andersoni* in the western United States and Canada at 4000- to 10,000-foot elevations.¹⁸ Small mammals such as chipmunks and ground squirrels serve as the amplifying host for the immature forms of the tick; adult ticks feed on larger mammals. Infections are acquired through recreational and occupational pursuits in tick habitats. Infections occur from March through November and peak in April through June. Ninety percent of patients report a tick bite or tick exposure.⁶¹

After an incubation period of 3–6 days, clinical manifestations include fever, chills, myalgias, headache, and weakness. In 15% of cases, a petechial or maculopapular rash develops. Leukopenia and thrombocytopenia may also develop. Five to ten percent of children develop meningitis or encephalitis; other rare complications include pericarditis, orchitis, and pleuritis.¹⁸ Serologic tests are often not positive for up to two weeks after symptom onset, but PCR can be diagnostic with the first 24 hours of symptoms. The virus infects marrow erythrocytic precursors, so detection of virus in the peripheral blood may last up to six weeks.⁶²

Dengue Fever

Dengue fever consists of four closely related, but serologically distinct viruses, DEN-1, DEN-2, DEN-3, and DEN-4. While infection to one serotype induces life-long immunity to the same serotype (primary infection), secondary infection with a different serotype can occur in hyperendemic areas. The primary vector for all four strains is *Aedes aegypti*, which is endemic to all latitudes between 25 degrees north and 25 degrees south. *A. aegypti* is a daytime feeding, peri-domiciliary mosquito that may breed in any container with freshwater. This is an efficient vector involved with yellow fever and chikungunya viruses. Epidemic infections have been reported between the latitudes of 30 degrees north and 40 degrees south of the equator, depending on season and climatic conditions.⁶³

Many infections are asymptomatic. Clinical manifestations are diverse and occur after a 3- to 14-day incubation period (average of 4–7 days). In travelers, symptoms from dengue can essentially be excluded if illness develops more than 14 days after returning from a dengue-endemic region.⁶⁴ The classic constellation of symptoms are self-limited and characterized by a biphasic febrile illness associated with headache, retroorbital pain, prostration, and marked myalgias, thus the common name of “break-bone fever.” Adenopathy, palatal vesicles, and scleral injection may also occur early in the disease course. A macular rash may occur on the first day of symptoms. Near the time of defervescence marked cutaneous hypersensitivity may also result in a truncal maculopapular rash that subsequently spreads to the extremities and face. Gastrointestinal and respiratory symptoms occur in approximately 30% of patients. Hemorrhagic features may be associated with dengue fever and include epistaxis, petechial rash, melena, or menorrhagia; clinical diagnosis may be confirmed with a tourniquet test. The most severe variant is dengue hemorrhagic fever that may progress to dengue shock syndrome and death. Typically the hemorrhagic forms of dengue and shock syndrome only occur after a second or third infection with certain serotypes. The cardinal features are plasma leak syndrome, marked thrombocytopenia, and hepatomegaly or a transaminitis. Persistent emesis, severe abdominal pain, lethargy, and hypothermia may indicate impending shock. Treatment is supportive. Prophylaxis by immunization is feasible, and experimental live attenuated vaccines are under study.

Oropouche Fever

Oropouche virus is distributed in Panama and the Amazon region of Brazil and Peru. Vectors include the blood-feeding midge, *Culicoides*, and mosquitoes. *Culicoides paraensis* is suspected as the primary epidemic vector. Although the ecological dynamics are not completely understood, natural hosts are likely wild birds, monkeys, and sloths.

The self-limited disease is characterized by sudden onset of fever, severe headache, gastrointestinal symptoms, myalgia, and leukopenia. Aseptic meningitis is an uncommon complication.

Sand Fly Fever

Sand fly fever is caused by a group of serologically distinct viruses and is distributed through the Mediterranean area extending from the Balkans into China, as well as into the Middle East and southwestern Asia. The vector *Phlebotomus papatasi* is nocturnal with limited flight range and small size enabling it to penetrate screens and mosquito nets. *P. papatasi* breeds in both rural and urban habitats. The Sand fly fever virus is transmitted transovarially by the vector and no vertebrate reservoir has been definitively demonstrated.

In endemic regions, immunity rates are high as infection is usually acquired in childhood when disease is mild or inapparent. High attack rates occur with natural disasters and among tourists and visiting military personnel. Previously coined as “3-day fever,” clinical disease consists of a brief, debilitating febrile illness without rash. Complete recovery is the rule.

Viruses Causing Arthritis

Several arboviral infections, particularly the alphaviruses, manifest with acute febrile illness, a maculopapular rash and polyarthritis. Rheumatic involvement includes arthralgias, periarticular swelling, and less commonly, joint effusions. Articular manifestations are more common in adults than children. Treatment is with analgesics and non-steroidal anti-inflammatory drugs. Important human pathogens include Chikungunya, O-nyong-nyong, Sindbis, and Ross River virus.

Chikungunya Virus

Chikungunya virus is endemic to sub-Saharan Africa and the Asian tropics with intermittent epidemics in urban communities. The natural transmission cycle involves *Aedes furcifer*, a forest mosquito,

and nonhuman primates. Chikungunya virus is hyperendemic in areas infested with *A. aegypti*, which is the principle vector to humans.

Chikungunya is Swahili for “that which bends up” referring to the severe arthralgias that manifest with infection.² After a 2- to 3-day incubation period there is abrupt onset of fever and arthralgias with constitutional symptoms such as chills, headache, photophobia, conjunctival injection, anorexia, abdominal pain, and nausea. Migratory polyarthritis primarily involves the small joints of the hands, wrists, ankles, and feet with lesser involvement of larger joints. Rash may appear several days after disease onset and typically correlates with defervescence. The rash is most prominent on the trunk and limbs and may desquamate. Older patients may develop persistent stiffness, arthralgias, and joint effusions for several years, especially in HLA-B27 patients. The O-nyong-nyong virus is related to Chikungunya virus. After causing an epidemic in eastern and central Africa in the 1960s, only sporadic cases have been reported in Kenya. Currently no vaccines are available.

Epidemic Polyarthritis (Ross River Virus Infection)

Epidemic polyarthritis, or Ross River Virus disease, is distributed across Australia and the western South Pacific. Infection is most common in spring and summer. The virus is transmitted by *A. vigilax* and *A. camptorhynchus* in coastal areas and by *Culex annulirostris* inland through kangaroo hosts and transovarial transmission.⁶⁵

Clinical manifestations occur after a 7- to 11-day incubation period with severe joint pain. A sparse maculopapular truncal and limb rash may occur before, during or after the onset of joint symptoms. The rash may involve the palms, soles, face, and buccal mucosa. Constitutional symptoms, including fever, are not prominent and often absent. Rheumatologic symptoms involve the wrist, ankle, metacarpophalangeal, interphalangeal and knee joints and are severe enough to interfere with sleep, ambulation and grasp. Joint involvement is symmetric although severity of inflammation may be asymmetric. Periarticular swelling and tenosynovitis are common; a third of patients will have true arthritis. Symptoms typically resolve within 3–6 months.

Sindbis Virus

Sindbis virus is maintained through an avian-*Culex* mosquito transmission cycle in Europe. Diseases caused by the Sindbis virus include Pogosta disease, Karlian fever, and Okelbo disease.

After a 7-day incubation, the disease begins with rash and arthralgia with only mild, and often absent, fever, and other constitutional symptoms. The rash persists approximately one week and begins on the trunk spreading centrifugally with evolution from macules to papules that often vesiculate. Migratory multi-articular and incapacitating arthralgias involve the wrists, ankles, phalangeal joints, knees, and elbows. Joint pain may persist for up to a year.

Epidemiology of Viral Hemorrhagic Fevers*

James W. LeDuc

► INTRODUCTION

Hemorrhagic fevers caused by viruses are generally rare diseases, but as witnessed recently some, like Ebola, have attracted sufficient attention of press and laypeople that they have become part of our normal vocabulary. Historically, some were also weaponized as biological warfare agents, and today there is considerable concern that they could be used as terrorist weapons. The clinical condition known as hemorrhagic fever is, in fact, quite variably and may result from infection with any one of several different viruses or bacteria. In general, they present as a febrile disease that progress to manifest some degree of hemorrhage, often in the form of increased capillary permeability, which may lead to death in a significant proportion of those clinically ill. The number of distinct viruses able to cause hemorrhagic fevers continues to grow as we recognize new viruses, such as those associated with hantavirus pulmonary syndrome and the arenaviruses of South America (Table 15-4). All hemorrhagic fever viruses, with the possible exception of dengue viruses, are zoonotic agents that exist in nature in a silent cycle that involves nonhuman vertebrate hosts and often arthropod vectors. Transmission to humans is by the bite of an infectious arthropod vector, by small particle aerosol from infectious urine or feces of infectious rodent host (or occasionally by bite from these hosts), or through nosocomial transmission, often under conditions where routine safe hospital practices are not being followed. Person-to-person transmission may occur, but is usually not the dominant mode of transmission. Hemorrhagic fever viruses do not share a common taxonomic origin; they are found among four different virus families: Arenaviridae, Bunyaviridae, Filoviridae, and Flaviviridae.

Arenaviruses

Until recent, only three arenaviruses were associated with hemorrhagic fever: Lassa fever caused by Lassa virus of West Africa; Argentine hemorrhagic fever caused by Junin virus of Argentina; and Bolivian hemorrhagic fever caused by Machupo virus of Bolivia. In the past decade, however, two new pathogenic arenaviruses have been discovered, and it is likely that others will be recognized as humans continue to occupy previously sparsely populated regions of the world (Table 15-5).

Lassa Fever

First recognized during 1969 in Nigeria, Lassa fever has focused worldwide attention on problems related to the management and control of highly hazardous viruses. This was the result of several West African nosocomial outbreaks in rural hospitals in Nigeria, Liberia, and Sierra Leone, where direct secondary transmission with high mortality occurred. These outbreaks have often devastated rural hospital staffs, claiming physicians and nurses as well as the index patient's families and friends. Moreover, Lassa fever is the most common dangerous viral disease of international travelers, with imported cases among travelers from Africa reported in Europe, the Middle East, Asia, and North America.

The disease appears to be restricted to West Africa, occurring principally in savannah landscapes or tropical areas severely modified by human agricultural activity, with the majority of cases seen in Liberia, Sierra Leone, Guinea, and Nigeria, and accounting for 10% or more of admissions to some hospitals. Approximately 80% of people infected with Lassa virus have mild or no overt symptoms; in its severe form, Lassa fever is a protean febrile disease attacking many vital organs including heart, lungs, liver, pancreas, and kidneys. Jaundice is unusual but pulmonary and peritoneal effusions are commonly observed. A fulminating hemorrhagic picture with shock occurs in only about 20% of hospitalized cases. Overall, only about 1% of all

infections with Lassa virus end in death; however, approximately 15–20% of patients hospitalized with Lassa fever die from the illness. Death rates are especially high among pregnant women and their fetuses during their third trimester of pregnancy, when about 95% of fetuses of infected mothers may die. Up to 25% of maternal deaths are due to Lassa in some hospitals. Lassa virus has also been isolated from milk, suggesting that there is a clear risk to nursing infants. Virus is present in blood and effusions for many days and has been recovered from throat washing and urine. Deafness is an important sequela of Lassa fever, with studies in Sierra Leone indicating that

approximately one-quarter of prospectively studied Lassa patients developed hearing loss. Antibodies to Lassa virus are also more common in deaf residents of endemic areas. While no specific vaccine is available for Lassa fever, the disease does appear to respond well to treatment with the antiviral drug, ribavirin. Unfortunately, access to this drug is significantly hampered due to lack of availability, cost, and licensure issues.

Lassa virus is maintained by peridomestic rodents of the genus *Mastomys*. Original studies indicated that *M. natalensis* was the principal reservoir host, but this actually represents a complex of sibling species difficult to differentiate by physical characteristics alone. It is now thought that the species most likely to harbor Lassa virus are *M. erythroleucus* and *M. hildebrandtii*, which are distinct from *M. natalensis*. These large mice, which resemble juvenile house rats (*Rattus rattus*), live in close proximity to humans and readily enter households. Indeed, many villages in eastern Sierra Leone may average one to four *Mastomys* in each house, with as many as 20% infected with Lassa virus. Mice are chronically infected and shed virus in their urine for many weeks, leading to infectious aerosol that may contaminate the environment and foodstuffs, or directly lead to infection by inhalation or contact on cuts or mucous membranes. In addition, in some areas these mice are consumed by villagers for food, leading to greater risk of Lassa infection.

Prospective, laboratory-based studies of Lassa fever in eastern Sierra Leone have demonstrated that transmission is endemic, with peak activity in the dry season months of January through May. Attack rates range up to 5 per 1000 per year, with a case-fatality rate of 18%, much lower than reported during earlier outbreaks. Epidemiological investigations conducted in villages, however, showed that up to half the population had been infected with the virus and annual infection rates as high as 8% have been documented, giving an infection-case ratio of about 16:1. Persons of all ages and both sexes are infected and may suffer severe clinical illness; why only certain individuals become very sick is still not known.

Surveillance for Lassa fever presents a difficult challenge. Geographical surveys in West Africa have disclosed significant foci of infection in areas where the disease has never been clinically detected. Because the clinical spectrum observed in laboratory-documented infection is so wide, it is now clear that only the most severe cases could be clinically suspected, and probably then only if a cluster of such cases occurred with transmission to hospital staff. Thus, specific diagnosis is essential and best done by measurement of virus-specific IgM antibodies, which appear in all patients within 7–10 days after onset of symptoms, or by direct measurement of viral antigen or nucleic acids earlier in the course of illness. Mortality in Lassa fever is directly related to virus concentration in blood; consequently, the potential hazards associated with such laboratory work and the paucity of virological laboratories in West Africa have limited the application of these technologies.

TABLE 15-5. ARENAVIRUSES KNOWN TO CAUSE HUMAN DISEASE

Virus	Abbr.	Host	Original Isolation	Disease
Lymphocytic choriomeningitis	LCM	<i>Mus musculus</i>	USA	Lymphocytic choriomeningitis
Lassa	LAS	<i>Mastomys sp.</i>	Nigeria	Lassa
Junin	JUN	<i>Calomys musculinus</i>	Argentina	Argentine hemorrhagic fever (AHF)
Machupo	MAC	<i>Calomys callosus</i>	Bolivia	Bolivian hemorrhagic fever (BHF)
Guanarito	GUA	<i>Zygodontomys sp.</i>	Venezuela	Venezuelan hemorrhagic fever (VHF)
Sabia	SAB	Unknown	Brazil	Brazilian hemorrhagic fever

Because persons coming from rural West Africa may introduce Lassa virus into other countries at any time, it is important that any nation that has significant commerce with Africa have appropriate facilities and up-to-date plans for the isolation and care of travelers infected with Lassa virus, and have a strategy to identify and clinically monitor those who have come into contact with the ill person while traveling and before the diagnosis was established. Clinical and laboratory isolation facilities are indicated, and these should be designated to provide protection to the medical care team as well as to the general community. Fever surveillance, but not quarantine, for 3 weeks is indicated for all persons in direct face-to-face contact with Lassa patients prior to their effective isolation.

Control of Lassa fever represents a major biological challenge. Vaccine development is hampered by technical problems and the absence of an economically sustainable market. Rodent control is effective in reducing virus transmission to humans, but is likewise difficult to sustain or easily applied over the broad distribution of *Mastomys*.

Argentine Hemorrhagic Fever

Like Lassa fever, Argentine hemorrhagic fever (AHF) is maintained by a rodent and is transmitted to humans by infectious urine. The disease is caused by Junin virus, first discovered in the 1950s in the rich agricultural pampas of Buenos Aires, Cordoba, and Santa Fe Provinces of Argentina. Until recently, the incidence of AHF ranged from 50 to more than 2000 cases annually during the autumn and winter months of February through July. Adult males comprise the great majority of cases, due to their occupational exposure through farming and related agrarian activities. Onset of symptoms is usually gradual with fever and malaise progressing to myalgia, headache, and dizziness and followed by signs of central nervous system (CNS) involvement such as tremor of the limbs and tongue, gastrointestinal symptoms including nausea and vomiting, and indications of vascular instability that may progress to shock. Severely ill patients may bleed from the gums, gastrointestinal tract or mucosal surfaces, and suffer from severe neurological symptoms including coma and convulsions.

Case fatality rate is from 5% to more than 15% but prompt immunotherapy may reduce the mortality rate to 1% or less. Inapparent infections rarely occur. Viremia is sporadic or of low titer and nosocomial infections, although reported, are very unusual. Attack rates may be quite high in circumscribed, small communities.

Chronic viremic and viruric infection of rodents has been shown to be the principal means of virus maintenance and, by strong inference, of transmission to humans. The main host of AHF is the field mouse, *Calomys musculus*. Similar in size to house mice (*Mus musculus*), this indigenous rodent invades crops during the fall from permanent harborage along roadsides, railways, and other linear habitats. Population densities are highest in fields of maize. Migratory workers harvesting maize by hand were the principal victims during the 1950s and early 1960s, although now combine and truck operators have attack rates estimated as 20–50 times those of the earlier migrant laborers. Aerosols as well as blood and fluids from mice crushed in the combines are now thought to be the primary source of infection. Prospective study of *C. musculus* suggests that most infected animals acquire the virus horizontally after weaning, although vertical transmission clearly occurs.

A live, attenuated vaccine, Candid 1, developed jointly by the Government of Argentina, the Pan American Health Organization, the United Nations Development Programme, and the United States Army Medical Research and Development Command, has been evaluated and found to be safe and 95% efficacious in preventing AHF. Nearly 250,000 at risk individuals in the endemic region of Argentina have now received the vaccine, leading to a dramatic drop in AHF incidence (Figure 15-1).

Bolivian Hemorrhagic Fever

Similar to AHF in both the clinical disease produced and the way it is maintained in nature, Bolivian hemorrhagic fever (BHF) is caused by Machupo virus. The disease was first recognized in 1959, and by the early 1960s nearly 500 cases had been recorded, with a case fatality rate of approximately 30%. In 1963–1964 a large outbreak occurred in San Joaquin after a population explosion of the primary

Figure 15-1. Reported cases of Argentine hemorrhagic fever (AHF) and number of persons vaccinated, 1958–2004.

rodent host, *Calomys callosus* led to hundreds of mice invading the town, resulting in an extremely high BHF attack rate among residents.

The ecology of BHF is different from that of AHF in several ways. The reservoir host is *C. callosus*, a larger rodent that is naturally found at the edge of riverine forest-savannah formations. When humans cut the forest to plant gardens, *C. callosus* invades these plots and the houses of humans as well. Thus, disease transmission by the continual excretion of virus in the urine of this species occurs in and near homes, resulting in disease among all members of the populations. To exemplify this point, in July 1994 a cluster of BHF cases was identified among a family residing in Magdalena, a small town of about 5000 inhabitants in the north-central district of Beni near the border with Brazil. Eight of nine family members were infected, and seven, aged 10 months to 50 years, died. In general, BHF is limited to the sparsely populated subtropical savannah of Beni province, where cases occur in adults and children. There is no sex difference in the attack rate, and peak incidence is usually during the late rainy season and early dry season months of February to July. Outbreaks of BHF have been controlled and prevented by vigorous rodent control programs in affected towns and on ranches. The live, attenuated Junin vaccine cross protects against BHF in monkey models, and may offer an alternative to rodent control among rural populations at high risk of BHF. Limited experience with the antiviral drug ribavirin suggests that it may be useful in treating BHF.

Venezuelan Hemorrhagic Fever

This newly recognized disease was discovered when a cluster of hemorrhagic fever cases was seen in the city of Guanarito in the central Venezuelan state of Portuguesa in 1989. A total of 104 presumptive cases with 26 deaths was recorded, and the causative agent, named Guanarito virus for the city from which it came, was isolated. Clinical disease is similar to that documented for AHF and BHF, although pharyngitis appears to be more common. Both sexes are affected almost equally, but to date the majority of cases have been in persons over the age of 16 years. Most cases have occurred during the dry season of December to March in Portuguesa state, and like AHF and BHF cases, those infected are usually rural residents involved in agricultural activities. The cane mouse, *Zygodontomys brevicauda* appears to be the primary reservoir host, and laboratory studies have demonstrated that this rodent may sustain long-term viremia and viruria.

Sabia Virus

Only three cases of Sabia virus have been recognized, the original fatal infection of a young woman hospitalized in São Paulo, Brazil in 1990, and two subsequent laboratory infections acquired, first in Belem, Brazil, and later in New Haven, Connecticut, by scientists attempting to characterize this new virus. Both survived, with the later cases apparently responding well to treatment with ribavirin administered soon after the diagnosis was suspected. Attempts to identify a rodent host of Sabia virus have to date been unsuccessful, and there is little known about the natural history of the virus, although it is clear from the laboratory infections that it is easily transmitted by aerosol.

Lymphocytic Choriomeningitis

Lymphocytic choriomeningitis (LCM) virus is the prototype member of the family Arenaviridae. It is maintained in nature through chronic infections of the peridomestic mouse, *Mus musculus*, and both the virus and vector have been recognized virtually worldwide.

Unlike other arenaviruses discussed above, human disease due to LCM virus is almost never fatal or hemorrhagic. Clinical syndromes range from an acute undifferentiated febrile illness to forms characterized by aseptic meningitis and mild encephalitis, the neurological symptoms and signs usually appearing during a second febrile period that begins 1–5 days after termination of an initial febrile episode of 3–7 days' duration. Clinical diagnoses of 150 patients proved to have LCM virus infection during hamster-associated outbreaks indicated

that about half had "flu-like" symptoms, 22% were diagnosed as aseptic meningitis, 5% as encephalitis, 1% as myelitis, and 23% as "healthy." LCM virus may also cause abortion in pregnant women or lead to hydrocephalus, chorioretinitis or mental retardation in the newborn child.

The virus is maintained in nature by chronic infection of feral *Mus* mice, and infection is acquired both horizontally from infected parent to progeny and vertically through contact among individuals of this species. Mice infected in utero or from maternal milk secrete significant quantities of virus in the urine for weeks, months, or throughout their entire lives. Transmission to humans occurs on exposure to infectious rodent urine, most commonly in the form of aerosols associated with nests. An alternate host of significance in recent years in both Europe and the United States is the Syrian hamster. Outbreaks have occurred among personnel in medical research institutions where hamsters were housed, as well as among persons keeping hamsters as pets. These animals are also chronically infected with continuous viruria.

Because of this very specific transmission pattern, attack rates in human populations are almost impossible to determine. Infection is probably more common than is realized, since specific viral techniques are needed to make the diagnosis. Over 30 years ago about 10% of aseptic meningitis and encephalitis cases studied in one U.S. center over a period of several years were caused by LCM virus. The accumulated literature suggested that adults are infected more often than children and that most *Mus*-related infections occur in fall and winter. Between 1965 and 1975, hamster-related outbreaks of 7, 48, and 181 proven cases occurred in New York, California, and 10 other states. Between November 2003 and January 2004, four solid organ transplant recipients from a common donor died 9–76 days following transplant, and disseminated LCM virus was identified in 3 of the 4 recipients.

There is no specific treatment and no vaccine is available for LCM infection. Good standards of environmental sanitation and testing of hamster colonies for endemic LCM virus infection represent available methods for avoiding human contact with this agent.

Filoviruses

Among the most severe and mysterious viral pathogens to ever emerge, Marburg and Ebola viruses have burst on an unprepared world only since 1967. Knowledge of these agents is largely restricted to a few distinct human outbreaks, although intense investigations triggered by large Ebola outbreaks in Kikwit, Zaire in 1995 and Gulu, Uganda in 2000 are providing better definition to the problem. Filoviruses are morphologically similar but immunologically distinct. They are long, pleomorphic rods reminiscent of but distinguishable from rhabdoviruses, such as rabies, and are now placed in a new family, the Filoviridae. Clinical disease seen during each of the individual cases or outbreaks affecting a total of well over 1000 persons was almost always very severe and similar in all instances. The incubation period averaged about one week, but on occasion was longer, and fatal infections were uniformly marked by the advent of a hemorrhagic diathesis after 4–7 days of generalized symptoms. Disseminated intravascular coagulation was documented in most such cases where it was sought. A maculopapular rash, necrotizing non-icteric hepatitis, and chemical pancreatitis were common findings. Case-fatality rates ranged from 25% to 88%, and person-to-person transmission, largely nosocomial, occurred in each major epidemic. During the Gulu Ebola-Sudan outbreak, RT-PCR could detect Ebola virus 24–48 hours prior to detection by antigen capture, and RNA copy levels in patients who died averaged 2 log (10) higher than those in patients who survived. Little is known about the ecology of the filoviruses. There is no vaccine for either Ebola or Marburg virus, although promising results have been obtained using a combination of DNA immunization and/or adenoviral-vectored vaccine in protecting nonhuman primates against Ebola challenge, and early clinical trials are now underway. There are no known antiviral drugs for

filoviruses. Immune horse serum has been produced for Ebola, but its efficacy in treatment or prevention of disease is unknown.

Marburg Virus

Marburg virus was first discovered following the importation of African Green Monkeys, *Cercopithecus aethiops*, into Germany and Yugoslavia from Uganda. These monkeys were used for production of kidney cells for use in preparation of poliovirus vaccine; the monkeys served as the source of Marburg virus infection for laboratory workers initially, with secondary spread to both medical staff and family members. A total of 31 cases and 7 deaths occurred in Marburg, Germany, and another two in Belgrade, Yugoslavia, both of whom survived. Subsequent investigations failed to disclose any evidence of natural infection in this or other monkey species in the region of their capture in Uganda. Subsequent isolated cases of Marburg infection have sporadically appeared in Zimbabwe, Democratic Republic of the Congo, Kenya, and most recently Angola where in 2005, 374 people were infected and 329 died. The ecology of Marburg virus remains virtually unknown.

Ebola Virus

An outbreak involving 318 cases and 280 deaths occurred in Yambuku, Zaire, in 1976, led to the discovery of Ebola virus. Investigations suggested that reuse of contaminated needles served to amplify the outbreak with devastating affects; all those infected by needle died. At nearly the same time, a second outbreak was in progress in Maridi, Sudan that involved 284 cases and left 151 dead. Surprisingly, when virus isolates from these two outbreaks were compared, they proved *not* to be the same virus. While morphologically similar, they are antigenically and genetically distinct and clearly represented two separate events. These viruses are now referred to as Ebola-Zaire and Ebola-Sudan, and both have been associated with subsequent outbreaks: Ebola-Zaire with a fatal case in Tandala, Zaire in 1977–78; Nzozia, Kenya in 1980; Kikwit, Zaire in 1995; and various locations in Gabon and the Republic of Congo more recently. Ebola-Sudan reappeared in 1979 in Nzara, Sudan, in Gulu, Uganda in 2000–01 during which 425 cases and 224 deaths occurred, and in southern Sudan in 2004.

In 1990, another Ebola virus was discovered, and like Marburg virus, it was associated with the importation of nonhuman primates for medical research. But rather than originating in Africa, these animals had been imported from the Philippines. Infected monkeys suffered a severe, often fatal hemorrhagic disease, but although there is serological evidence of at least 16 human infections, none were symptomatic. This strain has been named Ebola-Reston for the northern Virginia suburb near Washington, DC where the first epizootic was discovered.

Ebola-Côte d'Ivoire is the most recently recognized strain and originated from a single human infection acquired when a primatologist studying free-living chimpanzees in the Tai Forest of western Côte d'Ivoire was infected while taking clinical specimens from a chimpanzee that had recently died of a hemorrhagic illness. This animal was one of several that had succumbed during a series of epizootics that had devastated the troop over the course of a few years. The patient suffered a febrile illness with rash, but fully recovered and it was only learned that her infection was due to a new strain of Ebola after she had been discharged from hospital. There was no indication of spread to the medical staff.

The major outbreaks of Ebola virus have all been associated with hospitals or clinics where nosocomial transmission was associated with reuse of needles or other unhygienic practices, from intimate contact between patients and care-givers at home, or from burial rituals that facilitated transmission. Recent outbreaks in Gabon and the Republic of the Congo appear to have originated following human contact with chimpanzees either killed or found dead and prepared as food. In the Kikwit and Gulu outbreaks, transmission was halted when patients were isolated, strict barrier nursing procedures implemented and burial rituals controlled. Isolated cases seen in modern, well-equipped medical facilities have not experienced sustained nosocomial transmission; however, importation of an Ebola case from Gabon

to South Africa resulted in the fatal infection of a South African nurse and serves as warning that with modern air travel, even an outbreak in a remote area represents a risk to all countries. Although the blood of patients contains large amounts of virus, there is little to suggest that infectious aerosols played a major role in these epidemics.

The ecology of Ebola viruses is unknown, although it is clear from observations in Côte d'Ivoire, Gabon, and the Philippines that nonhuman primates encounter the virus in nature. It appears that monkeys and apes suffer a severe disease similar to that seen in humans, and as such are unlikely to be major reservoirs of the virus. Recent experimental infections of various species of plants and animals naturally occurring in areas where Ebola outbreaks have occurred found that fruit and insectivorous bats supported Ebola virus replication and circulation of high titers of virus without becoming ill. It remains to be determined if such infections actually occur in nature and are epidemiologically relevant.

Flaviviruses

Viruses of the family Flaviviridae comprise some of the most important hemorrhagic fevers known. They include viruses transmitted primarily by mosquitoes, others by ticks, and are found in both the tropics and temperate zones. Dengue hemorrhagic fever is one of the true emerging diseases of the twentieth century, with increases in incidence both in Asia, where it has been endemic since the 1950s, as well as in the American tropics, where the past decade has witnessed massive outbreaks in many Latin American countries. Yellow fever is the prototype member of the family.

Dengue Hemorrhagic Fever

In addition to the classic syndrome of breakbone fever, all four dengue virus serotypes are capable of producing a more severe, sometimes fatal syndrome variously called dengue hemorrhagic fever (DHF) or dengue shock syndrome. Although there is historical evidence that this disease occurred during major dengue outbreaks in Greece and Australia more than 70 years ago, it has been recognized since 1948 only in certain areas of Southeast Asia, some islands of the western Pacific Ocean, the Middle East, and with the reinfestation of many parts of the Americas with the principal mosquito vector, *Aedes aegypti*, more frequently in Latin America. This geographical distribution is still far smaller than that of dengue virus infection, but is growing as multiple serotypes of dengue become established.

A fundamental problem is clinical definition of DHF. Persons with dengue virus infections who have a positive tourniquet test reaction have been included in this taxon by some authors. Many patients with otherwise self-limited illnesses may have scattered petechiae in the skin, and these phenomena are frequently recorded during dengue outbreaks in parts of the world where the more serious form of the disease is rare or absent. The fully developed DHF clinical picture consists typically of the abrupt onset, after a 2- to 7-day incubation period, of fever and myalgia, significant thrombocytopenia, hepatomegaly, and various bleeding manifestations, including hemorrhagic petechiae, epistaxis, and gastrointestinal bleeding. There is loss of intravascular protein with attendant hemoconcentration, metabolic acidosis, and in 10–40% of cases there is both objective and clinical evidence of shock. The mortality rate during the shock crisis ranges from 1% to 20%, depending on the vigor and efficacy of supportive therapy.

The basic virus cycle, the seasonal pattern of occurrence, and the arthropod vectors of DHF do not differ from those of classic dengue infection; hemorrhagic fever is seen either in annual rainy season outbreaks in large metropolitan areas where all dengue serotypes are endemic or during epidemics where a given serotype is introduced after a variable period of absence.

Extensive work on this problem has been done in Bangkok, Thailand, where the primary vector is *Ae. aegypti*. There the majority of hemorrhagic fever patients are children under 10 years of age. Annual hospitalization rates on an age-specific basis may reach 5–8 per 1000. Females are affected more often than males, 1.2:1 to 1.4:1,

despite the fact that dengue virus infection rates in this population do not differ by sex. There are no differences in attack rates between the major ethnic groups: Thai and Chinese.

Hemorrhagic fever occurred significantly more often in children with immunological evidence of secondary dengue virus infection than in those who had a primary response. From this observation it has been postulated that DHF is an immunopathological process selectively occurring among persons experiencing a second dengue infection in a rather short interval.

In vitro and in vivo experimental studies demonstrated that dengue virus replication in mononuclear phagocytic cells, the apparent primary target cells for infection, was enhanced in the presence of small amounts of heterologous dengue antibody. Such antibodies have been found in cord blood of infants born in virus-endemic areas of Southeast Asia. In addition, the first recorded epidemic of DHF in the Americas occurred in Cuba in 1981. This outbreak was caused by dengue 2 virus, just four years after a major epidemic of type 1 infection that was the first dengue experience on that island in more than 30 years. Similar observations have been made in Brazil, Venezuela, Mexico and other Central, South American, and Caribbean countries in recent years as multiple dengue serotypes were introduced and residents were exposed to second dengue infections. It has also been shown that primary dengue infection can cause DHF; however, the risk of DHF following primary infection is 0.25% compared with 3.1% after secondary infection. Complex variables, including virus strain differences and host genetic factors, remain to be elucidated before a clear understanding of the relative risk factors influencing DHF emerges. Of note, in Cuba the risk of contracting DHF was greater in whites than in blacks, despite similar rates of secondary infection with dengue 2 virus.

Methods for surveillance and control of DHF are the same as those described earlier for classic dengue fever. At present, there is no vaccine for dengue; however, clinical trials are in progress for live, attenuated tetravalent dengue vaccines and chimeric vaccines. Should any of these vaccines prove to be safe and efficacious, they will certainly play a significant role in determining how future dengue and DHF epidemics are controlled.

Yellow Fever

Yellow fever is the prototypical viral hemorrhagic fever. It now occurs only in tropical and subtropical regions of Africa and the Americas, but historically it was an important passenger accompanying travelers during the burgeoning European colonial period of the eighteenth and nineteenth centuries, causing urban epidemics in major seaport cities of the United States, the United Kingdom, and Europe. Indeed, the roots of our current system of quarantine, infectious disease control, and a now defunct chain of national marine hospitals can be traced to attempts to understand and control yellow fever in the past century. Yellow fever is caused by a flavivirus closely related to the dengue virus and several other arthropod-transmitted agents of the *Flavivirus* genus. A single infection confers lifelong immunity; thus the modern pattern of disease occurrence consists of recurrent outbreaks with intervals of several years in areas where an extra human virus cycle is maintained.

Clinical response to infection with yellow fever virus ranges from mild, undifferentiated fever to severe illness in which hemorrhagic, hepatic, and renal manifestations predominate. In patients who survive or do not manifest an early fulminating hemorrhagic syndrome, jaundice typically develops after 4–6 days of illness, when viremia wanes and humoral antibodies appear. Renal tubular necrosis may occur during the second week of illness and, before the advent of peritoneal or hemodialysis, it accounted for nearly one-third of fatalities. Notwithstanding these various clinical forms of disease, it is the clustering of jaundice cases with fatality rates of 10–50% that usually brings yellow fever outbreaks to public health attention, a feature of fundamental value in differential diagnosis between this disease and most other viral hemorrhagic fevers.

Attack rates during urban epidemics of yellow fever in the eighteenth and nineteenth centuries were often staggering, ranging to

20 cases per 100 persons, with up to a 5% mortality rate. In the past 30 years one of the largest epidemics on record was in southwestern Ethiopia, where an estimated 100,000 cases occurred in a population of 2 million, with 30,000 deaths. More recently, an epidemic in Gambia caused 2.5 severe illnesses per 100 inhabitants of nine villages with a case-fatality rate of 19%. Serological studies carried out before an emergency immunization campaign revealed that about 12 persons had been infected for each severe clinical case; this ratio was 8 in apparent infections to 1 clinically apparent case where yellow fever infection was the first exposure to a flavivirus, but 45:1 where the infection was secondary to a previous experience with a yellow fever-related virus. Between 1987 and the early 1990s, Nigeria sustained a series of sylvatic and urban outbreaks, with several thousand officially notified cases and a case-fatality rate exceeding 50%. A total of 18,735 cases and 4522 deaths were reported to the World Health Organization from 1987 to 1991, mostly from Africa, and represents the greatest amount of yellow fever activity for any 5-year period since 1948. These figures represent but a fraction of the real burden of yellow fever. Humans of all ages, race, and gender are equally susceptible to yellow fever virus infection.

Observed patterns of human yellow fever are based on enzootic cycles of virus maintenance; despite decades of investigation, several major ecological mysteries persist. Classic urban yellow fever is transmitted in a human-mosquito cycle by the mosquito, *Ae. aegypti*, the same vector as for dengue viruses. African in origin, this species has been disseminated throughout the tropics and subtropics of the entire world. Yet yellow fever has never occurred in India or in the densely populated countries of Southeast Asia. Control of this mosquito and of urban yellow fever during the 1920s in the Americas led to the recognition of a forest cycle causing “jungle” yellow fever. Each year tens to several hundred cases are reported from the countries comprising the Amazon, Orinoco, and Magdalena River systems of South America, and the virus makes additional periodic incursions into Panama, the island of Trinidad, or Bolivia. Mosquito vectors are arboreal, diurnally active species of the genera *Haemagogous* and *Sabethes*, which oviposit in tree holes, and transovarial transmission of the virus has been demonstrated for some vector species. Monkeys are the only proven nonhuman vertebrate hosts in this cycle, and certain species incur high mortality, which is frequently an early warning of pending human outbreaks. Although attack rates in humans are usually low, disease is concentrated in adult males involved in road building, lumbering, or agriculture where destruction of forest is in progress. The virus appears to wander about the vast tropical rain forest, returning to cause human disease at intervals of 5–10 years.

Yellow fever ecology in Africa is more complex. Monkeys and arboreal *Aedes* species, such as *Ae. africanus*, appear to maintain enzootic cycles with only scattered cases of human disease in the rain forests of central and eastern Africa. Larger outbreaks in rural and semi-urban settings take place in the savannah and savannah-transition belts around the forests with extensions into western Africa. Here human-mosquito cycles are important and vectors include *Ae. luteocephalus*, *Ae. simpsoni*, and *Ae. fuscifer*, which breed in tree holes. Recent experimental documentation of transovarial mosquito transmission of virus indicates that many questions concerning yellow fever ecology require reexamination. African monkeys are generally not susceptible to fatal yellow fever virus infection and thus do not provide an early signal of human outbreaks.

There is no specific treatment for human yellow fever, but prevention and control of epidemics can be achieved by use of one of the most successful live attenuated vaccines known to science. The 17D vaccine is highly immunogenic and has a very low incidence of clinical reaction. The vaccine confers long-lasting (perhaps lifetime) immunity, although international requirements for persons traveling to endemic or epidemic areas call for re-immunization every 10 years. Rates for serious side effects are generally low; however, the occurrence of a rare, often fatal adverse event named yellow fever vaccine-associated viscerotropic disease has been recognized recently, especially among older recipients of the vaccine, and this led to an update of the Advisory Committee on

Immunization Practices recommendations for yellow fever vaccine [MMWR November 8, 2002/51 (RR17); 1-10]. No untoward effects on the human fetus have been reported, but in the absence of definitive data prudence requires due exercise of judgment regarding degree of potential exposure before immunization of pregnant women. In spite of the availability of an excellent vaccine, travelers continue to visit at risk areas without the benefit of vaccination, all too often with devastating results. In 1996, two separate travelers to the Amazon Basin of Brazil died of yellow fever on return to their homes in Switzerland and the United States. As "ecotourism" and the ease of international travel in general continues to grow, both individual travelers and their health care providers need to remain cognizant of the risk of yellow fever and ensure that proper vaccination is received prior to travel.

Adjuncts to mass vaccine programs during urban epidemics of yellow fever include destruction of *Ae. aegypti* breeding sites (sanitary engineering and cleanup efforts) and the use of insecticides to reduce both adult and larval mosquito populations. These measures are futile in controlling jungle yellow fever.

Kyasanur Forest Disease

Kyasanur forest disease (KFD) was first recognized in 1957 in a forest area of the state of Karnataka (Mysore) in southwestern India. Attention of health authorities was drawn to a dramatic epizootic among monkeys in this forest, and it was feared that yellow fever had at last arrived in India. The causative agent was, indeed, shown to be a flavivirus, but it proved to be immunologically related to tick-borne flaviviruses causing encephalitis and Omsk hemorrhagic fever in the Soviet Union.

The incubation period of human disease is 3–8 days. Clinical forms, characterized by gastrointestinal hemorrhage, mild encephalitis, or both are commonly observed, and the disease may follow a biphasic clinical course, with the second phase starting on days 7–21. Case-fatality rates are 2–10%, and the inapparent/apparent infection rate has been estimated at about 1:1. Within the slowly expanding endemic region in the state of Karnataka, the disease occurs in a strongly focal pattern, and the number of cases recorded annually ranges from 50 to more than 1000. Attack rates in given villages may reach 5 per 100 in a given year, but it is clear that variables related to the natural virus cycle, rather than immunity in human populations, are responsible for the large swings in disease occurrence.

KFD is strongly seasonal, most cases being recorded during the inter-monsoon drier spring months from February through June. Adults are infected more commonly than children, males slightly more often than females. This pattern reflects the seasonal activity of both the forest-dwelling tick vectors and humans. Larval and nymphal stages of *Haemaphysalis spinigera* and *H. turturis* are most active at this time, and people enter the forest to gather wood and wild plants for food during this annual pause in their agricultural year. Domestic livestock serve as an important source of blood of adult *Haemaphysalis* ticks but do not take part in the virus transmission cycle.

Human infection is most commonly acquired after the bite of tick nymphs. Transovarial transmission of KFD virus by *H. spinigera* ticks has been demonstrated, and the agent has been recovered frequently from forest monkeys, rodents, and squirrels. Birds are infected by KFD virus, although there is no conclusive proof that they serve as a source of tick infection.

Hospital-based surveillance of acute febrile disease with hemorrhagic or neurological manifestations is maintained in the endemic area, and diagnoses are made principally by serologic procedures. A tick-borne encephalitis virus vaccine was tried in an attempt to prevent infection, but was not effective, and an inactivated KFD vaccine was previously tested in the affected region that appeared to reduce incidence of disease among recipients of the vaccine. Research on improved vaccine is required.

Alkhurma Virus

Recently a new virus related to KFD and tick-borne encephalitis viruses was recovered from persons working in Saudi Arabia and named Alkhurma virus. Two fatal infections were documented in individuals

suffering from a hemorrhagic illness; signs and symptoms included fever, hemorrhagic phenomena including epistaxis, echymosis at needle puncture sites, extensive subcutaneous bleeding, bloody diarrhea or rectal bleeding, and hematemesis. A total of nine cases were confirmed serologically or by virus isolation; three had rash, and two had encephalitis manifested by convulsions, semi-coma and coma. Six others had either unusual irritability or drowsiness. Virus was recovered from specimens taken during the course of their illnesses, and genetic characterization suggests that the virus is a new flavivirus very closely related to or perhaps a genetic subtype of KFD. Epidemiological investigations indicated that all nine patients were adults, eight were male, and six worked as butchers and one was a zoo worker routinely exposed to raw meat. The butchers routinely slaughtered and handled meat of sheep most frequently, but also processed beef and camels. A confirmed route of transmission has not been determined, but several patients had cut their hands during the course of their work. Tick bites were also a possible source of infection. To date, a total of 16 cases with four deaths have been confirmed by virus isolation.

Omsk Hemorrhagic Fever

Omsk hemorrhagic fever (OHF) is restricted to the mixed forest-steppe region of western Siberia. First recognized during World War II, clinical cases reported per year ranged from the teens to a few hundred during the next 2 decades but have apparently decreased dramatically in recent years, with only sporadic cases in muskrat trappers and their families. A virus closely related to that of tick-borne encephalitis causes OHF, and the geographical areas of occurrence of these agents overlap, rendering many epidemiological aspects of OHF rather imprecise in the absence of a laboratory method for clear differentiation of these infections.

The disease resembles KFD. The incubation period of OHF in humans ranges from 3–7 days. Fever is typically present in two distinct waves. During the first interval of 5–12 days there are signs of bronchopneumonia and hemorrhagic manifestations, while mild neurological signs appear during the second febrile period of 2–7 days. Case-fatality rates are less than 5%. No data are available regarding human attack rates or inapparent/apparent infection ratios. Transmission of infection to humans occurs either by tick bite, the principal vector being the adult form of *Dermacentor pictus*, or by direct contact with infected muskrats, *Ondatra*, introduced into this region from Canada in the 1920s to generate a fur industry. Humans may also become infected via water contaminated by muskrat corpses or feces.

Although there is no doubt that muskrats experience serious disease with high viremia when infected by OHF virus, it is not clear how they acquire the infection. Experimental studies show that this mammal is readily infected orally and that OHF virus is naturally present in water frequented by muskrats and other rodents. Persons trapping and skinning these animals formerly accounted for many cases during the winter and early spring months, and the possibility of aerosol transmission exists, since several laboratory infections have been recorded from such exposure. Muskrat populations have declined dramatically for unknown reasons in recent years, so that today the few cases reported occur mainly between April and September, are secondary to tick bite, and affect principally farm workers.

Cross-protection against OHF may be afforded by tick-borne encephalitis vaccines; however, given the low incidence of infection, vaccination is not a practical measure except for laboratory workers and, perhaps, muskrat hunters.

Bunyaviruses

Viruses of this family are widely distributed, and infection of humans may range from asymptomatic to fulminant hemorrhagic disease and death. Many viruses of this family have not yet been associated with human disease. Four major genera include human pathogens; *Orthobunyavirus*, *Phlebovirus*, *Nairovirus*, and *Hantavirus*. Viruses of the genus *Orthobunyavirus* are most often transmitted by mosquitoes, and with the exception of Ngari virus, which was obtained from two hemorrhagic fever cases during a large outbreak of predominantly

Rift Valley fever (RVF) virus in East Africa in 1997–1998, viruses of this genus are not known to cause hemorrhagic disease. Phleboviruses take their name from sand flies (genus *Phlebotomus*) that often serve as vectors; however, RVF virus is thought to be transmitted primarily by mosquitoes. Ticks serve as the principal vector for nairoviruses, and the hantaviruses are maintained in nature by chronically infected rodent hosts, similar to the arenaviruses.

Rift Valley Fever

Until 1977, outbreaks of RVF were limited to small numbers of cases observed in eastern and southern Africa in association with major epizootics among large wild and domestic animals. In that year, however, portions of the lower Nile River delta in Egypt were struck by an explosive epidemic-epizootic in which an estimated 200,000 human cases with at least 598 deaths were recorded. Since then, major outbreaks have reappeared in Egypt, and been documented following massive rainfall and flooding in Kenya and Somalia in 1997–1998, and then for the first time ever the virus was seen outside the continent of Africa when it was introduced into Yemen and southern Saudi Arabia in 2000. Between August 2000 and September 2001, 886 RVF cases were reported in Saudi Arabia with a mortality rate of 13.9%, while 1087 cases and 121 (11.1%) deaths were reported in Yemen.

Clinical illness due to RVF virus in humans as observed in eastern and southern Africa is usually an undifferentiated acute febrile illness marked by high but brief fever and no sequelae. Serious complications of clinical ocular serous retinopathy with central scotomata are seen in about 1% of cases, and in another 1% fulminant acute, usually non-icteric hepatitis and hemorrhage with death develop. Nothing resembling the Egyptian epidemic had ever occurred before, however. In this outbreak patients with seemingly typical self-limited illnesses suddenly had hemorrhagic manifestations (gastrointestinal and other mucous membrane bleeding and skin petechiae) and died within 1–3 days. Infection-morbidity rates were not accurately determined, but it is estimated that up to 20% of persons of all ages and both sexes were infected in the Ismailia district. A similar outbreak occurred in 1993, although not as severe as that of 1977–1978, but nonetheless leading to as many as 6000 human infections in Aswan Governorate, and ultimately spreading to Sharkiya and Giza Governorates in the Nile River Delta. A unique characteristic of this outbreak was the preponderance of ocular disease, an infrequent and late manifestation seen during the earlier Egyptian outbreak.

Although the ecology of RVF virus in Africa is still not clear, there is evidence suggesting that biological transmission of the agent may be principally attributed to mosquitoes of the genus *Aedes*. In eastern Africa, the association of RVF maintenance cycles with specific breeding habitats of *Ae. mcintoshi* in shallow depressions called “dambos” has been elucidated in Kenya. During periods of high rainfall, flooding of dambos results in an abundance of *Aedes* and transmission of virus from transovarially infected mosquitoes as they feed on various species of vertebrate hosts, including domestic livestock, with secondary cycles of virus transmission being affected by *Anopheles*, *Culex*, and *Erethmapodites* vectors. Mechanical transmission by biting arthropods seems likely in addition because of the very high viremia levels (10^6 – 10^9 infectious units) reached in many domestic animals, and direct transmission to humans handling infected large animals or their carcasses is a recurrent phenomenon. Both contact with infectious blood and infectious aerosols are suspected as mechanisms.

The vectors involved in the Egyptian epidemic-epizootics have not been conclusively elucidated; the principal candidate for the 1977–1978 outbreak is the mosquito *Culex pipiens quinquefasciatus* which was present in large numbers in houses and environs during the months of October and November, when most cases occurred. This species was likewise abundant in collections made during the 1993 outbreak, but definitive demonstration that this is the principal epidemic vector remains elusive.

Retrospective evidence now suggests that the virus may have reached Egypt from the Sudan, where animal epizootics were documented during the 5-year period before 1977. Subsequent outbreaks

involving animals and humans have been reported in Mauritania (1987) and Madagascar (1990), in addition to the reoccurrence in Egypt in 1993. Similarly, the importation of RVF virus into the Arabian Peninsula in 2000 is thought to have been the result of movement of animals and humans across the Red Sea following the major outbreak in East Africa in 1997–1998, although definitive proof is lacking. National and international concern over this emergent disease is not limited to public health workers. RVF virus causes a serious pantropic infection in domestic animals with significant mortality and high rates of abortion. Nations are vitally interested in preventing its introduction into their animal industries; thus work with this virus in the United States and many other countries is either totally proscribed or limited to facilities with a maximum containment configuration.

To date there is no treatment for the human disease, although interferon and interferon inducers show promise in preclinical studies. Inactivated vaccines provide immunity for two years after two or three doses and have been used to immunize livestock. Such products, however, are of little use should an outbreak occur in a previously uninfected country. The dynamics of virus transmission revealed in Egypt and East Africa suggest that a live vaccine for animals that will confer rapid protection and curtail arthropod virus transmission is urgently needed. A live vaccine developed in South Africa is produced, but has been associated with abortion in sheep. More recently, a live vaccine (MP-12) developed in the United States appears safe and highly effective but requires additional field-testing. Such a vaccine, together with emergency mosquito-control measures, forms a rational armamentarium against a major tragedy, which could strike inside or away from Africa. Killed vaccines for humans have been used to protect laboratory workers and military populations.

Crimean-Congo Hemorrhagic Fever

Although compatible clinical account of Crimean-Congo hemorrhagic fever (CCHF) in central Asia date to the thirteenth century, epidemics occurring during World War II in the Crimea provided the first modern recognition and the name of this clinically serious syndrome. The causative agent of the disease was finally isolated in newborn mice in 1968. It was found to be a member of the large Bunyaviridae family, genus *Nairovirus*, and, surprisingly, was antigenically indistinguishable from a virus of African origin, Congo virus, originally discovered in 1956. This virus was subsequently proved to be responsible for previously independent nosologic hemorrhagic entities termed Bulgarian and central Asia hemorrhagic fever and has been designated as Crimean-Congo hemorrhagic fever virus.

The clinical disease caused by CCHF outside Africa is one of the most virulent viral hemorrhagic fevers. The incubation period is brief, 2–9 days, and the onset of fever and nonspecific symptoms is sudden. Hemorrhagic manifestations, often with severe blood loss, appear after 3–7 days of illness. There are various mild neurological manifestations as well, and surviving patients occasionally suffer peripheral neuritis, emotional disturbances, or both for months or even years. The disease is acquired by exposure to infected ticks or by close contact with persons who have the disease. Case-fatality rates average 13–25% for tick-transmitted disease, but nearly 40% for contact infection, which is frequently nosocomial where strict isolation of patients and use of protective clothing are not practiced. Attack rates in certain areas of the Soviet Union have reached 14 per 1000 in epidemic years. The infection morbidity ratio in the Astrakhan and Rostov regions has been estimated at about 6:1.

Depending on the geographical area, a large variety of tick species has been incompletely incriminated in the natural cycle and transmission to humans of CCHF virus. In Bulgaria and the valleys of the lower Don and Volga rivers of the Soviet Union, *Hyalomma marginatum*, a two-host species, is the principal vector. Immature stages parasitize hares, small rodents, and ground-feeding birds, while adults favor large domestic animals, such as cattle and sheep, and also attack humans. Persons engaged in pastoral and agricultural activities are most often attacked, and most cases occur during April–July, the period of peak activity of the adult ticks. Outbreaks of disease in central Asia are less strongly seasonal but tend to occur most often during summer months

and are thought to be transmitted by ticks of the genera *Hyalomma*, *Rhipicephalus*, and *Boophilus*, which have life cycles ranging from single to as many as three hosts, most of which are large domestic animals. This epidemiological pattern extends from Kosovo and Albania to the Arabian Peninsula, Iraq, and Iran as far east as Pakistan. Human cases have also been recognized in Africa, including temperate South Africa and tropical areas of eastern, western, and central Africa. The virus has been recovered on numerous occasions from ticks, cattle, and hedgehogs in these areas. The case-fatality rate (30% in South Africa) is similar to that in Eastern Europe and countries of the former Soviet Union, and there is no evidence of a difference in virulence between virus strains.

The dynamics of virus maintenance in nature are not clear. CCHF in countries of the former Soviet Union has decreased significantly since 1970, but the biological correlates of this phenomenon were not elucidated. There is good evidence that CCHF virus is maintained serially in *H. marginatum* ticks by overwintering in infected nymphs and by both transtadial and transovarial passage. Hares experience viremia and can, therefore, infect larval and nymphal ticks, but birds apparently serve only as hosts for tick reproduction. Viral biology in ticks and vertebrate hosts in Asia and Africa is even less well known.

Soviet workers state that virus-specific passive antibodies are of value in therapy of CCHF if given during the initial three days of illness. An immune globulin formulation for intravenous administration is used in Bulgaria, with good results reported. A formalized mouse brain vaccine has been produced and tested in more than 150,000 persons in Bulgaria, but no definitive conclusions as to efficacy have been reported. Prevention of disease was stressed in countries of the former Soviet Union through use of personal measures, such as special clothing, tick repellents, and the systematic dipping of livestock to control adult stages of tick vectors. Whether these measures or natural forces are responsible for the observed decline in disease in the Volga and Don River basins during this decade is not known.

The lack of an animal model of CCHF disease is an obstacle to development of a vaccine and an antiviral drug. Ribavirin may be an effective therapeutic agent. In uncontrolled trials in South Africa, early initiation of intravenous therapy is said to be lifesaving, and oral ribavirin is thought to be effective in treatment of CCHF disease in Iran. Given orally, the drug may also be useful for postexposure prophylaxis of case contacts. Future work on this disease is dependent on construction of more maximum containment laboratories since CCHF virus is a BSL-4 pathogen, and it is well to remember that CCHF is the hemorrhagic fever most likely to be confused with a noninfectious cause of acute gastrointestinal hemorrhage, with potentially devastating consequences to patient and medical staff alike as has been documented repeatedly.

Hemorrhagic Fever with Renal Syndrome

Hemorrhagic fever with renal syndrome (HFRS) is a general term used to denote a constellation of similar clinical diseases caused by related viruses of the genus *Hantavirus*, family Bunyaviridae. Many synonyms exist for this disease, including epidemic hemorrhagic fever, Korean hemorrhagic fever, hemorrhagic nephroso-nephritis, nephropathia epidemica, and others. Like arenaviruses, the hantaviruses are maintained in nature by chronic infection of rodent hosts, with humans becoming infected following aerosol exposure to infectious excreta or occasionally by bite. Unlike arenaviruses, nosocomial outbreaks or person-to-person transmission have not been recorded for viruses that cause HFRS (but see *Hantavirus Pulmonary Syndrome* below). Many different hantaviruses have now been recognized, and each appears to be associated with a specific rodent host (Table 15-6). Consequently, the distribution of individual hantaviruses is dependant upon the distribution of its rodent host, and risks of human infection are directly related to the amount of potential contact existing between these rodents and humans. The prototype hantavirus is Hantaan virus, cause of epidemic hemorrhagic fever in China and Korean hemorrhagic fever in Korea, which occurs in a wide belt across Eurasia from Japan and Korea to the Ural mountains of Russia, including much of China. Hantaan virus is maintained

by the striped field mouse, *Apodemus agrarius*, and humans are most frequently infected in the fall and early winter months, when adults in rural areas are exposed as part of harvest activities. Also commonly infected are military populations while on field maneuvers, shepherds, woodcutters, campers, and others involved in outdoor activities. Other hantaviruses causing HFRS include Seoul virus, associated with domestic rats (*Rattus rattus*, *R. norvegicus*) and found virtually worldwide, wherever rats are abundant; Puumala virus, maintained by the bank vole, *Clethrionomys glareolus* and abundant in western Europe, especially in western Russia and Scandinavia; Saaremaa virus, similar in distribution and human disease to Puulama virus, but thought to be maintained in nature by *Apodemus agrarius*; and Dobrava virus, now known only in the Balkans region of Europe, and thought to be hosted by *Apodemus flavicollis*. Other hantavirus-specific rodent associations have been described, but evidence that they represent threats to human illness are lacking.

Incidence rates of HFRS vary by country, the virus present, and by the natural variation in abundance of their principal rodent hosts. In China, approximately 100,000 cases occur annually or about 0.1 per 1000 population, and rates of about 0.2–0.5 per 1000 have been recorded among the Korean military. The incidence of nephropathia epidemica due to Puumala virus is about 0.01 to greater than 0.2 per 1000, depending upon the abundance of its rodent host. The incidence rates of Seoul, Saaremaa, and Dobrava viruses are unknown, but likely to be less than those for Hantaan and Puumala.

Classic HFRS has a variable but potentially long incubation period of up to four weeks. The disease is characterized by five phases: a *febrile phase* of 3–7 days' duration with fever, malaise, headache, abdominal pain, nausea, vomiting, facial flushing, petechiae, and conjunctival hemorrhage; a *hypotensive phase* of a few hours to three days' duration, when hypotension, shock, visual blurring, hemorrhagic signs and a drop in blood pressure occur; an *oliguric phase* of 3–7 days' duration during which oliguria or anuria predominates and hemorrhagic manifestations may worsen; a *diuretic phase* of days to weeks' duration when polyuria predominates; and a prolonged *convalescence phase* of weeks to months. Mortality rates for classic HFRS due to Hantaan virus range from 1–10%, varying greatly depending upon the quality of care available. Seoul virus causes a similar but generally milder disease with mortality rates less than 1%, as does Puumala virus. Dobrava virus appears to have a mortality rate at least equal to classic Hantaan, although relatively few patients have been documented. Seoul virus has also been associated with outbreaks of HFRS traced to infected laboratory rat colonies. Seoul virus is known to be abundant in urban rats in many large cities, including in the United States, and studies among Baltimore residents suggest that past infection with Seoul virus may be associated with subsequent development of hypertensive renal disease.

Diagnosis of HFRS is hampered by the lack of readily available diagnostic tests and the fact that it is not often considered in the differential diagnosis of physicians in non-endemic countries. A placebo-controlled trial of intravenous ribavirin conducted in 1986–1987 in China showed that initiation of treatment early in the course of the disease reduced mortality and the incidence of renal failure and hemorrhage.

Control of HFRS relies primarily on reduction of potential human-rodent contact through good sanitation and waste management, rodent control, and rodent-proofing buildings. It is difficult to reduce exposure to rodents in rural populations, especially for those individuals staying in temporary campsites, but careful management of foods and waste may reduce the number of rodents attracted. Inactivated vaccines have been developed and used in Korea and China, although their efficacy in some cases has yet to be systematically demonstrated. Molecularly based vaccines for both Hantaan and Puumala viruses are also under development.

Hantavirus Pulmonary Syndrome

Hantavirus pulmonary syndrome (HPS) was first recognized in 1993 when a cluster of fatal unexplained adult respiratory distress syndrome

cases occurred among otherwise healthy young adults in the southwestern United States. The disease is a severe, systemic illness characterized by fever, myalgia, cough, headache, and gastrointestinal symptoms, followed by abrupt onset of non-cardiogenic pulmonary edema and shock, often leading to death. Initial investigations determined that the disease was caused by a new hantavirus, subsequently named Sin Nombre virus, and found to be maintained in nature by the deer mouse, *Peromyscus maniculatus*. Nearly 400 cases of HPS have now been documented in the United States, with a mortality rate of about 36%. About

three-quarters of cases are rural, and males make up more than 60% of the cases documented in the United States to date. Recently cases of HPS have been seen in individuals residing in areas outside the natural range of *P. maniculatus*, and it is now clear that several other genetically and antigenically related viruses are capable of causing HPS (Table 15-6), including newly recognized hantaviruses found in South America and maintained by field rodents there. A disturbing finding is the apparent person-to-person transmission of Andes virus causing HPS among individuals infected in Argentina.

Rickettsial Infections

Marta A. Guerra • David L. Swerdlow

► OVERVIEW

Introduction

Rickettsial diseases are widely distributed throughout the world and are a significant cause of illness and death within the human population. Most are zoonotic diseases maintained in the environment through complex cycles involving mammalian reservoirs and invertebrate vectors that can also serve as reservoirs. The actual incidence and prevalence of these diseases are difficult to estimate because they may be under diagnosed and underreported in endemic areas due to their nonspecific clinical presentations and difficulties in laboratory diagnosis and interpretation of results. Rocky Mountain spotted fever has been a nationally notifiable disease in the United States since the 1920s. The ehrlichioses were added to the list of notifiable diseases in 1999. The remaining diseases occur sporadically, usually in localized areas of the United States, and reporting requirements vary by state.¹

Classification of Pathogens

Considerable progress has been made recently in clarifying the taxonomy, biochemistry, genetics, and morphology of rickettsial organisms. The Order Rickettsiales consists of two families, *Rickettsiaceae*, composed of the genera *Rickettsia* and *Orientia*, and *Anaplasmataceae*, composed of five genera of which two, *Ehrlichia* and *Anaplasma*, will be discussed here.² There are at least 26 recognized etiologic agents causing infections in humans within the Order Rickettsiales. (Table 15-7)

Structure and Replication of Pathogens

The organisms within the Order Rickettsiales are obligate intracellular bacteria that multiply only within living cells. They are small coccoid to rod-shaped bacteria, usually 0.3–0.5 \times in diameter and up to 2.0 \times in length with typical bacterial cell walls and cytoplasmic membranes, contain both DNA and RNA, and divide by binary fission. Species in the family *Rickettsiaceae* replicate within the cytoplasm of the host cells, and those in the spotted fever group are trophic for endothelial cells. Species in the family *Anaplasmataceae* replicate within cell membrane-derived vacuoles within hematopoietic cells. They may be cultured and isolated in several laboratory animal species, arthropod vectors, embryonated eggs, and some cell cultures.

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Natural History

The natural life cycles of rickettsial and ehrlichial organisms involve arthropod vectors (lice, fleas, mites, or ticks) and, to a lesser extent, various mammalian vertebrate hosts.³ In ticks and mites, transovarial transmission of the agent to the offspring frequently occurs. The vector transmits the agent to animals or humans by direct bite inoculation, or fecal contamination of the skin through the bite wound, scratches, or abrasions. With the exception of louse-borne typhus where humans are the major reservoirs, humans are incidental hosts and are not necessary for the perpetuation of these organisms in the natural environment.

Most of the rickettsial and ehrlichial diseases are characterized by the syndrome of severe headache, fever, myalgias, and a quite variable rash. Some species are also associated with characteristic presentations. Rickettsial infections cause a generalized capillary and small vessel vasculitis, resulting in damage to the host's skin, brain, lungs, and other organs. Chronic infection or late relapse (especially in epidemic typhus) and long-term persistence of some species of rickettsiae in lymph nodes or other tissues have been documented.⁴ Ehrlichial infections affect hematopoietic cells and are characterized by thrombocytopenia, leukopenia, and altered liver and splenic function.

Diagnosis

Serology is the most common method of laboratory diagnosis, however, diagnostic titers are not achieved until the second week of illness or later. Indirect fluorescent antibody (IFA) testing is the most widely accepted serological diagnostic technique, although the use of EIA/ELISA diagnostic tests is increasing. IFA tests are now available for all the human rickettsial and ehrlichial diseases.⁵ The complement-fixation (CF) test using acute- and convalescent-phase sera and the nonspecific Weil-Felix (WF) reaction are still widely available, but both tests lack sensitivity. A four-fold or equivalent rise in titer 3–4 weeks apart by any technique other than the WF reaction is considered diagnostic. Immunohistochemistry, if available, may demonstrate organisms in skin lesions, such as the rash or eschar, and can rapidly confirm a suspected diagnosis. Polymerase chain reaction (PCR) assay performed on tissue or whole blood, and culture of the agent can also be used to confirm a diagnosis if samples are obtained before treatment is initiated.

Treatment

Antibiotic treatment with tetracyclines, especially doxycycline, is usually effective if started early in the course of the disease.⁶ Although the use of tetracyclines is not recommended for children because of the potential for tooth discoloration, this class of antibiotics is the most effective in treating rickettsial infections, and data suggest that a short

TABLE 15-7. RICKETTSIOSES CAUSING INFECTION IN HUMANS

Disease	Etiologic Agent	Principal Vector(s)	Natural Hosts of Vector(s)	Geographic Distribution
Rocky Mountain spotted fever	<i>Rickettsia rickettsii</i>	<i>Dermacentor</i> , <i>Amblyomma</i> , and <i>Rhipicephalus</i> tick species	Various small mammals, including rodents, lagomorphs, dogs	North and South America
Rickettsialpox	<i>Rickettsia akari</i>	Mouse mite (<i>Allodermanyssus sanguineus</i>)	House mouse (<i>Mus musculus</i>); other rodents	Worldwide
Unnamed	<i>Rickettsia parkeri</i>	Gulf Coast tick (<i>Amblyomma maculatum</i>)	Rodents, birds, large mammals	Western hemisphere
Mediterranean spotted fever (or boutonneuse fever)	<i>Rickettsia conorii</i> (Malish or reference strain)	<i>Rhipicephalus</i> and <i>Haemaphysalis</i> tick species	Dogs, small mammals	Mediterranean region, Africa
Israeli spotted fever, Astrakhan spotted fever, Indian tick typhus, Kenyan tick typhus	<i>R. conorii</i> complex			Middle East, Caspian, and Black Sea region, India
African tick bite fever	<i>Rickettsia africae</i>	<i>Amblyomma</i> tick species	Cattle & wild ungulates	Sub-Saharan Africa, Caribbean
North Asian tick typhus	<i>Rickettsia sibirica</i>	<i>Dermacentor</i> , <i>Haemaphysalis</i> , <i>Rhipicephalus</i> tick species	Livestock, small mammals (rodents)	Northern Asia, China, Pakistan
Lymphangitis-associated rickettsiosis	<i>Rickettsia sibirica mongolotimonae</i>	<i>Hyalomma</i> tick species	Cattle, migratory birds	Sub-Saharan Africa, France, China
Queensland tick typhus	<i>Rickettsia australis</i>	<i>Ixodes</i> tick species, especially <i>I. holocyclus</i>	Small marsupials, rodents	Eastern Australia
Flinders Island spotted fever	<i>Rickettsia honei</i>	<i>Aponomma hydrosauri</i> ; <i>Ixodes</i> , <i>Rhipicephalus</i> , and <i>Amblyomma</i> species	Reptiles, rodents, cattle, small mammals	Australia, southeast Asia, North America
Japanese spotted fever	<i>Rickettsia japonica</i>	Ticks—multiple species		Japan
Cat flea rickettsiosis	<i>Rickettsia felis</i>	Cat flea (<i>Ctenocephalides felis</i>)	Opossums, cats, rodents	North and South America, Europe, Africa, Asia
Unnamed	<i>Rickettsia heilongjiangensis</i>	<i>Dermacentor</i> tick species	Mammals	Eastern Asia
Unnamed (DEBONEL/TIBOLA)	<i>Rickettsia slovacica</i>	<i>Dermacentor</i> tick species	Mammals	Europe
Unnamed	<i>Rickettsia helvetica</i>	<i>Ixodes</i> tick species	Rodents	Europe, Asia
Unnamed	<i>Rickettsia aeschlimannii</i>	<i>Hyalomma</i> , <i>Rhipicephalus</i> tick species	Cattle, sheep, boars, migratory birds (?)	Mediterranean region, eastern Europe, Africa
Epidemic typhus (louse-borne typhus)	<i>Rickettsia prowazekii</i>	Human body louse (<i>Pediculus humanus corporis</i>)	Humans; flying squirrels	Africa, Central and South America, Asia
Murine typhus (endemic typhus)	<i>Rickettsia typhi</i>	Oriental rat flea (<i>Xenopsylla cheopis</i>)	<i>Rattus</i> species, cats, opossums	Worldwide
Scrub typhus	<i>Orientia tsutsugamushi</i>	Larval trombiculid mites (<i>Leptotrombidium</i> species)	Small wild rodents, birds	Southeast Asia, Australia, Pacific islands
Human monocytic ehrlichiosis	<i>Ehrlichia chaffeensis</i>	Lone star tick (<i>Amblyomma americanum</i>)	White-tailed deer	United States, Korea
Human granulocytic anaplasmosis	<i>Anaplasma phagocytophilum</i>	<i>Ixodes scapularis</i> , <i>I. pacificus</i> , <i>I. ricinus</i>	Rodents, white-tailed deer	United States, Europe
Unnamed	<i>Ehrlichia ewingii</i>	Lone star tick (<i>Amblyomma americanum</i>)	Dogs, white-tailed deer	United States
Sennetsu fever	<i>Ehrlichia sennetsu</i>	Trematodes (?)	Fish (?)	Japan

course of treatment does not cause significant staining of permanent teeth.^{7,8} The use of doxycycline in pregnant women has not been well studied, and chloramphenicol remains the recommended antibiotic of choice for rickettsial infections, although caution must be taken when administering it during the third trimester because of risks associated with “gray baby syndrome.”⁹ In rare cases, use of chloramphenicol may cause aplastic anemia. For suspected infections, therapy must be initiated on the basis of clinical presentation and epidemiological setting before a laboratory diagnosis is available. Delay in the start of treatment while awaiting confirmation of the diagnosis may result in more severe disease and fatal outcomes.¹⁰ General supportive measures and the host’s immune response are important factors in recovery.

Prevention and Control

Prevention and control of rickettsial and ehrlichial diseases depend on avoidance of vector-infested sites, and vector and reservoir host control by habitat modification or use of appropriate pesticides. If exposure is unavoidable, appropriate clothing should be worn, such as long-sleeved shirts and long pants, which may be pretreated with permethrin products. N,N-diethyl-meta-toluamide (DEET)-containing repellants should be applied to exposed skin following directions on the label. In tick-infested areas, persons should check themselves frequently for the presence of ticks. Attached ticks should be removed carefully with tweezers and exposure to fluids of the ticks should be minimized with the use of gloves. In the United States,

most cases of rickettsial diseases are associated with occupational or recreational exposures to the vectors. These diseases are also being increasingly recognized in international travelers visiting remote areas of endemicity.¹¹ Travelers should be aware of the diseases to which they may be exposed and the appropriate methods for decreasing exposures. No vaccines are currently available for prevention of these diseases.

► SPOTTED FEVER GROUP

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever (RMSF), caused by *Rickettsia rickettsii*, is the best known and most severe of the tick-borne rickettsioses. RMSF has been recognized as a distinct entity in the United States since the late 1800s; various researchers, including Ricketts in Montana (1906), defined the disease and described the natural cycle of the agent.¹² It is also the etiologic agent of spotted fevers in Central and South America.^{13,14,15}

The vectors of *R. rickettsii* organisms are various ixodid ticks, which also serve as a reservoir for *R. rickettsii* because of the passage of the RMSF agent by transovarial transmission. Ticks may also become infected by feeding on rickettsiemic vertebrate hosts such as rodents, small and medium-sized mammals, and dogs. In North America, the vectors are the American dog tick *Dermacentor variabilis* in the east, and the Rocky Mountain wood tick *Dermacentor andersoni* in the west. *Rhipicephalus sanguineus* has been implicated as a vector in Mexico and Central America^{13,16} and, recently, in Arizona.¹⁷ *Amblyomma cajennense* has been found to be the major vector of spotted fevers in South America.^{15,18}

Human cases of RMSF have been reported throughout the United States, with the highest prevalence in the south Atlantic and south-central states.¹⁹ The incidence of RMSF peaks during late spring and summer when ticks are most abundant, although the disease occurs in temperate climates through the winter at a low incidence. RMSF is most commonly diagnosed among people exposed occupationally or recreationally to tick-infested areas. Cases are more frequently diagnosed among males, whites, and children. Two-thirds of the cases occur in children under 15 years of age. The highest incidence of RMSF was among children 5–9 years of age.²⁰

Illness usually begins abruptly 2–12 days after tick exposure. A high, persistent fever, severe headache, and myalgias are characteristic, while nausea, vomiting, abdominal pain, and conjunctivitis occur frequently. The maculopapular rash, present in about 90% of the cases, may not appear until the third day or later. The rash often begins on the ankles or wrists, and may spread rapidly to the rest of the body; later, it becomes petechial in 50% of cases, often accompanied by edema. Involvement of the palms and soles is quite characteristic, but is a relatively late event occurring in only 50% of cases. Headache is typically severe, and focal neurologic deficits may occur, occasionally with permanent neurological sequelae. Necrosis of the skin lesions or gangrene of extremities occurs in up to 4% of cases. Thrombocytopenia, anemia, elevated liver function tests, coagulopathy, renal failure, pulmonary edema, and involvement of all organ systems may be seen. The overall fatality rate is approximately 20% if untreated. It may be higher in adults over 30 years, in males, and in glucose-6-phosphate dehydrogenase-deficient persons.

Immunohistologic examination of skin lesions for the presence of rickettsial organisms may provide immediate confirmation. In severe infections, PCR assays performed on whole blood or tissue may also yield a rapid diagnosis. These tests are available at reference laboratories or at the Centers for Disease Control and Prevention. Most laboratory diagnoses for RMSF, however, are made retrospectively by documenting a four-fold or equivalent rise in titer between acute and convalescent serum samples.

Treatment should be initiated promptly on the basis of epidemiological setting and clinical suspicion without waiting for laboratory confirmation.²¹ The antibiotic of choice is doxycycline for adults and children. For pregnant women, chloramphenicol remains the preferred treatment for RMSF. Treatment with doxycycline should be continued for 7–10 days or 48–72 hours after defervescence and clinical improvement. For adults, the recommended dose is 100 mg orally or intravenously every 12 hours, and for children, 2.2 mg/kg orally every 12 hours.²² Delay in the initiation of proper antibiotic therapy may lead to complications, such as neurologic manifestations, pneumonitis, myocarditis, and renal failure.^{23,24} Supportive care is important in the management of the complications of RMSF. Prevention and control of RMSF depend on avoidance of vector-infested sites, and vector and reservoir host control by habitat modification or use of appropriate pesticides. RMSF has been acquired in laboratory settings, and it may be transmitted by direct inoculation of contaminated blood.

Mediterranean Spotted Fever

Mediterranean spotted fever (MSF), also known as Boutonneuse fever, is caused by *Rickettsia conorii* and has been reported from southern Europe, Asia, the Middle East, India, and Africa.^{11,25} Strains closely related to MSF include Kenya tick typhus, Astrakhan fever, Israeli tick typhus, and Indian tick typhus. The brown dog tick, *Rhipicephalus sanguineus*, is the principal vector and reservoir of MSF.²⁶ Adult *R. sanguineus* ticks preferentially feed on dogs, and are found in the peridomestic environment, including houses and kennels. The immature stages may be more likely to feed on other hosts in addition to dogs, and human cases usually occur during late spring, summer, and early fall when all stages of *R. sanguineus* are abundant.²⁷ Patients with MSF usually give a history of exposure to high grass or bush and contact with dogs, although a history of tick bite is not often reported.

MSF is a mild to moderately severe illness with an incubation period ranging from 6–10 days. It is less frequently associated with the progressive, hemorrhagic tendency of RMSF. There is an abrupt onset of high fever accompanied by headache, arthralgia, and myalgia lasting a few days to 2 weeks.^{28,29} A maculopapular rash appears by approximately the third day in 96% of cases. It may persist for 6–7 days and is usually generalized. A single eschar (tache noir) is present at the site of tick attachment in 30–90% of cases. Antibiotic therapy shortens the course and severity of the illness. The drug of choice for treatment is doxycycline at 100 mg twice a day for 1–2 weeks for adults, although a single dose of 200 mg has been shown to also be effective.³⁰ The disease is usually self-limited, but 10% of cases may have severe complications such as neurological involvement or multiorgan failure, with an overall case fatality rate of 2.5%.²⁸

For prevention of MSF, measures must be taken to decrease the risk of tick bite. Clothes and shoes should be worn to cover bare skin, clothes should be treated with acaricides before wear, and exposed skin should be treated with repellants. For travelers visiting tick endemic areas, information on tickborne diseases should be made available before travel so that symptoms consistent with these diseases can be recognized.

African Tick Bite Fever

During the early part of this century, African tick bite fever (ATBF) had been recognized as a rural tick-borne disease of the African continent, and was considered synonymous with Mediterranean spotted fever. However, two distinct clinical presentations of rash-like illness occurring after tick bites were noted during the 1930s in southern Africa.³¹ One was consistent with Mediterranean spotted fever, which was usually associated with urban environments, but the other was found in patients with a history of travel into the bush and contact with game, cattle, and ticks. In 1992, after a human case of ATBF was diagnosed in Zimbabwe, the strain was characterized as *Rickettsia africae*.³²

The most important vectors and reservoirs of ATBF are *Amblyomma* ticks, principally *A. hebraeum* in southern Africa, and *A. variegatum* in central, west, and east Africa.³³ The major hosts of *Amblyomma* ticks are cattle and wild ungulates, but these ticks are not host-specific and will feed on any available host. There are few reports of cases within Africa,^{34,35,36} but it is likely present among the indigenous populations. Most reported cases of ATBF have been diagnosed in travelers returning from trips to Africa, although less than 50% reported tick bites.¹¹ *R. africae* has also been detected in *A. variegatum* in several islands of the West Indies.³⁷

After an incubation period of 5–10 days, ATBF is characterized by abrupt flu-like symptoms, including fever, headache, and myalgia. Multiple eschars with regional lymphadenopathy are seen in approximately 50% of patients, while a generalized cutaneous rash is present in 15–46% of cases. Patients with ATBF respond well to treatment with doxycycline and defervescence occurs within 1–2 days. Complications are rare and no fatal cases have been reported.

For prevention of ATBF, measures must be taken to decrease the risk of tick bite. Clothes and shoes should be worn to cover bare skin, clothes should be treated with acaricides before wear, and exposed skin should be treated with repellents. For travelers visiting tick endemic areas, information on tick-borne diseases should be made available before travel so that symptoms consistent with these diseases may be recognized early.

Rickettsialpox

Rickettsialpox (vesicular rickettsiosis) was first recognized as a distinct clinical entity in apartment dwellers in New York City in 1946, and *Rickettsia akari* was identified as the etiologic agent.³⁸ Cases were subsequently detected in several other cities in the northeastern United States, with an annual incidence of nearly 200 cases.³⁹ In the last few decades, only a few cases per year have been confirmed in the United States.^{40,41} It is unknown if the decrease is due to an actual decrease in cases or misdiagnosis. Rickettsialpox has also been recognized in Korea, Russia, and Croatia.^{42,43,44}

Rickettsialpox is transmitted to humans through the bite of a bloodsucking mite, *Lipomyssoides sanguineus*, a parasite of the house mouse, *Mus musculus*, which is a reservoir for *R. akari*. The mite also serves as a reservoir since transstadial and transovarial transmission of the agent has been documented. *R. akari* has also been isolated from other rodent species, such as the Korean vole, *Microtus fortis pelliceus*,⁴⁵ indicating the possible existence of other transmission cycles.

Rickettsialpox is a relatively mild disease. After an incubation period of 9–14 days, a papular lesion with surrounding erythema develops at the site of mite feeding, accompanied by regional lymphadenopathy. The papule ulcerates centrally, forming an eschar. Systemic symptoms, including fever, headache, backache, myalgias, and occasionally photophobia, develop approximately one week after the initial lesion. Within a few days of the onset of symptoms, a generalized maculopapular rash develops on the face, trunk, and extremities, but not on the palms and soles. The rash, which can resemble chickenpox, becomes vesicular, and eventually heals without scarring. Symptoms resolve within 6–10 days and recovery can occur without treatment. Although no fatalities have been known to occur, rickettsialpox can be moderately severe, and a short course of treatment with doxycycline may be warranted.

Rickettsialpox is recognized as an urban disease occurring in large cities with crowded areas infested with rodents.⁴⁶ Residual insecticides and rodent-control measures may limit or eliminate the vector and reservoir, and thus rickettsial transmission to humans.

Other Spotted Fever Rickettsioses

North Asian tick typhus (Siberian tick typhus, North Asian tick-borne rickettsiosis) is clinically similar to MSF but is caused by a separate species, *Rickettsia sibirica*. It occurs in western Russia, Mongolia, and China.⁴⁷ The vectors include ticks of the genera *Dermacentor* and

Haemaphysalis.^{48,49} Various rodents and other wild mammals in addition to transovarial passage may play a role in the maintenance of these rickettsiae in nature. Another rickettsiosis of the spotted fever group caused by *Rickettsia japonica*, has been described in Japan.⁵⁰ Japanese spotted fever (JSF) has been found to cause fever, headache and the characteristic rash with 90% of cases reporting an eschar.⁵¹ The most probable vectors of *R. japonica* are *Haemaphysalis flava* and *Ixodes ovatus*.

Other spotted fever group rickettsiae that have been recently identified as human pathogens. *R. slovaca* in Europe has been associated with a tick-borne disease with clinical features including a necrotic lesion at the site of tick attachment surrounded by erythema and regional lymphadenopathy.^{52,53} *R. sibirica mongolotimonae* (formerly *R. mongolotimonae*) in Asia, Europe, and Africa has also been associated with a lymphangitis.⁵⁴ Infection with *R. helvetica* in Europe and Asia has presented clinically as a mild febrile illness with no cutaneous rash.^{55,56} *R. heilongjiangensis* has been isolated in China in *Dermacentor sylvarum* and has been found to cause rickettsial-like disease in eastern Russia.⁵⁷ *R. aeschlimannii*, detected in *Hyalomma marginatum* ticks from Africa,⁵⁸ has also been found to cause human infection in a traveler visiting Morocco.⁵⁹

In Australia, *Rickettsia australis*, has been identified as the etiologic agent of North Queensland tick typhus which has been found to occur along the eastern coast.⁶⁰ The only two tick vectors currently identified are *Ixodes holocyclus* and *tasmani*. Another rickettsiosis found in Australia caused by *Rickettsia honei* has been identified on Flinders Island and the southeastern coastal region.⁶¹ The tick vector has been identified as *Aponomma hydrosauri* which feeds primarily on reptiles.⁶² Spotted fever rickettsioses of undetermined etiology have been also discovered in Thailand, Hong Kong, and Yucatan.⁶³

A newly recognized spotted fever rickettsiosis in North America is caused by *Rickettsia parkeri*.⁶⁴ This agent had originally been isolated from *Amblyomma maculatum*, the Gulf Coast tick, in Texas in 1939.⁶⁵ In 2002, a case-patient presented with fever, headache, myalgia, multiple eschars, and lymphadenopathy, and later developed a maculopapular rash on the trunk, extremities, and palms and soles. *R. parkeri* was cultured and identified from patient specimens. *R. parkeri* has also been detected in Uruguay in *Amblyomma triste*, a tick species that feeds on humans, and may be responsible for cases in South America reporting fever, regional lymphadenopathy, maculopapular rash, and single eschars.⁶⁶

Avoidance of tick bite is the only reliable method for prevention of the tick-borne rickettsioses. Eradication of the vectors, the natural hosts, or the pathogens from their well-established niches in nature is not feasible. Protective clothing, tick repellents on skin or clothing, regular searching of the body for ticks and removal of them with tweezers, and chemically impregnated collars or acaricidal shampoos for domestic pets are often useful preventive strategies.

► TYPHUS GROUP

Epidemic and Flying Squirrel-Associated Typhus

Epidemic or louse-borne typhus is one of the oldest diseases in recorded history. This disease has disappeared from much of the world except in remote areas of Africa, Asia, and Central and South America. It may, however, reappear under conditions of war or natural disasters where crowding and unsanitary conditions may prevail. There appear to be endemic foci in highland areas of Ethiopia⁶⁷ and Peru,⁶⁸ and within homeless populations in urban areas.⁶⁹ Recent outbreaks have occurred in Rwanda and Burundi associated with refugee populations.⁷⁰

Epidemic typhus is caused by *Rickettsia prowazekii* and is transmitted by the human body louse, *Pediculus humanus corporis*. Lice become infected when feeding on humans actively infected with *R. prowazekii*. The rickettsiae multiply within the louse and are excreted

in the feces. There is no transovarial or transtadial transmission. Humans become infected when the organisms enter the body through the bite lesion or through skin abraded from scratching. Other potential mechanisms of infection include either mucosal contact or inhalation of dried louse feces. The lice die within 10–12 days of infection; however, *R. prowazekii* may remain viable for months to years in the dried state. Transmission between humans usually requires close personal contact or exposure to contaminated clothing or bedding. The agent is not shed in human secretions, so there is no direct person-to-person transmission.

After an incubation period of 1–2 weeks, clinical symptoms of epidemic typhus start abruptly with the onset of fever, chills, headache, muscle aches, and generalized weakness. Approximately five days later, a maculopapular rash usually develops beginning on the trunk and spreading to the limbs. The rash may become darker and confluent, covering the entire body, but usually sparing the face, palms, and soles. During the second week, neurological symptoms may develop resulting in delirium or coma. If untreated, death may occur during the third week. The case fatality rate can exceed 10–15% in untreated cases.⁷¹ Doxycycline is the antibiotic of choice for treatment and is usually curative if given early in the course of the disease.

Even though there is immunity to reinfection, epidemic typhus may recur decades later in recovered patients that maintain viable organisms sequestered in their bodies. This illness is known as Brill-Zinsser (BZ) disease, which usually has a milder presentation with little or no rash. BZ disease may serve as a mechanism for the maintenance of the organism within the human population, which is the main reservoir of *R. prowazekii*.

Prevention of epidemic typhus is accomplished primarily by elimination of the louse vector through application of insecticides to individuals and their clothing, and to the bedding on which the eggs are laid and lice reside. Several applications may be required periodically, since the eggs are resistant to most insecticides and continue to hatch. Clothes and bedding may also be washed in hot water ($\geq 130^{\circ}\text{F}$) to kill lice and eggs. Head lice and pubic lice should also be treated if present. Similar treatment of family or other close contacts is advisable. Once deloused, the patient need not be quarantined, but others who have been exposed should remain under surveillance for the disease for two weeks. In epidemic settings, treatment of the entire community with insecticide is often the most practical and effective approach to eliminate the louse vector. A single dose of doxycycline (100 mg) has been found to be effective for treating symptomatic cases and this may be the most practical approach when dealing with large epidemics.⁷⁰

The southern flying squirrel, *Glaucomys volans*, found in the eastern United States, has been implicated as an animal reservoir for *R. prowazekii*.⁷² From 1976 to 2002, 43 cases of flying squirrel-associated typhus have been documented in humans.^{73,74,75,76,77} Flea species that parasitize rodents have been found to be infected with *R. prowazekii*; however, no specific arthropod vectors have been identified.⁷⁸ This flying squirrel-associated typhus agent may have a lower virulence than the louse-borne variant, although better health, hygiene and living conditions, and appropriate antirickettsial treatment might explain the decreased (<1%) case fatality rate.

Murine Typhus

Murine typhus (also known as endemic or flea-borne typhus) is caused by the agent *Rickettsia typhi* (formerly *Rickettsia mooseri*), which is transmitted by the Oriental rat flea *Xenopsylla cheopis*. The reservoir of *R. typhi* is *Rattus rattus* and other rodent species. Murine typhus occurs in tropical, subtropical, and temperate zones throughout the world, principally in Southeast Asia, Africa, Central America, and the Mediterranean region.^{79,80,81} In the United States, it is most prevalent in Texas, southern California, and Hawaii.^{82,83,84,85} Fewer than 80 cases are now recorded annually in the United States, although the disease is probably greatly underreported. Murine typhus occurs primarily in seaports, urban areas, and certain rural settings infested by wild rats (e.g., grain-storage facilities). A seasonal

incidence peak occurs in late summer and fall, although the disease peaks in late spring and early summer along the Gulf Coast. Cases tend to be sporadic or can occur in clusters or small outbreaks related to common exposure of a rat-flea focus.

The main life cycle involves a reservoir of rodents (principally *R. rattus* and *R. norvegicus*) and the vector, *X. cheopis*. The rat flea acquires *R. typhi* by feeding on an infected host, remains infected for life, and is capable of transmitting the rickettsiae to its offspring. *R. typhi* multiplies in the flea and is excreted in the feces which can contaminate skin breaks or mucous membranes. Direct flea bites or inhalation of aerosolized feces may also cause infection. The human flea, *Pulex irritans*, and the human body louse may also play a role in transmission. Numerous wild vertebrates are natural hosts and may bring infected fleas into close proximity. Dog and cat fleas have been suspected as occasional vectors for humans. There is no documented person-to-person transmission.

Recently, a cycle for *R. typhi* involving the cat flea (*Ctenocephalides felis*) and opossum (*Didelphis virginiana*) has been demonstrated in the United States.^{86,87} This cycle has also been found to maintain a similar pathogenic organism, *Rickettsia felis*, (formerly known as ELB agent)⁸⁸ which has caused disease similar to murine typhus in Latin America and France,^{89,90} as well as in Texas.⁸⁷

Murine typhus is usually somewhat milder than epidemic typhus, although severe disease can occur. The incubation period is 1–2 weeks. The disease is characterized by an abrupt onset of symptoms, usually fever and severe headache. Fever lasts 1–2 weeks, often accompanied by persistent headache, myalgia, vomiting, abdominal pains, conjunctivitis, splenomegaly, and pneumonitis; delirium, stupor, or coma occurs rarely. Between the fifth and seventh day a macular rash usually appears in 50–80% of the patients, starting on the chest and abdomen, and spreading to the back and proximal limbs over 2–3 days. The antibiotic of choice is doxycycline. Ciprofloxacin has also been found to be effective.⁹¹ Fever subsides within 2–3 days after initiation of treatment. Without treatment, symptoms may resolve within two weeks. Death occurs in approximately 1% of cases, and a single attack confers immunity. Delayed neurologic sequelae can occasionally occur and may resolve over time.⁹² Serological diagnosis may be difficult due to the cross-reactivity between *R. typhi* and *R. prowazekii*. Additional testing such as Western blot or cross-adsorption studies may be performed to obtain a specific diagnosis. PCR assays performed on whole blood or skin biopsies may also yield a confirmatory diagnosis.⁹³

Prevention requires ongoing control of the natural host and vector, rodent-control measures, and use of appropriate insecticides. Local public health authorities should be consulted for advice on approved residual-action insecticides to apply to rat habitats. Flea control should be achieved initially, followed by rat trapping and poisoning, rodent-proofing of buildings, and elimination of rodent shelter and food attractants. Failure to control the flea population initially may lead to human outbreaks as the infected fleas move from dying rats to humans.

► ORIENTIA GROUP

Scrub Typhus

Scrub typhus (also known as tsutsugamushi disease, mite-borne typhus, Japanese-river fever, tropical typhus, and rural typhus) is caused by the agent *Orientia tsutsugamushi* (formerly *Rickettsia tsutsugamushi*), which exhibits genetic, antigenic, and pathogenic diversity with numerous serotypes recognized.⁹⁴ *O. tsutsugamushi* strains are distributed widely throughout southeastern Asia, the islands of the western Pacific, and northern Australia.

Scrub typhus was a frequent source of illness in U.S. troops during World War II in the South Pacific and during the Vietnam conflict. It remains a leading cause of illness in indigenous populations throughout endemic areas. Cases of scrub typhus most frequently occur among farmers, forestry workers, and others involved in outdoor occupations or recreational activities. However, this disease has

also been diagnosed in urban areas with no history of exposure to the reservoirs. In North America, scrub typhus is primarily diagnosed among returning travelers.⁹⁵

There has been a reemergence of scrub typhus in recent years. In Japan, India, and Korea, the incidence of scrub typhus is increasing predominantly during the winter and spring.^{96,97,98} Recent outbreaks have occurred in the Himalayan region of India⁹⁹ and in Micronesia.¹⁰⁰

Scrub typhus is transmitted to humans following the bite of trombiculid mites, also known as chiggers. The agent is passed in the feces of the larval mites and enters the body through abraded skin. Trombiculid mites of the subgenus *Leptotrombidium* serve as both vectors and reservoirs due to transovarial transmission of *O. tsutsugamushi*. Their normal hosts are wild rodent species that have also been found to be reservoirs for the agent. The ecological niches of *O. tsutsugamushi* are highly variable, being especially common in wet tropical and subtropical areas, including equatorial rainforests, along river banks and coastal areas, and, occasionally, in semideserts, Himalayan alpine meadows, and areas of harsh, cold winters.^{101,102,103,104} Endemic foci usually occur in areas undergoing ecological transition, such as abandoned farmland or human-made forest clearings, where a favorable habitat has been created for the hosts of the mites, particularly *Rattus* species. The chiggers or mites are not host-specific and will attack any animal, including humans, which invades their limited territory. Transmission may be affected by seasonal exposure of humans, or by chigger activity which is dependent on temperature, humidity, and availability of rodent hosts. No person-to-person transmission has been documented. Transmission has been documented in laboratory settings through respiratory exposure¹⁰⁵ and via skin puncture with infectious equipment.¹⁰⁶

The clinical spectrum of scrub typhus is broad, with most infections of mild to moderate severity. After an incubation period of 7–21 days, the first sign of disease in 85–90% of patients is a vesicular lesion at the site of mite feeding, which later becomes an eschar or ulcer, with regional lymphadenopathy. Fever commences a few days later accompanied by headache, myalgia, and occasionally conjunctivitis or cough. A maculopapular rash may appear at the end of the first week starting on the chest, abdomen, and trunk, and spreading to involve the proximal arms and legs. Rarely, the rash may spread to the face, palms, and soles. In severe cases, pneumonitis, encephalitis, cardiomyopathy, and septic shock may occur,¹⁰⁷ with mortality ranging from 5–40% if no antibiotic therapy is given. The course of the disease and prognosis may vary depending on the strain. Infection with one strain provides only short-term immunity against subsequent infection by others, and immunity even to homologous strains lasts for only 1–3 years. Nevertheless, a second and even third attacks may be milder or atypical.

Doxycycline for one week is the recommended treatment for uncomplicated cases. If treatment is not initiated, the fever and symptoms may persist for more than three weeks. Because of possible antibiotic resistance to doxycycline, the use of macrolide antibiotics is being considered.¹⁰⁸ A single dose of 500 mg azithromycin has been found to be effective in the treatment of mild scrub typhus.¹⁰⁹

To prevent infection in local populations, focal areas known to be endemic should be avoided. In addition, vertebrate hosts and protective vegetation can be eliminated and the area can be treated with pesticides. For travelers, personal prophylaxis with protective clothing, treatment of clothing with insecticides and application of mite repellants such as DEET to the skin is useful.¹¹⁰ Prophylactic use of doxycycline at a weekly dose of 200 mg for short-term exposures has been shown to be effective. There is no commercial vaccine for scrub typhus.

► EHRLICHIOSES AND ANAPLASMOSIS

Overview

Ehrlichial species are increasingly found to be causes of emerging and possibly reemerging diseases in North America and Europe.^{111,112}

The first agent of the genus *Ehrlichia* identified to cause disease in humans was *Neorickettsia sennetsu* (formerly *Ehrlichia sennetsu*), which caused a mononucleosis-like nonfatal syndrome called Sennetsu fever described in Japan in 1954.¹¹³ Since then, other species of *Ehrlichia* have been shown to be animal pathogens, such as *E. canis* and *E. ewingii* (dogs), *E. equi* and *E. risticii* (horses), and *E. phagocytophila* (sheep). Each ehrlichial species targets different cells, such as neutrophils, monocytes, erythrocytes, platelets, and endothelial cells. They cause mild to severe febrile illness with occasional rash; however, in elderly or immunocompromised persons, the illness may be severe and result in multi-organ failure.

Human Monocytic Ehrlichiosis

In 1987, an acute, febrile syndrome similar to RMSF was first reported in humans. The etiologic agent of human monocytic ehrlichiosis (HME) was identified as *Ehrlichia chaffeensis*,¹¹⁴ and found to be transmitted by the vector, *Amblyomma americanum*, the lone star tick.¹¹⁵ The definitive host of *A. americanum* is the white-tailed deer, *Odocoileus virginianus*, which has also been found to be the principal wildlife reservoir for *E. chaffeensis*. There is transstadial transmission of *E. chaffeensis* in *A. americanum*, but transovarial transmission has not been proven. Numerous wild and domestic mammals serve as hosts for the immature stages of the vector tick; however, their roles as reservoirs have not been well studied.

Cases of HME have been diagnosed in central, southeastern, and mid-Atlantic United States, within the range of the vector tick. *A. americanum* has recently expanded its range into the northeastern United States resulting in cases.^{116,117} Most cases occur from May through July corresponding to the peak feeding time of *A. americanum*. All stages of this tick readily bite people. Most case-patients are males over 50 years of age who usually become infected through occupational or recreational exposure.

Symptoms of HME begin after a mean incubation period of 7–10 days following a tick bite. Acute onset of fever, myalgia, and headache develops, occasionally with vomiting, diarrhea, abdominal pain, or cough. A maculopapular rash is present in less than 50% of cases. More than 40% of cases require hospitalization. Severe complications include central nervous system involvement, acute respiratory distress syndrome, renal complications, and multi-organ failure. The case fatality rate is approximately 3%.¹¹⁸

Early diagnosis must be based on clinical and epidemiological risk factors since the majority of patients are seronegative during the acute phase. A four-fold rise in titer by IFA serology in acute and convalescent samples and PCR performed on blood or tissue are confirmatory. Detecting morulae in monocytes is often unsuccessful. Treatment of choice is doxycycline and should be continued for at least two weeks. Preventive measures include avoidance of exposure to ticks, as well as prompt removal of ticks when found.

Human Granulocytic Anaplasmosis

Human granulocytic anaplasmosis (HGA) was first characterized in 1992 when an agent resembling *E. equi* and *E. phagocytophila* was found to cause disease in humans.¹¹⁹ Recently, these three agents have been reclassified into a single species, *Anaplasma phagocytophilum*.² Cases of HGA have been reported from the upper Midwest, northeastern United States, and northern California.¹²⁰ *A. phagocytophilum* is transmitted by *Ixodes scapularis*, the deer or black-legged tick.¹²¹ The tick vector in California is *I. pacificus*. The white-footed mouse, *Peromyscus leucopus*, is believed to be the principal reservoir in addition to other mammals, such as gray squirrels, raccoons, striped skunks, and opossums.^{122,123} Cases of HGA have also been diagnosed in Europe, where the principal tick vector is *Ixodes ricinus*.¹²⁴ It is usually seen in adult men with a history of outdoor activities from late spring through fall.

HGA presents as a nonspecific febrile illness starting 7–10 days after a tick bite.¹²⁵ The most common symptoms are fever, malaise,

myalgia, and headache.¹²⁶ Other symptoms include arthralgia, nausea, and cough. In healthy adults, the disease is mild and may be asymptomatic. However, in the elderly or immunocompromised, HGA may be severe with multi-organ failure. The case fatality rate is estimated at less than 1%.¹²⁷ Diagnosis can be made through serology (IFA), microscopic detection of morulae within granulocytes, culture, and PCR. Doxycycline is the recommended treatment for HGA for a duration of 7–10 days, or until 3–5 days after fever has subsided. Prevention of HGA involves avoidance of tick-infested areas or using appropriate repellants on clothing, such as permethrin, and on the body, such as DEET-containing products. Frequent body checks for ticks and prompt removal of attached ticks after being in a tick-infested area should reduce the risk of acquiring tick-borne diseases.

Q Fever

Herbert A. Thompson • David L. Swerdlow

► INTRODUCTION

Coxiella burnetii causes Q fever in humans. It is a zoonosis and infects a broad range of animal species, including both domestic ruminants and wildlife. Humans usually acquire the disease via inhalation of contaminated dust or dried material from barnyards, lambing pens, or dairy operations, or from handling of or use of animal products including wool or hides, or from ingestion of unpasteurized cow or goat milk. Cases occur that cannot be directly traced to contact with animal or animal products, and these are usually caused by wind-borne material, sometimes carried for miles from the zoonotic source.¹ The organisms can persist in a viable state for several months in dried animal parturition products, in dried tick feces, in manure or animal by-products, or in unpasteurized milk.² The stability is due to the presence of a spore-like form that develops toward the end of a growth period.³ The highest risk of exposure occurs at the time of lambing or calving. The organism propagates very well in placental material, and concentrations as high as 10⁹ organisms per gram of placental tissue have been titered.⁴

► HISTORY

Q fever was discovered almost simultaneously in the United States and Australia before World War II. In Montana, the prototype isolate was made from a tick by Davis and Cox while studying Rocky Mountain spotted fever ecology.⁵ In Australia, outbreaks of disease in abattoirs were investigated by Derrick.⁶ His isolates from human blood were characterized by Burnet and Freeman.⁷ Late in World War II, recognition and characterization of the disease in the Mediterranean theatre soon suggested that the Balkan Grippe, a flu-like febrile illness with symptoms similar to the recognized cases, and affecting both allied and axis soldiers by the thousands earlier in the war, was probably Q fever.^{8,9} The human disease was considered a rarity in the United States until outbreaks of Q fever occurred in meat packing plants in Texas and the upper Midwest in the late 1940s.¹⁰ The ecology and epidemiology of the organism was well-described by Heubner et al for the Southern California Dairy industry, and by Lennette and colleagues for the Northern California sheep industry.^{11,12} Subsequent study led to the modification of milk pasteurization temperatures, raising them to meet the killing requirements for the Q fever organism.¹³

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Other Ehrlichioses

Two ehrlichial species previously associated only with canines have recently been found to cause infection in humans. An agent resembling *E. canis* was isolated from a chronically infected asymptomatic human in Venezuela.¹²⁸ Subsequent studies showed that the agent was closely related (99.9%) to *E. canis* Oklahoma, and was isolated from *R. sanguineus* ticks.¹²⁹ In the United States, *E. ewingii* has been recognized as a cause of granulocytic ehrlichiosis in humans, especially among those that are immunosuppressed.^{130,131} Patients exhibited fever, headache and thrombocytopenia, and all recovered after treatment with doxycycline. As diagnostic methods improve and new laboratory techniques are developed, additional species may emerge as causes of human infection.

► EPIDEMIOLOGY

Q fever has been described worldwide; however, the incidence varies greatly both between countries and within countries. Since surveillance is limited the actual incidence is largely unknown. Reported incidence rates are affected by a variety of geographic and political factors including the presence of animal husbandry and medical care practices. For example, in France the disease is diagnosed mainly in the south, near Marseille, probably because of the presence of a large rickettsial disease reference center. In contrast, the highest prevalence reported in France, based on serologic testing, was in a rural population in the Alps, with antibodies indicating past infection detected in 30% of the village population.¹⁴ As elsewhere, in the United States Q fever is often misdiagnosed and underreported. During the last two decades, outbreaks in the United States have been associated with sheep and goat farming, and to the use of sheep in research by academic institutes.¹⁵ The disease, however, is observed primarily in sporadic cases, and these are almost always occupationally related. From 1978 through 1999, 436 cases of human Q fever were reported in the United States, averaging 20 cases per year (range 6–41).¹⁵ Q fever became a nationally notifiable disease in 1999 with state health departments reporting cases to CDC. From 2000 through 2004, 255 human Q fever cases were reported from 37 states and the District of Columbia. The average number of cases was 64 per year which was threefold higher than before the disease became notifiable. Cases were predominantly male (77%), and the median age was 51 years. Thirty-nine percent of cases occurred in April, May, or June, similar to the seasonality seen in Europe and the highest incidence rates were from western and midwestern states such as Wyoming, Oregon, Idaho, North Dakota, Nevada, and Nebraska as well as Kentucky and Tennessee.¹⁶

► CLINICAL MANIFESTATIONS

The incubation period varies with the dose, and may be as short as seven days or as long as five weeks. Almost half of the seroconversions occurring in humans are believed due to mild or inapparent infections. The acute disease presentation includes severe headache, fever, malaise, myalgia, vomiting, sweats and chills, and photophobia. Often the onset is very sudden, and it is not unusual for the patient to remember the exact day, hour, and minute that symptoms emerged. Approximately one-half will develop pneumonitis or pneumonia typified by interstitial infiltrates. A dry unproductive cough is common. Neurological involvement other than the intense frontal headache is uncommon, but blurred vision, peripheral visual field aberrations, and limb numbness have been

reported. Hepatitis associated with granuloma formation in the liver is common in some countries and may be related to the strain or the method of inoculation. One-half or more of symptomatic acute cases will display elevated liver enzymes. Treatment with tetracyclines usually shortens the course of the disease, but untreated cases will often self-resolve as well. Chronic Q fever is a risk for those with compromised immunity or vascular or cardiac defects, especially heart valves. Chronic disease is defined as that which occurs six months after the acute infection. Rarely, chronic Q fever endocarditis presents in the absence of any known prior disease. Chronic hepatitis has also been described. All chronic forms are much harder to treat, and presently a course of tetracycline plus hydroxychloroquine for 18–36 months or more is recommended for Q fever endocarditis.^{17,18} Untreated cases are usually fatal. Because of the organism's proclivity to infect placental tissues, pregnant women are considered to be at risk for the disease and should take measures to avoid exposure.

Recent evidence now suggests that a third manifestation of Q fever, that of post-infection fatigue syndrome, can occur in a percentage of patients who had previously suffered recognizable (and often treated) acute disease. This syndrome is postulated to be host-determined, and is possibly due in part to cytokine dysregulation, and specifically to a failure of some human genetic types to shut down production of interleukins after an infection is controlled.^{19,20} In a recent study of Q fever cases associated with an outbreak on a goat-farming cooperative in Newfoundland, 52% of Q fever cases reported persistent symptoms. Responding to a quality of life survey instrument, patients reported an impact on their quality of life similar to persons with other chronic illnesses such as type 2 diabetes mellitus or active coronary artery disease.²¹ However, the existence of Q fever fatigue syndrome remains controversial and is difficult to prove conclusively; it has been suggested that some of the reports of alterations in quality of life may represent biased responses to questionnaires.^{21,22}

► DIAGNOSIS

Immunity to acute disease depends upon both cellular and humoral factors. Innate immunity plus B- and T-lymphocyte-based responses both play a role. IgM antibody to phase II surface proteins can develop within seven days of onset, followed by IgM antibodies reactive to phase I (lipopolysaccharide). IgG antibodies to both phase I and II antigens follow. Both IFA and ELISA methods are used to detect antibody, and serology remains the most reliable way to diagnose or confirm the disease. A fourfold rise in either phase I or phase II antibody levels in acute and convalescent samples taken 2–3 weeks apart is considered indicative of recent infection. Usually early infections are characterized by increases in antibodies (IgG and IgM) to phase II antigens and chronic infections such as endocarditis are characterized by increases in antibodies to phase I antigens.²³ PCR tests are helpful and can detect early infections prior to antibiotic use, as well as chronic disease. Culture is difficult and hazardous and can be unreliable and therefore is not recommended as a diagnostic method.

► TREATMENT

Treatment of acute Q fever is most often achieved by use of tetracyclines, usually doxycycline. Some of the quinolones have also been used effectively. The dose for adults is 100–200 mg twice daily. Therapy is usually for 14 days; the patient should be afebrile for several days and clinically improved before stopping. Although tetracyclines should in general not be given to children younger than eight years of age, many experts feel that the benefit of treating outweighs the potential risk of dental staining and currently doxycycline is recommended in children with Q fever.¹⁸ Endocarditis cases are treated by combination therapy, either doxycycline plus rifampin, doxycycline plus a quinolone, or, more effectively by doxycycline combined with hydroxychloroquine.

The organism is obligately dependent upon intracellular growth in macrophage phagolysosomes, and this acidic environment is believed to be neutralized by the hydroxychloroquine drug, thus inhibiting growth of the microbe. If doxycycline combined with hydroxychloroquine is used, the treatment should be continued for 18–36 months.^{17,18} Surgical replacement of the valve may be necessary, in particular if there is hemodynamic failure. Disinfection of *Coxiella* is best achieved using 5% Microchem plus (Micro-Chem Hospital Disinfectant Cleaner, National Chemical Laboratories of PA, 401 N. 10th St. Philadelphia, PA 19123), or 70% ethanol. The organism is not completely eliminated by 10% bleach.²⁴

► VACCINE

An efficacious, formalin-killed cellular vaccine, Q-Vax by CSL, is licensed and used in Australia, where Q fever remains the most economically important zoonosis.^{25,26} In Europe, efforts are made to control Q fever in heavily endemic regions in Germany, and the use of animal vaccination is employed in some instances. An attenuated vaccine has been in use for human vaccinations, in Western Russia and Eastern Europe. In the United States, the Department of the Army holds an IND on a killed cellular vaccine, and it is some times available for at-risk personnel through the Army's Special Immunizations Program.^{8,27} As is also true of Q-Vax, the U.S. Army cellular vaccine may produce severe local reactions to previously exposed individuals, and pretesting, including the use of a skin test, is necessary.^{8,25}

► POTENTIAL FOR BIOTERRORISM/BIOWARFARE USE

Coxiella burnetii is recognized as a potential biological warfare weapon. It was heavily researched by the U.S. Army after World War II, and in those studies use of human volunteers established the very low infective dose of 1–10 organisms. It was subsequently weaponized by this and several other countries. Since it is readily grown in embryonated eggs, is stable and has good arsenal characteristics, is readily spread by aerosols, has a very low infective dose for humans, and is extremely stable in the environment, it is on the B tier list of biowarfare threat agents.²⁸ Although its use may not lead to high mortality, it could provoke disabling disease.^{29,30} Terrorists possessing sophisticated bioengineering capabilities could modify this organism to render it more virulent in humans. Furthermore, drug resistant forms of the organism, for both quinolones and tetracyclines, have been isolated from natural populations.³¹

► CONCLUSIONS

Coxiella burnetii, a zoonosis found throughout the world, causes Q fever in humans. Human infections usually follow contact with domestic livestock and are more common in rural endemic areas. The illness is usually mild but can become chronic and severe. Endocarditis occurs among patients with underlying heart disease, in particular valvular disease, and may require long-term therapy and surgical intervention. The diagnosis of acute Q fever is usually based on changes in acute and convalescent serology, although molecular identification can also be used.^{30,31} Acute illness is treated with doxycycline, chronic with a combination of antibiotics and sometimes surgery. Because of the physical characteristics of the highly infectious spore form, *Coxiella burnetii* is a potential agent of bioterrorism which has been weaponized in the past.³⁰ Because the disease is often not suspected, diagnosed, or reported, educational efforts to increase awareness of the disease and improvements in diagnostic capabilities and surveillance are needed to increase our ability to identify and respond to natural and manmade outbreaks in the future.

Plague

J. Erin Staples

► INTRODUCTION

Plague is a zoonotic disease of rodents that is spread by fleas and occasionally causes severe illness in humans. Once known as “the Black Death,” plague continues to produce panic and irrational responses in some instances. The recent threat of bioterrorism (BT) and the designation of the causative bacteria, *Yersinia pestis* as a Category A BT agent, has led to renewed concern about this disease.

► HISTORY

Three plague pandemics have been recorded in history.^{1,2} The first pandemic severely affected the Byzantine Empire in the sixth and seventh centuries AD. The second pandemic began in central Asia and spread to Europe in the fourteenth century, where it is estimated that one-fourth of the affected populations perished in the early course of the pandemic. In England, as many as half the total population died. Public health quarantine measures date from this time.³ The second pandemic waned over several centuries and plague eventually disappeared from Europe. The third (modern) pandemic era began in China in the late nineteenth century when, in 1894, plague struck Hong Kong and then spread by rat-infested steamships to all inhabited continents. Within a few years of its initial spread, millions of persons had died of plague in India, and outbreaks had occurred in many countries of the world, including the United States.

During the modern pandemic, plague became established in rodent populations in widely scattered foci around the world.^{1,4,5} In some areas it persisted for only a few years (gulf coastal areas of the United States and Australia), or a few decades (Hawaii and the Philippine Islands), but in many areas it became entrenched. Currently, plague foci are found scattered throughout most of the world (Fig. 15-2). These scattered residual plague foci are not amenable to elimination, and it is unknown whether they will be stable, die out spontaneously, or expand.

► THE PLAGUE ORGANISM

Y. pestis is a gram-negative, bipolar staining, nonsporulating, nonmotile coccobacillus belonging to the *Enterobacteriaceae* family. Based on its ability to ferment glycerol and to reduce nitrate, *Y. pestis* can be divided into three main biovars: Antiqua, Mediaevalis, and Orientalis.

Y. pestis expresses a variety of factors important for virulence and transmission. These are encoded on its chromosome and three plasmids and include Fraction I (F1) antigen, V antigen, Yersinia outer-membrane proteins or Yops, pH6 antigen, plasminogen (pla) activator protease, and Hemin storage (hms) locus.² While some of these factors are expressed when the organism is grown at the optimal temperature of 28°C, many are expressed or have differential activities at higher temperatures (35–41°C).

► PLAGUE IN NATURE

Y. pestis is maintained in nature in cycles involving infected rodents and their fleas. Other mammals, such as lagomorphs (rabbits, hares), carnivores (canids, felids, mustellids), and humans, are incidental hosts that only occasionally serve as direct (not flea-mediated) sources of infection to other animals or humans. Natural plague cycles are classified as either enzootic or epizootic. Enzootic cycles involve relatively disease-resistant rodent populations where the disease is maintained with a low mortality.

Enzootic plague is typically associated with a low risk of human infection and is not readily noticed.^{1,4,6,7} In epizootic plague, *Y. pestis* infection is amplified in susceptible rodents and their fleas. The resultant rodent die-off promotes rapid and dangerous spread of plague, since infected fleas leave dead hosts to seek other blood sources, including humans. Rodent die-offs from epizootic plague are likely to be noticed, especially when diurnal rodents, such as prairie dogs, are affected.^{4,7} Enzootic and epizootic wild rodent plague cycles vary greatly in the rodent and flea species involved and in the environmental characteristics of different foci of infection.^{1,4,6,7} The complex interplay between contiguous or overlapping cycles is poorly defined in most areas of the world.

► FLEA VECTORS

Fleas are the only arthropods known to transmit *Y. pestis* in nature.^{5,8} The efficiency of transmission varies by flea species and with environmental conditions, such as temperature and humidity.^{9,10} High vector flea densities (flea indices) on rodent hosts are associated with increased likelihood of spread. Although fleas vary in their propensity to bite humans, any flea should be considered to be a potential plague vector. When some highly efficient vectors, such as the oriental rat flea (*Xenopsylla cheopis*) take an infected blood meal, plague bacilli multiply to enormous numbers, thereby blocking the flea's foregut (proventriculus). The starving fleas avidly seek new hosts and, while attempting to feed, regurgitate *Y. pestis* into the bite wound, thus enhancing the chances of transmission. The vector efficiency of the oriental rat flea is markedly decreased at temperatures above 28°C, since at these higher temperatures blockages undergo enzymatic lysis.^{10,11}

► VERTEBRATE HOSTS

Historically, plague has been associated with domestic rats (the black or roof rat, *Rattus rattus*; and the brown or Norway rat, *Rattus norvegicus*) and their fleas.^{2,4} Epizootics involving these commensal rodents constitute the most serious hazard to humans because exposure occurs in the domestic environment, often in circumstances of crowding, and because the oriental rat flea is a highly efficient vector that readily feeds on humans.

In the United States, enzootic plague is thought to occur in a variety of small burrowing rodents, such as voles and deer mice, whereas epizootic plague occurs conspicuously among prairie dogs, various ground squirrels, and chipmunks.⁴⁻⁷ The most frequent sources of human plague in the United States are thought to be cycles of *Y. pestis* involving the rock squirrel, *Spermophilus variegatus*, and the California ground squirrel, *S. beecheyi*, and their fleas (especially, *Oropsylla montana*). These cycles appear to be influenced by climatic variables, such as maximum daily temperature and winter precipitation.^{7,12} Even when other rodents or domestic cats and dogs are implicated as the source of fleas infecting humans, often the ultimate source of the infected fleas has been these ground squirrels or related species.

Wild carnivores or predatory birds may transport infected rodent fleas to susceptible rodent populations, and rodent fleas may be transported to humans by dogs, cats, or other mammals. Humans may also be bitten by infected fleas in the vicinity of abandoned burrows and through contact with infested rodent nest materials. Humans have also become infected by dissecting infected mammals, including lagomorphs, rodents, and carnivores, when the organism gains entry through breaks in the skin.^{13,14} Most carnivores, although rarely infected by eating infected prey, rarely develop a bacteremia and seldom, if ever, serve as a source of *Y. pestis* to their fleas. Wild and domestic cats, however, may develop severe and fatal plague.^{15,16}

Figure 15-2. Global distribution of plague. (Source: Compiled from WHO, CDC, and country sources, courtesy of J. Monteneri and K Gage, CDC.)

Cats with oropharyngeal and pneumonic plague can infect humans who come into direct contact with their infective exudates and secretions, and a small but increasing number of fatal primary pneumonic plague cases has resulted from such exposures.^{17–19}

► CURRENT WORLD DISTRIBUTION

Plague persists as a public health problem in many areas of the world and remains as one of three epidemic diseases still subject to the International Health Regulations and notifiable to the World Health Organization (WHO).²⁰ In the 15-year period 1989–2003, the WHO reported a total of 38,359 cases of plague with 2845 plague deaths from 25 countries.²¹ The mean annual number of reported cases for the period was 2557 per year, with a low of 876 cases in 1989 and a high of 5419 cases in 1997. Currently, Africa accounts for more than 80% of the total number of cases, Asia for 14% and the Americas for the remaining 6%. Significant plague outbreaks have recently been reported from India,^{22,23} Madagascar,^{24,25} Zambia,²⁶ Mozambique,²⁷ Ecuador,²⁸ Malawi,^{29,30} Indonesia,²¹ Algeria,³¹ and Democratic Republic of the Congo.³²

In the era of global travel and the potential threat of bioterrorism, outbreaks of plague are a source of concern. An outbreak of plague in India in 1994 caused international alarm and great cost to India due to disruptions in travel and trade.³³ In formulating a response to outbreaks in other countries, officials should consider that: (a) plague infections respond rapidly to commonly available antibiotics; (b) surveillance of international arrivals from an epidemic area should readily detect persons with pneumonic plague (the only contagious form of concern) because of its severe and fulminant character; (c) pneumonic plague transmission requires close, direct contact with the ill person; and, (d) interdiction of travel and trade, if warranted at all, should be specific to the actual plague focus and not applied countrywide. Unjustified, punitive responses are likely to inhibit plague reporting. A coordinated national surveillance for pneumonic plague was rapidly implemented in the United States during the recent perceived emergency arising from reports of plague outbreaks in India.³⁴

In 1989–2003, the United States reported 100 plague cases (mean of 7 cases per year) and 10 deaths (CDC unpublished). A high of 14 cases and 2 deaths was reported in 1994. Although wild rodent plague occurs in the 17 contiguous western states that have territory west of the 100th meridian, 77% of human plague cases arise in the southwestern states of New Mexico, Arizona, and Colorado, and about 9% in California. Human plague in the United States is typically sporadic with only single cases or small common-source clusters in an area, almost always

following exposure to fleas of wild rodents or infected animal tissues. The United States reports only confirmed cases of human plague, and its reporting is thought to be complete. In some areas of the world, reported cases may reflect only a part of the total; on the other hand, during plague outbreaks some countries include suspect cases as well as confirmed cases in their reports to WHO.

Changes in the ecology and epidemiology of plague are to be expected where relatively stable ecological features are disrupted by major industrial and agricultural development. For example, intensive irrigation of deserts for agricultural purposes, particularly for grain production, may produce burgeoning rodent populations close to human habitation, work or recreational sites. In such settings, exposure of humans may result from the amplification of existing known or even unrecognized wild rodent plague foci, by spread from wild rodent populations to commensal species, or by noncontiguous (per saltum) spread of plague-infected rodents or their fleas in shipments of agricultural products.¹ Human encroachment on rodent habitat through the building of cabins or homes may also lead to increased risk of human infection.

► SURVEILLANCE

According to the International Health Regulations, each state's health authorities shall report to WHO all human plague cases and the presence of the plague bacillus in any part of a country's territory with a description of the epidemiologic circumstances and of the precautions taken to prevent its spread to other territories.²⁰ In the United States, it is mandatory to report all suspect human plague cases to local, state, and federal authorities (Centers for Disease Control and Prevention, Fort Collins, Colorado).

The current case definitions for plague as outlined by the WHO:

Suspect plague:

- Compatible clinical and epidemiological features; and
- Suspicious organisms seen or isolated from clinical specimens

Presumptive plague:

- *Y. pestis* F1 antigen detected in clinical materials by direct fluorescent antibody testing or by some other standardized antigen detection method; or
- Isolate from a clinical specimen demonstrates biochemical reactions consistent with *Y. pestis* or PCR positivity; or

- A single serum specimen is found positive for diagnostic levels of antibodies to *Y. pestis* F1 antigen, not explainable on the basis of prior infection or immunization

Confirmed plague:

- Isolate identified as *Y. pestis* by phage lysis of cultures; or
- A significant (\geq fourfold) change in antibody titre to the F1 antigen in paired serum specimens

Additionally, compatible illness in a person epidemiologically linked to a confirmed case may be considered a presumptive case. Each human plague case should, if possible, be epidemiologically investigated. Surveillance of animal plague activity should be carried out in areas where plague has occurred in recent decades. Direct surveillance is accomplished by bacteriological testing of rodents found dead from natural causes. A sensitive indication of epizootic rodent plague may be obtained surveying carnivores for antibodies to *Y. pestis*. Further, field reconnaissance may be undertaken to detect rodent die-offs, and rodents and fleas may be collected and processed for evidence of plague infection. The data should then be evaluated to determine the potential risk to humans and whether control measures are needed.¹

► HUMAN PLAGUE

Human plague occurs in primary and secondary forms. The classic primary form of *Y. pestis* infection in humans, bubonic plague, occurs in about 80–90% of cases. Other clinical forms (e.g., septicemic, pneumonic, meningial, and ocular) usually occur as complications of bubonic plague. Bubonic plague almost always occurs as the result of a bite by an infected flea, and a small local papule or vesicle is sometimes present at the bite site. Rarely, local ulceration, with lesions similar to tularemia (eschar), can occur at the site of entry. In addition to flea bites, inoculation of the organism can occur through the mucous membranes of the eye, oropharynx, and through broken skin following direct contact with infected materials or animal tissues. The usual incubation period is 2–6 days, but it may be longer. Illness is manifest by fever, chills, headache, myalgia; gastrointestinal symptoms such as nausea, vomiting, or diarrhea may also occur. Patients with bubonic plague experience pain and tenderness in lymph nodes proximal to the site of inoculation, followed by lymph node enlargement (bubo). Left untreated, the disease may progress to secondary pneumonic or meningial plague with a high risk of death.

Septicemia in the absence of lymph node involvement is referred to as primary septicemic plague. As with bubonic plague, blood-borne dissemination to other organs may lead to plague pneumonia or meningitis and, if untreated, generally results in septic shock and rapid death. In the absence of a bubo as a hallmark, primary septicemic plague may be complicated by delayed diagnosis.³⁵

Secondary pneumonic plague results from hematogenous spread from bubonic or septicemic plague and often involves multiple lobes of the lungs. In contrast, primary pneumonic plague results from close (< 2 meters) contact with a person or animal expelling fine droplets of *Y. pestis* organisms by vigorous coughing. Primary pneumonic plague often begins with unilobular involvement and a dry cough (CDC unpublished). *Y. pestis* does not survive as a saprophyte, and true aerosol or droplet nuclei transmission has not been recognized. Untreated, pneumonic plague is often fatal within 1–3 days after symptom onset.³⁶

Although cases of primary and secondary pneumonic plague continue to occur, there have been no instances of person-to-person transmission in the United States since two limited pneumonic plague outbreaks occurred in 1919 (Oakland) and 1924 (Los Angeles). From 1925 through 2003, 50 (11%) of 462 patients developed secondary plague pneumonia, and 13 patients had primary pneumonic plague, mostly from domestic cat exposures¹⁹ (and CDC unpublished). Hundreds of individuals who were known or possible contacts of these patients with pneumonic plague were given chemoprophylaxis

and no spread to contacts was recognized. A recent increase in the United States of both secondary and primary (cat related) pneumonic plague cases as well as the theoretical possibility of a bioterrorism event involving aerosolized *Y. pestis* has raised a concern about possible spread of pneumonic plague to household contacts or medical personnel.³⁶

Pharyngeal or tonsillar plague has occasionally been associated with exposure to infected respiratory particles from patients or animals with pneumonic plague and with the ingestion of infected animal tissues.^{37,38} Rarely, gastrointestinal plague has been found to occur in individuals eating infected animal tissues (CDC unpublished).

► DIAGNOSIS AND TREATMENT

A careful epidemiologic history is essential in considering a diagnosis of plague. When plague is suspected, it is imperative to obtain diagnostic specimens promptly and, if the clinical and epidemiological evidence is sufficiently strong, to initiate specific therapy without awaiting laboratory results. Bubonic plague is best diagnosed with culture of material aspirated from a bubo; if the aspiration is “dry,” sterile saline should be injected into the node and then aspirated. Multiple blood cultures and, if indicated, throat and sputum cultures should also be obtained. Materials for culture should be taken before specific antibiotics are given.

Y. pestis grows slowly in most culture media. On agar plates incubated at 37°C (98.6°F), colonies are barely discernible at 24 hours and are small (1–3 mm in diameter) at 48 hours.³⁹ Smears of bubo aspirates, exudates, respiratory secretions, and suspect organisms isolated in bacteriologic media should be stained with a polychromatic stain, such as Wayson’s or Giemsa, to demonstrate the characteristic bipolar staining of *Y. pestis*. However, other gram-negative bacilli may appear to be bipolar and identification of *Y. pestis* by staining characteristics alone is unreliable. Fluorescent antibody (FA) testing to detect the highly specific *Y. pestis* F1 antigen also provides presumptive identification only, because interpretation of fluorescence is subjective and sometimes inconclusive. New rapid diagnostic tests (dipsticks) for detecting F1 antigen have been developed and may have a role in the future.⁴⁰

Isolation of *Y. pestis* in microbiologic media and its lysis by a specific bacteriophage provides definitive (confirmatory) identification of *Y. pestis*.^{1,39} Paired serum samples obtained at least three weeks apart should be tested for antibody to *Y. pestis* and can be used to confirm the diagnosis if there is a fourfold increase or change in titer. Suspect clinical materials and cultures should be forwarded to reference diagnostic laboratories for confirmatory identification.

The antibiotic of choice for treating *Y. pestis* infection is streptomycin.⁴¹ Although not approved for this purpose, gentamicin is an acceptable alternative,⁴² and is more widely available. Other drugs approved for the treatment of plague include tetracyclines and chloramphenicol. Chloramphenicol traditionally has been the agent of choice for plague meningitis, pleuritis, or endophthalmitis because of its high tissue permeability. Recently, however, *Y. pestis* isolates from humans in Madagascar have shown multidrug resistance for these antibiotics *in vitro*.⁴³

Other antibiotics that have been used to effectively treat plague but have not been specifically approved for that purpose include ciprofloxacin⁴⁴ and co-trimoxazole.⁴⁵ Co-trimoxazole (a combination of trimethoprim and sulfamethoxazole) has been reported to be effective in treating bubonic plague, but the few reports of its efficacy involve a small number of patients, almost all adults.^{45,46} The penicillins, cephalosporins, and macrolides are not sufficiently effective against *Y. pestis*, and should not be used.

► HOSPITAL PROCEDURES AND CARE OF CONTACTS

Because patients with bubonic or septicemic plague may develop secondary plague pneumonia, initial respiratory droplet precautions should be used for patients with suspected plague until pulmonary involvement has been excluded. Personnel caring for patients with

pneumonic plague should observe strict respiratory droplet precautions, including the use of eye protection. After forty-eight hours of effective antibiotics and clinical improvement, an individual can be considered noninfectious⁴⁷. Isolation beyond this time is not necessary unless the patient has draining exudates.

Household members and others sharing the same environmental circumstances should be placed under surveillance because of the possibility of exposure to the same zoonotic source as the index case; antibiotic prophylaxis may be indicated if there is a concern about exposure to infected fleas, but is not indicated as a routine practice. All persons who have had close contact with a pneumonic plague patient in the previous six days should be offered postexposure prophylaxis for seven days. Tetracycline, doxycycline, or ciprofloxacin are acceptable prophylactic agents.⁴⁷ Exposed persons should also be kept under close observation, including measurement of body temperature at least twice daily. Should fever develop, the person should be immediately hospitalized in isolation for diagnostic evaluation, and plague-specific treatment should be given if indicated.

► PREVENTION AND CONTROL

Surveillance, education, and environmental management are the cornerstones of plague prevention. Public health authorities should identify and monitor active plague foci and maintain a system for rapid identification and evaluation of any suspect human cases or plague

epizootics. Persons in known plague foci should protect themselves and their domestic pets from fleas, and should maintain a living and working environment free of rodents. Environmental sanitation should include rodent proofing of buildings, removal of other harborage such as wood piles, brush and junk heaps, and removal of any rodent food sources, such as garbage or animal feed. Persons should be instructed to avoid sick or dead animals and to use gloves when handling animals killed by hunting or trapping.¹

Plague vaccine is no longer commercially available. The original formalin inactivated plague vaccine had frequent side effects and provided only partial protection against bubonic plague. Research is currently underway to develop other plague vaccines that would protect against pneumonic plague and be better tolerated.⁴⁸ Short-term antibiotic prophylaxis with a tetracycline or with trimethoprim-sulfamethoxazole may occasionally be recommended for persons considered to be at high risk for plague because of caring for plague patients or because of unavoidable exposures in active epizootic or epidemic areas.⁴⁹

Killing fleas with insecticides is the principal control measure in situations where epizootic plague places persons at risk of exposure. Rodent burrows, rodent runs, and other places where rodents and their fleas may be found should be sprayed or dusted with appropriate insecticides by trained persons. The decision to control plague by killing rodents should be left to health authorities, and should be done only when adequate flea control measures are in place. Control of rodents without environmental sanitation may worsen the situation, since the void may be quickly filled by a more susceptible, immature population of rodents.

Malaria

S. Patrick Kachur • Alexandre Macedo de Oliveira • Peter B. Bloland

► INTRODUCTION

Malaria remains one of the most widespread, potentially fatal infectious diseases. It is an important public health concern both in those countries where transmission occurs regularly, as well as in areas where transmission has been largely eliminated. Malaria is an extremely complex condition that manifests differently in different parts of the world, depending on a range of variables that includes: the infecting parasite species and their susceptibility to antimalarial drugs; the distribution and efficiency of insect vectors; climatic and environmental conditions; and the genetic composition, acquired immunity, and behavior of human populations. Children, pregnant women, and nonimmune visitors to malarious areas are at greatest risk of severe or fatal infections. Multiple strategies exist to combat malaria, but none of these are both appropriate and affordable in all malaria-endemic areas. Public health efforts to prevent or control malaria must be carefully tailored to the intensity of local transmission and local conditions of the parasite, vector, environment, and human population as well as the level of resources available. Although the global malaria eradication campaign of the 1950s and 1960s was unsuccessful in many countries, the intense international effort did yield lasting improvements in some areas, and provided valuable experience for the integrated malaria control programs recommended today.

Malaria transmission can occur in 107 countries and territories worldwide.¹ Thirty-six percent of the global population lives in areas where there is risk of malaria transmission. Seven percent of the world's people reside in areas where malaria has never been

under meaningful control, but another 29% live in areas where malaria was once transmitted at low levels or not at all, but where significant transmission has been reestablished.² The development and spread of drug-resistant strains of malaria parasites and insecticide-tolerant strains of the mosquito vector have been identified as key factors in this resurgence. Other important considerations are the shifting patterns of support for malaria-related research and control activities in endemic countries and among international donors, which left many endemic countries without resources or technical capacity for malaria control activities once international support for the eradication campaign disappeared. The World Health Organization (WHO) also lists environmental disruption for agricultural or economic reasons, sociopolitical unrest, and population migration among the probable precipitating causes of the most serious malaria problems.

Each year an estimated 300–500 million clinical cases of malaria occur, making it one of the most prevalent infectious diseases.¹ Malaria can be, in certain epidemiologic circumstances, a devastating disease with high morbidity and mortality, demanding a rapid and comprehensive response. In other settings, it can be a more pernicious public health threat. In many malarious areas of the world, especially sub-Saharan Africa, malaria is ranked among the most frequent causes of morbidity and mortality among children and is often the leading identifiable cause. WHO estimates that more than 80% of the more than 1 million deaths attributed to malaria each year occur in African children.¹ These estimates of global burden are necessary because few malaria endemic countries can report accurate health data. There have been recent calls to improve the quality of estimated morbidity and mortality data.^{3–5} In addition to its morbidity and mortality burden, the economic effects of malaria infection can be tremendous. These include direct costs for treatment and prevention, as well as indirect costs such as lost productivity from morbidity and mortality, time spent seeking treatment, and diversion of household resources. The

Note: The findings and conclusions in this chapter are those of the author and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Figure 15-3. Malaria-endemic areas of the world.

annual economic burden of malaria infection in 1995 was estimated at US \$1.7 billion, for Africa alone.⁶ This heavy toll can hinder economic and community development activities throughout the region.

Malaria transmission occurs primarily in tropical and subtropical regions in sub-Saharan Africa, Central and South America, the Caribbean island of Hispaniola, the Middle East, the Indian subcontinent, Southeast Asia, and Oceania (Fig. 15-3). In areas where malaria occurs, however, there is considerable variation in the intensity of transmission and risk of malaria infection. Highland (>1500 m) and arid areas (<1000 mm rainfall per year) typically have less malaria, although they are also prone to epidemic malaria when parasitemic individuals provide a source of infection and climate conditions are favorable to mosquito development.² Although urban areas have typically been at lower risk, explosive, unplanned population growth has contributed to the growing problem of urban malaria transmission.⁷

Although sustained malaria transmission in the United States was eliminated in the 1950s, more than one thousand cases of malaria are reported in the United States each year.⁸ In recent years, nearly all of the malaria cases reported in the United States have occurred among immigrants, refugees, and travelers from parts of the world where ongoing transmission persists. A small number of malaria cases are acquired within the United States and its territories. Some of these cases are congenitally acquired; some are unintentionally induced by blood

transfusion or organ donation; and a small number of cases appear to be transmitted by local anopheline mosquitoes.⁹ These rare instances of mosquito-borne malaria in the United States are of concern because they demonstrate the potential for reintroduction of transmission, even in temperate climates where malaria has been eradicated.

► **AGENT AND LIFE CYCLE**

In humans, malaria infection is caused by one or more of four species of intracellular protozoan parasite. *Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae* differ in geographic distribution, microscopic appearance, clinical features (periodicity of infection, potential for severe or complicated disease, and tendency for clinical relapses or recrudescences), and immunogenic potential (Table 15-8). Although *P. vivax* infections are more common, worldwide, *P. falciparum* malaria represents the most serious public health problem because of its tendency toward severe or fatal infections.

Routes of Transmission

Malaria is typically transmitted by the bite of an infective female *Anopheles* sp. mosquito. Mosquito-borne cases are referred to as *autochthonous malaria* to distinguish them from cases transmitted in

TABLE 15-8. CHARACTERISTICS OF THE FOUR SPECIES OF HUMAN MALARIA

	<i>P. falciparum</i>	<i>P. vivax</i>	<i>P. ovale</i>	<i>P. malariae</i>
Exoerythrocytic Cycle	6–7 days	6–8 days	9 days	14–16 days
Prepatent Period	9–10 days	11–13 days	10–14 days	15–16 days
Incubation Period (mean)	9–14 (12) days	12–17 (15) days	16–18 (17) days	18–40 (28) days
Severity of Primary Attack	Severe	Mild to severe	Severe	Severe
Duration of Primary Attack*	16–36 hours or longer	8–12 hours	8–12 hours	8–10 hours
Duration of Untreated Infection*	1–2 years	1.5–5 years	1.5–5 years	3–50 years
Relapse	No	Yes	Yes	No
CNS Complications*	Frequent	Infrequent	Infrequent	Infrequent
Anemia*	Frequent	Common	Infrequent	Infrequent
Renal Insufficiency*	Common	Infrequent	Infrequent	Infrequent
Effects on Pregnancy*	Frequent	Infrequent	Unknown	Unknown
Hypoglycemia	Frequent	Unknown	Unknown	Unknown

other ways. *Congenital malaria* refers to infection passed from mother to infant *in utero*. *Induced malaria* refers to infection that is passed directly from one individual to another through contaminated blood or blood products, injection equipment, or organ transplant.¹⁰ Until the 1950s, induced malaria infection was widely practiced as a treatment for late neurosyphilis.¹¹ While this treatment has been replaced by effective antibiotics, the practice of malariotherapy has reemerged several times in recent decades, primarily as an alternative medicine practice in economically developed countries.¹² Finally, when a route of transmission cannot be established, even after careful investigation, a case may be classified as *cryptic malaria*.¹³

Life Cycle

Although there are important differences between them, the four human malarias share a common life cycle. Malaria infection begins when an infective female mosquito injects *Plasmodium* sp. sporozoites into the blood stream while feeding (Fig. 15-4). The sporozoites circulate only momentarily; those which survive host immune defenses infect cells of the liver parenchyma. There they undergo asexual reproduction (exo-erythrocytic schizogony) producing hepatic schizonts. In 6 to 14 days, these schizonts mature and rupture, releasing merozoites into the blood stream. Merozoites then invade red blood cells where they undergo a second phase of asexual reproduction (erythrocytic schizogony), developing into rings, trophozoites and finally erythrocytic schizonts. Once mature, the infected red blood cells rupture, releasing still more merozoites into the blood stream, and starting another cycle of asexual development and multiplication. Clinical symptoms are associated with the

rupture of erythrocytic schizonts and usually develop after several cycles of erythrocytic schizogony. The classical clinical presentation of periodic fever occurs when the cycles of erythrocytic schizogony are synchronized. Malaria parasites continue to proliferate until: (a) immune responses eliminate the infection, (b) effective antimalarial drugs kill all the erythrocytic parasites, or (c) the host dies from the infection.

Eventually, some merozoites develop into sexual forms called gametocytes. Both male and female gametocytes circulate without causing symptoms and can be ingested by a mosquito during a subsequent blood meal. Sexual reproduction occurs within the mosquito midgut. The fertilized zygote quickly transforms into an amoeboid ookinete which penetrates the midgut wall and forms an oocyst. After several days to weeks, the oocyst ruptures, releasing sporozoites, which migrate through the coelomic cavity to the salivary glands. The life cycle starts again when the infective mosquito bites another human. The mosquito is essential to the development of the malaria parasite as well as its transmission. The sporogonic cycle—the period of time between ingestion of gametocytes and becoming infective to humans—varies among the different species of parasite and anopheline vectors and can be affected by environmental conditions as well.

The timing of events in the life cycle of malaria parasites and the number of merozoites produced from each schizont differ among the four *Plasmodium* species that infect humans. Additionally, *P. vivax* and *P. ovale* can produce a dormant form (hypnozoites) which can persist in the liver for months to years, causing periodic relapses of parasitemia and illness (Table 15-8). Hypnozoites result only from

Figure 15-4. The malaria life cycle.

primary sporozoite inoculation in mosquito-borne infections and are not present after cases of induced or congenital malaria. While *P. falciparum* and *P. malariae* do not form hypnozoites, infection with these parasites can persist in the blood at subpatent or undetectable levels following resolution of symptoms. This very low level parasitemia can result in recrudescence of clinical disease. Except in partially immune persons, *P. falciparum* rarely recrudesces more than several months after initial infection. However, recrudescence of *P. malariae* infections can occur 40 years or longer after infection.

► CLINICAL FEATURES AND DIAGNOSIS

Patients with malaria can present with a wide variety of symptoms and a broad spectrum of severity depending upon such factors as the infecting species and level of acquired immunity in the host. In general, partial immunity to malaria is acquired only after repeated exposure. Individuals who survive repeated malaria infections can tolerate the presence of malaria parasites in their blood with a minimum of symptoms. In areas where malaria transmission is intense, the first exposure to malaria occurs very early in childhood. After many subsequent infections, the likelihood of severe illness or death lessens.

Clinical Presentation

Typical symptoms among nonimmune individuals with malaria include fever, chills, myalgias and arthralgias, headache, diarrhea, vomiting, and other nonspecific signs. Splenomegaly, anemia, thrombocytopenia, pulmonary or renal dysfunction, and neurologic findings may also be present. When synchronous infections (occurring when a majority of schizonts rupture at the same time) develop, each species of *Plasmodium* causes a characteristic pattern of periodic fever. The paroxysms of *P. vivax* and *P. ovale* malaria classically occur every 48 hours, while those of *P. malariae* occur every 72 hours. *P. falciparum* infections often feature a daily or irregular pattern of symptoms. However, this classic presentation with predictably recurring fever and chills is highly variable and may not be present at all, particularly in *P. falciparum* infections, early in the course of an illness, when the patient is taking medications that have antipyretic or antimalarial activity, or when partial immunity exists.

Signs and symptoms of malaria can be greatly modified by the patient's immune status; malaria infections among partially immune individuals range from asymptomatic to severe. The presenting signs and symptoms may be atypical or subtle, especially among infants and young children. The classical presentation of periodic fever sometimes seen in nonimmune individuals with synchronous infections are frequently absent among partially immune individuals. Because the manifestations of malaria illness can be so nonspecific, it is a common practice in malaria-endemic areas, to treat all febrile illnesses as malaria, especially in children and pregnant woman, who are at greatest risk for severe or fatal disease.

Severe or Complicated Infections

Uncomplicated malaria infection can progress to severe disease or death within hours. The potential for severe and complicated illness is particularly ominous in patients with high levels of parasitemia and without partial immunity from prior exposure to malaria infection. *P. falciparum* is the major cause of severe disease and death; severe or fatal malaria rarely results from infections with *P. vivax*, *P. ovale*, and *P. malariae*, unless there is another contributing cause of death or coinfection with *P. falciparum*. An extremely rare exception, is splenic rupture, which can occur with acute nonfalciparum malaria.¹⁴

Neurological manifestations are the best known potentially fatal complication in nonimmune adults and children. Malaria with central nervous system (CNS) symptoms can progress from fever with subtle mental status changes to coma and death within hours. Cerebral malaria refers to unarousable coma not attributable to any other cause in a patient infected with *P. falciparum*.¹⁵ In Africa, it has been estimated that 10–40% of patients hospitalized with cerebral malaria will die, even when treatment is optimal.^{16,17} The mean time between onset

of illness and death among Gambian children was 2.8 days.¹⁸ Although less widely recognized than cerebral malaria, metabolic acidosis appears to be an important manifestation of severe malaria and indicator of poor prognosis, especially among African children.¹⁹ Other acute complications comprise renal failure (especially in nonimmune adults), hemolytic anemia, hypoglycemia, disseminated intravascular coagulation, shock, and acute pulmonary edema (particularly in nonimmune adults). Among African children hospitalized with severe malaria, the presence of impaired consciousness or respiratory distress can identify those at highest risk of death.²⁰ In patients who survive severe or complicated malaria, long-term sequelae are uncommon and can include permanent CNS deficits or lasting impairment of kidney or liver function.

Not all of the severe manifestations of malaria can be attributed to acute disease. Persistent, repeated, or inadequately treated infections can cause chronic anemia, especially among young children or populations with underlying nutritional deficiencies. Malaria-associated anemia can become severe enough to require transfusion and is an important cause of malaria-related mortality. The rate of development and severity of anemia depend on the level and duration of parasitemia.¹⁵ In patients with acute malaria, severe anemia may contribute to CNS and cardiopulmonary signs.

Falciparum malaria can also have devastating effects during pregnancy. In nonimmune women acute malaria during pregnancy can be more severe than malaria in nonpregnant women and carries a high risk of maternal and fetal death if not treated promptly and adequately. Among partially immune women, however, malaria during pregnancy can produce chronic infection of the placenta with little or no increase in overt clinical disease.^{21,22} Placental malaria infection, in turn, is a cause of low birth weight, the greatest single risk factor for infant mortality.^{23,24} In most populations, malaria is most significant during a woman's first and second pregnancies, although in populations with a high prevalence of HIV infection, placental malaria infection can occur in all pregnancies.²⁵

Whereas rates of severe disease and mortality among nonimmune populations are typically not age related, there is a disproportionate level of mortality among children in partially immune populations. In Africa, where the majority of malaria-associated deaths occur, the highest mortality affects children less than five years of age. In the Gambia, it has been estimated that malaria accounted for 25% of all deaths among children less than five years.¹⁸

Recent comparisons between malarious areas suggest that disease manifestations, age profile, and severity of illness vary widely with the intensity of malaria transmission.^{26,27} The overall or community level of immunity to malaria is highest in areas where malaria transmission is the most intense. In such communities, the burden of malarial illness and death is shifted to the youngest age groups. Additionally, severe malaria tends to manifest itself more frequently as anemia than as cerebral disease in the setting of intense transmission. As transmission intensity decreases, community level immunity is lessened, illness is seen more frequently in all age groups and the incidence of cerebral disease increases relative to anemia.

Pathophysiology

The usual incubation period from infective mosquito bite to onset of symptoms ranges from 9 to 30 days or longer, depending on the species of parasite (Table 15-8), host immune status, infecting dose, and use of antimalarial drugs. The clinical symptoms associated with malaria infection are caused by a complex interplay between the parasite and the host immune response. Symptoms are associated with the asexual erythrocytic stage parasites. Exoerythrocytic forms (sporozoites, exoerythrocytic schizonts, and hypnozoites) and gametocytes do not cause clinical symptoms.

In general, higher levels of parasitemia are associated with clinical symptoms in partially immune populations and with severe or complicated disease in nonimmune persons. Larger infecting doses have been clearly associated with shorter prepatent and incubation periods. The size of the infecting dose does not appear to correlate consistently with

severity of infection, level of parasitemia, number of paroxysms, or likelihood of complications.^{28,29} Even if the absolute number of parasites in an infecting dose does not, there is some evidence that the antigenic diversity of the inoculum does correlate with more severe disease.³⁰

Almost all instances of severe or fatal malaria are caused by *P. falciparum* infections. This tendency has been linked to several peculiar features of falciparum parasites. First of all, exoerythrocytic and erythrocytic schizonts of *P. falciparum* release larger numbers of merozoites when they rupture, resulting in a more rapid rate of increasing parasitemia. *P. falciparum* is also able to infect both mature and immature red blood cells (RBCs). In contrast, *P. vivax* and *P. ovale*, which cause milder clinical presentations, selectively infect immature RBCs and reticulocytes. Erythrocytes infected with *P. falciparum* adhere to the vascular endothelium of post-capillary venules. Several antigens which may mediate this property—adherence factors—have been characterized and implicated in severe or complicated malaria.^{31,32} Finally, under laboratory conditions, *P. falciparum*-infected erythrocytes can form rosettes with uninfected red blood cells. This *in vitro* phenomenon has also been correlated with severe disease.³³

The host response to malaria infection also contributes substantially to the pathogenesis of the disease. Several specific mediators have been suggested both for uncomplicated infections and for severe and complicated malaria.³⁴ Malaria fever appears to arise from cytokines released by host mononuclear cells when erythrocytic schizonts rupture. Tumor necrosis factor alpha (TNF α) has received the most attention.³⁵ Elevated levels of TNF α have been detected in patients during malaria fever^{36,37} and immediately preceding paroxysms of *P. vivax* infection.³⁸ Elevated levels of other cytokines, including interferon- γ and interleukins-1 and -6 have also been described and may contribute to fever in malaria infection.³⁶

The occurrence of severe and complicated malaria remains unpredictable and incompletely understood; however, it appears that both parasite and host immunologic effects play important roles in each of the major complications. Cerebral malaria, the gravest presentation of severe malaria, appears to be caused by a combination of factors. The most important event in this process is the sequestration of infected RBC in the deep capillaries in the brain, which can be related to sludging of infected RBC, lack of deformability of these cells, and cytoadherence of infected cells to noninfected cells, and vascular endothelium.¹⁵ The presence of the parasite induces the release of cytokines, specifically TNF and interleukins (IL), and high levels of these cytokines are correlated with indicators of severity, such as hypoglycemia, hyperparasitaemia, and anemia.¹⁵ The coma in cerebral malaria appears to be result of metabolic encephalopathy, resulting in abnormalities in neurotransmitter synthesis, release, and binding.³⁹ In addition, there is evidence that TNF induces the production of nitric oxide, which is also involved in malaria-induced coma.⁴⁰

Renal failure is a common manifestation among adults with severe malaria and has been attributed to acute tubular necrosis, the pathogenesis of which is not completely understood.⁴¹ Malaria-related anemia may evolve from direct effects—such as hemolysis of infected cells or their removal by the spleen—as well as immunologic effects including inhibition of erythropoiesis, immune-mediated removal of noninfected RBCs, and autoantibodies to RBC antigens.⁴²

Diagnostic Approaches

The diagnosis of malaria must be considered in all febrile patients who have traveled to or lived in malaria-endemic areas or who have received blood products, tissues or organs from persons who have been to such areas. Direct microscopic examination of intracellular parasites on stained blood films is the current standard for definitive diagnosis in nearly all settings. However, several other approaches exist, or are in development, which may be appropriate under special conditions.

Clinical Diagnosis

Although reliable diagnosis cannot be made on the basis of signs and symptoms alone because of the nonspecific nature of clinical malaria, clinical diagnosis of malaria is common in many malarious areas. In much of the malaria-endemic world, resources and trained health personnel are so scarce that presumptive clinical diagnosis is the only realistic option. Clinical diagnosis offers the advantages of ease, speed, and low cost. In areas where malaria is prevalent, clinical diagnosis usually results in all patients with fever and no apparent other cause being treated for malaria. This approach can identify most patients who truly need antimalarial treatment, but it is also likely to misclassify many who do not.⁴³ Overdiagnosis contributes to misuse of antimalarial drugs. Clinical diagnosis of malaria can lead health workers to overlook other obvious and treatable causes of fever in a febrile patient.⁴⁴ Considerable overlap exists between malaria and other diseases, especially acute lower respiratory tract infection, and bacteremia.⁴⁵ Attempts to improve the specificity of clinical diagnosis for malaria by including signs and symptoms other than fever or history of fever have met with only minimal success.⁴⁶

A definitive diagnosis of malaria can be made by several approaches, including light microscopy, special staining, rapid antigen detection, and detection of parasite nucleic acid sequences. Definitive diagnosis can decrease the use of antimalarial drugs by patients not needing malaria therapy, improve the ability to identify patients in need of treatment for nonmalarial illnesses, direct antimalarial therapy to specific species of malaria, and monitor impact of malaria infection and treatment over time. General disadvantages of definitive diagnosis include the cost of equipment and supplies, time expended training and supervising personnel and conducting the test, and the need for handling blood. In some malaria-endemic settings, providers frequently disregard definitive diagnostic tests when the results are at odds with their clinical suspicion.⁴⁷

Microscopic Diagnosis

Simple light microscopic examination of stained blood films is the most widely practiced and useful method for definitive malaria diagnosis. With a minimum of equipment and recurring expense, fast and reliable diagnosis of malaria can be obtained even under the most difficult conditions. In areas where *P. falciparum* causes only a portion of malaria infections, microscopic diagnosis allows differentiation between species, a capability not possible at present with some of the newer technologies. Another advantage of this approach is that an experienced microscopist can also quantify the level of infection and distinguish clinically important asexual parasite stages (rings, trophozoites, and schizonts) from the sexual forms (gametocytes) which may persist without causing symptoms. This can be critical for determining whether a given treatment has been effective. While several different stains can be used, Giemsa gives the best results. Specific disadvantages are that slide collection, staining, and reading can be time consuming and microscopists need to be trained and supervised to ensure consistent reliability. Although electricity is not needed as long as there is sunlight, the availability of electricity improves reliability and extends the hours during which diagnosis can be made available. Even when performed correctly, simple microscopic diagnosis does have some important limitations. In partially immune persons, asymptomatic parasitemia may be detected which can be of limited clinical significance and may cause the clinician to overlook another cause of illness. Conversely, in nonimmune persons, symptoms may develop before there are detectable levels of parasitemia. For this reason, several blood smear examinations are needed to positively rule out a diagnosis of malaria in a symptomatic patient.

Antigen Detection Tests

A third diagnostic approach involves the detection of parasite antigens, originally through enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay (RIA) techniques. Multiple experimental tests have been developed targeting a variety of parasite antigens.^{48–50} Rapid test kits are now commercially available which detect

the histidine rich protein (HRP-II) of *P. falciparum*. Compared with light microscopy, this test yielded rapid and highly sensitive diagnosis of *P. falciparum* infection.^{51,52} Other kits can detect parasite enzymes including aldolase and lactate dehydrogenase and are not species specific. By combining the two approaches in a single test kit some manufacturers have produced products that can differentiate falciparum malaria from nonfalciparum infections.

Although none are approved in the United States, rapid diagnostic tests are already being deployed in some malaria-endemic countries. Advantages to this technology are that no special equipment or personnel is required, the test and reagents are stable at ambient temperatures, and no electricity is needed. The principal disadvantage is a high per-test cost. Especially in settings where malaria transmission is low or where drug resistance patterns require risky or expensive treatments, these tests can be cost-effective. Aside from cost, other limitations to this technology are their variable sensitivity caused by antigenic diversity among wild-type parasites and the persistence of positive test results. Detectable antigen can persist for up to 10–14 days after adequate treatment and cure, and the tests cannot adequately distinguish a resolving infection from treatment failure due to antimalarial drug resistant parasites. Other constraints to using the current generation of rapid diagnostic tests more broadly include inconsistent quality of products from different manufacturers, and the susceptibility of reagents to extreme conditions of temperature and humidity.⁵³

Molecular Diagnosis

Detection of parasite genetic material through polymerase-chain reaction (PCR) techniques has gained prominence as a research tool. It will almost certainly have a growing role in the diagnosis of malaria. Specific primers have been developed for each of the four species of human malaria. One important use of this new technology is in detecting mixed infections or differentiating between infecting species when microscopic examination is inconclusive.⁵⁴ In addition, improved PCR techniques could prove useful for tracing molecular epidemiology in investigations of malaria clusters or epidemics.⁵⁵

Serologic Tests

Techniques also exist for detecting antimalaria antibodies in serum specimens. Specific serologic markers have been identified for each of the four species of human malaria. Positive studies generally indicate past infection. Serology is not useful for diagnosing acute infections because detectable levels of antimalaria antibodies do not appear until weeks into infection and persist long after parasitemia has resolved. Moreover, the test is relatively expensive, and not widely available. However, in particular settings, such as screening large numbers of blood donors in the epidemiologic investigation of a transfusion-induced case of malaria, serologic studies can be an appropriate and valuable tool.¹⁰

► TREATMENT

Antimalarial Drugs

There are a limited number of drugs which can be used to treat or prevent malaria. Because of rapidly developing and spreading resistance to antimalarials and the relatively slow process of developing new antimalarials, the number of useful drugs is dwindling. All currently available antimalarial drugs are discussed here even though not all are practical or appropriate to use in any given situation, and only a small number are recommended or obtainable for use in North America.

Quinine. Quinine was first isolated from Cinchona bark in 1820 and has since been the fundamental chemotherapeutic agent for the treatment of malaria, especially severe disease. Quinine and its dextroisomer, quinidine, are rapidly acting drugs which target the erythrocytic asexual stages of all malaria parasites. It is available in both oral and parenteral preparations and can be used in infants and pregnant women. Side effects include nausea, dysphoria, blurred vision, and tinnitus and typically resolve after treatment has ended. *P. falciparum*

from most areas of the world responds well to quinine; because of this, shortened courses of quinine can be used in conjunction with a second drug to reduce the likelihood of quinine-associated side effects. *P. falciparum* from many areas of Southeast Asia require full course quinine treatment in conjunction with a second drug (see Table 15-9).

Chloroquine. Chloroquine (CQ) is a 4-aminoquinoline derivative of quinine first synthesized in 1934. Historically, chloroquine has been used as the drug of choice for the treatment of non-severe or uncomplicated malaria and for chemoprophylaxis. Chloroquine acts primarily against erythrocytic asexual stages, although it has gametocidal properties. Because of widespread resistance to this drug, its usefulness is increasingly limited. Where chloroquine retains efficacy, it can be safely used for treatment or prophylaxis of infants and pregnant women. Side effects are uncommon and not generally serious. They include nausea, headaches, gastrointestinal disturbance, and blurred vision. Some patients, especially if dark-skinned, can experience pruritus.

Amodiaquine. Amodiaquine (AQ) is closely related to chloroquine (and exhibits some degree of cross-resistance with CQ) but has fallen out of favor because of a high incidence of adverse reactions (including agranulocytosis and hepatitis), primarily when used for prophylaxis. In response to mounting chloroquine resistance, some African countries have adopted amodiaquine or amodiaquine-containing treatments for routine treatment of uncomplicated malaria. In areas where CQ resistance is high, AQ efficacy will be compromised, even when combined with artemisinin compounds.

Antifol Antimalarial Drugs. These drugs are various combinations of dihydrofolate reductase inhibitors (proguanil, chlorproguanil, pyrimethamine, and trimethoprim) and sulfa drugs (dapson, sulfalene, sulfamethoxazole, sulfadoxine, and others). Although these drugs have antimalarial activity when used alone, parasitologic resistance can develop rapidly. When used in combination, they produce a synergistic effect on the parasite and can be effective even in the presence of resistance to the individual components. Typical combinations include sulfadoxine/pyrimethamine (Fansidar), sulfalene-pyrimethamine (metakelfin), chlorproguanil-dapsone, and sulfamethoxazole-trimethoprim (cotrimoxazole). Side effects are uncommon, however, severe adverse reactions can occur. When sulfadoxine-pyrimethamine was used prophylactically among American travelers, it was associated with a high incidence of severe cutaneous reactions (1 per 5000–8000 users) and mortality (1 per 11,000–25,000 users).⁵⁶ These side effects do not appear to occur as frequently when the drug is used for treatment. Concerns about sulfa drug use during pregnancy are outweighed by the known risks to mother and fetus associated with untreated malaria. The use of folate supplementation may increase the frequency of treatment failure with antifol combination drugs.⁵⁷ Drugs in this class are particularly likely to rapidly select for resistance, although chlorproguanil-dapsone has a short elimination time and may be efficacious in parasites resistant to other antifol antimalarial drugs.⁵⁸

Atovaquone. Atovaquone is a hydroxynaphthoquinone that is currently being used most widely for the treatment of opportunistic infections in immunosuppressed patients. It is effective against chloroquine-resistant *P. falciparum*, but because of a high incidence of recrudescence, atovaquone is usually given in combination with proguanil.^{59,60} A fixed dose antimalarial combination of 250 mg atovaquone and 100 mg proguanil is currently being marketed and is recommended as one option for treatment and chemoprophylaxis in settings where chloroquine-resistant malaria is endemic. The combination is reportedly safe and effective against erythrocytic forms of all four species of human malaria and appears to induce causal prophylaxis.^{61,62}

Tetracyclines. Tetracycline and derivatives such as doxycycline are used for both treatment and prophylaxis. In areas where response to quinine has deteriorated, tetracyclines are often used in combination with quinine to improve cure rates. Tetracyclines are also used in conjunction with shortened courses of quinine to decrease the likelihood

TABLE 15-9. DRUGS USED TO TREAT MALARIA AS RECOMMENDED BY THE U.S. CENTERS FOR DISEASE CONTROL AND PREVENTION

Drug	Adult Dosage	Pediatric Dosage
Uncomplicated <i>Plasmodium falciparum</i> in areas WITHOUT chloroquine resistance and <i>P. malariae</i>		
(i) Chloroquine phosphate	1000 mg (salt) po as initial dose, followed by 500 mg (salt) po in 6–8 hrs, then 500 mg (salt) po daily for 2 days (total of 2500 mg salt) ^a	10 mg/kg (base) po immediately, followed by 5 mg/kg (base) po in 6–8 hrs, then 5 mg/kg (base) po daily for 2 days (total of 2–5 mg/kg base) ^a
<i>P. vivax</i> ^b or <i>P. ovale</i>		
(i) Chloroquine phosphate	As above	As above
AND		
Primaquine phosphate ^{c,d,e}	30 mg (base) po qd for 14 days	0.6 mg/kg (base) po qd for 14 days
Uncomplicated <i>P. falciparum</i> acquired in areas WITH chloroquine resistance		
(i) Quinine sulfate	650 mg (salt) po tid for 3–7 days ^e	10 mg/kg (salt) po tid for 3–7 days
AND		
Doxycycline ^f	100 mg po bid orally for 7 days	4 mg/kg/day divided bid for 7 days
Tetracycline ^f	250 mg po qid orally for 7 days	25 mg/kg/day divided qid for 7 days ^h
Clindamycin	20 mg base/kg/day divided tid for 7 days	20 mg base/kg/day divided tid for 7 days
(ii) Mefloquine ^{g,h}	750 mg (salt) po as initial dose and 500 mg (salt) po 6–12 hours later	15 mg/kg (salt) po initial dose and 10 mg/kg (salt) po 6–12 hours later
(iii) Atovaquone-proguanil	4 adult tablets (250 mg atovaquone/100 mg proguanil) po qd for 3 days	Adult tablet: 250 mg atovaquone/100 mg proguanil Ped tablet: 62.5 mg atovaquone/25 mg proguanil 5–8 kg: 2 ped tabs po qd × 3 d 9–10 kg: 3 ped tabs po qd × 3 d 11–20 kg: 1 adult tab po qd × 3 d 21–30 kg: 2 adult tab po qd × 3 d 31–40 kg: 3 adult tab po qd × 3 d >40 kg: 4 adult tab po qd × 3 d
Severe <i>P. falciparum</i> malaria		
(i) Quinidine gluconate ⁱ	10 mg/kg (salt) loading dose IV over 1–2 hrs, then 0.02 mg/kg/min continuous infusion until po therapy can be started	Same
AND		
Tetracycline ^f	As above	As above ^h
Doxycycline ^f	100 mg IV bid until able to take oral	2 mg/kg IV bid (Children <45 kg)
Clindamycin	10 mg/kg IV then 5 mg/kg IV every 8 h until able to take oral	10 mg/kg IV as loading dose and 5 mg/kg IV tid until able to take oral

^aA standard dosing option: (Adults): 600 mg (base) once daily for 2 days, followed by 300 mg (base) once on the third day; (Children): 10 mg/kg (base) once daily for 2 days, followed by 5 mg/kg once on the third day.

^b*P. vivax* parasites from Papua New Guinea and Indonesia are resistant to chloroquine and patients should be treated with quinine plus either doxycycline or tetracycline, and primaquine. Doxycycline and tetracycline are not indicated in pregnant women. *P. vivax* in Southeast Asia (Burma, Thailand, Indonesia), India, and South America (Guyana) have also been shown to be resistant to chloroquine.

^cPrimaquine is used to eradicate hypnozoites from the liver of infected individuals. Because of the probability of reinfection, routine use of primaquine in endemic areas is generally not recommended. Primaquine is also gametocytocidal; for this reason, some malaria control programs use primaquine therapy to help decrease transmission. The overall efficacy of this practice in most areas is questionable.

^dPatients who require primaquine should be screened for G6PD deficiency prior to therapy. Patients with mild G6PD deficiency (A variant with 10–60% residual enzyme activity) can be treated with 45 mg (adult dose) once per week for 8 weeks. Severely deficient patients (B variant with < 10% residual enzyme activity) should not be treated with primaquine because of risk of severe and potentially fatal hemolysis. Primaquine should not be used during pregnancy.

^eQuinine sulfate given for 3 days should be used in conjunction with a second drug for 7 days. *P. falciparum* infections from some areas of Southeast Asia, most notably Thailand, should be treated with 7 days of quinine sulfate and 7 days of an effective second drug such as doxycycline.

^fThe benefits of using tetracycline and doxycycline in children under 8 years must be weighed against the known risks of adverse effects.

^gMefloquine at treatment doses has been associated with a high incidence of serious neuropsychiatric side effects (1/2000 to 1/1200). Incidence was higher among patients treated with 25 mg/kg and much higher (1/173) among patients receiving 25 mg/kg after failing 15 mg/kg. Splitting the dose (15 mg/kg on the first day followed by 10 mg/kg 24 hours later) may reduce side effects of high dose mefloquine.

^hIn Thailand, response to treatment with 15 mg/kg mefloquine is poor and even treatment with 25 mg/kg results in low grade resistance in about 50% of cases and high grade resistance in about 15%.

ⁱQuinine dihydrochloride can also be used, if available (it is not available in the United States). Adults: 600 mg diluted in 300–500 ml normal saline, infused over 1–2 hours. Dose repeated every 8 hours until patient able to take oral quinine sulfate (as described for p.o. quinine sulfate); Children: 25 mg/kg divided into 3 doses per day, infused over 1–2 hours until patient able to take oral quinine sulfate (as described for p.o. quinine sulfate).

Source: Adapted from: CDC Web site www.cdc.gov/malaria

of quinine-associated side effects and poor adherence. Tetracyclines should not be used during pregnancy, breastfeeding, or in children less than eight years of age because they can disrupt the development of teeth and bones. Common side effects include nausea, vomiting, diarrhea, *Candida* superinfections, and photosensitivity.

Primaquine. Primaquine, an 8-aminoquinoline, is primarily used as a tissue schizonticide for the purpose of reducing the likelihood of relapse due to hypnozoites of *P. vivax* and *P. ovale*. Recent studies have shown that primaquine has reasonably good efficacy (74% against *P. falciparum* and 90% against *P. vivax*) when used for prophylaxis.⁶³ Although

it has activity against blood stage asexual parasites, the concentrations required to achieve blood schizonticidal action are toxic; primaquine is also a potent gametocytocidal drug and has been used in community-based control programs to reduce the prevalence of gametocyte-carrying individuals in the population. People with glucose-6-phosphate dehydrogenase (G6PD) deficiencies can experience severe and potentially fatal hemolytic anemia if treated with primaquine. Individuals with mild to moderate G6PD deficiency (A variant) can tolerate a weekly dosing regimen, but primaquine should be avoided entirely in persons who demonstrate severe deficiency with less than 10% residual enzyme activity. The most severe Mediterranean B variant and related Asian variants of G6PD deficiency can occur at high rates among some groups or regions; Kurdish Jews (62%), Saudi Arabia (13%), Myanmar (20%), and southern China (6%). Migration, mutation, and intermarriage have spread these variants throughout the world. Primaquine should not be used in pregnancy because the drug may cross the placenta and cause hemolytic anemia in a G6PD-deficient fetus.

Mefloquine. Mefloquine is a quinoline-methanol derivative of quinine. It can be used either therapeutically or prophylactically in most areas with chloroquine- and antifol-resistant malaria. Resistance to mefloquine, however, occurs frequently in western Cambodia and along the Thai-Cambodian and Thai-Burmese borders; *in vitro* resistance has been reported to occur in areas of Africa and South America.⁶⁴ Mefloquine has been associated with a relatively high incidence of neuropsychiatric side effects when used at treatment doses, but is otherwise well tolerated. Neuropsychiatric side effects are rare (1 in 10,000 to 1 in 15,000) in persons taking prophylactic doses. Although not licensed for use during pregnancy or in very young infants, mefloquine appears to be both safe and effective in those groups. Mefloquine can be difficult to use in small children because it frequently causes vomiting and because no pediatric formulation is available.

Halofantrine. Halofantrine is a phenanthrene-methanol compound with activity against the erythrocytic stages of the malaria parasite. Its use has been especially recommended in areas with multiple drug-resistant falciparum malaria. The drug can produce cardiac conduction abnormalities (specifically, prolongation of the PR and QT interval), limiting its usefulness.⁶⁵ A subsequent study suggests that cardiac abnormalities are dose dependant and can be severe in patients with preexisting cardiopathy; the authors suggest electrocardiography be conducted on all patients prior to treatment with halofantrine.⁶⁶ A micronized formulation has improved halofantrine's originally poor oral bioavailability, however, it should be given on an empty stomach. Fatty foods dramatically increase absorption, improving the drugs antiparasitic activity, but increasing the risk of cardiac complications. Recrudescences can occur with one round of treatment and, especially when treating nonimmune individuals, a second course should be given seven days later. Retreatment of patients who had failed mefloquine therapy with halofantrine was less successful than primary treatment with halofantrine, suggesting the possibility of clinical cross-resistance between the two drugs.^{67,68} Halofantrine therapy after mefloquine or quinine therapy also increases risk of cardiac problems.

Clindamycin. Clindamycin has only limited antimalarial activity when compared to other available antimalarial drugs. Recrudescence rates are high following treatment with clindamycin alone. Combined with other drugs, such as quinine, clindamycin is frequently useful for treatment of pregnant women or very young children.

Pyronaridine. Pyronaridine is a drug synthesized and used in China for over 20 years. While the drug was reportedly 100% effective in one trial in Cameroon,⁶⁹ it was only between 63% and 88% effective in Thailand.⁷⁰ Further testing is required before pyronaridine can be recommended for use. It is likely to be combined with drugs in the artemisinin class.

Piperaquine. Piperaquine is a bisquinoline antimalarial drug used widely in China and Southeast Asia in the 1960s and 1970s. Piperaquine-resistant malaria was documented in the 1980s. Recently the drug is

being used as a component of an artemisinin-containing combination treatment under development (Artekin).⁷¹

Artemisinin Compounds. A number of sesquiterpene lactone compounds have been derived from the plant *Artemisia annua* (artesunate, artemether, dihydroartemisinin, and artemenic acid). These compounds are used for treatment of severe malaria and have shown very rapid parasite clearance times and faster fever resolution than occurs with quinine. Studies to determine if this faster action produces improved survival suggest that there is a quicker improvement of coma following treatment with artemisinins.⁷² More recently, a study in African children showed that rectal artesunate was as effective as parenteral quinine for treating cerebral malaria.⁷³ When used alone, especially for durations of less than five days or less, recrudescence rates are high. For this reason the combination of artesunate and mefloquine was introduced for treating malaria in areas of Southeast Asia where mefloquine efficacy had been declining.⁷⁴ This was associated with reduced malaria transmission⁷⁵ and lessened drug resistance in the same area.⁷⁶

Because of these findings and because of the advanced state of chloroquine- and antifol-resistant malaria throughout much of the world, advocates have called for the deployment of artemisinin-containing combination therapies (ACTs) in endemic countries.⁷⁷ In addition to mefloquine-artesunate, coadministration of sulfadoxine/pyrimethamine plus artesunate, or amodiaquine plus artesunate have been introduced in parts of Africa and Latin America. Only one fixed dose ACT product, *artemether-lumefantrine*, has prequalified with the WHO. Evaluation studies are underway to verify whether or not ACTs are associated with deferring resistance and reducing transmission outside Southeast Asia.⁷⁸ A growing number of malaria-endemic countries have recently adopted ACTs for first-line treatment of malaria; however, to date, the widespread deployment of ACTs has been limited by their poor availability, their relatively high cost, and concerns about safety.⁷⁹

Treatment of Malaria

The diagnosis of malaria should be considered in any person who has fever and has been in a malarious area within the past six months. In addition, reports of induced, introduced and cryptic malaria transmission in the United States should alert clinicians that malaria can cause illness even in patients who have not visited malarious areas.⁸⁰ *P. falciparum* infection in a nonimmune person can rapidly develop into severe, complicated, or fatal malaria. Therefore, a high index of suspicion and a rapid, accurate diagnosis are critical. The choice of appropriate therapy will depend on the infecting species, the density of infection, the presence or absence of complications, the possibility of drug resistance, and the drugs that are available for treatment. Assistance with diagnosis and treatment recommendations is available in the United States from the Centers for Disease Control and Prevention Malaria Hotline (telephone 770-488-7788 during working hours and 770-488-7100 for after hours). A list of CDC-recommended treatment drugs is included in Table 15-9.

Patients infected with *P. vivax*, *P. ovale*, or *P. malariae* and patients with uncomplicated *P. falciparum* infections acquired in areas where drug resistance has not been documented should be treated with a 3-day course of oral chloroquine. A 14-day course of primaquine should also be given to patients infected with *P. vivax* or *P. ovale* to eradicate dormant liver-stage parasites (hypnozoites). This combination of chloroquine and primaquine will prevent relapse in a majority of cases, but some strains of *P. vivax* from Southeast Asia and Oceania appear less susceptible to primaquine and require longer duration of therapy.⁸¹

The choice of treatment for uncomplicated *P. falciparum* infections acquired in areas where drug resistance has been documented is more difficult. In the United States, recommended regimens include quinine combined with tetracycline, doxycycline, or clindamycin; mefloquine alone; or atovoquone-proguanil.⁸² The derivatives of artemisinin appear to be effective, as well, but are not licensed for use in the United States. In malaria endemic countries, the recommended treatments for uncomplicated malaria vary widely based on drug resistance patterns, affordability, and policy considerations.⁷⁹

Artemisinin-containing combination therapies are being increasingly used in malarious countries.

Parenteral therapy is recommended for falciparum malaria when CNS or renal complications are present or when there is a high density infection (>5% of the RBCs are infected). Infections acquired in areas without chloroquine-resistant *P. falciparum* may be treated with intravenous chloroquine. However, if the infection has been acquired in areas endemic for chloroquine-resistant *P. falciparum* (CRPF), intravenous quinine or quinidine is necessary. In addition to parenteral therapy, exchange transfusion is often recommended when cerebral malaria, renal failure, or very high density (>10% of RBCs infected) infection is present.⁸³ A recent meta-analysis, however, failed to demonstrate that exchange transfusion was associated with a survival advantage.⁸⁴ Treatment options are more limited for children and pregnant women. Tetracyclines can not be used in pregnancy or in children less than eight years old. Primaquine is contraindicated for pregnant women because of the risk of hemolysis in the fetus. While most of the other antimalarial drugs are well tolerated in children, many are difficult to use because they are not available in pediatric formulations. Experience is limited but evidence suggests that mefloquine can be used in children who weigh less than 15 kg, although infants may be more likely to vomit following treatment doses.⁸⁵ Treatment doses of chloroquine, sulfadoxine-pyrimethamine (SP), quinine, and quinidine are considered safe during pregnancy, but there is a theoretical risk of kernicterus when SP is given in the third trimester. For chloroquine-resistant infections in pregnant women, quinine is preferred, especially in the first trimester. Some experience suggests that mefloquine and artemisinin derivatives may be useful in the second and third trimesters.⁸⁶

► GEOGRAPHIC DISTRIBUTION

Figure 15-3 shows the areas of the world where malaria transmission occurs. Over 60% of clinical cases and 80% of malaria deaths are acquired in sub-Saharan Africa.¹ Some indication of the geographic distribution of malaria can be gleaned from the numbers of malaria cases imported into the United States, but these figures are also shaped by changing patterns of international travel. The overwhelming majority of these infections are imported and occur in U.S. residents who have traveled to or immigrated from malaria-endemic countries. Small numbers of cases (fewer than 10 per year) are acquired within the United States and its territories. While comparatively few persons travel between the United States and Africa, a disproportionate number of the U.S. cases are acquired on that continent. Surveillance data suggest that a growing proportion of malaria cases imported into the United States occur among immigrants and naturalized citizens who return to their countries of origin to visit friends and relatives.⁸

Distribution of Four Plasmodium Species

Not all species of malaria are transmitted in all malarious areas. While *P. falciparum* is transmitted in nearly all areas where malaria occurs, it accounts for over 90% off all malaria infections in sub-Saharan Africa and nearly 100% of infections in Haiti. *P. falciparum* causes two-thirds or more of malaria cases in Southeast Asia. *P. vivax* is only rarely transmitted in sub-Saharan Africa because most ethnic groups lack the RBC marker required for invasion by this parasite,⁸⁷ but predominates in Central America, most of malarious South America, and the Indian subcontinent. Recent reports have documented the resurgence of vivax malaria in the central Asian republics of the former Soviet Union. *P. malariae* has a patchy distribution, but may be transmitted in most of the malarious world. In contrast, *P. ovale* transmission is limited to tropical Africa and Papua New Guinea.

Distribution of Drug-Resistant Strains

Chloroquine-resistant *P. falciparum* (CRPF) was first recognized almost simultaneously in Thailand and South America in the late 1950s. CRPF was documented on the east coast of Africa in 1978. In the past 25 to 30 years, CRPF has spread and intensified to the point that only Central America, northwest of the Panama Canal, the island of Hispaniola (Haiti and the Dominican Republic), and limited regions of the Middle East

remain free of chloroquine resistance. In all other endemic areas malaria is, to varying extent, resistant to chloroquine. In some regions, chloroquine resistance has intensified to the point where chloroquine no longer has a significant effect on *P. falciparum* parasites and can no longer be relied upon to provide effective treatment or prophylaxis. Finally, there is recent evidence that chloroquine-resistant *P. vivax* has emerged in South America, Southeast Asia, and the Indian subcontinent.^{88,89}

Drug resistance is not an all-or-nothing phenomenon. In any given area, a wide range of parasitologic responses can be found, from complete sensitivity to complete resistance. In parts of East Africa, resistance has intensified to the point where 80% to 90% of *P. falciparum* infections are moderately to highly resistant.⁹⁰ In response to these high rates of resistance, Malawi switched from chloroquine to sulfadoxine-pyrimethamine for first-line therapy for *P. falciparum* in 1993. Other African countries followed suit in the late 1990s and early part of the 21st century. Since the establishment of the Global Fund to fight AIDS, tuberculosis and malaria, many countries have adopted the use of some form of artemisinin-containing combination therapy and are in the process of changing and implementing new national treatment recommendations. The problem of drug resistance is not limited to chloroquine. In Southeast Asia, falciparum malaria has rapidly developed resistance to one compound after another. After chloroquine was abandoned as first-line therapy for malaria in Thailand in 1972 in preference to sulfadoxine-pyrimethamine (SP), resistance to that drug developed and intensified. In 1985, SP was briefly replaced by a combination of SP and mefloquine.⁹¹ Currently, greater than 50% of *P. falciparum* infections show resistance to MQ (15 mg/kg) in some areas of Thailand.⁶⁴ Cure rates were improved to 70% to 80% by increasing the dose of mefloquine to 25 mg/kg, but the incidence of side effects also increased. Increasing the dose of mefloquine from 24 mg/kg to 72 mg/kg over 72 hrs improved cure rates from 65% to 99%, but also increased the toxicity. Currently, multidrug-resistant malaria is most frequently being treated with a combination of mefloquine and artesunate.

Drug resistance develops rapidly to dihydrofolate reductase inhibitors (such as pyrimethamine and proguanil) when used alone.⁹² In Southeast Asia and South America, parasitologic response to quinine has also been deteriorating.⁹³ Clinically relevant resistance to newer antimalarials, such as halofantrine, has been reported, especially in areas with established mefloquine resistance.^{67,68} Declines in *in vitro* efficacy of lumefantrine and the artemisinins has been described in Southeast Asia, although this resistance has not evolved to the point of being clinically evident.

► TRANSMISSION

Human malaria is transmitted by the bite of female mosquitoes belonging to the genus *Anopheles*. Of the 400 or so species of *Anopheles* in the world, approximately 60 are important vectors of malaria. However, a particular species of *Anopheles* may be an important vector in one area of the world and of little or no consequence in another. Table 15-10 lists several of the anophelins that have been incriminated as principal malaria vectors, their geographic distribution and information on their susceptibility to malaria, preferred hosts and breeding sites.

There are four stages in the mosquito life cycle—egg, larva, pupa and adult. Eggs are deposited singly on water in suitable breeding sites where the developing embryo hatches as a larva after two or more days. At this stage the mosquito undergoes a complete metamorphosis emerging as an adult. The length of each developmental stage is temperature dependent. Generation times in the tropics can be as brief as five days. The life span of adults under natural conditions is difficult to determine but in the case of malaria vectors is clearly longer than the time required to become infective, and probably 3-4 weeks.

Levels of Transmission and Endemicity

Malariologists have devised a number of systems for characterizing malaria transmission. The stability of transmission has important implications for the clinical features of malarial illness, the degree of population immunity, and the optimal mix of preventive approaches

TABLE 15-10. FEATURES OF COMMON MALARIA VECTORS

Species	Distribution	Susceptibility to Malaria	Host Preference	Typical Breeding Sites
<i>An. albimanus</i>	Western hemisphere from southeast Texas, Mexico, Central America, to Ecuador, Venezuela, and Caribbean	Low	Animal	Wide range from temporary collections of water to ponds, streams, and lakes
<i>An. culicifacies</i>	Indian subcontinent	Low	Animal	Sunlit collections of freshwater, including rice fields
<i>An. Darlingi</i>	South America east of the Andes	Moderate	Human	Clear, fresh, partially shaded lagoons or marshes
<i>An. Dirus</i>	Southeast Asian forests	High	Human	Shaded water collections
<i>An. gambiae</i> , <i>An. Funestus</i>	Tropical Africa	High	Human	Freshwater collections exposed to sunlight
<i>An. maculatus</i>	Foothills of Southeast Asian countries and Indian subcontinent	Moderate	Human	Sunlit hilly streams
<i>An. Minimus</i>	Southeast Asian hills	Moderate	Human	Margins of slow-moving sunlit streams
<i>An. stephensi</i>	Urban areas of the Indian subcontinent	Moderate	Human	Shaded wells, cisterns, cans, roof gutters

that is relevant in a given area. *Stable* malaria transmission is intense, varies little from season to season, and can be difficult to interrupt. Populations living in areas with stable transmission generally acquire partial immunity, so that severe and fatal illness tends to occur only in young children or pregnant women. *Unstable* malaria transmission is intermittent and highly variable. Populations in areas of unstable transmission rarely develop sufficient immunity for protection, so that severe and fatal disease can occur in persons of all ages and there is a high risk for epidemic malaria.⁹⁴

Malaria transmission can also be characterized by its intensity. In *holoendemic* regions there is intense malaria transmission year round and population immunity is high, particularly among adults. While older children and adults may become infected and develop clinical disease in these settings, severe or fatal malaria occur almost exclusively in children between the ages of one and four years old. In *hyperendemic* areas, malaria transmission is seasonal and the population's level of immunity does not confer adequate protection from disease for all age groups. As a result, severe and fatal malaria infections occur in children and adults. In *mesoendemic* areas there is some malaria transmission and population immunity is low. Finally, in *hypoendemic* areas there is very little transmission and little or no immunity to the parasite. While malaria may constitute a minor public health burden in mesoendemic and hypoendemic communities, the low levels of population immunity leave these areas prone to devastating malaria epidemics and higher risk of severe or fatal outcome for those infected.⁹⁴ The level of endemicity in a region can be quantified by determining the percentage of children (2–9 years old) with enlarged spleens and malaria parasites in their blood (Table 15-11).⁹⁵ In general, as the level of endemicity decreases, the stability of transmission also declines and the risk of epidemic malaria increases.

Host Factors Affecting Distribution

Several heritable characteristics of human hosts also affect the distribution of the human malaras. Similarly, endemic malaria has influenced the rates of genetic polymorphisms and genetic diseases in many human populations. Genetic factors can influence the hosts' susceptibility to malaria infections and their likelihood of developing severe or complicated malaria.⁹⁶ For example, *Plasmodium vivax* invades red blood cells by recognizing the Duffy antigen on their surface. Persons who are genetically Duffy-negative, therefore, will be unable to sustain vivax infections. For this reason, *P. vivax* does not occur among West African populations, who lack this blood group marker.

Perhaps the most well-recognized group of host genetic factors associated with malaria are the hemoglobinopathies. Hemoglobin S,

in its homozygous state causes sickle cell disease. Although persons with sickle cell disease or its heterozygous carrier state can develop malaria infections, heterozygous individuals are afforded 80-95% protection from severe or complicated *P. falciparum* infections.⁹⁷ Other hemoglobinopathies, including hemoglobins C and E, the α - and β -thalassemias, and persistence of fetal hemoglobin have also been associated with protection from severe or complicated malaria illness.⁹⁸ It appears that falciparum parasites are not able to metabolize these variant hemoglobin molecules. In addition to the hemoglobinopathies, other alterations in RBC structure or function can affect host susceptibility to malaria. Recent studies have demonstrated some protective effect for persons who carry the genes for hereditary ovalocytosis⁹⁹ and glucose-6-phosphate dehydrogenase deficiency.¹⁰⁰ Studies have also associated resistance to malaria, and its severe manifestations with the highly variable human leukocyte antigens (HLA) of the major histocompatibility complex (MHC).¹⁰¹ In a large case-control study in the Gambia, children with severe malaria were less likely to have the class I antigen HLA B53 or one form of the class II antigen HLA DR13.⁹⁷ The association was stronger for severe malaria than for mild infections. Polymorphisms in the gene that codes for TNF α have also been shown to alter the risk of severe malaria.^{102,103}

Nutrition

The interaction between undernutrition and malnutrition and malaria is complex and incompletely understood. Some nutritional deficiencies apparently protect against malaria and others exacerbate malaria infection. Although cerebral malaria was found more commonly among well nourished children in Nigeria than children with clinical marasmus or

TABLE 15-11. LEVELS OF ENDEMICITY BY SPLEEN AND PARASITE RATES IN CHILDREN 2–9 YEARS OF AGE

Endemicity	Spleen Rate (%)	Parasite Rate (%)
Hypoendemic	0–10%	0–10%
Mesoendemic	11–50%	11–50%
Hyperendemic	>50% (>25% in adults)	51–75%
Holoendemic	>75% (low in adults)	> 75%

kwashiorkor,¹⁰⁴ children in the Gambia had no difference in risk of cerebral malaria¹⁸ or risk of nonsevere malaria infection¹⁰⁵ based on weight-for-age. Iron deficiency in children may protect against malaria infection and oral or parenteral iron supplementation has been shown in some studies^{106–108} to increase malaria prevalence or incidence. Other studies, however, show that hematologic recovery is maximized with a combination of iron supplementation and effective malaria therapy.⁵⁷ Parenteral iron supplementation during pregnancy has been shown to increase the risk of malaria infection among primigravid women¹⁰⁹ but not among multigravid women.¹¹⁰ Zinc and vitamin A deficiency may increase the frequency and severity of malaria in children.^{111–114} Concomitant administration of folate or iron with antifol antimalarials (i.e., sulfadoxine-pyrimethamine) has been shown to increase the risk of treatment failure, although this finding has not been consistently reproduced.^{57,115}

Malnutrition can also be worsened because of malaria. Malaria causes increased destruction and decreased production of RBCs, exacerbating existing nutritional anemias. In addition, the anorexia and vomiting frequently associated with malaria infection can further limit food intake and contribute to further nutritional deficiency.¹¹⁶ The effects of malnutrition on immunologic responses to malaria are unclear. The prevalence and degree of parasitologic resistance to both chloroquine and SP was worse among malnourished Rwandan refugees,¹¹⁷ possibly because of impaired immune function. Malaria can have immunosuppressive effects and can increase the risk of infection with other pathogens including *Salmonella*.¹¹⁸

Social and Behavioral Factors

The relationships between malaria transmission and human behavior are multiple and complex. Many of the human behaviors that favor malaria transmission stem from broad social, cultural, and economic forces. Such factors include poverty, agricultural and industrial development, population mobility and urbanization.⁹⁴ In addition to these broad social forces, malaria transmission and control are invariably affected by local beliefs, attitudes and practices.

In most malaria-endemic areas, poverty is also deeply entrenched and can influence the distribution of malaria as well as other health conditions. As described above, the undernutrition associated with poverty contributes to malaria mortality, especially in children. Impoverished families often reside in substandard housing that affords little protection from anopheline mosquitoes. In poor communities, inadequate sanitation and drainage control can create ideal breeding sites for some malaria vectors. In addition, the lack of economic resources, at both the national and household levels, leaves residents of highly malarious areas with few options for malaria prevention and control, and limited access to appropriate health care services.¹¹⁹ Poverty-related medical practices such as misuse and underdosing of antimalarial medications play an important role in the development and spread of drug-resistant malaria.¹²⁰

Agricultural development can contribute to malaria transmission in a number of important ways. Clearing forests for crop production can create ideal breeding sites for anopheline vectors.^{121,122} In addition to deforestation, the changes in water use and altered populations of wild and domesticated animals that typically accompany agricultural development can also affect the likelihood of human-mosquito contact and malaria transmission.¹²³ Finally, it has been suggested that the agricultural use of pesticides may contribute to mosquito resistance to DDT and other insecticides.¹²⁴

Human mobility has had a tremendous effect on the global malaria situation as well. Among 20 countries with high risk of malaria transmission in the Americas, 16 identified human mobility as a major cause of persistence of transmission.¹²⁵ Migration has been associated with the spread of drug-resistant malaria in Africa and Southeast Asia.^{126–128} Migrant farm workers have been linked to outbreaks of autochthonous transmission of malaria in the United States, raising the concern of the possibility of reestablishment.⁹ These outbreaks provide evidence that movements of individuals or small numbers of people can have an effect on malaria. Movements of large populations either into or out of

malaria endemic areas, however, carry a much higher risk of disastrous consequences.

In the process of urbanization, construction for new settlements often creates additional anopheline breeding sites.¹²⁹ When populations first settle new towns they often choose to locate near water supplies and in recently disrupted local environments. While rural areas are generally considered at greatest risk for malaria, anopheline vectors have become well adapted to conditions in many cities.¹³⁰ Moreover, the rapid rates of urbanization in many malarious areas easily outpace the expansion of health and environmental services. As a result, many new urban residents are forced into marginal areas, slums and squatter settlements where malaria transmission may readily occur.¹³¹ Furthermore, these peripheral (peri)-urban areas often include populations who migrate between larger settlements and rural areas for employment and might easily introduce malaria. The increasing proportion of residents of malarious countries who live in urban and peri-urban settings, demands that additional attention be given to understanding and controlling malaria in these settings.

In addition to these globally determined processes, local social, cultural and behavioral patterns can influence the transmission of malaria as well as a community's acceptance of and compliance with malaria control activities. Culturally-defined patterns of housing and sleeping behavior can reduce or favor malaria transmission and will affect the appropriateness and acceptability of most vector-control strategies.¹³² Local perceptions of fever, complicated malaria and their causes can influence local acceptance of malaria control activities. Likewise, local attitudes toward antimalarial drugs can affect compliance with treatment and prophylaxis programs.¹²⁰ Careful involvement of community members can overcome some of these potential problems.¹³³

► MALARIA PREVENTION AND CONTROL

Historical Perspective

In 1955, the eighth World Health Assembly launched a program to eradicate malaria worldwide.¹³⁴ The eradication effort produced dramatic results, especially in temperate climates and island nations. However, throughout the 1950s and 1960s, malaria persisted as a serious health threat in most continental tropical countries.¹³⁵ Indeed, sub-Saharan Africa was excluded from the eradication effort altogether.¹³⁶ The global program relied heavily on a strategy of focused domestic application of DDT. Since it was anticipated that insecticide resistance would develop, eradication was considered a time-limited activity. From the start, the program placed little emphasis on research, attitudes of local populations, or regional differences in vector behavior.⁹⁴

By 1969, a revised global malaria strategy had evolved. The new approach emphasized malaria control, by integrating multiple prevention measures tailored to local conditions. Global funding for malaria declined. By the late 1970s, countries were encouraged to integrate malaria control activities into their basic health service programs, as international health policy shifted, favoring decentralized, horizontal approaches like primary health care and child survival over highly centralized vertical programs like malaria eradication. Ultimately, these changes in international priorities and support, combined with the emergence of drug-resistant parasites and insecticide-resistant vectors, contributed to the resurgence of malaria worldwide.¹¹⁹

Some early malaria control projects combined two or more preventive strategies, such as residual spraying with mass distribution of drugs,¹³⁷ to produce a greater public health impact. Contemporary malaria control efforts aim to reduce malaria-related morbidity and mortality, through a combination of multiple interventions that disrupt the parasite-vector-human cycle at several points. This stratified approach is based on the observation that the effectiveness of different malaria control options can depend heavily on local conditions.¹³⁸ Some understanding of these conditions is, therefore, needed in order to develop a malaria control project. First of all, basic malaria surveillance data are necessary to determine the level of endemicity, assess the seasonality of transmission, and identify the level of risk in different population

groups. It can be more efficient to target some interventions to population groups at most risk for severe consequences of malaria infection, such as children, pregnant women, and nonimmune visitors to endemic areas. In some areas, drug efficacy testing will be needed to understand the relative prevalence of antimalarial drug-resistant parasites, and develop effective treatment and chemoprophylaxis policies. An understanding of local attitudes and beliefs is also important, since these can affect the acceptability of some interventions, particularly those that depend on changing human behavior. Finally, entomologic studies to identify the principle vectors are necessary for selecting appropriate vector control options. These scientific inputs should be used to devise an integrated malaria control program that will be well suited to local conditions of malaria epidemiology, the vector, climate, geography, and human populations. The array of possible combinations is vast, but includes four general types of intervention methods: case management, chemoprophylaxis and intermittent preventive treatment, personal protection, and vector control measures.

Case Management

Whereas vector control through residual spraying was the principal feature of malaria eradication, case management is the cornerstone of integrated malaria control activities in most endemic areas.¹³⁸ Prompt diagnosis and treatment of patients with uncomplicated malaria can prevent severe and complicated illnesses and avert deaths. It can also be a useful tool for controlling transmission. Diagnosis and treatment options vary widely from one endemic area to another depending on the level of transmission, the availability and cost of different antimalarial drugs, local patterns of antimalarial resistance, and the resources available for diagnosis and treatment. In areas of intense sustained transmission, particularly in sub-Saharan Africa, it is commonly recommended that all children with fever receive treatment for malaria. This approach has been adopted in many countries and has been incorporated into the WHO/UNICEF initiative for the integrated management of childhood illness (IMCI).¹³⁹ The most practical approach to diagnosis and management of febrile illness is less clear in areas of low malaria endemicity. Furthermore, because of the relative lack of health personnel and resources in many highly endemic areas, even this simple approach to case management is often difficult to implement and sustain.

Unfortunately, the spread of antimalarial drug resistance in recent years has further complicated case management efforts. The presence of multiple drug-resistant malaria in Southeast Asia has necessitated several rapid changes in recommended therapies. However, antimalarial treatment options in many nations still favor chloroquine as first-line drug, even where it is ineffective in more than half of *P. falciparum* infections. In 1993, Malawi became the first African nation to switch from chloroquine to sulfadoxine-pyrimethamine for first-line therapy of uncomplicated malaria. Similar policy changes have been made in other countries. Currently, many nations are adopting artemisinin-containing combination therapies (ACT) with support from international donors.

Recent international efforts to improve malaria case management in endemic countries have included the integrated management of childhood illness (IMCI), a clinical algorithm for simultaneously addressing malaria and the other major treatable causes of child mortality.¹³⁹ The intervention involves training health workers and providing adequate supplies and supervision. Health facility components of IMCI have been shown to reduce overall child mortality and improve health care delivery in malaria-endemic countries.^{140,141} Extending effective malaria case management beyond formal health facilities has also been shown to reduce severe malaria and child mortality.^{142,143} However, this approach remains controversial, especially as the spread of drug-resistant parasites has forced many endemic countries to abandon familiar antimalarial drugs like chloroquine in favor of newer regimens of unproven safety.

In addition to treating acute infections, some case management strategies in low transmission, or epidemic prone areas include follow-up treatment with primaquine. This strategy is generally recommended either to reduce the risk of relapse in *P. vivax* or *P. ovale* infections, or

to eliminate circulating gametocytes in treated patients. Eradicating gametocytes following treatment can be a useful method for blocking further transmission, however, the doses frequently used may not be sufficient to prevent all relapsing infections. Primaquine is rarely recommended in settings of intense transmission where reinfection is likely to occur before relapse.

Chemoprophylaxis and Intermittent Preventive Treatment

Antimalarial drugs are always recommended for prophylaxis of non-immune travelers visiting malaria-endemic areas. In some instances, chemoprophylaxis can also be an important component of malaria control activities in endemic areas, especially for groups at high risk of severe consequences from malaria, such as pregnant women, young children, and nonimmune migrant populations. In nonimmune travelers, the choice of drugs for prophylaxis must be made on an individual basis. Providers should consider the traveler's destination, the presence of antimalarial-resistant strains, the type of exposure and accommodations, the timing and duration of travel, and the traveler's age, drug allergies, other medications and medical history. Recommendations may also differ depending on the source of the advice and the range of antimalarial preparations available in the traveler's home country or destination. The recommendations of the U.S. Centers for Disease Control and Prevention (CDC) appear in Table 15-12. For places where chloroquine-resistant malaria has not been documented, weekly chloroquine is the drug of choice. For destinations where chloroquine-resistant *P. falciparum* is transmitted, weekly mefloquine, or daily doxycycline, or atovaquone-proguanil are recommended for prophylaxis. Chemoprophylaxis should be started one or two days before arriving in a malaria endemic destination (one week for mefloquine or chloroquine) and continued during travel and for four weeks after leaving the malarious area (1 week for atovaquone-proguanil).¹⁴⁴

Most of the antimalarial drugs commonly used for chemoprophylaxis (except atovaquone-proguanil) act only on intraerythrocytic stages of the parasite. Even when they are effective and used appropriately, these medications do not prevent primary infection, exoerythrocytic schizogony, nor the establishment of hypnozoites in the liver. An individual infected with *P. vivax* or *P. ovale* will only rarely develop clinical symptoms of the primary infection while taking effective antimalarial chemoprophylaxis, but may become acutely ill weeks or months later when the infection relapses from the dormant liver stage. A 14 day course of primaquine can eliminate hypnozoites in travelers exposed to intense or prolonged *P. vivax* or *P. ovale* transmission even if they have no symptoms. Postexposure prophylaxis with primaquine should not be given to most short-term travelers; it should be reserved for those with long-term rural exposures (such as returned missionaries or Peace Corps volunteers) or travelers returning from areas of intense *P. vivax* transmission (such as Papua New Guinea).¹⁴⁴

Large-scale chemoprophylaxis is generally not practical for whole populations residing in endemic areas long term and it may favor the development and spread of drug-resistant parasites. In endemic areas, chemoprophylaxis during pregnancy was widely recommended. This was so because even partially immune women become more vulnerable to malaria infection when pregnant and the infection can have devastating effects for both mother and child, including premature birth, anemia, low birth weight and infant death. Voluntary compliance with weekly chloroquine prophylaxis programs was quite poor. In areas with CRPF, intermittent treatment with two doses of SP during the second and third trimesters has been shown to reduce placental malaria infections and reduce the risk associated with malaria in pregnancy.¹⁴⁵ This strategy has been shown more effective than weekly chemoprophylaxis even in settings where chloroquine resistance is moderately low.¹⁴⁶

Currently this strategy of intermittent preventive treatment is recommended for pregnant women in most malaria-endemic countries. Community and individually randomized trials have demonstrated that the strategy of intermittent preventive treatment can also benefit other malaria risk groups including infants and children under five years.^{147,148} Studies are underway to establish the ideal drug regimen

TABLE 15-12. DRUGS RECOMMENDED BY THE U.S. CENTERS FOR DISEASE CONTROL AND PREVENTION FOR CHEMOPROPHYLAXIS OF MALARIA^a

<i>Drug</i>	<i>Adult Dosage</i>	<i>Pediatric Dosage</i>
Travel in areas with chloroquine-sensitive <i>Plasmodium falciparum</i> :		
(i) Chloroquine phosphate	300 mg base (500 mg salt) orally, once a week	5 mg/kg base (8.3 mg/kg salt) orally, once a week; up to maximum adult dose of 300 mg base/week.
Travel in areas with chloroquine-resistant <i>Plasmodium falciparum</i> : ^b		
(i) Mefloquine ^c	228 mg base (250 mg salt) orally, once a week	15–19 kg: 1/4 tablet weekly 20–30 kg: 1/2 tablet weekly 31–45 kg: 3/4 tablet weekly > 45 kg: 1 tablet weekly
(ii) Doxycycline	100 mg orally, once a day	> 8 years of age: 2 mg/kg orally, once a day up to maximum adult dose of 100 mg/day
(iii) Atovaquone-proguanil	1 adult tablet (250 mg atovaquone/100 mg proguanil) orally, once a day	Adult tablet: 250 mg atovaquone/100 mg proguanil Ped tablet: 62.5 mg atovaquone/25 mg proguanil 11–20 kg: 1 ped tab po qd 21–30 kg: 2 ped tab po qd 31–40 kg: 3 ped tab po qd >40 kg: 1 adult tab po qd
Prevention of relapses:		
Primaquine ^d	30 mg base orally, once a day for 14 days	0.6 mg/kg base orally, once a day for 14 days

^aChemoprophylaxis should begin 1–2 days prior to travel (1 week for mefloquine), continued while in the malarious area, and for 4 weeks after leaving the malarious area (1 week for atovaquone-proguanil).

^bDrugs used are equally effective and presented in no particular order.

^cMefloquine is contraindicated for persons with known hypersensitivity to the drug and is not recommended for persons with a history of serious psychiatric or seizure disorder. Small children who are given mefloquine for prophylaxis should receive a weekly dose of 5 mg/kg. Mefloquine should not be used by traveler to Thai-Cambodia and Thai-Burma borders.

^dPrimaquine can cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency. Primaquine should not be given during pregnancy.

Source: Adapted from CDC travel website: www.cdc.gov/travel.

and dosing schedule and quantify the survival benefit that intermittent preventive treatment could have in these age groups. A related but distinctly different strategy, mass drug administration, involves treating all members of a community with a curative dose of effective malaria treatment. This is occasionally attempted as a last-ditch effort to terminate a malaria epidemic. The value of mass drug administration is not evident except in some highly specific epidemiologic situations.¹⁴⁹

Personal Protection

There are numerous personal protective measures individuals can use to reduce their own and their household's risk of malaria infection by preventing contact with mosquitoes. Since no antimalarial is 100% effective for chemoprophylaxis, nonimmune travelers should also be advised to follow personal protective measures that reduce contact with infective mosquitoes. These include protective clothing, insect repellants, screening of windows and doors, and insecticide-treated curtains and bed nets. While personal protection measures can be effective at the individual level, their role in population-based control strategies is less clear.

In recent years, however, studies have demonstrated that community-wide distribution of insecticide-treated mosquito nets and curtains can reduce transmission and decrease malaria morbidity and mortality in nearly every transmission setting.¹⁵⁰ The strategy is best applied in settings where the vector bites primarily at night and indoors. The challenge will be translating positive research project findings into effective, sustainable, and equitable public health programs.^{151,152}

Vector Control

Vector control strategies were key elements in the malaria eradication effort and remain an important and valuable component of malaria control activities today. Among the vector control options available are insecticide spraying to kill adult mosquitoes and the use of pesticides and environmental measures to reduce mosquito larvae. In addition, a number of innovative vector control strategies are promising. The aim of vector control is to reduce human-mosquito contact, thereby reducing malaria transmission.

Differences in the behavior patterns of adult mosquitoes have a marked effect on their capacity to transmit malaria as well as on the choice of control methods used. Preferred time of biting, for example, can vary from daytime to late at night. The efficacy of many control measures varies depending on the mosquito activity cycle. For example, mosquito nets, an effective barrier to mosquitoes at night, probably have little effect on malaria transmission by daytime biters. Similarly, control measures that are used indoors, such as residual spraying with insecticides, may have little effect on mosquitoes that bite outdoors. Preferred resting sites (after a blood meal, the female "rests" while oogenesis proceeds) may be indoors where they can be targeted by house spraying or outdoors where spraying is not effective. Mosquitoes also exhibit biting preferences that affect their capacity to transmit malaria. Some are anthropophilic (preferring humans) while others select animals (zoophilic). Most, however, are opportunists and will bite humans if given a chance. Choosing when and where to implement a given vector control strategy, therefore,

requires a thorough understanding of the taxonomy and biology of local vector species.

Wide-scale spraying to kill adult mosquitoes was a prominent component of malaria eradication programs in many parts of the world. Insecticides with residual action lasting up to six months, sprayed on the inside walls of houses are most effective when most human-anopheline contact occurs indoors. In many settings of high transmission, insecticide-treated nets are frequently a more cost-effective approach.¹⁵³ However, residual spraying can be very valuable in specific circumstances, such as refugee settlements and agricultural and industrial development projects, where large numbers of nonimmune persons are introduced into endemic areas. More recently, malaria-endemic countries, multinational agencies, and donor governments have revitalized indoor residual spraying campaigns in a number of malaria-endemic settings.

Chemical application at breeding sites can kill mosquito larvae and, theoretically, reduce malaria transmission. Larger scale water management projects can also reduce mosquitoes and are credited with eradicating malaria from much of the southern United States. However, in many endemic areas, breeding habitats are too numerous and inaccessible to be treated or eliminated entirely through these approaches. The use of larvicides is, however, warranted in some settings, especially in urban areas where malaria transmission can frequently be linked to a discrete number of accessible breeding sites.

Future Vector Control Options

Although not yet fully operational, a number of innovative strategies for vector control appear promising. Biologic control agents and naturally occurring predators can be introduced to reduce the numbers of immature and adult stage mosquitoes. Aquatic plants and larvivorous fishes can reduce larvae in breeding sites.¹⁵⁴ Alterations of the vector genome may ultimately allow populations of malaria-transmitting mosquitoes to be replaced with genetically transformed mosquitoes that cannot sustain transmission.¹⁵⁵ Finally, vaccines that induce hosts to produce anti-vector antibodies may ultimately be able to alter parasite development and/or reduce the survival of mosquito vectors.¹⁵⁶

Vaccine Development and Testing

Development of malaria vaccines has proceeded along three lines. Sporozoite vaccines are directed against the stage of the malaria parasite that is injected into the human host when a mosquito takes its

blood meal. An effective sporozoite vaccine would protect the recipient from infection and thus, from all symptoms of a malarial illness. Merozoite or blood-stage vaccines are directed against the asexual blood stages of the parasite, which are responsible for malaria symptoms. It is likely that such vaccines would mimic naturally acquired immunity to malaria; recipients might continue to have occasional malarial illnesses, but the severity and duration of symptoms would be reduced and malaria-related mortality would be prevented. Transmission-blocking vaccines prevent development of the sexual stages of the malaria parasite in the human host or mosquito vector. Such vaccines would have no impact at all on an individual patient's symptoms, but would reduce the level of transmission within the community by rendering mosquitoes noninfective.

Numerous candidate vaccines have been developed, but no clearly effective vaccine has yet been identified. The first field trials of the asexual blood stage candidate vaccine, SPf 66, showed that it did not afford significant protection from *P. falciparum* malaria,^{157,158} despite earlier encouraging results from experimental trials. A recent report demonstrated promising results for a pre-erythrocytic vaccine in a clinical trial, although long-lasting immune response could not be achieved.¹⁵⁹

► CONCLUSION

Between the past history of an unsuccessful eradication program and the future promise of an effective vaccine and improved options for treatment and prevention, malaria remains a major public health concern worldwide. A growing number of strategies are currently available for malaria control, but none is universally effective or appropriate. Research is needed to develop additional options as well as to describe the best approaches to operationalizing existing strategies. At present, the best hope for malaria control in endemic areas is an integrated approach, which combines multiple strategies and which is carefully matched to local conditions of the parasite, vector, and human populations. In addition, in recent years malaria has received increased attention from international donors and policy makers world-wide and particularly in endemic countries. More resources are available for malaria control than at any time since the eradication era. These resources coupled with new treatment options and newly proven intervention opportunities promise to make significant progress against an ancient and persistent public health threat.

Lyme Disease

Larissa Minicucci

Lyme disease is a tick-borne zoonosis caused by the spirochete, *Borrelia burgdorferi*. Infection in humans may result in a multisystem, multistage, inflammatory disease principally affecting the skin, joints, nervous system, and the heart. Several syndromes comprising Lyme disease were recognized in Europe beginning in the late nineteenth century; however, the disease was first comprehensively described in Connecticut in 1977.¹ Rodents and ticks are the principal reservoirs and amplifying hosts of *B. burgdorferi* infection; deer are the usual maintenance hosts for tick vectors; and humans are incidentally infected when they intrude into the natural enzootic cycle. Lyme disease occurs throughout the temperate northern hemisphere and is the most commonly reported vector-borne disease in the

United States. From 1991–2002, the annual reported incidence in the United States doubled to more than 23,000 cases a year.² The disease is slowly expanding its geographic range, and the incidence of human cases continues to rise in both new and established foci of infection. The ecology and epidemiology of Lyme disease are complex, and practical methods for prevention and control at the community level require a multifaceted approach.

► AGENT

After considerable searching for an infectious cause of Lyme disease, novel spirochetes were identified in the midgut of the adult deer tick, *Ixodes dammini* (the black-legged tick, now known as *Ixodes scapularis*).³ The spirochete was cultured from ticks in a modified Kelly's medium (BSK), and shortly thereafter cultured from the blood, skin, and cerebrospinal fluid of patients with early Lyme disease. The spirochete was named *Borrelia burgdorferi* in 1984 (Fig. 15-5).⁴

Note: The findings and conclusions in this chapter are those of the author and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Figure 15-5. *Borrelia burgdorferi*, the spirochetal agent that causes Lyme disease. (Source: Photo courtesy of Dr. Robert Gilmore, CDC.)

Borreliae are flexible helical cells comprised of a protoplasmic cylinder surrounded by a cell membrane, periplasmic flagella, and an outer membrane that is loosely associated with the underlying structures.⁵ The genome of *B. burgdorferi* was sequenced in 1997⁶ and found to contain a linear chromosome with twelve linear and nine circular plasmids.⁷ *B. burgdorferi* is comprised of several immunogenic lipids, carbohydrates, and proteins, including three major outer-surface proteins, Osp-A (30 kDa), OspB (34 kDa), and OspC (23 kDa), and a prominent 41 kDa antigen located on the flagellum.⁸

A number of genetic differences have been described within and between *B. burgdorferi* genospecies from Europe and the United States. The strain infecting humans in the United States is designated *B. burgdorferi*, *sensu stricto*, of which strain B31 is the prototype; the two dominant *B. burgdorferi* genospecies in Europe and Asia are *Borrelia garinii* and *Borrelia afzelii* (Group V5461).⁹ While all three *Borrelia* species typically cause erythema migrans (EM) at the location of the tick bite, they appear to have somewhat different disease courses. Arthritis appears to occur more frequently following infection with *B. burgdorferi*; neurologic manifestations are more common with *B. garinii*; and cutaneous manifestations occur more frequently in association with *B. afzelii* infection.¹⁰

► ECOLOGY

Arthropod Vectors

Cycles of *B. burgdorferi* are found throughout temperate North American and Eurasian regions in the range of *Ixodes ricinus* complex ticks. *I. scapularis* is the principal vector in the northeastern and upper midwestern United States (Fig. 15-6); *I. pacificus* transmits *B. burgdorferi* in the western United States; *I. ricinus* is the principal

vector in western and Central Europe extending into parts of Asia; and, *I. persulcatus* is the main vector in central and eastern Russia, China, and Japan.¹¹

In the United States, spirochete infection rates in adult ticks vary by region with 73% of *I. scapularis* ticks in the northeast, 57% of *I. scapularis* ticks in the Midwest, and 4% of *I. pacificus* ticks in the Pacific region found to be infected.¹² Infection rates in nymphal ticks similarly vary by region; this life stage is believed to be responsible for most human cases, as peak nymphal activity between April and August strongly coincides with the peak incidence of disease onset in humans. In the endemic northeast, nymphal infection up to 24.4% has been found,¹³ and in northern California a slightly lower rate of 13.6%.¹⁴

Utilizing indirect fluorescent antibody staining (IFA), evidence of *B. burgdorferi* has been identified in other ticks and blood-sucking insects, such as mosquitoes, horse flies, and deer flies. However, there is no indication that the organism is adapted for survival in these arthropods, or that mechanical transmission has any epidemiologic importance.¹⁵

Environmental Factors

In the eastern United States, *I. scapularis* is most often found in deciduous forest habitat with abundant leaf litter.¹⁶ This habitat is essential as these ticks require shade and a high humidity in their microenvironment to prevent desiccation.¹⁷ A study of tick distribution on large suburban residential properties in Westchester County, New York found infected *I. scapularis* ticks on 60% of properties, with the greatest tick densities occurring in wooded areas, followed by fringe habitat, and much lower densities among ornamental shrubbery and on lawns.¹⁸ Similarly, in the central United States, *I. scapularis* is most often associated with deciduous forests and moist soils with sandy or loam textures. Ticks are not associated with grassland areas or conifer forests in this region.¹⁹ In the Pacific region, *Ixodes pacificus* have been found in redwood and Douglas fir forests as well as open grasslands. However, the *Ixodes* sp. ticks can demonstrate flexibility and inhabit diverse habitats such as dense shrub-like areas along coastal regions.²⁰

Vertebrate Hosts

I. scapularis larvae and nymphs can be found on at least 31 species of mammals and 49 species of birds.¹¹ However, in the endemic northeastern United States, the white-footed mouse (*Peromyscus leucopus*), serves as the preferred vertebrate host for the immature stages of the tick vector, and it is the most competent vertebrate reservoir of *B. burgdorferi*, typically with infection rates of up to 75%.²¹ The chipmunk is also a competent reservoir host in the eastern United States and may be more important than the white-footed mouse in maintaining cycles of infection the north central region.²²

Deer, mainly white-tailed (*Odocoileus virginianus*), have an essential role in the enzootic cycle of Lyme disease in North America, acting as the principal host for adult *Ixodes* sp. ticks. Interestingly, the rapid increase in the deer population during the latter half of the twentieth century appears to have coincided with the emergence of Lyme

Figure 15-6. Various life stages of the *Ixodes scapularis* tick, vector of *Borrelia burgdorferi*.

Figure 15-7. Schematic diagram of the life cycle of *Ixodes* sp. ticks, the vectors for *Borrelia burgdorferi*. Infection moves from the rodent reservoir to larval and nymphal stages, and transstadially from larva to nymph to adult tick. Humans are most often exposed in late spring and early summer after the bite of a nymphal tick.

disease.²⁰ However, deer do not appear to be an important reservoir for *B. burgdorferi* as cervid serum has borreliacidal properties.²³

The low infection rates of *Ixodes* vectors in the southern and western regions of the United States may be partly explained by the preferential feeding of immature stages of the tick on lizards. Lizards have been found to be incompetent reservoirs for *B. burgdorferi*.²⁴ It is known that several bird species serve as maintenance hosts for tick vectors, and some, such as robins, may serve as lesser reservoir hosts of *B. burgdorferi*.²⁵

Life Cycle

The life cycle of the *Ixodes* tick spans a 2-year period (Fig. 15-7). The basic elements involved in this cycle in North America include three stages of the tick (larva, nymph, adult), each of which typically takes one blood meal, and several reservoir hosts, mainly small rodents such as the white-footed mouse and the chipmunk. Deer and other large- and medium-sized animals serve as a mating ground for adult ticks and provide adult females with the blood meal required for egg production.

Larvae most frequently feed in the summer from July through September, and nymphs typically feed from May to July. This reversed feeding pattern may promote transmission of *B. burgdorferi* since nymphs feeding in the spring may infect rodents that later in the year will serve as a source of infection for larvae. Adult females feed mainly during the fall, but can also feed throughout winter and early spring. Transstadial transmission of *B. burgdorferi* from larva to nymph helps maintain the infective cycle, while transmission from an infected adult female to her eggs rarely occurs.^{11,26}

In Eurasia, the cycle is quite similar, although the bank vole (*Clethrionomys glareolus*) and wood mouse (*Apodemus* sp.) serve as the principal rodent reservoirs of infection, and the roe deer and other cervids typically serve as maintenance hosts for vector ticks.²⁰

Humans are incidental hosts of *B. burgdorferi*. In the United States, persons are most often infected by the bite of nymphal-stage ticks, usually in the late spring and early summer, and much less frequently by adult female ticks, which feed mostly in the late fall and winter. Due to their smaller size, nymphs may be more likely to escape detection and feed for a period sufficient to transmit infection.²⁰

► DISEASE MANIFESTATIONS AND MANAGEMENT

Clinical Manifestations

Infection with *B. burgdorferi* may manifest either as an asymptomatic or subclinical infection, or as Lyme disease, an inflammatory process that generally can be categorized into early localized, early disseminated, or late disseminated stages of infection.²⁷ The portal of entry for *B. burgdorferi* is the dermis, at the site of infective tick attachment, and the spirochete will live primarily as an extracellular pathogen.⁶ Following inoculation, infection spreads by cutaneous, lymphatic and hematogenous routes.

Early Localized. After an incubation period of 7–10 days (range 3–32 days), 70–80% of patients develop a characteristic erythema migrans (EM) rash, which is the hallmark of early localized infection. This expanding, annular, erythematous rash is usually accompanied by mild constitutional symptoms of fever, headache, myalgia, arthralgia, and occasionally by regional lymphadenopathy.

Early Disseminated. Early disseminated infection usually occurs within days to weeks after the onset of localized infection. The skin, nervous system, musculoskeletal system, and heart may be affected. Multiple, secondary EM lesions may occur. Some patients develop neurologic signs and symptoms, most commonly aseptic (lymphocytic) meningitis, cranial neuropathy, or radiculoneuritis. Many patients also describe migratory musculoskeletal pains in joints, bursae, tendon, muscle, or bone. Persons with early disseminated Lyme disease may also develop cardiac conduction abnormalities, most often mild, transient atrioventricular block.

Late Disseminated. Manifestations of late disseminated disease occur weeks to months after infection in approximately 60% of untreated patients. The most common late-stage manifestation is intermittent oligoarticular arthritis in one or a few joints, usually large, weight-bearing joints, such as the knee. Less frequently, persons with late disseminated infection develop neurologic symptoms including subtle cognitive disturbances, spinal pain, or distal paresthesias.^{27,28}

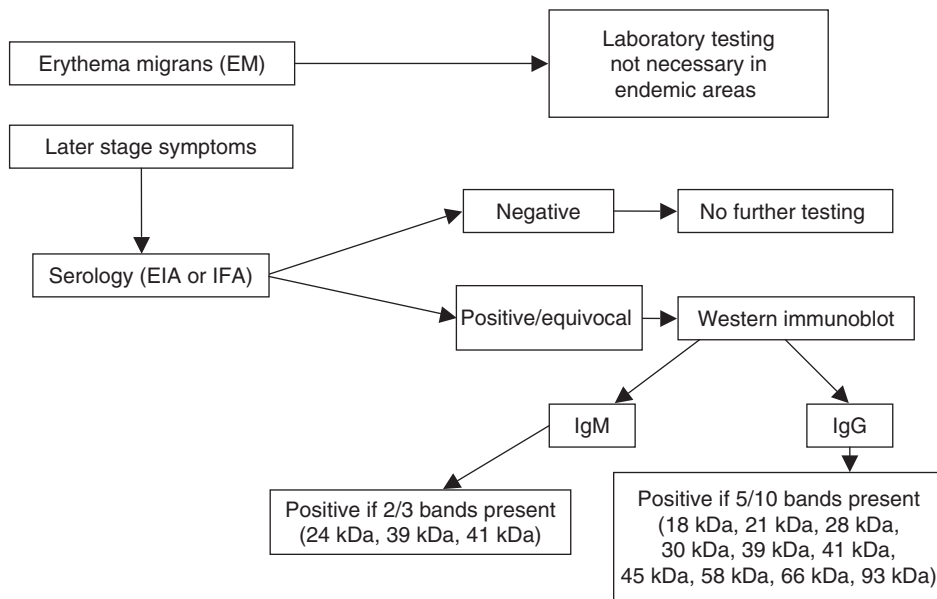

Figure 15-8. Diagnostic algorithm for clinical and laboratory diagnosis of Lyme disease. Western Blot interpretive criteria are provided.

Diagnosis

A clinical diagnosis of Lyme disease can be made in persons presenting with characteristic early manifestations, such as EM, in an endemic area. History of recent tick exposure significantly increases the probability of a true diagnosis of Lyme disease, and laboratory testing is generally unnecessary in such individuals.

Serodiagnostic testing may be indicated when clinical signs indicate late-stage disease (i.e., arthritis), when a presentation is atypical, or when a history of exposure is not clear. The recommended test approach utilizes a sensitive first test, either enzyme-linked immunosorbent assay (EIA) or indirect fluorescent antibody (IFA) testing, followed by Western immunoblotting (WB) of specimens that test positive or equivocal using the first test. Specimens that test negative by EIA or IFA do not require further testing. Specific WB banding criteria have been recommended for both IgM and IgG antibodies (Fig. 15-8).²⁹ IgM antibodies typically appear within the first several weeks after exposure, and this response may persist for months or years. IgG antibodies can be detected in most patients after one month of active infection, and likewise may persist for years after symptoms have resolved.⁸ Antibiotic treatment of early localized disease may blunt or abrogate the immune response;³⁰ however, seronegative late-stage Lyme disease is uncommon. Therefore, clinical history should be considered when interpreting serologic test results.

While much less common than serologic methods, other diagnostic modalities may include culture or polymerase chain reaction (PCR). *B. burgdorferi* can be cultured from 80% or more of biopsy specimens taken from early EM lesions.³¹ Culture of other specimens including blood, cerebral spinal fluid (CSF), and synovial fluid is less rewarding. PCR has been successfully utilized as a research tool on clinical specimens such as skin biopsies, blood, synovial fluid, and CSF;³² however, the use of PCR as a primary diagnostic tool is not supported.³³

Some laboratories offer tests that have not been adequately evaluated for accuracy and clinical usefulness, including urine antigen tests, immunofluorescent staining for cell wall-deficient forms of *B. burgdorferi*, and lymphocyte transformation tests. Use of these tests is not recommended.³⁴

Clinical Management

For patients exhibiting clinical signs consistent with Lyme disease, having a history of exposure in an endemic area, and/or laboratory confirmation of Lyme disease, antibiotics should be administered based on clinical signs and duration of illness. The Infectious Disease

Society of America has published guidelines for the treatment of Lyme disease.³⁵ Untreated and inadequately treated infection may result in subsequent cardiac, dermatologic, neurologic, or musculoskeletal sequelae.

Morbidity can infrequently be severe, chronic, and disabling, especially if the disease is not treated in its early stages, but Lyme disease is rarely, if ever, a principal cause of death. Similarly, maternal Lyme disease is not a proven cause of intrauterine death or congenital malformations, although this association has been suggested.³⁶ Infection does not confer lasting protective immunity, and more than one occurrence of primary EM is not uncommon among persons at high environmental risk.³⁷

Concurrent infection with other tick-borne illnesses is a possibility in Lyme disease patients. Coinfection with *B. burgdorferi* and *Babesia microti* (the agent of babesiosis) has been associated with a severity and duration of illness greater than expected for either infection alone.³⁸ The importance of differentiating illness caused by *Borrelia*, *Babesia*, and *Ehrlichia* spp., and other as yet unidentified agents transmitted by the same tick vectors, has recently been highlighted.^{39,40}

► EPIDEMIOLOGY

Transmission to Humans

Lyme disease is transmitted through the saliva of an attached feeding tick. There is no evidence that *B. burgdorferi* is passed directly from one person to another, and infection is not known to be transmitted by sexual contact or through breast milk.⁴¹ Transplacental infection of the fetus has been documented in several case reports; however, these reports have been unable to confirm that *B. burgdorferi* is a cause of fetal illness.³⁶ Although *B. burgdorferi* can be cultured from blood in just over 40% of individuals with early untreated acute infection,⁴² transfusion-acquired infection has not been documented.⁴³

Global Distribution

Endemic Lyme disease occurs in portions of the United States and Canada, the British Isles, Scandinavia, western Europe, and states of the former Union of Soviet Socialist Republics, from the Baltics east through Russia to the Pacific Coast. Lyme disease has also been reported from northeastern China and eastern regions of Japan.⁴⁴ Distribution within Canada is localized to areas of southern British Columbia and the southeastern region of Ontario.⁴⁵ In the highly

Figure 15-9. Number of reported Lyme disease cases by year—United States, 1991–2003.

endemic areas of North America and Europe, Lyme disease incidence and epidemiologic patterns are similar.⁴⁶

Surveillance Statistics for the United States

Lyme disease was made a nationally notifiable disease in 1991. A uniform national case definition was adopted for surveillance purposes at that time, and reporting is now mandatory in all 50 states.² Lyme disease is the most commonly reported vector-borne infectious disease in the United States. In 2003, a total of 21,273 cases of Lyme disease were reported by 44 states and the District of Columbia, compared with 9470 cases in 1991 (Fig. 15-9). The national incidence of reported cases was 7.2 per 100,000 population in 2003. Cases are concentrated in the northeastern region, the north-central region, and in northern California (Fig. 15-10). Incidence rates greater than 7.2 per 100,000 population were reported by 12 states (Rhode Island [68.39], Pennsylvania [46.34], Connecticut [40.28], New Jersey [33.42], New York [28.13], Delaware [25.93], Massachusetts [23.81], New Hampshire [14.76], Wisconsin [13.52], Maine [13.40], Massachusetts [12.54], and Minnesota [9.37]). These states account for more than 95% of all reported cases nationally.⁴⁷

Lyme disease affects persons in all age groups, but the highest rates are found in children aged 5–9 years and adults aged 55–59 years. Males and females are nearly equally affected with males accounting for 53% of cases in 2003.⁴⁷

Lyme disease case reporting is subject to misclassification, misdiagnosis, and underreporting. In Connecticut, from 1991–1992, only 7% of physicians comprising the four primary care specialties that report the majority of all Lyme disease cases had reported a case. Follow-up interviews with a sample of physicians in the four specialty areas suggested that less than 20% of all cases diagnosed and treated as incident cases of Lyme disease had been reported.⁴⁸ A 1996 study in Maryland suggested that Lyme disease was underreported by 10- to 12-fold in that state, and that many more patients are seen and treated for presumptive Lyme disease and for tick bite alone than patients meeting the case criteria for reporting.⁴⁹

Lyme Disease Emergence

Lyme disease is one of a number of emerging tick-borne diseases in the United States.⁵⁰ Several accounts from at-risk areas have demonstrated a rapid increase in Lyme disease incidence. A longitudinal study of a community of about 160 persons residing in Great Island, Massachusetts, found a slow buildup of incidence to a peak of 3 cases per 100 residents with a total cumulative prevalence of 16% over a 20-year period.⁵¹ A similar restricted population in the northern coastal area of Ipswich, Massachusetts, experienced an epidemic of Lyme disease in the 1980s. The attack rate from 1980 through 1987 was 35% among 190 residents living within 5 km of a nature preserve heavily infested with ticks.⁵²

Figure 15-10. Reported cases of Lyme disease, by county—United States, 2003.

One dot placed randomly within country of residence for each reported case.

The introduction and buildup of Lyme disease to highly endemic levels within some states and regions is a considerable public health concern. This occurrence has been most pronounced in suburban residential areas in northeastern states.⁴⁴ Such rapid emergence has been well documented in New York State: the number of counties endemic for Lyme disease increased from four to eight from 1985 to 1989, and the number of counties with documented *Ixodes* ticks increased from four in 1985 to 22 in 1989.⁵³ The possibility of rapid emergence continues to exist in other known endemic areas due to growing deer populations that support the *Ixodes* tick vector, increased residential development of wooded areas, and tick dispersal to new areas.²

Movement of deer and increased reforestation are considered the principal factors in the geographic spread of Lyme disease,⁵⁴ although migrating birds may also play a role in the dispersal of infected ticks.⁵⁵ Studies mapping the distribution of ticks, reservoir rodent hosts, seropositivity of animals such as dogs and deer, and the incidence of human cases over time provide valuable information on the spread of Lyme disease in the United States. Seropositivity of dogs appears to be a sensitive and reliable epidemiologic marker of the geographic distribution of *B. burgdorferi*.⁵⁶

Areas with Unconfirmed Endemicity

The reporting of cases from areas where ticks are not known to transmit *B. burgdorferi* to humans, such as throughout many southern, midwestern, and mountain states, remains enigmatic. In the southern United States, *I. scapularis* has a low *B. burgdorferi* infection rate and rarely feeds on humans.⁵⁷ Epidemiologic studies in Missouri of persons with EM-like lesions and of area-matched controls provide evidence that the disease there is associated with the bites of the lone star tick (*Amblyomma americanum*), and is not caused by *B. burgdorferi* or other known tick-borne infection. The lone star tick is widely distributed throughout the southern and mid-Atlantic regions, and it is the most common human-biting tick in the South.⁵⁸ A spirochete named *Borrelia lonestari* has been cultured successfully from *A. americanum* ticks⁵⁹ and implicated as the causative agent of EM in a patient following the bite of an *A. americanum* tick.⁶⁰ However, additional work has failed to show a link to either *B. burgdorferi* or *B. lonestari* as the cause of EM in individuals residing in the southeast and south-central United States.⁶¹ Enzootic cycles of *B. burgdorferi* involving *I. dentatus* ticks and rabbits in the eastern and southern United States,⁶² and *I. spinipalpis* ticks and wood rats in the Rocky Mountain foothills of eastern Colorado,⁶³ are not believed to pose a public health risk since these ticks rarely feed on humans.

Risk Factors for Infection with the Lyme Disease Spirochete

Lyme disease is a disease of place. The principal risk factor for Lyme disease in the United States is permanent or seasonal residence in an area with a high infestation of infected ticks. Clustering of cases by county, by township, and even by neighborhood is highly correlated with the abundance in the environment of tick vectors. Others at relatively high risk include persons who live or vacation in northeastern coastal areas and in northcentral woodlands.⁶⁴ Persons at greatest risk are residents of rural or suburban properties that are wooded or are contiguous with wooded tracts inhabited by deer.⁶⁵ The presence of ground cover and leaf litter in the yard as well as actively participating in clearing brush in spring and summer revealed significant associations with Lyme disease.^{66,67}

Recreational activities in natural areas, such as hiking, camping, fishing, and hunting also expose persons to infective tick bites, especially during the late spring and summer months. Specifically, outdoor use of maintained trails for more than five hours per week⁶⁸ and gardening for more than four hours per week⁶⁵ have been shown to be risk factors for the development of Lyme disease. Checking for ticks during outdoor activity and use of repellents prior to outdoor activities have been both associated with a reduced risk of Lyme disease.⁶⁵

Outdoor occupations, such as landscaping, brush clearing, forestry, and wildlife and parks management, may place persons at

high risk in some areas. A comprehensive study of workers in endemic counties of southeastern New York showed that persons with a history of outdoor employment were twice as likely to be seropositive as those without such a history. Although this difference was not statistically significant, the seroprevalence rate of outdoor employees was 5.9 times higher than a comparison group of anonymous blood donors from the same region of New York.⁶⁹

Pet ownership may pose a slight risk as animals may bring unattached nymphal ticks into the home, placing humans at risk for tick bites. Ownership of cats has been found to be associated with an increased risk of acquiring Lyme disease in several small studies.^{70,71} A study of dogs and persons living in the same households in two highly endemic areas in Massachusetts showed that dogs were more likely to have serologic evidence of *B. burgdorferi* infection than their human coresidents, but dog ownership was not associated with an increased risk for their owners.⁷² Dogs, however, may act as competent reservoirs for the Lyme disease spirochete, and therefore, it would be prudent to utilize tick prevention measures such as collars and repellents on pet dogs.⁷³

► PREVENTION

Prevention of Lyme disease can be accomplished through personal protective measures, clinical interventions, environmental modifications, and community interventions.

Personal Measures

The public should be informed about tick-infested areas in endemic regions and should be encouraged to avoid risky exposures, especially in spring and summer.⁷⁴ Information on the distribution of ticks in an area can usually be obtained from health departments, park personnel, or agricultural extension services.

One of the most important preventive measures is the early detection and proper removal of attached ticks. When in tick-infested areas, a daily check for ticks and their proper removal is an important measure to prevent infection. Studies have shown that transmission of *B. burgdorferi* from an infected tick is unlikely to occur during the first 24–36 hours of attachment.^{75,76} Tweezers should be used to grasp the tick mouthparts, removing the tick by steady, gentle traction.

Additional precautions to take in tick-infested areas include wearing long sleeved shirts, and tucking pants into socks or boot tops to prevent ready access of ticks to skin.^{77,78} Insect repellents containing N,N-diethyl-meta-toluamide (DEET) (up to 30% concentration) can be applied to exposed skin other than the face, and DEET or permethrin compounds (which kill ticks on contact) can be sprayed on clothing.^{77,79}

Clinical Interventions

Early recognition and appropriate treatment of EM is one of the best strategies to prevent complications of Lyme disease in the clinical setting.⁷⁴ Antibiotic prophylaxis to prevent Lyme disease after a known tick bite is not routinely warranted, but may be considered in specific circumstances. A recent study has shown that a single prophylactic dose of doxycycline given within 72 hours after a tick bite can reduce the risk of developing Lyme disease.⁸⁰ The risk of asymptomatic infection or disease in untreated persons, however, remains low at less than 5%, even when bitten by known vector species in highly endemic areas.⁷⁵ A human vaccine for Lyme disease was previously available, but was withdrawn from the market in February 2002 reportedly due to low sales.⁷⁴ Thus, this prevention modality is no longer available, but three vaccines are currently available for dogs.⁸¹

Environmental Modifications

In endemic residential areas of the northeastern United States, wood lots and unkempt edges of yards pose a significantly greater risk than lawns and ornamental shrubby areas.¹⁸ Removing leaf litter and woodpiles, clearing trees and bushes around houses and yard edges, and consistent mowing will remove habitat suitable for deer, ticks, and rodent

reservoirs of infection, resulting in a reduction in the number of ticks that transmit Lyme disease in the ensuing transmission seasons.^{82,83}

Area application of acaricides to residential properties has been found to be highly effective in suppressing vector ticks,⁸⁴ but targeted approaches may be warranted due to the variable effects on nontarget arthropod species.⁸⁵ New approaches have been designed to interrupt the transmission cycle at the level of the rodent reservoir. A product in which mice are treated with the acaricide, fipronil, upon entering a bait box demonstrated a reduction in tick infestations on white-footed mice in a southeastern Connecticut community.⁸⁶

Trypanosomiasis

Louis V. Kirchhoff

► AMERICAN TRYPANOSOMIASIS (CHAGAS' DISEASE)

American trypanosomiasis, or Chagas' disease, is caused by the protozoan hemoflagellate *Trypanosoma cruzi*.¹ This parasite is enzootic and endemic in Latin America and the southern and southwestern United States. Only a handful of instances of vector-borne transmission of *T. cruzi* to humans in the United States have been reported. The number of *T. cruzi*-infected persons living here, however, has increased markedly in recent decades as large numbers of people have emigrated from the endemic countries in Latin America to the United States.² As many as 80,000–120,000 of these immigrants may be infected with *T. cruzi* and they present diagnostic and therapeutic challenges to the persons who provide their medical care. Moreover, since most of these infected persons harbor the parasite asymptotically, they pose a risk of transmission of the parasite by blood transfusion and organ transplantation, and 10 such cases have already been described here.^{3–5}

Biology and Transmission

Transmission of *T. cruzi* to its mammalian hosts typically occurs when feces of a blood-sucking insect vector containing infective organisms contaminate mucosal surfaces, the conjunctivas, abrasions, or the bite wound. The parasites penetrate local cells and after multiplying intracellularly, as the host cell dies, infective forms are released and invade adjacent cells or are swept to distant sites via the lymphatics or the bloodstream. In this manner a cycle is established in the mammalian hosts of *T. cruzi* that alternates asynchronously between non-dividing infective forms that circulate in the bloodstream and intracellular multiplying forms. The cycle is completed when an insect vector ingests blood containing the circulating infective forms. Not surprisingly, transfusion of blood donated by persons who harbor *T. cruzi* can result in new infections,⁶ as can transplantation of organs obtained from infected donors. In addition, *T. cruzi* can be passed from mother to fetus, causing spontaneous abortion or congenital Chagas' disease,⁷ and laboratory accidents resulting in transmission of the parasite occur with disquieting frequency.⁸

Pathology and Clinical Features

Acute Chagas' disease is usually a mild illness with a death rate of less than 5%. As parasites spread hematogenously from the site of initial entry and multiplication, they can cause malaise, fever, edema of the face and lower extremities, hepatosplenomegaly, and generalized lymphadenopathy. Muscles are often parasitized, and severe myocarditis develops in a small number of patients with acute infections.⁹ The organisms can also invade the central nervous system, and meningoencephalitis is a rare complication.¹⁰ In immunocompetent persons, acute Chagas' disease resolves spontaneously over 4–8 weeks, and patients then enter the indeterminate phase of

Community Interventions

There are no known practical measures for controlling tick vectors over large areas. Management of deer populations and control of ticks on deer may be effective strategies for reducing the intensity of enzootic transmission in already established foci of infection.⁸⁷ The control of ticks on deer using self-dosing systems for applying topical acaricides has shown some success in pilot trials.⁸⁸ However, community education addressing methods of tick control and preventive measures against Lyme disease may be the most effective strategy utilized at the community level.⁷⁴

T. cruzi infection. This asymptomatic phase is characterized by subpatent parasitemias and for the most part easily detectable antibodies to a variety of *T. cruzi* antigens. Most infected persons remain in the indeterminate phase for life, and this sets the stage for transmission of the organism by transfusion and organ transplantation.

Years or decades after the resolution of acute *T. cruzi* infection, symptomatic chronic Chagas' disease develops in approximately 10–30% of infected persons. The heart is most commonly affected, and pathologic changes can include thinning of ventricular walls, biventricular enlargement, mural thrombi, and apical aneurysms.¹¹ Lymphocytic infiltration, diffuse interstitial fibrosis, and atrophy of myocardial cells are often seen in stained specimens. The conduction system is often affected, typically causing right bundle branch block, left anterior fascicular block, and third-degree atrioventricular block. Associated symptoms reflect the cardiomyopathy, rhythm disturbances, and thromboembolism that gradually develop, and death usually results from heart block or congestive heart failure.^{12,13} In some patients megaesophagus and/or megacolon (megadisease) develop and cause regurgitation, dysphagia, repeated aspiration, and constipation.¹⁴ The pathogenesis of the lesions associated with chronic *T. cruzi* infection is not well understood, but the current consensus is that inflammation resulting from the persistent presence of parasites, resulting in denervation in affected organs plays a primary role.^{15,16}

Immunosuppression of patients who harbor *T. cruzi* chronically can cause a recrudescence of the infection, often with features that are atypical of acute Chagas' disease in immunocompetent persons.¹⁷ This is particularly true in Chagas' disease patients who undergo cardiac transplantation,¹⁸ as well as in persons coinfecting with *T. cruzi* and the human immunodeficiency virus.^{19,20}

Epidemiology

T. cruzi is found only in the Americas, where it is distributed unevenly from the southern United States to Chile and Argentina in triatomine insect vectors (kissing bugs) and many species of wild and domestic mammals. Humans become part of the cycle of transmission when infected insects take up residence in the primitive adobe, wood, and stone houses that are common in many parts of Latin America. Most new *T. cruzi* infections occur among poor children in rural areas and result from contact with infected vectors, and small numbers of transfusion recipients become infected each year in areas in which effective screening of donated blood is not universal.⁶ The incidence of acute Chagas' disease is unknown because most cases go undiagnosed. An estimated 10–12 million persons are chronically infected with the parasite, and roughly 25,000 deaths due to chronic Chagas' disease are thought to occur each year.

Acute Chagas' disease is uncommon in the United States. The total of autochthonous,²¹ transfusion-associated,⁴ organ transplant-related,⁵ and imported cases of acute *T. cruzi* infection in the past 30 years is about two dozen. Importantly, no acute infections among United States

tourists returning from endemic areas have been reported. In contrast, the number of persons with chronic *T. cruzi* infections in the United States has grown enormously as immigration from Latin America has burgeoned, especially from Mexico and Central America. Current estimates put the number of immigrants from Chagas-endemic countries now living in the United States at 13 million,^{2,22} 80,000–120,000 of whom are thought to be infected with *T. cruzi*.

Diagnosis

Acute Chagas' Disease. The first consideration in diagnosing acute Chagas' disease is establishing that possible exposure to *T. cruzi* has occurred. Exposure can result from residence in an area in which vector-borne transmission of the parasite occurs, a recent blood transfusion in an endemic area, in which universal screening has not been implemented being born to a mother who is at risk of harboring *T. cruzi*, or a laboratory accident involving the parasite.

The diagnosis of acute Chagas' disease is made by detecting parasites, and serological tests are not useful. In immunocompetent patients, examination of blood is the cornerstone of detecting *T. cruzi*. Circulating parasites are highly motile and frequently can be seen in wet preparations of buffy coat or anticoagulated blood. The organisms may also be seen in Giemsa-stained blood smears. In immunocompromised patients suspected of having acute Chagas' disease, other specimens such as bone marrow aspirates, cerebrospinal fluid, pericardial fluid, and lymph nodes should be examined microscopically. If these approaches fail to detect *T. cruzi* in a patient whose epidemiologic and clinical histories suggest that the parasite is present, growing the organism may be attempted. This can be done by xenodiagnosis, a method that involves feeding a patient's blood to laboratory-reared insect vectors, or preferably by culturing blood or other specimens in liquid medium.²³ These two methods take at least a month to complete, however, and this is far beyond the time at which decisions about drug treatment need to be made. Polymerase chain reaction-based assays have shown promise for diagnosing both acute and chronic *T. cruzi* infections,²⁴ but a lack of sensitivity has been a variable problem and to my knowledge none of these tests is available in kit form.

Chronic Chagas' Disease. Chronic Chagas' disease is usually diagnosed by detection of IgG that binds to specific *T. cruzi* antigens, and parasitologic studies are unnecessary. Many commercial serologic tests are used widely in Latin America, such as indirect immunofluorescence (IIF), and enzyme-linked immunosorbent assay (ELISA). A persistent problem with many of these assays, however, is the occurrence of false-negative and false-positive results. The latter typically occur with samples from persons having leishmaniasis, malaria, syphilis, autoimmune diseases, and other parasitic and nonparasitic illnesses. Because of this lack of accuracy, most authorities recommend that blood specimens be tested in two assays based on differing methodologies before results are accepted as definitive.²⁵

In the United States, specimens can be sent to the CDC for testing by IIF (770-488-4474). In addition, ELISAs manufactured by Hemagen Diagnostics (Columbia, MD) and Laboratorios Wiener (Rosario, Santa Fe, Argentina) have been cleared by the Food and Drug Administration (FDA) for clinical use. Finally, in my laboratory (319-335-6786), a radioimmune precipitation test (RIPA) is available. This test was shown to be highly sensitive and specific when used to test a geographically diverse group of sera from patients with Chagas' disease and control subjects,²⁶ and it has been used as a confirmatory assay in essentially all studies of *T. cruzi* infection in United States blood donors.^{27,28}

Treatment

Nifurtimox (Lampit, Bayer 2502) and benznidazole (Radimil, Roche 7-1051) are the only drugs currently recommended for treating patients with Chagas' disease. Although the parasitological cure rates are roughly the same for the two drugs, the side effects of benznidazole are less bothersome, and in Latin America it is considered the drug of choice.²⁹ Cure rates of more than 90% can be achieved in babies with congenital Chagas' disease treated in the first year of life³⁰, and perhaps

70% of patients with acute Chagas' disease are cured by full courses of treatment. Regarding chronic *T. cruzi* infections, the current consensus is that all infected people 18-years-old or less should be treated with one drug or the other, as it has been shown that a substantial portion of such patients can be cured. Cure rates among persons with decades-long *T. cruzi* infections may be less than 10% and long term benefit of such treatment has not been demonstrated clearly. Nifurtimox can only be obtained from the Drug Service of the Centers of Disease Control and Prevention (404-639-3670). Benznidazole is not available here.

Beyond the possible use of antiparasitic drugs, treatment of both acute and chronic Chagas' disease is symptomatic. In patients with symptomatic chronic heart disease therapy is directed toward ameliorating symptoms through the use of cardiotropic agents and anticoagulants. Pacemakers have been shown to be useful in patients with ominous rhythm disturbances associated with Chagas' disease. Cardiac transplantation is a viable albeit expensive option for patients with end-stage chagasic cardiomyopathy, and well more than 100 such transplants have been done in Brazil and the United States. Even though reactivation of acute Chagas' disease has occurred postoperatively in a substantial proportion of these patients and lymphomas have arisen as well, the overall survival of chagasic heart transplant patients has been better than that of patients transplanted for other reasons.¹⁸

Megaesophagus associated with chronic *T. cruzi* infections should be treated as is idiopathic achalasia, which may involve laparoscopy myotomy. Megacolon usually can be managed with high fiber diets and laxatives, but the occurrence of toxic megacolon and volvulus require surgical intervention.

Control

Since drug treatment is problematic and vaccines are not available, reducing *T. cruzi* transmission in Latin America must depend on serologic identification of infected donors in blood banks and on reducing contact with insect vectors through housing improvement and spraying of insecticides. Enormous progress in controlling transmission of *T. cruzi* has been made in the past 25 years through programs directed at vector control, screening of donated blood, and housing improvement, particularly under the aegis of the Southern Cone Initiative. Uruguay, Chile, and most recently Brazil (June 2006) have been declared free of transmission, and major progress has been made in other endemic countries such as Argentina and Bolivia. Control programs also are being implemented in the Andean nations and in Central America. No scientific or technical breakthroughs are necessary for the complete elimination of the transmission of *T. cruzi* to humans. Rather, it is a matter of political will and economics. United States tourists traveling in areas where *T. cruzi* transmission occurs should avoid sleeping in dilapidated houses in rural areas and should use mosquito nets and insect repellent to reduce exposure to vectors.

In December 2006, the Food and Drug Administration approved for the first time an assay for screening the U.S. blood supply for Chagas disease (Ortho *T. cruzi* ELISA Test System, Ortho-Clinical Diagnostics, Raritan, New Jersey).³¹ Donor samples that are repeat reactive in the Ortho test are then tested in the RIPA. In January 2007 the American Red Cross and Blood Systems, Inc., which together process about 65% of blood donated here, initiated testing with the Ortho assay. Data generated during the first two months of screening suggest that if 65% of the blood supply continues to be tested, roughly 1500 repeat reactive donors will be identified, about 350 of whom will be RIPA-positive, reflecting an overall prevalence of roughly 1 in 30,000. All repeat reactive donors will be permanently deferred from donation, since at present there is no reentry protocol for those found to be RIPA-negative. Additional options for screening donors for Chagas disease and confirmatory testing are on the horizon.^{32,33} Staff at the Division of Parasitic Diseases of the Centers for Disease Control and Prevention (CDC) are preparing a guidance document, which should be posted on the CDC website in mid-2007, that will contain detailed algorithms for assessment of the cardiac and gastrointestinal status of *T. cruzi*-infected donors as well as a discussion of the complex question of whether anti-parasitic treatment is indicated.

All immigrants from regions in which Chagas' disease is endemic should be tested serologically, as identification of infected persons should prompt physicians who care for them to perform appropriate diagnostic monitoring and therapy when indicated. This perspective is especially relevant now that a quantitative protocol for assessing the risk of developing clinically significant cardiac disease has been developed.³⁴ Persons who work with *T. cruzi* and infected vectors in the laboratory should wear gloves and eye protection.

► AFRICAN TRYPANOSOMIASIS (SLEEPING SICKNESS)

African trypanosomiasis, or sleeping sickness, is caused by two subspecies of trypanosomes, *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*, which are found in West and Central Africa and in East Africa, respectively. These flagellated protozoan parasites are transmitted by blood-sucking tsetse flies. The major biological difference between *T. cruzi* and African trypanosomes is that the latter multiply in the bloodstream and perivascular tissues of their mammalian hosts and do not have an intracellular form. In untreated

patients these organisms first cause a febrile illness that months or years later is followed by progressive neurologic impairment and death. *T.b. gambiense* and *T.b. rhodesiense* trypanosomiases differ primarily in that the latter follows a much more aggressive course.³⁵

Tens of thousands of new cases occur each year in a broad belt across Central and West Africa. In the United States imported cases appear every year or so, usually in tourists who have visited East African game parks.³⁶ In both acute and chronic African trypanosomiasis the diagnosis is made by detecting parasites, either in blood, in aspirates of lymph nodes or the trypanosomal chancre that can appear at the site of entry, or in cerebrospinal fluid. Treatment is complicated and often toxic, but usually is curative and varies from one patient to another depending on the infecting subspecies and on whether or not there is central nervous system involvement.^{10,37}

Control of African trypanosomiasis is based on reducing tsetse populations and drug treatment of infected persons. Major progress in reducing transmission has been made in many areas, but widespread foci of intense transmission still remain.^{38–40} Persons traveling to endemic countries can reduce their risk of acquiring sleeping sickness by avoiding areas known to harbor infected insects, by using insect repellent, and by wearing protective clothing.

Leishmaniasis

Mary E. Wilson

Leishmaniasis is endemic in 88 countries on four continents. In the Western Hemisphere forms of leishmaniasis are spread autochthonously between southern Texas and northern Argentina with the exception of Chile and Uruguay. Leishmaniasis is additionally spread in the Eastern Hemisphere in northern and eastern Africa, in the Mediterranean littoral, the Middle East, India, northeastern China, and other countries in Asia.

Leishmaniasis refers to a constellation of diseases caused by protozoa belonging to the genus *Leishmania*. The two *Leishmania* subgenera, *L. Viannia* spp. and *L. Leishmania* spp., behave differently in the sand fly vector. The clinical forms of leishmaniasis comprise a wide spectrum, and new entities are being recognized as travel and political conflict bring people from Western countries into endemic regions. Although varied in their clinical manifestations, the different *Leishmania* species share a common life cycle and transmission characteristics. All forms of leishmaniasis are initiated by the bite of a phlebotomine sand fly vector belonging to the *Lutzomyia* spp. in the New World or *Phlebotomus* spp. in the Old World. The sand fly deposits the infectious promastigote form of the parasite into the skin of a susceptible mammal. The extracellular flagellated promastigote then attaches to a mononuclear phagocyte, triggering phagocytosis through one or more macrophage receptor molecules. Once intracellular, the parasite retracts its flagellum and transforms to the obligate intracellular amastigote. Thereafter, the amastigote survives in the mammalian host as an obligate intracellular parasite of macrophages.

The three most common forms of leishmaniasis are cutaneous, visceral, and mucosal (or mucocutaneous) disease. More minor presentations occur, and there is considerable individual variability in disease severity and presentation. Infections due to each of the *Leishmania* species lead to a characteristic clinical disease syndrome, although case reports are making it clear that there is considerable variability in clinical presentation. The most common form is cutaneous leishmaniasis. Old World cutaneous leishmaniasis occurs in tropical and subtropical Asia, China, India, Africa, and the Middle East, whereas New World cutaneous leishmaniasis is found throughout South and Central America and extends north into southern

Texas. Visceral leishmaniasis also occurs widely and affects people in Latin America, Africa, India, Bangladesh, and China, as well as in countries surrounding the Mediterranean Sea, including France, Italy, and Spain. Severe mucosal disease due to *Leishmania braziliensis* occurs in Latin America, although mucosal involvement has been reported with a number of other *Leishmania* species throughout endemic regions. The biochemical differences between parasite species responsible for different clinical manifestations are largely unknown.¹

As with any infectious disease, clinical manifestations are determined not only by biological characteristics of the parasite species or strain, but also by differences in the susceptibility of individual hosts. It has been clearly established that there is genetic susceptibility to *Leishmania* infections in experimental mice. Murine susceptibility to *Leishmania donovani* infection maps to a single gene that has been cloned initially named *NRAMP1* and now renamed *SLC11A1*. The same gene governs susceptibility to mycobacterial and *Salmonella* infections.^{2,3} In contrast, murine susceptibility to infection with *Leishmania (L.) major* maps to a different locus or loci.⁴

Genetic factors underlying human susceptibility to leishmaniasis and other infectious diseases is a topic of intense research.^{4,5} Familial clustering of cutaneous, mucosal, and visceral leishmaniasis has been reported with some evidence that this clustering is due in part to genetic predisposition.^{6–10} Racial differences in the development of mucosal disease suggest that genetic factors may influence severe human disease manifestations.^{11,12} Specific loci that may explain the genetics of predisposition to leishmaniasis are under study, and genes encoding TNF α , IFN- γ RI, and SLC11A1 have been associated with different forms of leishmaniasis.^{3,13–17} Complicating these investigations, loci associated with susceptibility to the different *Leishmania* species differ, and individuals of different ethnic backgrounds differ in their susceptibility loci.^{3,5,13,16,18,19} In addition to genetics, nutritional factors are also critical in that malnutrition predisposes to the development of visceral leishmaniasis in Brazilian children.²⁰ Thus, the clinical manifestations of disease are determined not only by the species of *Leishmania* that predominate in a region but also by a number of environmentally determined and host factors, including genetic predisposition.

TABLE 15-13. LEISHMANIA SPECIES (SUB-GENUSES *L. LEISHMANIA* AND *L. VIANNIA*) COMMONLY CAUSING CLINICAL SYNDROMES IN THE NEW AND THE OLD WORLDS

New World	Old World
■ Cutaneous Leishmaniasis	
<i>L. mexicana</i> complex:	
<i>L. (L.) mexicana</i> , <i>L. (L.) venezuelensis</i>	<i>L. (L.) tropica</i>
<i>L. (L.) amazonensis</i>	<i>L. (L.) major</i>
<i>L. Viannia</i> subgenus:	
<i>L. (V.) braziliensis</i> , <i>L. (V.) panamensis</i> , <i>L. (V.) guyanensis</i> , <i>L. (V.) peruviana</i>	<i>L. (L.) aethiopica</i>
■ Leishmaniasis Recidivans	
	<i>L. (L.) tropica</i>
■ Diffuse Cutaneous Leishmaniasis	
<i>L. (L.) mexicana</i> , <i>L. (V.) braziliensis</i>	<i>L. (L.) aethiopica</i>
■ Mucosal Leishmaniasis	
<i>L. (V.) braziliensis</i>	
■ Visceral Leishmaniasis	
<i>L. (L.) chagasi</i> *, rarely <i>L. (L.) amazonensis</i>	<i>L. (L.) donovani</i> complex: <i>L. (L.) donovani</i> , <i>L. (L.) infantum</i> [†] <i>L. (L.) tropica</i> (viscerotropic leishmaniasis)

Please note that many exceptions to these generalities have been reported. Also, this is not a complete list of the *Leishmania* species.

**L. (L.) chagasi* and *L. (L.) infantum* are thought to represent the same species in different geographic locations, possibly imported by Europeans into South America.²¹

Clinical Disease Syndromes

The *Leishmania* species are divided into the subgenera *Leishmania* (*L.*) and *Viannia* (*V.*). The different *Leishmania* species typically cause distinct clinical syndromes, summarized in Table 15-13. Many reports of unusual manifestations have been reported, however. This is illustrated by the discovery of a previously unrecognized form of visceral leishmaniasis, termed “viscerotropic leishmaniasis,” caused by *L. tropica*, after the 1990–1991 Persian Gulf conflict.²²

Cutaneous Leishmaniasis. Localized cutaneous leishmaniasis is typically caused by *L. (L.) major*, *Leishmania (L.) tropica*, or *Leishmania (L.) aethiopica* in the Old World, or by *Leishmania (L.) mexicana*, *Leishmania (V.) panamensis*, *Leishmania (L.) amazonensis*, or *Leishmania (V.) braziliensis* in the New World. Different species cause disease of different severity or propensity to metastasize. The disease onset occurs between two weeks and several months after the sand fly bite. Cutaneous leishmaniasis lesions often appear as chronic ulcers with raised erythematous borders and a granulomatous base. Lesions begin as papules that gradually increase in size and eventually ulcerate. Alternate forms can appear as papules, plaques, nodules, or erysipeloid lesions. Metastatic lesions in nearby skin are common, and regional adenopathy can occur particularly with *L. braziliensis* infections. Lesions may last for months to more than a year. Occasionally, lymph nodes assume a sporotrichoid conformation. New World cutaneous leishmaniasis, particularly that caused by *L. braziliensis*, can take on more severe forms in which ulcers are deep and mutilating, and there is massive lymphadenopathy or chains of enlarged lymph nodes. Eventually most lesions heal spontaneously, leaving a flat atrophic scar. Although spontaneous healing is common, treatment can speed or ensure recovery. During disease and after recovery, patients usually exhibit strong delayed-type hypersensitivity (DTH) responses to *Leishmania* antigen, commonly called the Montenegro or leishmanin test.

Rare chronic forms of cutaneous leishmaniasis include diffuse cutaneous leishmaniasis (DCL) in which there are many localized papules that do not ulcerate. Satellite lesions and metastatic skin lesions arise, usually on the face and extremities. DCL is an anergic form of leishmaniasis with a negative Montenegro response, occurring primarily in South America. In contrast, leishmaniasis recidivans is a relapsing tuberculoid form of cutaneous leishmaniasis, usually caused by *L. tropica* in the Old World, in which lesions on the extremities or face slowly spread outward while healing in the center. This is associated with strong DTH reactivity. Both of these unusual forms of cutaneous leishmaniasis can lead to chronic disease lasting 20 years or longer.

Mucosal Leishmaniasis. After cutaneous infections with *L. braziliensis* or occasionally other *Leishmania* species, 2–3% of individuals can develop recurrent disease at mucosal sites distant from the original cutaneous lesion. Mucosal dissemination can occur between one month and more than 20 years after the original cutaneous ulcer. Mucosal leishmaniasis can begin with edema and erythema of mucosal sites in the nose or oropharynx. Progressive granulomatous inflammation can lead to destruction of the nose with perforation of the nasal septum, as well as to lesions involving the lips, tongue or the buccal, pharyngeal, or laryngeal mucosa. Death is rare but occurs due to involvement of the trachea or larynx and subsequent complications such as aspiration. Mucosal leishmaniasis is associated with strong cellular immune responses manifested as positive DTH reactivity and peripheral lymphocyte reactivity. The disease process is likely exacerbated by a hyperergic response to the parasite.

Visceral Leishmaniasis. Visceral disease is generally caused by parasites related to *L. donovani*, including *L. (L.) donovani* and *Leishmania (L.) infantum* in the Old World, and *Leishmania (L.) chagasi* in the New World. The latter two (*L. L. infantum* and *L. L. chagasi*) are likely one and the same parasite according to molecular genetic studies.²¹ Cases of visceral leishmaniasis due to other species (*L. amazonensis*, *L. tropica*) have been reported. This severe form of leishmaniasis usually begins between three and eight months after the bite of an infected sand fly. Most symptomatic patients develop the insidious onset of fevers, malaise, and weight loss associated with splenomegaly, hepatomegaly, anemia, leukopenia, thrombocytopenia, and hypergammaglobulinemia. Lymphadenopathy occurs in the Sudan but is not as common in other regions. Visceral leishmaniasis disease can lead to progressive suppression of specific and nonspecific cell-mediated immune responses with absent Montenegro reactivity, and associated bacterial infections causing pneumonia, diarrhea, or tuberculosis are common. These secondary infections contribute to the high mortality seen in untreated symptomatic disease. The spectrum of visceral leishmaniasis ranges from asymptomatic infection, occurring in 86–95% of infected Brazilians, to fulminant disease that may be fatal. Indeed, most fatalities due to leishmaniasis are due to the visceral form of disease.²³

Visceral leishmaniasis due to *L. infantum* has been reported in AIDS patients in Spain, France, and Italy as their presenting manifestation of HIV disease. Although most of these patients present with typical disease symptoms, unusual presentations have been documented. A previously unrecognized form of visceral infection, termed “viscerotropic leishmaniasis,” was reported in U.S. troops returning from the 1990–1991 Persian Gulf conflict. These individuals had varied symptoms and findings, including fever, chills, malaise, generalized lymphadenopathy, diarrhea, nausea, abdominal pain, and weight loss. One individual had no symptoms at all. Biopsy and culture of the bone marrow revealed *L. tropica*, a species previously thought only to cause cutaneous disease.²⁴

Visceral leishmaniasis can be followed by a syndrome termed post-kala-azar dermal leishmaniasis (PKDL). This manifests with generalized skin lesions ranging from hyperpigmented macules to nodules containing numerous organisms. This entity is particularly

common in East Africans who do not complete a course of therapy, and in the Indian subcontinent. Since PKDL allows parasites to survive in a cutaneous location, it may be important in allowing humans to serve as a reservoir of visceral disease.²³

Variability in clinical presentation and disease severity is due to several factors. The most evident is the distribution of the *Leishmania* species. For example, mucosal leishmaniasis occurs mostly due to *L. braziliensis*, which often causes an initial cutaneous lesion that can be accompanied by metastatic disease in mucosal tissues either simultaneously or months to years later. *L. braziliensis* is common in northeast Brazil and countries in the Andes including Colombia, Bolivia, Ecuador, and Peru.²⁵ This distribution accounts for the high incidence of mucosal leishmaniasis in these areas. Nonetheless host factors also contribute, with racial tendencies favoring or disfavoring mucosal dissemination.⁸ Familial aggregation of mucosal leishmaniasis is in part accounted for by genetic background in these populations, and specific alleles of several loci (*TNFA*, *IL6*) are being reported in association with this disease.^{6,16,26}

► DIAGNOSIS

The diagnosis of either cutaneous or visceral leishmaniasis should be considered in patients from endemic areas who present with typical findings of chronic cutaneous ulcer or fever with hepatosplenomegaly, respectively. Unfortunately, leishmaniasis is often not considered in immigrants or travelers seen by practitioners in countries where these diseases are uncommon. A diagnosis can be established by demonstration of the parasite in infected tissues (parasitological diagnosis). Cutaneous ulcers can be biopsied at lesion margins, and the parasite found either by histologic examination of sections stained with hematoxylin and eosin or Giemsa or by culture of the parasite in specific media obtained from the Centers for Disease Control and Prevention (CDC). Occasionally parasites can be visualized in impression smears of aspirates or lesions. Visceral leishmaniasis is demonstrated by the finding of *Leishmania* spp. amastigotes in bone marrow biopsy or aspirate, either by histology or culture, or occasionally in the peripheral blood of patients with concurrent AIDS and visceral leishmaniasis.²⁷ Practitioners in some endemic countries will demonstrate parasites causing visceral leishmaniasis by fine-needle aspiration of the spleen. Although this is more sensitive, the potential for hemorrhage makes this a less desirable test than a sternal marrow aspirate.

Anti-leishmanial antibodies are frequently elevated in immunocompetent individuals with visceral leishmaniasis, although such tests are unreliable in immunocompromised states such as HIV infection. Antibody tests include indirect fluorescent antibody (IFA) (used by the CDC), enzyme-linked immunosorbent assay (ELISA), and a direct agglutination test (DAT) optimized for use in developing countries. The DAT is useful in African countries and in India due to its simplicity in a field setting. However, the variability and expense of antigen preparations makes this inconsistently reliable.²⁸ Patients with active visceral leishmaniasis usually have antibodies to the recombinant antigen K39 (rK39) and this has provided the basis for a sensitive and specific ELISA.^{29,30} Furthermore, a rapid rK39 strip test has proven both sensitive and specific.

Disadvantages of all serologic tests are low responses in some individuals, persistence of serologic response after cure, and false positive reaction in some healthy individuals.²⁸ PCR and urine antigen-based tests are being explored, but are not yet standardized for clinical use.

Unfortunately, patients with cutaneous leishmaniasis do not reliably develop antibody responses, so serology is often not helpful in evaluating cutaneous ulcers. In addition, the few individuals documented with “viscerotropic” leishmaniasis had negative or low antibody titers, making serology unreliable test for this form of visceral disease. Cross-reactive antibodies may occur

in patients with Chagas’ disease or leprosy, decreasing the specificity of antibody based testing in regions where these diseases are co-endemic.

Delayed-type hypersensitivity responses to intradermally administered *Leishmania* antigen (the Montenegro or leishmanin test) usually develop during uncomplicated cutaneous and mucosal leishmaniasis. The Montenegro test is usually positive in other forms of leishmaniasis where the immune response is exuberant, including leishmaniasis recidivans and PKDL. The Montenegro is usually negative in individuals with forms of leishmaniasis with abundant parasite growth but suppressed immune responses, including diffuse cutaneous leishmaniasis and acute visceral leishmaniasis. Positive reactions usually develop after cure. Thus, skin testing serves as an adjunct to clinical and parasitological diagnosis but the test must be interpreted correctly. A number of laboratories have reported diagnosis of infection with the different *Leishmania* species by PCR, but these tests are not standardized and therefore cannot be universally relied upon as diagnostic tests.

► TREATMENT

Although small, inconspicuous cutaneous lesions can resolve without therapy, symptomatic visceral leishmaniasis is potentially fatal and requires treatment. Treatment is also recommended for lesions due to *L. braziliensis* because of their potential to develop into mucosal disease, and for large or cosmetically problematic cutaneous lesions. The mainstay of therapy for visceral leishmaniasis is pentavalent antimony (Sb^V), available as sodium stibogluconate and meglumine antimoniate through the CDC or in endemic countries. These compounds must be administered either intravenously or intramuscularly for 10–28 days for different forms of disease. Antimonials are associated with considerable gastrointestinal, liver, pancreatic, and cardiac toxicity, sometimes requiring cessation of therapy. Increasing reports of relapse or treatment failure may reflect drug-resistant parasite isolates. This is a particular problem in India where there can be up to 60% failure with antimony treatment.²⁸ Alternative treatments include amphotericin B or pentamidine, both of which also elicit toxicity. Liposomal amphotericin B has been successful in treating visceral leishmaniasis and provides a less toxic alternative.³¹ It is effective in 80% of cases even when administered as a single dose, making this a feasible alternative in developing settings where follow-up dosing of drugs cannot be guaranteed.³² Finally, Miltefosine is the first proven oral drug active against visceral leishmaniasis, and it has recently been approved for treatment in India.^{28,33} Alternatives in the future may include paromomycin (a parenteral aminoglycoside) and oral sitamaquine, both of which are still under investigation.²⁸ Recombinant interferon gamma has been used successfully as an adjunct to antimony therapy in cases of treatment failure, but this is not available other than for experimental purposes.

Many cases of cutaneous leishmaniasis will heal spontaneously without therapy. However, severe disease often prompts therapy to speed and/or ensure healing. In regions where *L. braziliensis* is common, treatment is indicated as an (unproven) measure to decrease the possibility of future dissemination to mucosal sites. Cutaneous leishmaniasis can be treated with antimony compounds, and these are recommended for *L. braziliensis* disease. As for visceral leishmaniasis, amphotericin B and pentamidine can be used as alternate drug choices. Other modes of treatment have been used for non-*L. braziliensis* cutaneous disease with varying success. Trials of topical paromomycin ointment, or topical imiquimod are promising. A trial of oral miltefosine for cutaneous leishmaniasis yielded 100% cure with the highest dose. Ketoconazole may be most useful for *L. mexicana*, and oral fluconazole may be used for *L. major* disease.²⁸ Other options include local heat therapy, topical antimony, itraconazole, and allopurinol.

Mucosal leishmaniasis always needs to be treated, and antimony compounds are the recommended antibiotic choice. Mucosal leishmaniasis, diffuse cutaneous leishmaniasis, and leishmaniasis recidivans are diseases with few parasites and a vigorous cellular immune response in affected tissues. These diseases are difficult to treat, often requiring repeated courses of the same or alternate therapies. Antimony, amphotericin B, and pentamidine have all been used in these situations. The combination of antimony plus either parenteral or topical granulocyte macrophage colony stimulating factor (GM-CSF) is a promising experimental regimen being tested for treatment of refractory cutaneous leishmaniasis due to *L. braziliensis*.^{34,35} Its utility in mucosal leishmaniasis has yet to be proven.

► TRANSMISSION OF LEISHMANIASIS

The World Health Organization has estimated that 350 million people are at risk for leishmaniasis. The annual incidence of cutaneous leishmaniasis is estimated at 1–1.5 million cases, and the incidence of visceral leishmaniasis is estimated to be 500,000 cases per year.³⁶ Major ongoing epidemics of visceral leishmaniasis are found in southern Sudan, eastern India, and urban centers in northeast Brazil. Furthermore, HIV and *Leishmania* coinfection is becoming increasingly recognized in European countries bordering the Mediterranean Sea such as Spain and France.²⁷

Leishmania spp. promastigotes are transmitted by female phlebotomine sand flies belonging to the genus *Phlebotomus* spp. in the Old World or the genus *Lutzomyia* spp. in the Americas.²⁵ More than 60 species of phlebotomine sand flies are described. At least 15 *Lutzomyia* spp. are anthrophilic and could transmit the *Leishmania* spp. There is specificity between the particular sand fly species that can host particular *Leishmania* spp. parasites for reasons that are largely undefined.³⁷ For example, *Lutzomyia longipalpis* is the natural host for *L. (L.) chagasi* but not *L. (L.) mexicana* or *L. (L.) major*.^{25,38} During a blood meal, female sand flies ingest macrophages containing amastigotes that subsequently transform into infectious promastigotes in the sand fly gut.³⁹ After 7–9 days of development, infectious metacyclic promastigotes in the sand fly proboscis are ready for inoculation into a new host.⁴⁰ Sand flies remain within close proximity of their habitat, and mammalian disease occurs when humans or a susceptible reservoir hosts venture into these environments. Depending on whether the particular sand fly species resides in an arid or semiarid, a sylvatic, or a peridomestic habitat, it feeds on mammals such as desert sand rats, anteaters, opossums, wild rodents, dogs, or humans.⁴¹

When cycles are maintained in semiarid conditions such as in the Middle East, sand flies often inhabit rodent burrows. The reservoirs of disease are small desert rodents. Thus, Old World cutaneous leishmaniasis is acquired when humans venture near uninhabited areas or villages near the desert where these rodents survive. American cutaneous leishmaniasis is maintained in a sylvatic cycle between small forest rodent reservoirs and *Lutzomyia* spp. sand flies.⁴¹ Most human infection occurs in the context of agricultural, settlement, forestry, or military activities. Major deforestation efforts in the tropical forests of South America have led to increases in cutaneous leishmaniasis in many regions.⁴²

Zoonotic and anthroponotic forms of both human cutaneous and visceral leishmaniasis have been identified. Zoonotic cutaneous leishmaniasis (ZCL) is found in Latin America, southwest and central Asia, and North Africa. ZCL in the New World caused by *L. (V.) braziliensis* and *L. (L.) mexicana* is associated with exposure to a large variety of rodents and larger mammals. The reservoir for Old World ZCL due to *L. (L.) major* is restricted to small rodents in rural regions. These diseases are often found in areas of deforestation at sites where new crops are planted and new rodent habitats are created. For example, urbanization of Manaus, Brazil has brought the population closer to the forest and to regions of

contact with the vector for *L. (V.) guyanensis*.⁴³ Another example occurs in Andean countries where there is population movement from high plateaus to low tropical regions, and increased human activity such as construction of dams.³⁷ Such movements have led to increased ZCL in Venezuela and Brazil. In the Old World, ZCL often corresponds with the building of dams and irrigation projects as well as with urbanization. Examples are found in Tunisia, Syria, and Senegal.

Anthroponotic cutaneous leishmaniasis (ACL) has been documented only in the Old World due to *L. (L.) tropica*. Risks include migration from rural to urban areas or movement of large populations such as refugees. Chronic forms of disease (e.g., recidivans leishmaniasis) are highly infective for the vector.⁴³ Recent cross-border movements contribute to urbanization of leishmaniasis, and outbreaks of ACL have occurred in refugee settlements in Afghanistan, Iran, Iraq, Syria, and Turkey.⁴⁴

Visceral leishmaniasis is also transmitted in foci with zoonotic or anthroponotic cycles. Zoonotic visceral leishmaniasis (ZVL) exists in Latin America, the Mediterranean and Asia. The causative parasites, *L. (L.) chagasi* in the New World or *L. (L.) infantum* in the Old World, are likely the same organism according to recent molecular analyses.²¹ The reservoirs for these parasites are domestic dogs or wild foxes/jackals for domestic or sylvatic cycles, respectively.⁴³ Additionally, recent epidemiological studies in Brazil have questioned the universal importance of the dog reservoir, introducing the hypothesis that alternate reservoirs may sometimes play a role.^{45,46} Endemic disease in East Africa and countries surrounding the Mediterranean Sea is maintained in wild rodent reservoirs, and human infection occurs only sporadically. Canine leishmaniasis is additionally a problem in Spain and France, providing a reservoir close to human habitat. The recent increase in HIV infection has led to a high incidence of visceral leishmaniasis in Spanish and French patients, sometimes caused by parasite zymodemes that rarely cause symptomatic infection in healthy hosts.⁴⁷

A major risk factor for New World ZVL is migration from rural to urban regions, driven by drought and economic needs in Brazil, Colombia, and Venezuela.^{43,44} Large outbreaks in urban areas of northeastern Brazil have been driven by population movement to the poor suburbs of large cities (flavelas), with housing built in areas favoring sand fly habitat. At the same time the sand fly vector has adapted to a peridomestic life cycle. Inadequate housing and sanitation, as well as proximity of human and domestic or farm animal housing, has created a favorable environment for the insect vector.⁴⁴ Thus sand flies survive in garbage heaps, crevices, and sometimes in the walls of houses. South American visceral leishmaniasis is most common in children, and their adult relatives often exhibit skin test positivity reflecting prior exposure and immunity against infection. Domestic dogs serve as major reservoirs of peridomestic infection in South America, leading the Brazilian government to actively survey for and treat canine leishmaniasis.^{9,48} The incidence of peri-urban ZVL in shantytowns surrounding large cities has increased exponentially in Brazil, particularly in the poor northeastern states.⁴⁸ ZVL is also increased in Europe at the periphery of cities where dogs and gardens encourage the proximity of the main reservoir and vectors of disease.⁴³ In addition the incidence of *L. infantum*–HIV-1 coinfection is increasing in southern Europe, and their co-distribution is overlapping more as leishmaniasis moves from rural to urban regions and HIV-1 moves in the reciprocal direction.^{43,49} Particularly at risk are the intravenous drug abusers in the region, a risk enhanced by the habit of needle sharing.⁴⁴

Anthroponotic visceral leishmaniasis (AVL) is primarily found in regions where *L. (L.) donovani* predominates in East Africa, India, Bangladesh, and Nepal. Humans are the sole known reservoir in these regions. The spread of disease is enhanced by chronic cutaneous form of the disease called post-kala-azar dermal leishmaniasis (PKDL), common in both the Sudan and India, in which parasites persist in the skin. Epidemics of AVL have occurred particularly in eastern African countries (e.g., Sudan) and the mortality has been high due to these

outbreaks. Contributing to these epidemics was the long-standing civil war in Sudan that led to migration of a large population of non-immune hosts into endemic regions.

Risk factors for AVL include population movement due to civil unrest and low socioeconomic status. In southern Sudan, movement of infected persons into previously unexposed populations during civil unrest led to an estimated 100,000 deaths in a population of less than a million, a more than 10% death rate. Fifty percent of the cases of visceral leishmaniasis worldwide occur in Bangladesh, India, and Nepal. Seventy-five percent of individuals in Bihar state, the state of peak AVL incidence in India, earn on the average less than US\$1 per day. Women have a particularly high mortality rate since they have less access than men and children to medical care.⁴³

All forms of leishmaniasis have increased over recent years.⁴³ Reasons include changes in human environment including population movements and deforestation. Estimates are that the world loses 20 million hectares of forest annually. Thus the incidence of these diseases is expected to continue rising particularly in poor populations. The need for better control of spread, and better treatment of existing disease is critical.

► PREVENTION AND CONTROL

Difficulties in gaining control over the different forms of leishmaniasis can be thought of in terms of the diseases that are transmitted via anthroponotic versus zoonotic versus peridomestic cycles. All face the fact that many affected persons reside in regions where access to medical care is limited. This is compounded by the fact that the long-standing first line drug regimens require lengthy parenteral administration and cause considerable toxicity, making therapy difficult to administer and monitor. In the case of anthroponotic disease such as occurs in India and possibly the Sudan, the presence of chronic cutaneous PKDL allows the disease to be maintained long-term and available for sand fly-mediated spread. Improved human disease detection and treatment would help diminish the disease.

Wild rodent or canid reservoirs of zoonotic leishmaniasis are difficult or impossible to eradicate. Attempts to poison rodents in their burrows are obviously effective only in very limited regions.⁵⁰ A major reservoir of South American ZVL is the domestic dog, which is available for surveillance and treatment. However, surveillance methods are far from complete, and even in the case of *L. chagasi* the dog may not be the only disease reservoir. Until living conditions can be improved to remove human habitat from sand fly breeding grounds and to make treatment and early disease recognition more available, the cycle is likely to be maintained.

Measures to control exposure to the insect vector in the form of effective insect repellents (DEET or permethrin) and the use of fine mesh netting during sleep, which can exclude the small sand fly

vector, are recommended for individual travelers to endemic regions. Attempts at vector eradication to control disease in endemic countries have been effective but short lived. As an illustration, the incidence of leishmaniasis decreased after World War II when there was widespread use of DDT to prevent malaria, but leishmaniasis resurged after the discontinuation of DDT spraying. Recent measures to control leishmaniasis include active insecticide spraying of houses and the use of bed nets with or without impregnated insecticide. Success of these measures occurs in environments where sand fly bites are primarily acquired in the home. For example, leishmaniasis is peridomestic in Nepal and the use of bed nets reduced the incidence of visceral leishmaniasis by 70%. Spraying houses with insecticide has reduced the incidence of cutaneous leishmaniasis in Peru and Kabul by 54–60%, respectively. It is not clear whether universal spraying or targeted spraying where disease is documented would be more effective. The relative value of permethrin impregnated bed nets compared to household spraying needs to be carefully assessed.²⁸ Furthermore, the expense of insecticides, the potential transience of effect, and risk of selecting for drug-resistant insects must be weighted against the benefit to the endemic country as a long-term solution to the control of leishmaniasis.

Measures to control the dog reservoir for visceral leishmaniasis in South America have included the use of insecticide impregnated dog collars, treating dogs directly with insecticides, and euthanizing infected dogs. The efficacy of these measures has been debated. Due to a long asymptomatic but infectious period during dog leishmaniasis, and because of the relative resistance of dogs to treatment, improved early diagnostic measures and better means of therapy are needed.

Due to the above-mentioned difficulties in interrupting the life cycle of *Leishmania* spp. infections by vector control or by reservoir eradication, a protective vaccine would be an ideal means of controlling the disease in endemic countries. In theory it should be possible to develop a vaccine, since cure of human leishmaniasis results in long-term immunity against reinfection with the same organism. Illustrating this, a solution to the high incidence of cutaneous leishmaniasis in the Middle East has been to expose a cosmetically acceptable area of the body to sand flies or live *L. major* promastigotes. Resolution of this purposefully induced disease results in protection against more disfiguring cutaneous leishmaniasis in the future.

Despite this naturally occurring protective immunity, however, there is not yet an established protective vaccine. Efforts have included trials of killed promastigote vaccines with or without BCG as adjuvant, and recombinant vaccines including a recombinant trivalent vaccine under evaluation for South American leishmaniasis.⁵¹ Nonetheless, all potential vaccines are still in various stages of development and a proven accepted protective vaccine is not yet on the horizon. Major hurdles to overcome to achieve control of leishmaniasis include the development of a safe, effective and long-lasting protective vaccine, effective affordable and easily administered therapy, and eradication of zoonotic disease reservoirs in endemic regions.

Lymphatic Filariasis

Amy D. Klion

Lymphatic filariasis is a chronic, often debilitating, infection caused by the filarial parasites *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*. More than 120 million people in 83 endemic countries of the tropics and subtropics are afflicted and as many as 1.2 billion residents of endemic areas are at risk for infection.¹ In 1993, the International Task Force for Disease Eradication targeted lymphatic filariasis as one of six “eradicable” or “potentially eradicable” infectious diseases.² Although the prevalence of lymphatic filariasis has continued to increase in some regions of the world, mostly as a result of unplanned urbanization and sociopolitical disturbances, almost half of all endemic countries had initiated national control programs by

the end of 2004 leading to a dramatic reduction in the prevalence of microfilaremia in the participating countries.³

► BIOLOGY AND LIFE CYCLES

Human infection occurs when infective larvae penetrate the skin during the bite of a mosquito vector and migrate to the nearest lymphatic vessel. Over the course of several months, they develop into thread-like adult worms (the males are approximately 40 by 0.1 mm and the females 100 by 0.25 mm in size). The average life span of the adult worms has been estimated at five years.⁴ Fertilized female worms

produce sheathed microfilariae, which are released into the bloodstream. In most areas of the world, these microfilariae are detectable in the peripheral blood only at night (nocturnal periodicity); however, a subperiodic form, in which microfilarial counts are maximal during the day, is found in some regions of the Pacific islands, eastern Malaysia, and Vietnam. Circulating microfilariae, ingested by the appropriate mosquito vector during a blood meal, develop over the course of several weeks into infective larvae, completing the parasite life cycle.

Most of the filarial parasites that infect humans, including *Wuchereria bancrofti* and *Brugia* spp., are infected with *Wolbachia*, intracellular endosymbiont bacteria that are required for filarial development, viability, and fertility.⁵ These bacteria play a significant role in the pathogenesis of filarial infection and provide novel targets for chemotherapy.

► DISTRIBUTION

Global prevalence mapping using a variety of techniques, including community surveys, global information systems (GIS) and statistical models, has been undertaken as part of the worldwide eradication campaign.⁶ These studies have confirmed prior epidemiologic data and have identified a number of previously unrecognized foci of infection, particularly in Africa.⁷

The geographic distribution of lymphatic filariasis is determined primarily by the ability of the parasite to adapt to different mosquito vectors. Consequently, *W. bancrofti*, which can be transmitted by a large number of *Anopheles*, *Culex*, and *Aedes* species, is the most widespread of the agents of lymphatic filariasis, occurring in parts of Africa, Asia, South and Central America, the Caribbean, and the Pacific. Transmitted predominantly by *Mansonia* species, *B. malayi* infection is restricted to areas of south and east Asia. *B. timori* infection has been reported from only two islands in Indonesia (Timor and Flores), where it is transmitted by *Anopheles barbirostris*. Lymphatic filariasis occurs in both urban and rural settings, as mosquitoes breed in unsanitary water sources, such as abandoned wells and septic tanks, pit latrines, and water storage tanks, found commonly in urban environments, as well as in rural swamps and rice paddies.

Although experimental infection of nonhuman primates is possible, animals other than humans do not appear to be natural reservoirs of *W. bancrofti* or *B. timori*. In contrast, *B. malayi* is a zoonosis in some parts of Malaysia, where leaf-eating monkeys, wild cats, civets, and pangolins are reservoirs of infection.⁸

► PATHOLOGIC AND CLINICAL MANIFESTATIONS

The spectrum of clinical manifestations of lymphatic filariasis is broad and includes asymptomatic microfilaremia, recurrent episodes of acute adenolymphangitis (ADL), chronic lymphedema/elephantiasis, and tropical pulmonary eosinophilia. Whereas the host immune responses to filarial and *Wolbachia* antigens are clearly involved in determining the clinical manifestations of infection,^{5,9} the determinants of these responses are complex and likely include genetic factors, as well as the timing and degree of exposure. Recurrent bacterial infections have also been implicated as an important factor in recurrent episodes of ADL and progression toward chronic lymphedema and elephantiasis.¹⁰

Numerous large population studies have shown that most, but not all, natives of endemic areas who acquire lymphatic filariasis are asymptomatic with circulating microfilariae detectable in the peripheral blood (microfilaremia).¹¹ However, despite the lack of obvious clinical signs or symptoms, pathologic changes—including alterations in lymphatic flow, as detected by lymphoscintigraphy,¹² lymphatic dilatation,¹³ and renal abnormalities (hematuria and proteinuria)¹⁴—have been demonstrated in these individuals. In contrast to the above-described asymptomatic microfilaremic patients, the majority of visitors to endemic areas who become infected present with signs and symptoms of acute infection.¹⁵

Symptomatic acute infection is characterized by recurrent episodes of fever, lymphadenitis, and/or retrograde lymphangitis,

sometimes referred to as “filarial fevers.” The lower extremities are affected more frequently than the upper extremities and breast, and in *W. bancrofti* infection, the scrotum or female external genitalia may also be involved. Episodes generally last from three to seven days unless they are complicated by abscess formation along the affected lymphatic, in which case healing may take several months. Additional early manifestations of *W. bancrofti* infection include orchitis and inflammation of the spermatic cord, which can lead to permanent thickening of the spermatic cord and/or hydrocele. Genital manifestations are rare in brugian filariasis.¹⁶

After years of infection, chronic lymphatic obstruction develops in some patients. Recurrent episodes of inflammation and infection lead to irreversible enlargement of the affected area with a thickened, warty appearance of the overlying skin (elephantiasis). In contrast to *W. bancrofti* infection, in which the entire limb is generally involved, the chronic lymphedema of brugian filariasis is characteristically limited to the distal portion of the involved extremity.¹⁶ Although elephantiasis itself is generally painless and well tolerated, ulceration and secondary infection are common and contribute greatly to the morbidity and mortality of lymphatic filarial infection. In the genital region, lymphatic obstruction may lead to rupture of the dilated lymph vessels into the urinary tract and intermittent chyluria.

A minority of patients with lymphatic filariasis present with the hyperresponsive syndrome of tropical pulmonary eosinophilia (TPE).¹⁷ The clinical manifestations of TPE are predominantly pulmonary, consisting of nocturnal wheezing, cough, and dyspnea, although constitutional symptoms may be present. Laboratory studies are notable for marked eosinophilia (both in the peripheral blood and the lower respiratory tract) and elevated serum IgE and antifilarial antibody levels. Chest radiographs typically show diffuse reticulonodular infiltrates, and pulmonary function tests are consistent with a predominantly restrictive pattern. Although most patients with TPE respond rapidly to a 3-week course of diethylcarbamazine (DEC), chronic respiratory tract inflammation and mild interstitial lung disease are not uncommon. Untreated, TPE may progress to irreversible interstitial fibrosis.

As is true of helminth infections in general, filarial infection is associated with a skewing of the immune response towards a Th2 phenotype. This has led to considerable interest in the effects of chronic filarial infection on the outcome of immunizations and of concomitant infections with pathogens, such as HIV and malaria, which require an effective Th1 type response. Despite experimental data suggesting increased susceptibility of filarial-infected cells to HIV infection,¹⁸ there have been no clinical reports of increased susceptibility to HIV infection or enhanced progression of HIV disease. In contrast, the response to tetanus vaccine does appear to be impaired in patients with lymphatic filariasis.¹⁹

► DIAGNOSIS

Until recently, definitive parasitologic diagnosis could only be made by demonstration of the characteristic sheathed microfilariae in a Giemsa-stained specimen of peripheral blood or, rarely, by excision of an adult worm. Because the microfilariae in lymphatic filariasis exhibit periodicity in many areas of the world, the timing of blood samples for parasite detection is critical and often inconvenient. Consequently, circulating filaria antigen assays for *W. bancrofti*, which are more sensitive and as specific as detection of microfilariae for diagnosis of active filarial infection and are unaffected by periodicity, have replaced the more conventional parasitologic methods in most situations.²⁰ Antigen detection assays are not available for *B. malayi* or *B. timori* infection; however, an Ig4 antibody dipstick assay based on a recombinant antigen has recently been developed and appears to be sensitive and specific for the detection of active *Brugia* infection.²¹ DNA-based polymerase chain reaction (PCR) assays for *W. bancrofti* and *B. malayi* are comparable in sensitivity and specificity to the circulating antigen assay and antibody dipstick for detection of microfilaremia and offer the advantage of tissue diagnosis from biopsy specimens.^{22,23} Whereas widespread use of such assays for diagnosis of human infection is not practical because of the high

cost, specialized equipment, and technical expertise required, these assays have been extremely useful in the monitoring of infection rates in mosquitoes (see Control and Prevention).²⁴

Polyclonal antifilarial antibody measurement is useful in documenting infection in patients with TPE and in visitors to endemic areas who have symptoms consistent with infection but no detectable microfilariae. However, such assays do not distinguish between the various filarial infections of humans, several of which have overlapping geographic distributions.^{25,26} Furthermore, they are often positive in uninfected residents of endemic areas, precluding their widespread use in this population.

Ultrasonography is not only useful for the identification of subclinical hydrocele, but can be used to confirm the diagnosis of lymphatic filariasis by documenting the presence of living adult worms (“filarial dance sign”) in the scrotal lymphatics of male patients²⁷ and in the axillary, breast, uterine, femoral and groin lymphatics of female patients.²⁸

► TREATMENT

The anthelmintics, diethylcarbamazine (DEC), ivermectin, and albendazole, have been the mainstays of treatment for lymphatic filariasis for many years. More recently, doxycycline has been shown to have antifilarial activity due to its effect on the bacterial endosymbiont, *Wolbachia*.^{29,30}

DEC is a piperazine derivative with excellent microfilaricidal activity at low doses. The mechanism of action of DEC is unknown but appears to depend on the host immune response. Although adult worms are affected by DEC treatment at higher doses,³¹ killing is inefficient and cure is uncommon. Ivermectin shows similar activity to DEC against microfilariae of lymphatic-dwelling filariae but has no effect on adult worms.³² It is thought to act by blocking the neurotransmitter α -aminobutyric acid (GABA).

Side effects of DEC and ivermectin treatment are generally mild, but include a number of systemic, inflammatory signs and symptoms, such as fever, headache, malaise, arthralgias, and localized swellings along the lymphatics. These are thought to be related to the release of filarial and bacterial antigens as a result of microfilarial death and increase in severity with increasing microfilarial load. Severe reactions may occur in patients with concomitant loiasis (DEC or ivermectin) or onchocerciasis (DEC only),^{33–35} however, and individuals from areas where these infections are endemic should be screened before treatment.

Albendazole is a poorly absorbed benzimidazole with activity against a wide variety of helminths, including filariae. Unlike DEC and ivermectin, albendazole has little direct activity on microfilariae, but appears to act predominantly on the adult parasite leading to decreased microfilarial production. Side effects of therapy are few when used at low doses, and because of the lack of rapid microfilaricidal activity, albendazole can be given safely to patients with *Loa loa* infection and/or onchocerciasis.

Doxycycline has both embryotoxic and adulticidal activity when given at doses of 200 mg daily for 6–8 weeks.²⁹ Although impractical for mass treatment, side effects of therapy are minimal and suppression of microfilaremia is sustained for up to 14 months. Shorter course doxycycline (three weeks) combined with single dose ivermectin/albendazole appears equally effective at reducing microfilarial loads, but has no detectable adulticidal activity.³⁰

Although there is no direct evidence for the development of drug resistance in lymphatic filariasis, diminished efficacy of DEC treatment in some patients with circulating microfilariae despite adequate drug levels suggests that resistance may occur in some situations.³⁶ Selection for benzimidazole mutations in response to albendazole therapy has also been reported, although the clinical significance of these findings remains uncertain.³⁷

In view of the recent data demonstrating pathologic changes even in asymptomatic patients, all infected individuals should be treated with the goal of preventing morbidity and decreasing disease transmission. The current recommended therapy for lymphatic filariasis is high-dose treatment with DEC (6 mg/kg/day for 12 days [*W. bancrofti*] or six days

[*Brugia*]).³⁸ Potential alternative regimens include single dose intermittent therapy with DEC, ivermectin and/or albendazole, or 6–8 weeks of doxycycline therapy, although large comparative studies are lacking.

For symptomatic patients with lymphedema, intensive local hygiene and prompt treatment of bacterial or fungal superinfection should be instituted as this has been shown in numerous studies to reduce lymphedema and decrease the frequency of episodes of adenolymphangitis.¹⁰ Hydrocelectomy should be considered for all symptomatic patients as it has been shown to improve work capacity, sexual function and integration into community activities.³⁹ Once elephantiasis is present, treatment modalities are few. Surgical bypass of affected lymphatic vessels has been performed in some patients, but the technical difficulty and high cost of this procedure has limited its usefulness.⁴⁰

► CONTROL AND PREVENTION

The major goals of current filariasis control programs are the interruption of transmission of infection (infection control) and reduction of suffering (morbidity control). Since vector control measures alone have been generally unsuccessful in decreasing the prevalence of infection, an integrated approach of (a) microfilaremia reduction through chemotherapy, (b) vector control, and (c) reduction of host-vector contact has been advocated. The optimal control strategies for a given endemic area will depend on the particular parasite and vector species involved as well as on the ecological, cultural, and political factors specific to the region.

Although there is no curative chemotherapy for lymphatic filariasis, both DEC and ivermectin have been demonstrated to suppress microfilaremia (90–95% reduction) in infected patients for up to one year after therapy is stopped. DEC-mediated salt and combination therapy using DEC with albendazole or ivermectin are more effective,⁴¹ but cannot be used in areas where onchocerciasis or loiasis are endemic. Although the addition of albendazole to ivermectin does not appear to substantially increase microfilaricidal efficacy as compared to ivermectin alone, this regimen continues to be used in areas where onchocerciasis limits the use of DEC, in part because of the broad spectrum anthelmintic benefits afforded by albendazole.⁴¹ Mass treatment in areas where *Loa loa* is endemic continues to be a problem and is an area of active research.⁴² Thus, the choice of an optimal regimen depends on the co-endemicity of other filarial parasites, drug availability, cost, and community acceptance.

In general, mass distribution programs are preferred over selective treatment of infected individuals for several reasons, including the cost of screening and the inability of current diagnostic methods to reliably identify prepatent infection (i.e., early infection prior to the release of microfilariae). The length of time that control strategies need to be continued to completely eradicate lymphatic filariasis from an endemic area is unknown. Initial estimates of 4–6 years appear to be overly optimistic in most regions for a number of reasons, including variable compliance with mass drug administration and inability to scale up programs due to insufficient resources.⁴²

Vector control in lymphatic filariasis (as in malaria) has been problematic, primarily because of the widespread distribution of potential mosquito vectors and their ability to adapt to varied ecological conditions.⁴³ Multiple strategies have been employed with varying success. Toxin-producing bacteria such as *Bacillus sphaericus* and *Bacillus thuringiensis*,⁴⁴ entomopathogenic fungi⁴⁵ and polystyrene beads (which expand to cover the surface of breeding areas in closed water systems and suffocate developing larvae)⁴⁶ have been used to control larvae of *Culex*, *Mansonia*, and *Anopheles* species. The elimination of breeding sites through the construction of improved water and sanitary facilities would be more desirable but is economically unfeasible in most endemic regions. Reduction of host-vector contact can be achieved with the use of insect repellents and protective clothing or, in areas where vector feeding is predominantly indoors, with indoor spraying with pyrethroids and other household measures (including screens, bed nets, and mosquito coils). In most instances, a combination of measures has been most effective.

The ability to prevent lymphatic filariasis through immunization would greatly enhance current control strategies by limiting the population at risk for infection. Although the presence of small numbers of long-term residents of filaria-endemic regions who have neither clinical nor laboratory evidence of infection suggests that protective immunity to filariasis may occur naturally, vaccine development has been hampered by the complexity of the human immune response to filarial infection and the lack of clinically relevant nonprimate models of infection. Consequently, a safe and effective vaccine is unlikely to be available in the near future.

An essential part of any successful control program is community participation. For this to occur, there must be a basic understanding of the methods of transmission, prevention, and control of infection. Several studies have demonstrated, however, that the majority of the people living in highly endemic areas are lacking in this basic knowledge.^{47,48} That an understanding of the mechanism of disease transmission is associated with a decreased risk of infection is suggested by the finding that 20% of the uninfected residents of an endemic area in India, but only 9% of infected residents, were aware that mosquitoes transmit filarial infection.⁴⁸ Although this association has not been formally proven by prospective longitudinal studies, community-wide education programs targeted at filariasis prevention and control are likely to include information of broad general health benefit (i.e., mosquito prevention and personal hygiene measures) and should be included in all integrated filariasis control programs.

Using combined chemotherapy and vector control programs, lymphatic filariasis has been eliminated from Japan, Taiwan, South Korea, and the Solomon Islands, and transmission has been dramatically reduced in a number of endemic countries, including China and Papua New Guinea.^{3,49} However, relaxation of control programs has led to the resurgence of the disease in other regions, including the Nile Delta and French Polynesia.⁵⁰ Furthermore, new areas of endemicity will likely continue to arise as global warming, urbanization, and other natural and human-made environmental changes create vector habitats in previously unsuitable locations. Consequently, long-term surveillance must be an integral part of filariasis control. The development of sensitive and specific assays that are suitable for large-scale epidemiologic studies of endemic populations and detection of infected vectors (i.e., circulating antigen²⁰ and DNA-based PCR assays²⁴) have facilitated such monitoring, both in areas of ongoing control and in areas at risk of becoming endemic for lymphatic filariasis.

Even if control measures are successful in eliminating transmission of lymphatic filariasis, the prevention of infection-related morbidity will remain a problem in the foreseeable future. Clearly, every effort should be made to promote local hygiene and early treatment of cellulitis in symptomatic patients, since these have been associated with a decrease in the number of episodes of adenolymphangitis. The approach to asymptomatic infected individuals is less straightforward, in view of the lack of long-term studies comparing disease progression in treated and untreated patients with microfilaremia. However, the demonstration of DEC-induced reversal of early lymphatic dysfunction by lymphoscintigraphy suggests that some of the early pathology seen in asymptomatic patients with lymphatic filariasis may be reversible with antifilarial treatment.⁵¹ Since the potential benefits of therapy (i.e., prevention of elephantiasis) are substantial and the risks minimal, it seems prudent to treat all individuals with documented filarial infection regardless of symptoms.

Diseases Transmitted Primarily from Animals to Humans (Zoonoses)

Viral Zoonoses—Rabies

Charles E. Rupprecht

► INTRODUCTION

Rabies is an acute progressive viral infection of the central nervous system.^{1,2} The disease has affected humans and other animals for millennia. Although warm-blooded vertebrates are susceptible to experimental infection, only mammals are important hosts in nature. Rabies persists among the Carnivora and Chiroptera. The domestic dog is a primary reservoir on a global basis. Regionally, many wildlife species may serve as maintenance hosts. Transmission occurs by animal bite. Humans are affected by incidental infection from animals. The etiological agents are rod-shaped RNA viruses that belong to the genus *Lyssavirus*, in the *Rhabdoviridae*, a diverse family that includes a number of other agents affecting vertebrates, invertebrates, and plants.

Distribution

Rabies exists on every continent, except Antarctica. Many island locations, such as in the Caribbean or Pacific Oceania, are fortunate and either never experienced rabies, or eliminated the disease by the application of control and quarantine measures. Other locations, such as parts of western Europe or the Americas, have controlled the disease in carnivores, but may experience enzootic disease among bats.

The occurrence of human rabies in Europe, Canada, and the United States has been reduced historically from scores of deaths annually to only a few cases per year. Human fatalities are much higher in the developing world.^{1,3,4} Typically, more than 50,000 persons, and millions of animals, die of rabies worldwide each year, and several million people receive rabies prophylaxis after exposure.^{1,3,4} Compared to developed countries, the diagnosis and reporting of human and animal rabies in many under developed areas of Asia, Africa, and Latin America is less than ideal. Data on the prevalence of the disease in many of these areas are often unreliable. The burden of rabies remains significant in many localities, where it causes

otherwise preventable deaths, substantial anxiety, serious adverse effects from outdated vaccines, and incalculable costs to many individuals and their families.⁴ For example, the number of persons vaccinated for potential rabies exposure each year in the United States is estimated between 20,000 and 40,000 cases per year, whereas prophylaxis approaches a figure of a million exposures in India alone.³

Epidemiology

The distribution of animal rabies is global in nature. Several different lyssaviruses serve as major etiological agents throughout the world. Each of these viral species is irregular in distribution and presumed reservoir attributes (Table 16-1). Owing to this diversity, with basic similarity to other RNA viruses, lyssaviruses lack proofreading enzymes. Consequently, during RNA replication, viral copy errors are made. Many of these replication errors are lethal, and do not result in competent progeny viruses. Molecular drift and eventual stability may occur when different variants arise and can overcome adaptive bottlenecks in certain animal populations. Such variants can be differentiated from each other by genetic, antigenic, and serological methods. Although a productive infection is essentially fatal for the affected individual, transmission occurs before host death, and viruses may persist in populations over time when their basic reproductive infectious value is below the biotic potential and threshold densities of the animal populations in question. A postulated “carrier state,” whereby a rabid animal sheds virus intermittently for prolonged periods without succumbing to disease, is unnecessary for disease perpetuation. Rabies would not be maintained over time if the availability of susceptible hosts drops below a critical value.

Rabies virus is the most important lyssavirus representative from a public health and veterinary perspective. The other lyssaviruses may appear as biological curiosities, but their epidemiology is poorly understood. New pathogen emergence, natural range extensions of infected animals, and unintentional international translocations may change viral distribution and prominence rapidly. Such alterations may result in sudden serious consequences, because vaccine cross-reactivity is less than ideal across the genus.

All mammals may be susceptible, but the occurrence of disease is skewed to certain major groups. For example, rabies manifests in two

Note: The findings and conclusions in this chapter are those of the author and do not necessarily represent the views of the Centers for Disease Control and Prevention.

TABLE 16-1. LYSSAVIRUSES

Virus	Distribution	Reservoirs	Comments
<i>Rabies</i>	Worldwide ^a	Chiroptera, Carnivora	Estimated >50,000 human deaths per year

major epidemiological forms: (a) "urban" rabies in domestic dogs and (b) "wildlife" rabies, principally in wild *Canidae* (foxes, raccoon dogs, etc.), *Herpestidae* (mongoose, meerkat, etc.), *Mephitidae* (skunks), *Procyonidae* (raccoons), and the *Chiroptera* (bats). Urban rabies is the more noticeable pattern in many parts of the developing world and usually constitutes the major source of human infection. The extent of wildlife rabies is undetermined in many countries, due to surveillance bias.

Within each region, different viral variants are compartmentalized within particular bat or carnivore hosts. Viruses can be perpetuated in a somewhat closed cycle within the same species (e.g., dog to dog), or spillover infection may occur to a different species (e.g., dog to cat). Whereas spillover infections may result in a dead end, such as a human bitten by a rabid dog, other compartmentalized infections may persist in host mammalian populations for decades, or longer, such as canine rabies in parts of Southeast Asia. Other non-reservoirs can be involved temporarily in rabies maintenance, such as coyotes. Such established occurrences are not uniform, but are spatio-temporally disparate. For example, in the early to mid-twentieth century, fox rabies was a serious problem in Europe, and resulted in widespread epizootics with foci still abundant in the eastern portion of the continent. In North America, where canine rabies was a primary threat before World War II, an apparent shift to wildlife was observed thereafter, primarily in red (*Vulpes vulpes*), gray (*Urocyon cinereoargenteus*), and Arctic foxes (*Alopex lagopus*), the latter a circumpolar reservoir. In Africa and Asia, jackals may be a prominent source of virus for other species. Historically, wolves have served as dangerous

vectors in the Middle East and portions of western Asia. Several genera of mongoose (*Herpestes*, *Cynillis*, etc.) are important in rabies transmission in South Africa, parts of Asia, such as India, and in several Caribbean islands (Puerto Rico, Cuba, Dominican Republic, and Grenada), where these animals were imported in the nineteenth century. In Central and South America, the common blood-drinking vampire bat (*Desmodus rotundus*) is a principal reservoir and vector of rabies for both humans and domesticated animals, and is estimated to cause annual losses in livestock exceeding several million dollars.

In the United States, a complex epidemiological pattern of disease exists, with widespread terrestrial carnivore rabies (skunk, fox, raccoon) overlaid by the disease in insectivorous bats.⁵ An epidemiological change in the distribution of rabies cases, from domestic to wild animals, has been reported in the United States during the last 50 years (Table 16-2). The prominence of rabies among dogs, and the obvious lack of equivalent surveillance in certain animals, such as wildlife, may have distorted the pattern. In past decades, skunk (*Mephitis mephitis*) rabies comprised over half of all wildlife rabies reports. Since the late 1970s, a marked increase occurred in raccoon (*Procyon lotor*) rabies cases in the eastern portion of the United States. The reported decrease in dog cases is a true diminution of the disease related to widespread canine immunization and the application of rabies control measures. Rabies in cats occurs sporadically, and is peripheral to infection in dogs and wildlife, as is the situation for livestock. Besides carnivores, the overall number of reports of rabid bats has increased after the disease was first described from Florida in 1953. However, the proportion of rabid bats has not changed significantly in relation to the total number of submitted specimens over the years. Thus, the apparent increase in bat rabies appears due to increased testing. On rare occasions, a rodent, such as a woodchuck, is diagnosed with rabies, although rodents are not reservoirs and no rodent species has been implicated as a source of the virus for humans and other mammals.

The decrease of rabies in dogs has been associated with a marked decrease of the disease in humans, and a difference in the species causing human disease. For example, before the 1950s, most cases of human rabies in the United States were related to dog bites. With the recognition of the role of wildlife, and the control of rabies in dogs, human cases have been identified related to skunk, fox, raccoon, bat, and other wildlife exposures. Most human cases are now due to viruses associated with bats, many without a firm history of bite documentation, either because the patient did not appreciate the risk from bats, or did not realize the exposure.

Transmission

Rabies embodies the quintessential elements of neurotropism.² Lyssaviruses may be perpetuated in certain animal populations over time, but they do not persist in an individual animal. From the standpoint of basic pathogenesis, lyssaviruses face three primary challenges: animal entry, progeny formation, and host exit. An animal bite is the main transmission mechanism. After inoculation into a wound, the virus may replicate locally in muscle tissue, or travel directly in a retrograde fashion via the axoplasm of peripheral nerves, from the local site to the central nervous system. In the brain, the virus replicates in the neuronal cytoplasm. Thereafter, virus passage occurs centrifugally before death to a number of innervated sites, including the major portals of exit, the salivary glands. Typically, viral shedding in saliva is concomitant with illness, but virus may be present in saliva for several days or more, before the onset of obvious clinical signs.

TABLE 16-2. NUMBER OF RABIES CASES IN THE USA

Year	Dog	Cat	Cattle	Fox	Skunk	Raccoon	Bat	Human
1943	8515	316	349	107	15	0	0	41
1953	5699	539	1021	1033	319	40	8	14
1963	573	217	459	622	1462	162	303	1
1973	180	139	381	477	1851	114	432	1
1983	132	168	204	111	2285	1906	910	2
1993	130	291	130	361	1640	5912	759	3
2003	117	321	98	456	2112	2635	1212	3

Experimental and epidemiological data have defined the period of salivary viral excretion in several domestic animals, in relationship to illness, simplifying public health management. If a healthy domestic dog, cat, or ferret bites a person, the animal should be observed under veterinary supervision for at least 10 days. If clinical signs of rabies develop, the animal should be euthanized and its brain examined for diagnostic evidence of viral infection. If the animal remains normal, the bitten person is not considered to have been exposed to the virus. Ordinarily, clinically rabid domestic animals, such as dogs, cats, and ferrets, succumb within 3–7 days of illness. However, wild rabid animals may excrete virus for a greater period before death, and may live longer after the appearance of clinical signs. Wildlife that bite humans should be euthanized immediately and the brain sent for diagnostic testing as quickly as possible.

Besides typical transmission related to animal bites, human cases have been reported due to other transdermal or mucosal non-bite exposures, such as improperly inactivated vaccine, viral aerosols, and tissue or organ transplantation.^{2, 6, 7} Aerosol transmission was implicated in two research workers exposed during experimental laboratory procedures, and suspected in two individuals who worked in many caves that contained millions of bats. Other means of infection, such as contamination by the oral route, have been demonstrated experimentally in animals. The actual role and importance of non-bite transmission, especially as a mechanism for maintaining virus in nature, is speculative.

Clinical Disease

Animals

Rabies has a prolonged and highly variable incubation period, the time after exposure until disease manifestation, and is remarkable in the variety of signs it may cause. An animal may develop rabies within two weeks or less, or it may show no illness for six months or longer. The incubation period in dogs and cats usually ranges from 20 to 60 days.

The only characteristic clinical attribute associated with rabies is the rather uncharacteristic nature of its presentation. In general, an animal manifests signs in either or both of two major forms: (a) “furious” rabies and (b) “dumb” or paralytic rabies. The form the disease assumes may depend in part on the dose of the virus, the viral variant, host factors, and the sequence of events involved as the virus invades the central nervous system. Furious rabies occurs frequently, and is more likely to lead to infection of other animals or humans. During early stages, the animal may appear more aggressive or affectionate than usual but is easily irritated and may bite with minimum provocation. Additionally, the animal may exhibit restlessness, with a tendency to snap at anything that comes its way. Dogs may attack automobiles, or exhibit pica. Rabid cats may hide or viciously attack anyone who approaches. Vocalizations become altered as paralysis sets in. In “dumb” rabies, the animal is not obviously irritable and may hide and become somnolent. In livestock, ataxia may be more notable. Other animals may appear to be choking. Human exposure may result from attempting to look in the animal’s mouth for evidence of a foreign object, or to administer medication. Cranial nerve deficits may be observed, rapidly followed by general paresis and paralysis, and death can occur 1–3 days after onset. Signs of disease in wildlife may be less reliable than in domestic species. By attempting to help, many human bites occur after handling of sick or paralyzed wild animals.

Signs of rabies may resemble those of other acute, progressive infectious diseases or toxic syndromes that affect the central nervous system. A clinical diagnosis may be supportive, but is inadequate alone. Laboratory tests are needed for a definitive diagnosis. Animal exposure to rabies may not necessarily lead to a productive infection or a fatal outcome. For example, bats, mongoose, skunks, foxes, raccoons, and other animals have been found with serological evidence of rabies virus exposure. In addition, clinical rabies has been observed on occasion in laboratory animals, followed by apparent recovery.²

Humans

The phases of rabies can be divided broadly into the incubation period, the prodromal period, the acute neurological phase, coma, death, and very rarely in extreme cases, recovery.^{6, 8} As in other animals,

the incubation period in humans is quite variable and is determined in part by the location of the bite, its severity, and the distance the virus must travel to the brain. Usually, the incubation period is quite short after facial bites and may be longer after bites on the extremities. A typical incubation period is approximately 4–6 weeks, but extremes of 10 days to more than 1 year have been recorded.

The disease usually runs its course within one week and is nearly always fatal. The terms “hydrophobia” and “aerophobia” derived from observations that patients may experience difficulty in swallowing, with spasms of the muscles of deglutition from a reflex contraction after contact with liquids or air currents, and hence an aversion to them. Periods of excitability (sometimes reaching the point of mania) may alternate with calm. Paralytic manifestations occur usually late in the disease. Prolonged survival has been reported after intensive care. Historically, five cases of survival from clinical rabies have been reported, when vaccination was used before the onset of clinical signs. Recently, a remarkable case of recovery was noted in a Wisconsin teenager, after an untreated bat bite, with no use of rabies biologicals.⁸ Proof of concept for experimental treatment will be required before any suggestion of a “cure” is accepted. Prevention of exposure and disease development is the most prudent and proper course of action.

Diagnosis

The suspicion of rabies is based on the consideration of many factors, including a history of animal exposure, suggestive clinical signs, and a compatible disease course. The historical demonstration of intracytoplasmic inclusions suggestive of Negri bodies within CNS neurons via histopathology is a method used less frequently throughout the world, because inclusions are not always present, and may be atypical or confused with other conditions. Modern confirmation is based upon laboratory detection of virus, antigen, antibodies, or nucleic acid. When available, fresh or frozen unfixed brain tissue or biopsy is the specimen of choice. In the terminal stages, viral products may be widely distributed outside the CNS at sites of innervation. In suspect animals, this involves euthanasia and postmortem collection of the brainstem and/or cerebellum. In humans, antemortem testing may be performed, and typical specimens may include serum, csf, saliva, and a full thickness skin biopsy from the nape of the neck.⁹

The direct fluorescent antibody (DFA) assay is the standard test of choice.¹⁰ The DFA test is highly sensitive and specific, and requires only a few hours to perform. The assay is based on the detection of viral antigen in a slide impression of brain tissue by direct staining and microscopic visualization of antigen-antibody reactions. Viral antigen can also be visualized in frozen skin biopsies or corneal impressions by the DFA test, within hours. Other tests are employed for viral isolation, serology, or detection of nucleic acids. Intracranial inoculation of brain or saliva specimens into laboratory rodents can take 7–14 days or more before results are available. Virus isolation in susceptible cells, such as neuroblastoma, is shorter than by animal inoculation, on the order of 1–7 days. Rabies virus antibodies can be detected in a few hours from patient serum or csf by ELISA or indirect FA testing. Antibody levels can be determined by virus neutralization tests performed either by animal inoculation techniques, or in cell culture, such as the rapid fluorescent focus inhibition test (RFFIT), which can measure antibody levels within 24 hours. Amplification of small quantities of viral nucleic acid by RT-PCR and genetic sequencing of products may be performed upon saliva and other tissue specimens, within 1–3 days. In formalin fixed tissues, viral antigen may be observed using immunohistochemistry, or by alterations to the DFA test procedures. A national protocol for the laboratory diagnosis of rabies in animals has been developed in the United States (http://www.cdc.gov/ncidod/dvrd/rabies/professional/publications/DFA_diagnosis/DFA_protocol-b.htm).

Prevention

Rabies can be prevented by avoiding exposure. In addition, specific prophylaxis can be considered after exposure, or vaccination may be administered in certain populations at risk before exposure. Current postexposure and preexposure recommendations are derived primarily

from the 1999 report of the Advisory Committee on Immunization Practices (ACIP), which should be consulted for further details.¹¹ Prompt cleansing of all wounds contaminated with rabies virus is of paramount importance during first aid. Local attention to bites and scratches should include cleansing with a soap solution, and thorough flushing of the wound. If possible, the wound should not be sutured immediately, to avoid the opportunity for further tissue contamination with virus. Use of antibiotics and tetanus prophylaxis may be indicated for wounds inflicted by animals.

Human Vaccination

In the 1880s, Pasteur developed a method of postexposure prophylaxis using desiccated nerve tissue from experimentally infected rabbits, with residual live virus in the vaccine preparations. Multiple doses were needed due to low vaccine potency. During the early twentieth century improved methods, using ultraviolet light, phenol, formalin, and other chemicals, were employed to inactivate the virus from nervous tissue in the vaccine preparations. Allergic reactions and other more serious neurological complications, including encephalitis, peripheral neuritis, and various paralytic phenomena, have been attributed to sensitization to myelin proteins present in nerve tissue-derived vaccines. Depending upon the biological, the historical frequency of paralysis during administration of vaccine containing nervous tissue ranged between 1:600 and 1:6000 per individuals vaccinated. To reduce this frequency, a suckling mouse brain vaccine was developed and widely used throughout Latin America until recent times. In the United States, a duck embryo vaccine was in routine use from 1957 until about 1981. This latter vaccine was used in a manner similar to older rabies vaccines, with 14–21 doses at daily intervals.

In the latter part of the twentieth century, advances were made in the improved development of cell culture vaccines against rabies. Use of a Human Diploid Cell Vaccine began in the late 1970s, and by the end of the century two other vaccines, Rabies Vaccine Absorbed, grown on rhesus monkey cells, and a Purified Chick Embryo Cell Vaccine, became available for human use in the United States. These potent vaccines produced a much more rapid conversion rate of antibody than previous products. Moreover, adverse reactions were much less common and less serious than nerve tissue vaccines. Local reactions included pain, erythema, swelling, or itching at the injection site in approximately 30–70% of recipients. Systemic reactions, such as headache, nausea, abdominal pain, muscle aches, and dizziness, were reported in approximately 5–40% of recipients. A few cases of Guillain-Barre syndrome, which resolved without sequelae in 12 weeks, were reported. Other subacute central and peripheral nervous system disorders were temporarily associated with vaccination, but no causal relationship was established. Hypersensitivity reactions characterized by general urticaria and sometimes arthralgia, arthritis, angioedema, nausea, vomiting, fever, and malaise were observed in some patients from minutes to 21 days following a booster, but hospitalization was

not indicated. The implicated antigen was a β -propiolactone-human serum albumin complex formed during preparation of vaccine. No reaction has been regarded as life threatening.

The current recommended postexposure regimen is five 1-ml vaccine doses. The first dose is given as soon as possible, preferably on the same day as exposure and each succeeding dose on days 3, 7, 14, and 28. Each dose is given intramuscularly in the deltoid region, or to infants in the anterolateral aspect of the upper thigh. The gluteal area should not be used due to variable effectiveness and the possibility of nerve injury. Specific recommendations for postexposure prophylaxis are modified depending on the circumstances of the event, species of animal involved, type and severity of exposure, and prevalence of rabies in the biting animal (Table 16-3). Knowledge of these facets requires adequate local surveillance and communication with relevant public health authorities.

Human Rabies Immune Globulin

To bridge the gap before the active induction of virus neutralizing antibodies from vaccine, rabies immune globulin (RIG) of human origin should be given to all naïve exposed persons. The only exceptions are those persons who have received prior rabies vaccination. The RIG should be given as soon as possible after exposure and, within reason, should be used regardless of the interval between exposure and the presentation for prophylaxis. If RIG was not given when rabies vaccine was started, it can be given up to the seventh day after the first vaccine dose. As much of the dose as feasible should be thoroughly infiltrated into and around the wound, and the remaining volume given intramuscularly. The first dose of vaccine should be given at the same time but at a separate site. Heterologous products, such as preparations made in horses, may be utilized abroad.

Human Preexposure Vaccination

For persons at risk of exposure to rabies, such as veterinarians, laboratory staff working with rabies virus, animal handlers, naturalists, and those working in parts of the world where rabies is a threat, it is desirable to provide active vaccination in advance of possible exposure. Three doses of vaccine are recommended on days 0, 7, and 21 or 28. Routine serology is not generally recommended after primary vaccination unless an alteration in the schedule occurs or the person is immune suppressed (e.g., illness, corticosteroids). Preexposure vaccination does not eliminate the need for prophylaxis after an exposure, but it reduces the postexposure regimen. Periodic (every six months to two years, depending on the degree of risk) antibody testing should be scheduled for those who remain at risk of rabies exposure. A single booster dose of vaccine is recommended if the antibody titer falls below complete neutralization at 1:5 by the RFFIT assay.

Because modern cell culture vaccines are expensive, the intradermal (ID) route of administration, using 0.1 ml per dose, was explored

TABLE 16-3. GENERAL CONSIDERATIONS FOR HUMAN RABIES POSTEXPOSURE PROPHYLAXIS (PEP) IN THE USA*

<i>Animal</i>	<i>Circumstances</i>	<i>Comments</i>
Dog, cat, ferret	Available, healthy	If animal exhibits illness in 10 day observation period, administer PEP.
	Suspected rabid Unavailable	Immediate PEP. Consider individually.
Livestock	Available/Unavailable	Consider individually, or upon test results.
Wildlife	Carnivores, bats	PEP, unless prompt testing is negative.
	Other species	Consider individually.
Small mammals	Available/Unavailable	Large bodied rodents in the eastern USA, such as woodchucks and beavers, have been found rabid. Shrews, moles, mice, rats, squirrels, rabbits, hares and other small mammals are infrequently rabid and rarely require PEP.

*This chart is intended only as a guide, based upon current ACIP recommendations. PEP is initiated whenever rabies is strongly suspected.¹¹

originally for preexposure vaccination, and later for postexposure use, especially in developing countries. Overall results were encouraging, although the antibody response may be somewhat lower and of shorter duration than with the 1.0-ml intramuscular dose. Previously, inadequate antibody titers resulted when the preexposure ID technique was used on patients during antimalarial chemoprophylaxis with chloroquine.¹¹ Although licensed for preexposure use at one time, no such rabies vaccine is currently marketed in the USA for ID use.

Veterinary Vaccines

The proper use of rabies vaccines in animals has led to a major impact upon the diminution of human cases in developing and developed countries.^{12,13} In the United States, vaccines for dogs, cats, and other domestic species contain inactivated or recombinant viruses. Some of these vaccines are administered annually. Other vaccines produce immunity lasting at least three years, and are generally considered the vaccines of choice. A compendium for animal rabies prevention and control, and recommendations for vaccination procedures, has been developed and is available through the National Association of State Public Health Veterinarians.¹³ This compendium reviews all licensed animal rabies vaccines in the United States and provides information on dose, age for immunization, and revaccination schedules, by species. Historically, on rare occasions, older modified-live rabies virus vaccines caused rabies in some animals. Such vaccines for parenteral application are no longer marketed in the United States.

Control

As a zoonosis, modern rabies control is focused directly upon animal populations. In some parts of the world, such as many island nations, rabies in domestic animals has been eliminated. Such activities have been supported by quarantine measures applied to dog populations, provided wildlife are not involved extensively in the propagation of the disease. Where rabies is established in wildlife, control also depends on measures that are effective in reducing susceptible populations to below a critical threshold required to maintain infection. By enforcement of ordinances designed to accomplish this activity, canine rabies has been eliminated from urban and suburban communities throughout Western Europe, the United States, and Canada.

The prophylactic vaccination of dogs is one of the most important methods of rabies control.^{12,13} When the disease is enzootic among

wildlife, routine vaccination of both dogs and cats should be practiced. Although effective where used, such programs may not reach free ranging dogs or feral cats. Therefore, it is essential to maintain other measures of control.¹³ Public education about responsible pet ownership should be encouraged. Licensure of dogs, early spay and neuter programs, and collection of stray, ownerless, or unwanted animals can be supportive. Especially where there is a threat of canine rabies, dogs in urban areas should be restrained on a leash or kept on the owner's fenced premises. Supervision of cats is indicated as well. Rabid cats now outnumber rabid dogs in the United States, and can bring into homes wildlife, such as bats, that may bite people. Animal bites should be reported to a public health agency. If rabies is present in a community, any dog, cat, or ferret which bites a person should be reported to local health or animal control authorities, and be confined and observed for signs of rabies. Biting wildlife should be euthanized and sent for diagnostic testing.

A more permanent solution to the rabies problem affecting humans and domestic animals would require appropriate control of the disease in wildlife. Effective rabies control in wildlife is difficult.¹⁴ Programs designed for population reduction are expensive, frequently controversial (especially among animal humane societies, ecologists, and conservationists), and the effects are often short-lived. Compared to the cost of trapping and killing predators, vaccination appears more productive as a rabies control tool. Oral vaccination of wildlife by distribution of baits that contain attenuated rabies virus or recombinant virus vaccines has been used widely in Europe and North America.¹⁵ Rabies control in bat populations is more difficult than among mammalian carnivores. Except for vampires, in which selective programs have been designed, other bats should not be killed or molested, because bats offer many ecological benefits, and destruction can increase public health and veterinary exposures as people and domestic animals contact dead or dying bats. Unlike terrestrial mammalian carnivores, house bat colonies do not experience widespread rabies outbreaks. Generally, few free-ranging bats are affected. Colonies should be excluded humanely from human dwellings, after young bats can fly, followed by construction attempts to prevent reentry.¹³ Until these overall problems in wildlife can be resolved, rabies control will remain a challenge in many areas, and the occasional human case fatality will occur, even after canine rabies elimination.

Bacteria

Bacterial Zoonoses—Psittacosis

Lauri A. Hicks • Maria Lucia Tondella

► PSITTACOSIS

Psittacosis, an infection caused by the bacteria *Chlamydia psittaci*, is a zoonotic disease transmitted from birds to humans. While *C. psittaci* infection in humans is referred to as psittacosis, infection in birds is usually referred to as avian chlamydiosis. Psittacosis is

most frequently attributed to exposure to parrots and parakeets (psittacine species); however, chlamydial infections have been documented in approximately 150 avian species.¹

Bacteriology

C. psittaci is an obligate intracellular organism with worldwide distribution. Chlamydiae replicate when the elementary body, the infective form, enters the cell and reorganizes into a larger, metabolically active reticulate body. The reticulate body undergoes binary fission to form more elementary bodies which are then released from the cell to infect other cells. This unique developmental cycle differentiates

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

these microorganisms and is the basis for their taxonomic classification into a separate order *Chlamydiales*. Recently, a taxonomic reclassification of the order *Chlamydiales* has been proposed and *C. psittaci* was moved to a new genus *Chlamydophila*.² However, this new classification has not been widely adopted because it is based almost exclusively on minor sequence differences in 16S and 23S rRNA genes, and has no new biological markers for genus or species differentiation.³ All chlamydiae share a group-specific lipopolysaccharide antigen but species-specific immunotype antigens are also present.⁴

Clinical Characteristics

Psittacosis usually presents as a febrile pneumonia characterized by a non-productive cough, myalgias, and headache. Chest radiograph may reveal pneumonic infiltrates more significant than the clinical symptoms or physical exam indicate. Pulse-temperature dissociation on exam, if present, that is, fever without an appropriate increase in heart rate, may help to distinguish psittacosis from other forms of bacterial pneumonia. Although pneumonia is the predominant clinical presentation, illness may range from a mild, flu-like illness to severe illness with multi-organ system involvement. Hepatitis, myocarditis, endocarditis, and meningitis have been documented.^{5–8} History of exposure to a sick bird is the most useful information for making a presumptive diagnosis of psittacosis; therefore, it is important for clinicians to elicit such information.

Diagnosis and Treatment

The clinical presentation of psittacosis may be difficult to distinguish from other causes of bacterial pneumonia, so the diagnosis can only be confirmed by isolation of the organism or serologic tests. *C. psittaci* is difficult to isolate and potentially hazardous to laboratorians. Therefore, diagnosis is usually confirmed by serologic means. A fourfold rise in IgG antibodies against *C. psittaci* detected by microimmunofluorescence (MIF) or complement fixation (CF) in paired acute- and convalescent-phase serum specimens is preferred for confirmation of a positive human case.⁹ IgM antibodies detected by MIF at a reciprocal titer of ≥ 16 is also diagnostic. A patient is considered to be a probable case in the presence of a single MIF or CF antibody titer of ≥ 32 after the onset of symptoms. Cross-reactivity with other chlamydiae such as *C. pneumoniae* and *C. trachomatis* occurs with CF, which can make the test results difficult to interpret. MIF is designed to be specific for *C. psittaci* although cross-reactivity with other chlamydiae can occur. Polymerase chain reaction (PCR) assays are also used as diagnostic tests with the advantage of species-specificity. Treatment consists of antibiotic therapy with tetracyclines or macrolides. With appropriate treatment, the disease is rarely fatal.

Transmission

Psittacosis is typically acquired from exposure to pet psittacine birds infected with *C. psittaci*, but disease can be contracted from any bird that carries the bacteria including poultry and wild birds. Mammals, including cows, sheep, goats, and cats may become infected with *C. psittaci*, but mammals rarely transmit disease to humans. However,

severe illness and fetal loss have been observed in pregnant women who have come in contact with infected sheep and goats.^{10,11}

Infection in birds, or avian chlamydiosis, usually presents as a gastrointestinal illness with secondary respiratory involvement.⁹ The disease may be fatal, but it is common for infected birds to manifest only minor evidence of illness, such as ruffled feathers, anorexia, or lethargy. Asymptomatic carriage is also common and recovery from illness may be accompanied by continuous shedding of the organism for several months. Infected birds shed the bacteria in their nasal secretions and feces. Humans acquire infection by direct inhalation of contaminated feces or respiratory secretions or aerosolization of fecal or respiratory dust. Persons in occupations that involve contact with birds, such as poultry workers, pet shop employees, or veterinarians are at higher risk for infection. The incubation period is typically 5–14 days but may be longer. Human to human transmission has only been rarely documented; therefore, standard infection control precautions are sufficient for persons with psittacosis.^{12,13}

Public Health Significance

In the United States, between 2000 and 2003, there were only 73 reported psittacosis cases (CDC, unpublished data). A decline in disease incidence in the United States has been observed since federal regulations were introduced in 1993 limiting commercial importation of psittacine birds. This is consistent with a study that revealed that the number of imported exotic birds correlated with the number of human psittacosis cases in the United States, Sweden, England, and Wales.¹⁴ Psittacosis is a nationally notifiable disease, but national surveillance numbers are likely an underestimate of the true disease burden, reflecting poor detection due to empiric antibiotic use without diagnostic testing and underreporting due to passive surveillance methods.

The most recent widespread outbreak of psittacosis in the United States occurred in 1995. Reports of dying birds among a shipment of over 700 birds to nine Atlanta-area pet stores triggered a public health investigation. Clinical symptoms of psittacosis or serologic evidence of *C. psittaci* infection was observed in over 30% of households with birds from the infected flock.¹⁵ This outbreak highlights how detection of avian chlamydiosis can lead to identification of human disease.

Prevention and Control

Pet stores and veterinarians should educate bird owners about psittacosis. Persons in contact with infected birds and the secretions or feces of these birds should take special precautionary measures. Personal protective equipment, including an N-95 mask and gown, should be worn while in contact with ill birds or while cleaning their cages.⁹ Proper fitting and wearing of personal protective equipment is imperative for disease prevention. Sick birds need to be evaluated promptly, and treated and quarantined under the care of a veterinarian according to published guidelines.⁹ Clinicians should consider testing for psittacosis in the patient with the appropriate exposure history and clinical findings. Psittacosis cases should be reported to local or state public health authorities promptly so that epidemiologic investigations may be conducted to prevent further cases.

Tularemia

Paul S. Mead

Tularemia is a potentially severe bacterial zoonosis caused by *Francisella tularensis*. Transmission to humans occurs through

arthropod bites, ingestion of contaminated food or water, inhalation of contaminated aerosols, and handling of infected animal tissues. Clinical manifestations are variable and depend on the route of inoculation, the dose, and the virulence of the organism. Most commonly, the disease presents in humans as an indolent ulcer at the site of cutaneous inoculation accompanied by regional lymphadenitis

Note: The findings and conclusions in this chapter are those of the author and do not necessarily represent the views of the Centers for Disease Control and Prevention.

(ulceroglandular form). Other forms include glandular, oculoglandular, oropharyngeal, gastrointestinal, septic, and pneumonic tularemia. Although uncommon, tularemia occurs widely in temperate and subarctic regions of North America and Eurasia. Currently in the United States, fewer than 200 cases are reported annually.¹ *F. tularensis* is classified as a Category A bioterrorism agent and has been evaluated as a potential weapon by several countries.

Agent

F. tularensis is a small (0.2 by 0.2 to 0.7 microns), nonmotile, pleomorphic, gram-negative coccobacillus. Although nonsporulating and strictly aerobic, the bacterium is a hardy saprophyte that can survive in water, moist soil, and in decaying animal carcasses. In the laboratory, *F. tularensis* is fastidious, slow growing, and requires cysteine, cystine, or other sulfhydryl containing media.

Isolates of *F. tularensis* can be divided into several subspecies based on virulence testing, biochemical reactions, PCR, and epidemiologic features. Two subspecies account for most human illness: *F. tularensis* subspecies *tularensis* (Jellison Type A) and *F. tularensis* subspecies *holarctica*, (formerly *paleartica*, Jellison Type B). Type A strains have an LD₅₀ in rabbits of fewer than 10 organisms and are generally considered more virulent. They are found almost exclusively in North America. Type B strains have an LD₅₀ of more than 10⁷ organisms in rabbits and are found in both North America and Eurasia. Recently, molecular assays have been developed to further discriminate within subspecies using pulsed-field gel electrophoresis (PFGE), multiple-locus variable-number tandem repeat analysis (MLVA), and whole-genome microarray study.²

Life Cycle of *F. Tularensis*

F. tularensis has been isolated from more than 100 species of wild mammals, at least nine species of domestic animals (including cattle, dogs, cats), 25 species of birds, amphibians, fish, and more than 50 species of arthropods. However, many of these animals may be infected only incidentally. Actual maintenance cycles, although incompletely defined, appear to differ among *F. tularensis* subspecies. Type A *F. tularensis* is believed to occur primarily in rabbits with transmission by ticks (*Demacentor* spp, *Amblyomma* spp, *Ixodes* spp) and tabanid or deer flies (*Cysops discalis*). Type B infections are often associated with aquatic environments and rodents such as beaver, muskrats, and voles. Transmission among these animals may occur through ingestion of contaminated water, soil, or food. Epidemiological studies on humans have also implicated mosquitoes as a potential mode of Type B transmission in Europe.³ Recently, *F. tularensis* has

been shown to survive within free living amoeba, suggesting that protozoa may also play a role in the life cycle of this organism.⁴

Epidemiology

Geographic Distribution

Tularemia is endemic throughout much of North America, from the arctic circle to Mexico, and much of Eurasia, including continental Europe, states of the Russian Federation, China, and Japan.⁵ In the United States, the highest incidences occur in South-central and Great Plains regions, and on the island of Martha's Vineyard, Massachusetts. (Fig. 16-1);¹ in Eurasia, high incidences occur in Sweden, Finland, and Russia.

Populations Affected

Tularemia is a primarily a rural disease. Persons at increased risk of infection include hunters, trappers, and wildlife specialists who handle potentially infected animals, persons in contact with water and soils contaminated by wild animals, persons exposed to bites of certain hard ticks and biting flies, and landscapers who mow or cut brush.⁶ Over time, these associations have generated various descriptive terms, including "wild hare disease," "rabbit fever," "deerfly fever," and "lawnmower tularemia." In addition, laboratory workers who work with cultures of *F. tularensis* can be at high risk of infection if proper laboratory precautions are not observed.

In the United States, 1368 tularemia cases were reported during 1990–2000, an average of 124 cases per year.¹ This compares with a high of 2291 reported cases in 1939.¹ Incidence is highest among children 5–9 years old, adults aged 50 years or more, and among males in all age groups (two- to threefold higher among persons over 15 years old). The great majority of cases occur among whites; however, incidence is highest among American Indians/Alaskan Natives at 0.5 per 100,000, as compared with 0.04 per 100,000 among whites and less than 0.01 per 100,000 among blacks and Asians/Pacific Islanders. Historically, cases have been reported from all states other than Hawaii; however, the states of Arkansas, Missouri, and Oklahoma regularly report more than half of all cases in the United States (Fig. 16-1).

Sources of Infection

Tularemia is notable for having an especially wide array of potential sources and modes of transmission, and the risk posed by any particular source often varies by season and location. In general, arthropod bites and animal contact are believed to be the most common sources of infection. In North American, several tick species are known

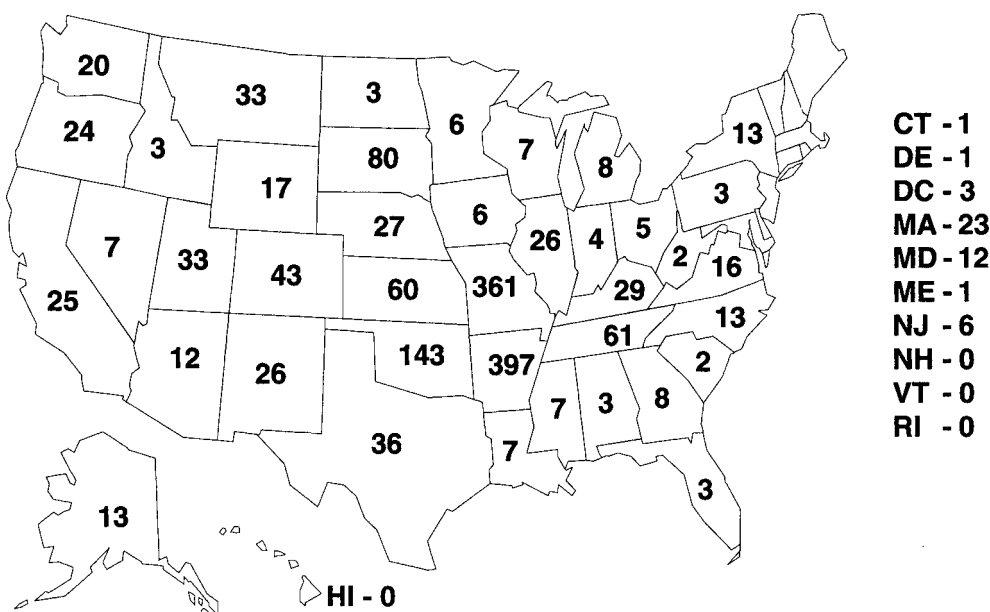

Figure 16-1. Reported cases of tularemia, by State, United States, 1990–2000.

vectors, principally the American dog tick (*Dermacentor variabilis*), the lone star tick (*Amblyomma americanum*), and the Rocky Mountain wood tick (*Dermacentor andersoni*).^{5, 6} Outbreaks due to bites by American dog ticks have occurred repeatedly in spring and early summer among native Americans in Great Plains states of the United States.⁷ Lone star ticks are thought to account for most cases in south-central states, and the wood tick accounts for scattered human cases across the western United States.⁶ Biting flies have been identified as the source of both outbreaks and sporadic cases in western states, especially semiarid areas of Utah, Nevada, California, and Wyoming.^{8, 9} Mosquitoes, although not established as a vector in North America, are believed to be important in transmitting the disease to humans in forested Scandinavian and Baltic regions, and mosquito-borne outbreaks have been reported from Sweden and Finland.¹⁰

Direct contact with hares, aquatic mammals, and contaminated water and soil are important sources of human infection in most of Eurasia. In Japan, the disease has been historically associated with the hunting and eating of wild rabbits,¹¹ and direct contact with rabbits still accounts for many cases in the southeastern United States. A number of outbreaks associated with exposure to muskrats, beaver, and contaminated water have been reported, including a large outbreak in trappers in Vermont.¹² In the United States, an increasing number of tularemia cases have resulted from bites or scratches by infected cats¹³ and recently individual cases have been linked to commercially distributed prairie dogs^{14, 15} and hamsters.¹⁶

Aerosolization of *F. tularensis* occurs, and may result in primary pneumonic tularemia; this has been especially problematic among laboratory workers, but has also been described following exposures to contaminated stored and fresh mown hay, and among workers in factories exposed to contaminated water sprays. In Sweden, a large outbreak of pneumonic tularemia occurred among farm workers exposed to hay contaminated by field voles.¹⁷ Cases of pneumonic tularemia on Martha's Vineyard, Massachusetts, have been linked to landscaping practices, especially mowing, cutting brush, and using power blowers.^{18, 19}

The Disease

Clinical Manifestations

Tularemia is a plague-like illness that begins suddenly 3–5 days (range 1–21 days) after exposure. The major clinical forms of tularemia are: ulceroglandular (45–85% of cases); glandular (10–25%); oculoglandular (<5%); septic (<5%); oropharyngeal (<5%); and, pneumonic (<5%). All forms are accompanied by similar nonspecific symptoms of fever (38–40°C), chills, headache, cough, and generalized body aches.^{20, 21} Without treatment, nonspecific symptoms may persist for several weeks and result in weight loss. Any of the principal forms of tularemia may be complicated by bacteremic spread, leading variously to sepsis, tularemic pneumonia, and meningitis.

Ulceroglandular disease is characterized by a local papule that appears at the site of inoculation within a few days of the onset of generalized symptoms. This papule usually becomes pustular, and then ulcerates about four days after it first appears. The ulcer may take the appearance of an eschar but usually has an indolent character. Lymphadenitis with pain, tenderness, and swelling of one or more regional nodes is usually apparent by the time of ulceration. Epitrochlear and axillary nodes are most commonly affected in persons infected through handling of contaminated materials. Children infected through arthropod bites often have cervical lymphadenopathy, while adults usually have femoral/inguinal adenopathy; these distributions reflect differences in the most common sites of arthropod bites.²¹ In rare cases, abscessed nodes may suppurate and discharge purulent material.

Glandular tularemia is very similar to the ulceroglandular form except that there is no cutaneous ulceration. In oculoglandular disease, which follows contamination of the eye by infectious fluids, ulceration is localized to the conjunctiva, and the cervical and preauricular nodes become enlarged.

Tularemia sepsis, or so-called “typhoidal” tularemia, presents as an acute, sometimes fulminant illness without localizing signs; the

diagnosis is most often made by identifying *F. tularensis* in cultures of the blood. The systemic inflammatory response syndrome may ensue accompanied by any of its usual complications. Hematogenous spread to other organ systems may lead to pneumonia, involvement of the kidneys, and to meningitis.

Oropharyngeal tularemia is acquired by ingesting contaminated food (almost always inadequately cooked meat) or water. Typically the patient develops exudative pharyngitis or tonsillitis, sometimes with ulceration, and cervical lymphadenopathy. Stomatitis occasionally occurs. Infrequently, the upper gastrointestinal tract may become involved, leading to persistent diarrhea.

Pneumonic tularemia can arise as a secondary complication of other forms of tularemia or, less frequently, as a primary pneumonia from exposure to an infective aerosol. Pneumonic infiltrates of varying character may be seen in one or more lobes, and are often accompanied by pleural effusion, and by hilar lymphadenopathy.²² Lung abscesses are sometimes seen. Pulmonic manifestations include cough (usually with minimal sputum production), sometimes pleuritic pain, and rarely, dyspnea.

Prior to the use of antibiotics, overall mortality from infections with Type A *F. tularensis* was in the range of 5–10%, but with fatality rates of 40–60% for septicemic and pneumonic forms of disease. Infection with Type B strains was associated with a fatality rate of only 1–3%. However, recent studies indicate that some Type A strains are associated with lower mortality in humans than Type B strains.²³ In 2000–2001, there were three fatalities reported among 271 case reported in the United States, for an overall fatality rate of 1.1%.²⁴

Diagnosis

The diagnosis of tularemia is made by clinical findings combined with information on potentially infective exposures. Differential diagnostic possibilities are many: in persons with glandular disease they include plague, sporotrichosis, lymphogranuloma venereum, chancre, and chancroid; in persons with oropharyngeal tularemia, other bacterial and viral causes of stomatitis, pharyngitis and cervical adenitis must be considered; in persons with pneumonia, they include legionnaires disease, histoplasmosis, and tuberculosis; and, in persons with tularemia sepsis, typhoid fever, and other causes of systemic inflammatory response syndrome.

The diagnosis of tularemia is confirmed by isolation of *F. tularensis*. Suspicion of tularemia should be conveyed to the microbiology laboratory to guide selection of appropriate media and to protect the safety of laboratory workers. Appropriate media for isolation from clinical specimens include Thayer-Martin agar, chocolate agar, cysteine heart agar with 9% chocolized blood (CHAB), buffered charcoal-yeast extract agar and thyoglycollate broth.²⁵ Inoculated plates should be incubated at 37°C and held for up to 14 days. Colonies are pinpoint after 24 hours of incubation, and may be only 3 mm in diameter at 96 hours. Because of its slow growth, *F. tularensis* may be obscured in culture by more rapidly growing organisms. Isolation from contaminated materials can be achieved by passage through laboratory mice in specialized laboratories or by growth on enriched cysteine heart agar blood culture medium supplemented with antibiotics (CHAB-A).²⁶

In addition to culture, materials other than blood should be streaked on glass slides for examination by fluorescent antibody testing. Other potentially useful rapid diagnostic procedures include enzyme-linked immunoassay and immunoblotting for IgM antibodies, polymerase chain reaction assays, and DNA probes; however these are not routine. The agglutination reaction for combined IgM and IgG immunoglobulins is the routine immunodiagnostic procedure in use in most laboratories. Reference laboratories use microagglutination methods that are more sensitive than tube agglutination procedures.

Many routine diagnostic laboratories have policies that exclude work on *F. tularensis*, since it readily aerosolizes and is a notorious cause of laboratory-acquired infections. Biosafety level 2 precautions are essential for routine procedures, and

biosafety 3 precautions are needed for animal studies. In the United States, the national diagnostic and reference laboratory for tularemia is located at the Centers for Disease Control and Prevention, Division of Vector-Borne Infectious Diseases, Fort Collins, Colorado. Identification by automated systems can be unreliable and is potentially dangerous.

Treatment

Streptomycin is the drug of choice based on experience, efficacy, and FDA approval. Gentamicin is considered an acceptable alternative, but some series have reported a lower primary success rate and some relapses.²⁷ Treatment with aminoglycosides should be continued for 10 days.²⁸ Tetracycline may be a suitable alternative to aminoglycosides for less severely ill patients, but must be given for at least 14 days as relapses can occur. Ciprofloxacin is not FDA approved for treatment of tularemia but has shown good efficacy *in vitro*, in animals, and in humans.^{27, 29–32}

Anthrax

Sean V. Shadomy • Nancy E. Rosenstein

► BACKGROUND

Anthrax, caused by the bacterium *Bacillus anthracis*, has been recognized as an infectious disease of both humans and animals for many centuries. While no longer causing substantial disease in the United States, it occurs in multiple developing countries worldwide and is a major bioterrorist threat. The name of the disease, *anthrax*, is derived from the Greek word *anthrakos*, meaning charcoal or carbuncle, and referring to the black skin lesions commonly seen with cutaneous anthrax infection.¹ Anthrax is likely to have originated over 6000 years ago in ancient Mesopotamia and Egypt, where it may have been the cause of the fifth plague of Egypt, although it may have existed as long as 12,000 years ago, when livestock were first domesticated.^{1,2} Virgil described an anthrax epizootic, observing that eating meat or wearing clothes made from the wool or hides of infected animals resulted in human anthrax. Devastating epizootics of anthrax were described in the middle ages, and a major outbreak of anthrax, then called the *black bain*, in Europe in 1613 is reported to have killed 60,000 people.³

In nineteenth century Europe, anthrax outbreaks resulted in significant loss of livestock. In France, at least 20–30% of the sheep and cattle died of anthrax each year.² This devastating effect of anthrax stimulated early microbiological studies of the disease in the mid 1800s. Delafond, Rayer, Daviane, and others described “bodies” or “little rods” in the blood of animals which died of the disease, and in the 1860s Davaine demonstrated that anthrax could be transmitted to healthy animals through the inoculation of blood from anthrax-affected sick or dead animals.^{2,4} Robert Koch was able to grow the anthrax bacillus in a sterile medium outside of an animal host and then infect mice with the resulting spores, thus first demonstrating in 1877 what have become known as Koch’s postulates, and making anthrax the first disease for which a single microorganism was proven to be the etiological agent. Louis Pasteur was the first to develop an effective vaccine for a bacterial disease, demonstrating his anthrax vaccine in 1881.²

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Prevention and Control

Prevention of tularemia is best achieved by avoiding exposure to bites of ticks and blood-feeding flies, and by avoiding direct contact with wild animal tissues. Persons exposed to biting fly- and tick-infested areas should when feasible wear protective clothing, tuck pants legs into socks, and apply repellents containing DEET to skin and clothing as directed by the manufacturer. Permethrin-based acaricides can be applied to clothing to kill ticks on contact. Frequent examinations should be made for ticks on clothing and skin, and attached ticks should be promptly removed. Persons should avoid contact with sick or dead animals, and hunters and trappers should always handle animal carcasses with impervious gloves. In order to reduce tick infestations in residential areas, pet dogs and cats should be restrained and kept tick-free using appropriate acaricides. A live attenuated vaccine (LVS) has been used previously to protect laboratory personnel who routinely work with *F. tularensis*, however is not widely available. Antibiotic prophylaxis is not recommended for persons having exposure to patients with pneumonic tularemia, since person-to-person respiratory spread has not been documented.

In the middle of the nineteenth century, inhalational anthrax, or *wool sorter’s disease*, was recognized as an occupationally-acquired disease among textile workers in England who sorted imported mohair and alpaca hair. It was not until 1879, over thirty years after the disease was first recognized, that John Bell determined that wool sorter’s disease was caused by inhalational anthrax infection. Recommendations were made the following year for the cleaning of imported mohair, and later these Bradford Rules, named for the city in England which was the center of the mohair wool industry, were improved by calling for ventilation to protect workers from contaminated dust. The Bradford Rules were codified in 1897, followed by the Anthrax Prevention Act in 1919 which called for formaldehyde disinfection of potentially infected imported mohair and wool.⁴ These rules and laws were successful in dramatically decreasing the incidence of the disease. In the United States, improvements in industrial hygiene, a decrease in the use of imported, contaminated raw animal materials, and immunization of at-risk workers helped to limit industrial inhalational anthrax exposure,⁵ and during the twentieth century there were only 18 inhalational anthrax cases in the United States.⁶ Vaccination has helped to restrict the disease among livestock and reduce the spread of anthrax to humans, however epizootics of anthrax still occur worldwide, especially in areas where vaccine use is not comprehensive, and these are frequently associated with cases of anthrax among persons exposed to infected animals.

Anthrax is one of the most serious of biowarfare or bioterrorism agents. It was used by Germany during World War I against livestock and draft animals, and Japan conducted field trials with anthrax in Manchuria during World War II.⁷ The United States and Britain conducted anthrax weapon research during World War II, and the Soviet Union, Iraq, and others nations did so afterwards.^{7,8} In 1979, a large epidemic occurred in the Soviet city of Sverdlovsk, following an accidental release from a military microbiologic facility.⁹ In 2001, twenty-two confirmed or suspected cases of anthrax occurred in the United States after *B. anthracis* had been sent through the mail in powder-containing envelopes.^{10–12} Eleven of the cases were of inhalational anthrax and 11 cutaneous, and 20 of the cases were either mail handlers or persons exposed to buildings where contaminated mail was processed or received.¹³ The source of exposure was unknown in two of the fatal inhalational anthrax cases,^{14,15} however it is suspected that the cases were exposed through cross-contaminated mail.

The Agent

B. anthracis, the etiologic agent of anthrax, is a large, gram-positive, nonmotile, spore forming bacterial rod. The bacillus grows well on a variety of bacterial culture media, with optimal growth at 37°C. On blood agar plates, it forms large, nonhemolytic, grey or white-colored colonies. The tenacious (sticky) character of these colonies can be demonstrated when lifted by an inoculating loop and has been described as standing up like *beaten egg white*.⁵ The virulence of *B. anthracis* is dependent on three plasmid-mediated virulence factors: edema toxin, lethal toxin, and a poly-D-glutamic acid capsule.¹⁶ The antiphagocytic poly-D-glutamic acid capsule is encoded for by the pXO2 plasmid.¹⁷ The pXO1 plasmid encodes for three exotoxin components, edema factor, lethal factor, and protective antigen (PA). Edema factor combines with PA to form edema toxin, which causes edema and inhibits neutrophil function, which may be the cause of host-susceptibility to infection with *B. anthracis*.^{18,19} Lethal factor (LF) combines with PA to form lethal toxin, which causes shock and death. Injection of LF in the mouse model has been shown to result in hypoxic tissue injury and liver failure, and death with shock-like manifestations.²⁰

Human Anthrax

Human anthrax has three major clinical forms; cutaneous, inhalational, and gastrointestinal.⁶ Cutaneous anthrax is a result of introduction of the spore through the skin; inhalational anthrax via the respiratory tract, and gastrointestinal anthrax via ingestion through the gastrointestinal tract. Cutaneous anthrax is the most common manifestation of infection with *B. anthracis*.

Cutaneous Anthrax. Cutaneous anthrax is associated with a characteristic skin lesion usually developing within 5–7 days following infection (range 1–12 days).^{5,21} Cutaneous anthrax develops after subcutaneous introduction of *B. anthracis* spores, frequently from contact with infected animals or animal products. Cuts or abrasions increase susceptibility to cutaneous infection. Over 90% of the cutaneous anthrax lesions occur in exposed areas such as the face, neck, arms, and hands. The lesion begins as a small, painless, but often pruritic papule, which quickly enlarges and develops a central vesicle or bulla. The vesicle ruptures or erodes, leaving an underlying necrotic ulcer. A characteristic black eschar develops over the surface of the ulcer. Satellite vesicles and ulcers may also form.^{22,23} Edematous swelling of the surrounding tissues is present, often with regional lymphadenopathy and lymphangitis.^{5,21} Historically, case fatality rates can be as high as 20% without appropriate treatment, however the case fatality rate is less than 1% with antibiotic therapy.¹⁶

Inhalational Anthrax. Inhalational anthrax develops following the inhalation of aerosols of anthrax spore-containing particles and the subsequent deposition of particles 5 µm or less in size in the alveolar ducts or alveoli. Naturally occurring inhalational anthrax usually results from the inhalation of *B. anthracis* spores aerosolized through industrial processing of materials from anthrax-infected animals, such as goat hair. Inhalational anthrax can also result from intentional release of aerosolized spores.⁵ The spores are phagocytosed by alveolar macrophages and transported to mediastinal lymph nodes where they germinate, multiply and release toxins, resulting in hemorrhagic necrosis of the thoracic lymph nodes and a hemorrhagic mediastinitis. Necrotizing pneumonia may also develop at the portal of entry in the lungs.²⁴ The incubation period for inhalational anthrax is typically 1–7 days, however incubation periods as long as 42 days were reported in the 1979 outbreak in Sverdlosk.⁹ During the 2001 bioterrorism event in the United States, the time between exposure and symptom onset ranged from 4 to 6 days.^{13,25} Inhalational anthrax has developed in experimentally infected primates up to 58 days after aerosol exposure and 30 days of post-exposure antibiotic treatment.²⁶

The course of inhalational anthrax may be biphasic. Early clinical symptoms are nonspecific, and include low-grade fever, malaise, fatigue, myalgia, and nonproductive cough, and may mimic other illnesses such

as influenza.^{27,28} Two to three days later, the second stage of acute toxicity begins with sudden onset of severe dyspnea, and hypoxemia. Patients become hypotensive, with profuse sweating, cyanosis and shock, and stridor.^{6,29} Bacteremia may result in lesions in other organ systems, including hemorrhagic meningitis and submucosal gastrointestinal lesions.²⁴ Untreated, inhalational anthrax is usually fatal; among the 18 cases reported in the United States in the twentieth century, the case fatality rate was 89%,⁶ and 77 cases of inhalation anthrax with 66 deaths (86%) were reported in the 1979 Sverdlosk outbreak.⁹ Antibiotic therapy can be successful, especially if initiated early in the course of disease,^{9,6,25} however even with early initiation of treatment 5 of the 11 inhalational anthrax cases (45%) associated with the 2001 bioterrorism event in the United States failed to respond to antibiotic therapy.¹³

On chest x-ray, the classic finding is widening of the mediastinum from the swollen lymph nodes and pleural effusions.³⁰ This was documented in 7 of the first 10 inhalational anthrax cases from the 2001 bioterrorism event.²⁵ In 2001, chest x-ray abnormalities, including mediastinal widening, hilar abnormalities, pulmonary infiltrates or consolidation, and pleural effusion, were documented in all 11 cases, however the abnormalities were often subtle and in 3 of the 11 cases initial chest radiographs were initially interpreted as normal.^{15,25,31}

During a potential bioterrorism episode, distinguishing inhalational anthrax from more common disorders such as community-acquired pneumonia (CAP), influenza and influenza-like illnesses (ILI) is critical, because of the narrow window of opportunity for successful treatment once symptoms appear. Several studies have attempted to determine certain signs and symptoms to distinguish cases of ILI from inhalational anthrax cases during a bioterrorist event.³² Nasal congestion, rhinorrhea, and a sore throat are present in the majority of ILI cases, but were present in only 10–20% percent of the inhalational anthrax cases in 2001; shortness of breath was present in 80% of the inhalational anthrax cases in 2001 but is routinely found in less than 10% of influenza or ILI cases. In a review comparing naturally occurring or bioterrorism-related cases of inhalational anthrax with cases of CAP or ILI, the presence of nausea, vomiting, pallor or cyanosis, diaphoresis, altered mental status, and elevated hematocrit predicted the presence of inhalational anthrax, however the most accurate predictors of inhalational anthrax were mediastinal widening or pleural effusion on chest x-ray. The presence of one or both of these radiographic abnormalities was 100% sensitive for inhalational anthrax, and 72% specific when compared to CAP, and 96% specific when compared to ILI.³⁰ The Centers for Disease Control and Prevention (CDC) developed interim recommendations for the clinical evaluation of persons with possible inhalational and cutaneous anthrax during the 2001 bioterrorist event,³¹ available at <http://www.cdc.gov/mmwr/preview/mmwrhtml/mm5043a1.htm>. The recommendations from CDC are subject to update as additional information and research becomes available, and updates may be obtained from the CDC website at <http://www.bt.cdc.gov/agent/anthrax/index.asp>.

Gastrointestinal Anthrax. Gastrointestinal anthrax develops following the consumption of undercooked meat from animals sick or dead as a result of anthrax, and tends to occur in family clusters or point source outbreaks, often accompanied by cutaneous anthrax cases acquired through the butchering and handling of infected meat. The incubation period of gastrointestinal anthrax is estimated to be 1–6 days,³³ and mortality is estimated to range from 25 to 60%.⁵ There are two clinical forms of gastrointestinal anthrax, oropharyngeal and intestinal. The oropharyngeal form develops following infection of the oropharyngeal epithelium. Edematous lesions develop on the epithelium and progress to necrotic ulcers with a pseudomembrane. Profound edema develops in the oropharynx and neck, and cervical lymphadenopathy, pharyngitis, and fever develop.^{33–35} The intestinal form develops following infection of the gastric or intestinal mucosa. The infected intestinal segments become edematous, lesions may become necrotic and ulcerated, and draining mesenteric lymph nodes become infected and enlarged.^{16,36} Patients may present with fever,

nausea and vomiting, anorexia, abdominal pain, and tenderness; symptoms may progress to hematemesis and bloody diarrhea, and patients may develop abdominal swelling as a result of voluminous, hemorrhagic ascites.^{36,37} In less severe cases, only mild diarrhea and abdominal pain may develop. The disease may progress to septicemia and toxemia, resulting in cyanosis, shock and death.⁵

Hematogenous Infection. With any form of anthrax infection, hematogenous spread can produce lesions in other organ systems, including hemorrhagic meningitis and submucosal gastrointestinal lesions.^{24,29} In a review of the necropsies and available specimens of 42 of the inhalational anthrax fatalities from the 1979 outbreak in Sverdlosk, Abramova, et al, reported hemorrhagic leptomeningitis in 21 (50%) of the cases and gastrointestinal submucosal hemorrhagic lesions in 39 (93%) of the cases.²⁴

Animal Anthrax

Anthrax in animals been reported on all continents, however the incidence varies greatly by geographic area. Outbreaks tend to occur in river valleys or areas affected by heavy rainfall. Prior to the introduction of effective veterinary vaccines in the late 1930s, anthrax caused heavy losses in cattle, sheep, and goats,² and it is still a major cause of loss of livestock in highly endemic areas, such as Iran, Iraq, Turkey, Pakistan, South America, and sub-Saharan Africa, where animal anthrax vaccination programs are not comprehensive. Anthrax can occur in most animal species, but primarily occurs in cattle, sheep, goats, horses, and wild herbivores. Birds tend to be resistant, however some species such as ducks and ostriches are reported to be susceptible.³ Animals usually are infected by the ingestion of contaminated vegetation, water, infected carcasses, or contaminated feeds such as bone meal from animals that have died from anthrax, and therefore most often develop the gastrointestinal form of the disease. The cutaneous form of the disease probably occurs in animals but is rare.¹⁶

In domestic livestock, the incubation period is typically 3–7 days but may range from 1 to 14 days or more. The clinical course ranges from acute to chronic. Acute illness, with sudden death in animals with no apparent signs within a few hours before death, can occur. In cattle, sheep, and goats, the acute illness is characterized by abrupt onset of fever, depression, and listlessness, which may be accompanied by anorexia, ruminal stasis, signs of abdominal pain, congested or hemorrhagic mucous membranes, hematuria, and blood-tinged diarrhea. Pregnant animals may abort, milk production in lactating animals often ceases or decreases, and milk may be blood-tinged. Edema of the tongue and subcutaneous edematous swellings on the ventral side of the neck, sternum, flank, and perineum may develop. Death usually occurs within 1–3 days of onset.¹ Distinguishing acute cases of anthrax in livestock from other causes of sudden death may be difficult. As a result, it is recommended that livestock found dead in the field not be butchered, and the meat from these animals should not be handled or consumed, especially in regions where anthrax frequently occurs. Occasionally, livestock survive infection without treatment, but this is uncommon. Chronic infection, characterized by localized edematous subcutaneous swelling, rarely occurs in cattle. Certain species are more resistant to infection, including swine and carnivores such as dogs and cats. The infection is localized to the intestinal tract and regional lymph nodes, and the animals frequently recover. In swine, both the oropharyngeal and intestinal forms of gastrointestinal anthrax occur.^{1,16}

Mode of Transmission

The natural reservoir of *B. anthracis* in the environment is the soil.³⁸ The normal cycle of transmission in susceptible animals involves ingestion of spores by an animal, with subsequent infection and development of disease. When the infected animal is ill, dying or dead, vegetative bacilli are shed in the environment in blood or other discharges, or upon opening of the dead animal such as by scavengers; the vegetative bacilli then sporulate and contaminate the

underlying soil. Spores may be spread by wind, fomites or other animals such as scavengers acting as mechanical vectors. Infection of another animal occurs when it consumes food or water contaminated by these spores.^{16,39} The spores may remain viable in the soil for many decades.⁸ Spores in the environment are resistant to desiccation, extremes in temperature and pressure, and ultraviolet and ionizing radiation, however chemical disinfection can eliminate spore contamination of the environment.^{8,39}

Outbreaks are associated with low-lying areas with high moisture content, organic content, and alkaline pH of the soil.^{38,39} The concentration of spores by water runoff into low-lying areas may lead to increased exposure of new hosts to spores on vegetation or in water in those areas, contributing to animal outbreaks.^{39,40} Animal anthrax outbreaks have also been traced to a variety of sources, such as animal-origin feed and fertilizer, river water contaminated by industrial wastes from plants processing animal products, and crops raised on contaminated soil.^{1,16} The incidence of epizootics among livestock has decreased in many developed parts of the world due to the use of animal vaccines and improved husbandry; however, epizootic anthrax is likely to continue to occur in highly endemic areas, such as Asia and sub-Saharan Africa, where the use of animal anthrax vaccines is not comprehensive. Anthrax is not communicable directly between animals, although infection can be acquired by scavengers feeding on carcasses.

Human anthrax infection is primarily secondary to epizootics in animals; however, the threat of intentional anthrax infection resulting from bioterrorist activities has elevated the concern about the potential risk for anthrax infection among persons not previously considered to be at risk. Infection in humans is frequently the result of butchering or handling of animals or parts of animals that are ill or dead from anthrax infection, or the consumption of undercooked meat from those animals. Human anthrax may also result from use of contaminated animal-origin products, such as shaving brushes, or yarn.^{3,6} Infection may also occur as an occupational disease. At-risk workers such as veterinarians and farmers may develop the disease through direct contact with infected animals or tissues at necropsy, or through the handling of animal carcasses. Laboratory workers are additionally at risk when working with samples containing anthrax spores.⁴¹ Industrial inhalational anthrax can result from the inhalation of particles containing anthrax spores generated during the cleaning and processing of contaminated animal hair, making anthrax an occupational disease in the animal hair and wool-processing, tanning, and gelatin industries. The incidence of anthrax infection among industrial workers decreased in the twentieth century following the introduction of disinfection of potentially contaminated animal hairs in England, and improvements in industrial hygiene, decreased use of imported, contaminated raw animal materials, and immunization of at risk workers in the United States.^{4,5} Recovery from anthrax infection will usually result in protective immunity.⁵

Occurrence

Anthrax infection in animals occurs practically worldwide. Outbreaks have been reported in southern and eastern Europe, and the disease is epizootic in many African, Asian, Central American, and other countries. It is infrequent in the United States, Canada, and many European countries, however sporadic outbreaks in livestock and wild herbivores are still reported. A growing number of countries in central and northern Europe, the Caribbean, South America, New Zealand, Taiwan, and others are now free of anthrax, and there has been a general decrease in the number of anthrax outbreaks worldwide.⁴² Because the spores can persist in the soil or environment for prolonged periods of time, anthrax may occur annually or cyclically in some areas whereas, in other regions, intervals of many years between outbreaks are typical.^{42,43} Epizootics tend to occur after periods of marked climatic or ecological change, such as heavy rainfall, flooding, or drought, or during periods of high humidity and high temperature.

Cases of human anthrax are usually associated with outbreaks in animals, and outbreaks of cutaneous and gastrointestinal anthrax are reported in many countries in conjunction with outbreaks in livestock.

However, underdiagnosis and underreporting of animal and human cases, especially in developing countries, limit knowledge of the true burden of the disease. In Zimbabwe, an epidemic of almost 10,000 human cases, mostly of cutaneous anthrax, occurred between 1978 and 1987 when prolonged political instability and armed conflict disrupted animal anthrax control activities.⁴⁴ In some countries with significant epizootic anthrax such as in sub-Saharan Africa or Asia several hundred cases occur each year. In the United States, anthrax infection in humans is rare. Between 1992 and 2000, only one case of cutaneous anthrax was reported in the United States, in association with an epizootic in cattle,⁴⁵ and the last fatal case of anthrax prior to the bioterrorist attacks of 2001 occurred in 1976, in a home where a craftsman died of inhalational anthrax after working with yarn imported from Pakistan.⁶ Recently in 2006 a case of inhalational anthrax occurred in a New York City resident who was making drums from dried, untreated animal hides. The subject recovered following a therapeutic regimen including multidrug antimicrobial therapy, drainage of pleural effusions, and human anthrax immune globulin.⁴⁶

Diagnosis

Because of the rapid progression of disease, antibiotic therapy should be initiated promptly following clinical or laboratory suspicion of anthrax infection, and immediate notification should be made to the local or state health department and public health laboratory. In the United States, the Laboratory Response Network (LRN) has been established by the Association of Public Health Laboratories and the CDC to provide the appropriate laboratory response for acts of bioterrorism, and includes the state public health laboratories. Diagnostic laboratories receiving specimens associated with potential bioterrorist events should contact a LRN laboratory for instructions on testing and handling the specimen. Preliminary diagnostic testing can be performed in hospital laboratories; however confirmatory testing including immunohistochemistry, gamma phage testing, and polymerase chain reaction (PCR) should be performed by LRN laboratories. Guidelines for the collection of specimens and testing procedures can be found on the internet at <http://www.bt.cdc.gov/labissues/>.^{29,47}

Treatment

Successful treatment of anthrax infections with the use of antiserum was demonstrated in 1903, to which the use of neoarsphenamine was added in 1926, and the use of penicillin for treatment was first reported in 1944.^{2,48,49} *B. anthracis* is susceptible to a variety of antibiotics including penicillin, chloramphenicol, tetracycline, erythromycin, streptomycin, and the fluoroquinolones.^{50,51} Testing of the isolates from the bioterrorism-related cases in the United States in 2001 showed susceptibility in vitro to rifampin, vancomycin, chloramphenicol, imipenem, clindamycin, and clarithromycin. Although the isolates were sensitive to penicillin and ampicillin, the presence of inducible beta-lactamases led the CDC to advise against the use of either of these drugs alone for therapy of anthrax cases associated with the 2001 bioterrorism event. The CDC issued interim recommendations for treatment of cases and exposure related to the bioterrorism event; however the agency cautioned that there were no clinical trials on which to base these recommendations.¹⁰

Penicillin has been used extensively for the treatment of cutaneous anthrax, and rapidly clears anthrax bacilli from cutaneous lesions.⁵² However, antibiotic treatment does not prevent progression to the eschar phase. Surgical excision of the cutaneous lesions is not recommended. During the bioterrorist event of 2001, the CDC recommended continuous therapy for 60 days with oral ciprofloxacin or doxycycline for treatment of cutaneous anthrax cases associated with the event based upon the possibility of aerosol exposure in patients with cutaneous anthrax. Treatment with ciprofloxacin or doxycycline was recommended for children and pregnant women, despite usual contraindications against their use, because of the seriousness of the disease and exposure. Treatment regimens used for inhalational anthrax were recommended for patients with cutaneous disease and signs of systemic involvement, extensive edema, or involvement of the head and neck.¹⁰

Antibiotic therapy should be initiated promptly in any patient with suspected inhalational anthrax. Early clinical results from treatment of the inhalational anthrax cases from the bioterrorism event in 2001 suggested that intravenous therapy with two or more antibiotics improved survival.²⁵ The antibiotic regimens used in the cases which survived included ciprofloxacin, rifampin, and vancomycin, or ciprofloxacin, rifampin, and clindamycin. Penicillin was not recommended due to the presence of inducible beta-lactamase in the *B. anthracis* isolates. Cephalosporins and trimethoprim-sulfamethoxazole should not be used for inhalational anthrax therapy. Corticosteroids have been recommended as adjunctive therapy for some patients with inhalational anthrax because of toxin-related morbidity, including patients with extensive edema, respiratory failure, and meningitis.¹⁰

There are few well studied cases of gastrointestinal anthrax or studies of its treatment. In the absence of clinical or study data, the CDC recommends following the treatment protocol for inhalational anthrax for the treatment of cases of gastrointestinal anthrax.¹⁰

Animal origin antiserum was previously used successfully in the treatment of anthrax.^{47,53} In animal models, passive immunization with immune serum containing antibodies against PA administered up to 24 hours after exposure proved effective in preventing infection,⁵⁴ and high-affinity antibodies from persons immunized against anthrax protected rats from injection of anthrax toxin.⁵⁵ Immunoglobulin from plasma harvested from persons immunized against anthrax is available from the CDC under an Investigational New Drug (IND) protocol for the emergency treatment of persons with life-threatening disease caused by anthrax infection and not responding to antibiotic therapy.⁵⁶

Postexposure prophylaxis (PEP) antibiotic therapy has been demonstrated in animal studies to be effective in preventing the development of inhalational anthrax following aerosol exposure to anthrax spores,^{26,57} and PEP may include vaccination in addition to antibiotic therapy. Three oral antibiotics have been approved by the Food and Drug Administration (FDA) for PEP. Ciprofloxacin (500 mg PO BID) and doxycycline (100 mg PO BID) are approved for use in adults and children, and levofloxacin (500 mg PO Q24h) is approved for use in adults 18 and older.^{57,59} The recommended duration of PEP antibiotic therapy is 60 days. The CDC recommends the use of amoxicillin (500 mg PO TID) for PEP when other antibiotics are not as safe to use, such as for children and nursing and pregnant women, in cases where the penicillin antibiotic susceptibility of the anthrax strain has been demonstrated, however this indication has not been approved by the FDA. Anthrax vaccine is available through the CDC as part of the PEP protocol for inhalational anthrax exposure as part of an investigational new drug (IND) protocol. Vaccine should be administered at time zero, two weeks, and four weeks in conjunction with antibiotic therapy, and antibiotic therapy should be continued for at least 7–14 days following the last vaccine dose.⁶⁰

Prevention and Control

Prevention of human anthrax infection is primarily dependent on the control of the disease in animals, especially livestock. Annual immunization of livestock in areas of endemic anthrax is recommended. The animal anthrax vaccine that is most commonly used is the avirulent Sterne strain live spore vaccine.⁶¹ Livestock should be vaccinated 2–4 weeks before the start of the season when outbreaks may be expected.

Animal anthrax cases and outbreaks should be reported to agriculture and public health officials. Affected premises or areas should be quarantined and any slaughter, butchering, and marketing of infected animals or their parts prevented. Antibiotic treatment of affected animals and immunization of all susceptible livestock on affected and surrounding premises is recommended. Investigation for sources of infection other than contaminated pastures may identify other sources, such as contaminated bone meal or feed, to be eliminated to prevent further infection. Carcasses of animals that die of anthrax, bedding, and other contaminated material should be either buried deeply or burned completely. Regulation of the processing, importation and use of bones or bone meal for use in animal feeds or fertilizer requires heating at sufficiently high temperatures to ensure destruction of anthrax spores. Dairy herds in an outbreak area

should be placed under surveillance if the herd has not been immunized previously.⁶² Febrile animals from these herds are to be isolated immediately and the milk discarded. All afebrile animals should be vaccinated when surveillance is initiated, and surveillance can be terminated 10 days after immunization of all animals.

Anthrax vaccine adsorbed (BioThrax, BioPort, Lansing, MI) is the only licensed human anthrax vaccine in the United States. The vaccine is recommended for persons engaged in activities with a high potential for generation of *B. anthracis* aerosols, for persons working with large quantities or concentrations of *B. anthracis* cultures, for veterinarians and others at high risk for handling potentially infected animals in areas with a high disease incidence, and for persons working in high-risk industries, such as those processing imported animal hides, hair, and wool, where industrial hygiene standards and restrictions are insufficient to prevent exposure to anthrax spores.⁶³ The protective efficacy of the vaccine against inhalational anthrax was demonstrated in the rhesus monkey model.⁶⁴ A field trial of an earlier, similar PA-based vaccine demonstrated the efficacy of the vaccine in preventing inhalational and cutaneous anthrax in mill workers at risk for infection.⁶⁵ The recommended vaccination schedule is complex, with six vaccinations administered over a period of 18 months, and an annual booster injection is required. Studies are currently evaluating the immunogenicity of a reduced number of doses and the intramuscular route.⁶³ Other potential vaccine approaches are currently under investigation. A recombinant PA vaccine (rPA) has been demonstrated in animal studies to provide 100% protection against aerosol challenge.⁶⁶ Other vaccines under investigation include a plasmid DNA vaccine encoding genetically detoxified PA and LF,⁶⁷ and less invasive vaccines such as intranasal or cutaneous rPA vaccines.⁶⁸

Brucellosis

Diane K. Gross • Thomas A. Clark

Brucellosis is a bacterial zoonosis of worldwide distribution and great economic importance for affected countries. This disease has been known by many colloquial names, including Malta fever, Mediterranean fever, and undulant fever. It remains endemic in many regions, particularly in the Middle East and Mediterranean.¹ However, several countries have been able to eliminate animal brucellosis through considerable effort.

Malta fever, as brucellosis was then known, was a common infirmity of British troops garrisoned on the island in the 1880s. Sir David Bruce first identified the causative organism of Malta fever in 1887 and named it *Micrococcus melitensis*. Approximately 20 years later, Themistokles Zammit, a Maltese physician, recognized raw goat milk as a vehicle of transmission of the bacterium to humans. Banning the consumption of goat milk by British soldiers greatly reduced the incidence of disease. Bernhard Bang, a Danish veterinarian and contemporary of Bruce, first identified the causative agent of contagious abortion in cattle. He named the organism *Bacillus abortus*. It was not until the 1920s that Alice Evans of the U.S. Public Health Service recognized that the two organisms were related and renamed the genus after Bruce. Since then many other species of *Brucella* have been recognized. *Brucella suis* was identified in 1914, and at least four species have been described since the 1950s.

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Disinfection of materials and surfaces contaminated with *B. anthracis* is complicated by the resistance of the spore. Surface decontamination of the soil requires significant resources and effort,⁸ and the decontamination of buildings or facilities that have been contaminated with *B. anthracis* spores is a substantial and costly effort. A variety of procedures are effective for the decontamination of small items or equipment. These include dry heat, steam under pressure, formaldehyde soaking or vapor exposure, ethylene oxide gas exposure, hypochlorite solution soaking, and gamma-irradiation, and some of these measures have been applied to the decontamination of contaminated buildings or areas. The potential risks associated with the disinfection method—such as the use of formaldehyde or ethylene oxide—need to be weighed against the potential risk for anthrax infection when considering the decontamination method of choice. The effectiveness of the disinfection methodology should be verified by appropriate cultures and quality control procedures.

Anthrax has been a scourge of man throughout history, and outbreaks of naturally occurring anthrax continue to occur worldwide, although they are relatively infrequent in developed countries, and parts of the world have been declared to be free of the disease. However, intentional anthrax infection resulting from bioterrorist activities has changed from a hypothetical to a real threat. Prompt identification and treatment of anthrax infection, especially inhalational anthrax infection, is essential to improve patient survival. The ability to recognize anthrax infection and an understanding of the epidemiology of the disease is necessary for timely diagnosis and treatment of cases, and for early identification of potential outbreaks and appropriate public health response.

The Agent

Historically, the genus *Brucella* has been divided into species and biovars based on host specificity, metabolic requirements, and antigen characteristics. This taxonomy is supported by molecular genotyping methods that can be used to differentiate among these species, although high DNA homogeneity suggests that *Brucella* may actually be a monospecific genus with multiple subspecies.² The current classification system is based on the historically recognized species.³ Identified *Brucella* species include *B. abortus*, *B. melitensis*, *B. suis*, *B. canis*, *B. ovis*, *B. neotomae*, and there is at least one recently described marine mammal species. Most human disease is caused by *B. abortus*, *B. melitensis*, and *B. suis*, though *B. canis* and the marine mammalian species have also caused disease in humans.

All species of *Brucella* are partially host adapted. They have preferred hosts, but can infect other species. *B. abortus* is found primarily in cattle, but also in bison, buffalo, elk, camels, and yak. The major host reservoirs of *B. melitensis* are goats and sheep, however it can also be found in other large ruminants. *B. suis* principally infects swine, both domestic and feral, as well as reindeer and caribou. Cattle and bison can also become infected with *B. suis*. The primary reservoir for *B. canis*, *B. ovis*, and *B. neotomae* are dogs, sheep, and the desert wood rat, respectively.

Brucellae are small, nonmotile, Gram-negative coccobacilli that are nonencapsulated and nonspore forming. These intracellular pathogens are aerobic, but some species may require supplemental CO₂ for isolation. *Brucella* species are further subdivided into biovars, differentiated in part by their substrate utilization, growth on selective media with dyes, and phenotypic characteristics. They are slow growing, fastidious organisms that may require prolonged incubation (up to 6 weeks) for isolation.⁴⁻⁶ Growth is best at 20–40° C (37° C optimal)

with a pH of 6.6–7.4.⁶ The organisms are resistant to drying and survive for long periods at low temperatures. They are destroyed by heat, acid, and common disinfectants including hypochlorite, iodophores, phenols, and formaldehyde.

The major cell surface antigen of *Brucellae* is the surface lipopolysaccharide (LPS). The LPS is an immunodeterminant and a virulence factor. It has two forms, smooth and rough, that differ based on side chain length and morphology. Smooth strains are generally pathogenic, while rough strains are attenuated or not pathogenic to humans. Commonly employed serologic assays detect antibodies to the smooth LPS (S-LPS). Other Gram-negative bacteria such as *Vibrio cholerae*, *Yersinia enterocolitica*, and *Francisella tularensis* possess very similar LPS antigens, and antibodies directed to these bacteria may cross-react on anti-brucella antibody assays.

Definitive diagnosis of brucellosis is made by isolation of the organism in culture from tissue, blood, bone marrow, or other body fluids. Bone marrow culture may have increased sensitivity over blood culture, especially in chronic disease.^{7,8} While *Brucellae* are slow growing organisms, automated incubation techniques employed by many clinical microbiology laboratories generally allow for isolation of the organism within 7 days.⁷

The diagnosis of brucellosis can also be made based on serologic testing for antibrucella antibody in the absence of isolation of the bacteria. Although many types of serologic test exist, the standard agglutination test (SAT), or tube agglutination, is simple and commonly used. It remains the gold standard for comparing other test methods. However, a modified format of the SAT, the microagglutination test (MAT) uses smaller volumes of serum and reagents, has a shorter incubation time, and may be more sensitive than the standard agglutination test.^{9,10} Agglutination tests for *Brucella* detect antibodies of IgM, IgG, and IgA classes and these tests can be conducted in the presence or absence of 2-Mercaptoethanol (2-ME). 2-ME is a reducing agent that digests IgM and is therefore useful in distinguishing IgM from IgG activity and acute from chronic infections. Enzyme-linked immunosorbent assay (ELISA) techniques are rapid relative to other serologic methods, and have been employed to diagnose brucellosis.

A fourfold or greater rise in antibody titer in paired serum obtained at least two weeks apart is considered confirmatory for brucellosis.¹¹ In practice, a rising titer or a single high titer may indicate active infection. A predominantly IgM response may indicate recent infection, while a predominantly IgG titer suggests chronic infection. Typically these tests use *B. abortus* antigen, to which antibodies directed to *B. melitensis* and *suis* also react. Antibodies directed to rough species of *Brucella* do not cross-react with *B. abortus* antigen, therefore routine anti-brucella antibody testing will not detect infection with *B. canis* or the RB51 vaccine strain of *B. abortus*.

Using either agglutination or ELISA methods, false negative reactions can occur as a result of extremely high concentrations of antibody, such as with the prozone phenomenon¹² or competitive inhibition. Cross reactions of antibodies directed to other Gram-negative organisms can cause false positive results. Therefore, confirmatory testing with an additional test, such as the MAT, or histopathologic examination may be helpful.

Immunohistochemical staining may be used to demonstrate the presence of *Brucella* antigen in clinical specimens, but this method is not routinely available in clinical facilities. Molecular identification methods using polymerase chain reaction (PCR) have been developed for *Brucellae*. These techniques provide a rapid, sensitive, and in some cases species-specific method for identifying isolates.¹³ They remain to be validated for use in detecting *Brucella* DNA from clinical specimens. Until novel molecular and rapid serologic methods achieve wider use, isolation in culture and traditional serologic tests will remain the mainstay for diagnosis of brucellosis.

The Disease

B. abortus, *B. melitensis*, *B. suis*, *B. canis*, and marine mammal species¹⁴ can cause symptomatic infection in humans. *B. melitensis* and *B. suis* are considered to have increased virulence in humans;

however, all zoonotic species, including the attenuated animal vaccine strains REV-1 and strain 19, can cause severe disease.

Brucellosis may manifest in almost any organ or system. It can cause hematologic, hepatobiliary, osteoarticular, cutaneous, neurologic, pulmonary, gastrointestinal, genitourinary, and rarely renal or cardiovascular disease. Clinical signs and symptoms are nonspecific and resemble many other febrile illnesses. The most common clinical manifestations include intermittent fever, night sweats, malaise, arthralgias, and myalgias. Less common manifestations include weakness, anorexia, weight loss, abdominal pain, and headache. The most common physical finding is arthritis, seen in up to 70% of patients, while hepatosplenomegaly and lymphadenopathy are reported in approximately 20–30% and 10–20% of the cases, respectively.^{15,16} Brucellosis may cause abortion in pregnant women, most commonly in the first and second trimester. Other serious complications are rare and include meningitis, endocarditis, and osteomyelitis. Neurological and psychiatric symptoms, including prolonged mental depression, have been infrequently reported as sequelae of brucellosis.

The incubation period of brucellosis is variable and may depend on the infecting dose, route of exposure, and virulence of the organism. The average incubation period is 1–3 weeks, but may range from five days to several months.¹⁷ Onset of illness can be acute or insidious, and if untreated, disease may last for months or years. Recurrence of signs and symptoms is common in untreated brucellosis, and relapse may occur with inadequate treatment, usually within 3–6 months following discontinuation of therapy. Chronic brucellosis is rare with appropriate treatment. Death, although rare, is most commonly caused by *B. melitensis* and results from endocarditis or neurobrucellosis.

Treatment of brucellosis requires combination antibiotic therapy for a prolonged period of time to decrease the incidence of relapse. The World Health Organization (WHO) recommends six weeks of combination therapy with doxycycline and rifampin or six weeks of doxycycline combined with 2–3 weeks of streptomycin sulfate.^{18,19} Oral doxycycline is the drug of choice; however oral tetracycline may be used. Oral trimethoprim-sulfamethoxazole is appropriate therapy for children younger than eight years of age, or other persons with contraindications to tetracyclines. Since there have been reports of treatment failures with the use of this regimen, some authors have recommended the use of an aminoglycoside (gentamicin sulfate or streptomycin sulfate) with doxycycline, at least initially.^{20,21} Monotherapy is not recommended for the treatment of clinical disease, due to the risk of relapse and resistance. Serious infections or complications, including endocarditis, meningitis, and osteomyelitis, should be treated with an aminoglycoside for the first 7–14 days of therapy in combination with doxycycline, followed by the use of rifampin and doxycycline for the remainder of the treatment. Surgical therapy may also be required and the duration of therapy may be extended for several months, depending on the clinical response.

Transmission

Brucellosis is transmitted to man from animals. In animals, *Brucellae* typically cause chronic, lifelong infection. Bacteria localize in animal reproductive organs, and are shed in large numbers in milk, products of conception, and other reproductive tract discharges. Humans can become infected by ingestion of infected material, direct contact of material with cuts and abrasions of the skin, inhalation of aerosols, or inoculation of material into the conjunctival sac. Although it is rare, person-to-person transmission can occur via sexual intercourse,²² transplacental or prenatal transmission,²³ breast feeding,^{24,25} and blood^{26,27} or bone marrow transfusion.²⁸ The most common route for acquisition of brucellosis is through the consumption of unpasteurized infected milk or dairy products, including soft cheeses. The organism is killed by pasteurization or boiling of milk, or fermentation and aging of cheeses, which increases acidity. Since *Brucellae* are not normally found in high concentration in muscle tissue and are killed at normal cooking temperatures, eating properly cooked meat from infected animals should not pose a risk for brucellosis.

Vaccines made from attenuated strains of *Brucella* are used to prevent brucellosis in livestock, including strain 19, RB51 (*B. abortus*) and REV-1 (*B. melitensis*). All three of the vaccine strains can cause disease in humans, although RB51 is considered to be of lower pathogenicity than strain 19 and REV-1.^{29,30} Human exposure to strain 19 and REV-1 has resulted in systemic disease. However, only localized infection has been documented in humans following exposure to vaccine containing RB51.³¹ Exposure to *Brucella* vaccine strains can occur by accidental injection or splashes onto mucous membranes and open wounds. Following inadvertent human exposure to livestock *Brucella* vaccine, antibiotics should be administered for 3 weeks, regardless of the route of exposure. Doxycycline and rifampin should be used in combination for exposure to strain 19 and REV-1. Serological testing can be performed to diagnose infection. A baseline blood sample should be collected with a second blood sample collected 2–3 weeks later. Since the RB51 vaccine strain is resistant to rifampin,³² doxycycline alone should be administered. Routine serologic testing is not currently available for detecting infection with the RB51 strain.

Brucellosis is the most commonly reported laboratory-acquired bacterial infection.³³ Aerosolization of bacteria is considered to be the primary mechanism of transmission, but infection has also occurred following inoculation from spilled blood culture bottle contents and mucocutaneous exposure to sprays of organism-containing suspensions. Sniffing of culture plates has been implicated in laboratory-acquired infections, and infections have occurred during routine manipulation of *Brucella* cultures outside of biological safety cabinets. The Centers for Disease Control and Prevention recommends Biological Safety Level 3 practices, containment, equipment, and facilities for all manipulations of cultures of pathogenic *Brucella* species, because of the high risk of transmission from contact with nonintact skin, mucus membranes, and aerosols.³⁴ Biological Safety Level 2 practices are recommended for activities with clinical specimens of human or animal origin containing or potentially containing pathogenic *Brucella* species, as the risk of transmission posed by these specimens is much lower.

Pathogenic *Brucella* species are considered U.S. Class B bioterrorism agents. The United States weaponized and stockpiled *B. suis* in the 1950s and 1960s. By the 1970s, the biological warfare program was terminated and the stockpiles dismantled. Other countries are also suspected of developing *Brucella* as an offensive biological weapon.^{35,36} As a bioterrorism agent, *Brucella* organisms have the potential for widespread dissemination and transmission, but would be expected to cause only moderate morbidity. Their use as a biological weapon is also tempered by the prolonged incubation period and many infections are asymptomatic. Emergency preparedness plans for brucellosis include drug stockpiles and medical supplies readily available for mass treatment, and surveillance for recognition and treatment of cases in the event of a bioterrorism event.^{37,38}

Occurrence

In the United States the epidemiology of brucellosis has changed with time. Brucellosis in cattle was a significant cause of human disease in the first half of the twentieth century. In 1947, *B. abortus* was widespread throughout the country and disease peaked at 6321 reported human cases. Transmission was mainly by consumption of unpasteurized milk. Following full implementation of the Federal State Cooperative Brucellosis Eradication Program, established in 1934, and regulations requiring milk pasteurization, a decrease in human and cattle disease occurred. A correlation between cattle seroprevalence and the incidence of human disease was observed in subsequent decades. In the 1960s and 1970s, domestically acquired brucellosis became predominantly an occupational disease of veterinarians, abattoir workers, and farmers. Swine were the most common source and *B. suis* the most common cause of infection.³⁹ Since the 1970s, reported cases of brucellosis have ranged from approximately 100 to 300 cases per year, with most cases occurring among

returned travelers or immigrants from endemic areas.⁴⁰ In the United States, brucellosis is a nationally notifiable disease, reportable to the local health authority. However, this passive surveillance system may underestimate the true frequency of brucellosis in the United States. Misdiagnosis of brucellosis may be common, due to the disease's protean clinical manifestations, difficulty in diagnosis, and relative infrequency with which it is observed.

Brucellosis in domestic livestock in the United States is now extremely rare. *B. melitensis* has not been reported in domestic sheep and goats in the United States since 1977. In 2004, forty-seven states were free of *Brucella*, and there were only five cattle herds newly infected with *B. abortus*.⁴¹ However, brucellosis currently affects certain wildlife populations. *B. suis* is endemic in feral swine in the southeastern United States, and *B. abortus* is endemic in elk and bison in the greater Yellowstone National Park area. The continued presence of brucellosis in these populations will make it difficult to sustain the goal of nationwide eradication of brucellosis from domestic animals in the United States in the near future.

Brucellosis occurs worldwide and is an important endemic disease in the Middle East, Mediterranean Basin, Central Asia, and parts of Africa and Central and South America. Over 30,000 human cases¹⁶ and 200,000 animal cases¹ are reported annually worldwide, although this number is likely a considerable underestimate of the true burden of illness.

Prevention

Eradication of brucellosis from animals, particularly domestic livestock, is the most effective method for preventing human disease. Until this can be accomplished, pasteurization of milk and dairy products will prevent foodborne infections. This has the added benefit of preventing other diseases transmitted by milk, including salmonellosis and tuberculosis. However, pasteurization alone will not prevent all human cases of brucellosis. Occupational and laboratory exposure can be decreased by encouraging safe handling of at-risk materials with an emphasis placed on the use of appropriate personal protective equipment. High risk groups should be educated about the clinical signs and symptoms of disease, as well as the need for early diagnosis and treatment. Currently there is no human vaccine for brucellosis available in the United States.

Postexposure prophylaxis should be offered to laboratory workers exposed to *Brucella* following a laboratory accident or manipulations of isolates without the recommended biosafety precautions. Exposed workers should receive doxycycline and rifampin for 3–6 weeks. Any workers developing a febrile illness consistent with brucellosis during this time should consult their physician.

Livestock brucellosis control programs involve vaccination and testing and slaughter of infected animals, used alone or in combination. These programs should be designed based on the overall prevalence of animal disease and tailored to the local epidemiology and epizootiology of brucellosis. For a control program to be effective, a country must have the veterinary and laboratory resources needed to administer the program, adequately identify livestock, and control animal movements. Surveillance for animal and human brucellosis is needed to develop and monitor the program.⁴² Although brucellosis control programs are costly and can be difficult to sustain, adequate control of brucellosis is cost-beneficial to a country in the long run.⁴³ Countries that have successfully eradicated brucellosis include Sweden, Denmark, Norway, and Switzerland.¹

Conclusions

Brucellosis is a disease of protean manifestations, and should be included in the differential diagnosis of febrile illness of unknown origin. While rare in the United States, it remains a significant cause of morbidity and economic losses in many developing countries. Control strategies should be locally relevant and sustained over many years to achieve reductions in human disease.

Leptospirosis

Thomas A. Clark

Leptospirosis is currently recognized as a zoonotic bacterial infection with worldwide distribution. Weil's disease, or severe icteric leptospirosis associated with renal failure, was described in 1886, though a similar syndrome was recognized in sewer workers earlier in the same decade.¹ Reports of illnesses that most likely represent leptospiral jaundice date back to the early part of the 1800s, however, and the recognition of leptospirosis as an occupational risk dates back as far. The causative organism of leptospirosis was recognized simultaneously in Japan and Germany in 1915.¹ Prompt recognition and treatment of leptospirosis continue to be problematic, due to the wide spectrum of clinical manifestations and imperfect diagnostic tests. The reported burden of leptospirosis likely only represents a small proportion of incident disease worldwide.

The Agent

Leptospire are slow growing, obligate aerobes and members of the spirochete family.² Structurally they are thin and tightly coiled about their long axis. They are actively motile, rotating with a whip-like motion. Surface lipopolysaccharides constitute the primary determinants of the host immune response, and allow characterization of antigenically related serovars of *Leptospira* into serogroups.³⁻⁵ Based on this phenotypic characterization, the genus *Leptospira* has traditionally been divided into two species: *Leptospira biflexa*, containing the nonpathogenic saprophytic serovars, and *Leptospira interrogans*, containing well over 200 known pathogenic serovars comprising 24 serogroups.⁶

More recently, *Leptospira* have been classified into genomospecies based on DNA relatedness.⁷ Such studies have described a high degree of heterogeneity among serovars of *Leptospira*. Genomospecies do not equate with traditional serovar and serogroup classifications, or with the traditional species divisions. Genomospecies may contain both pathogenic and saprophytic serovars of *Leptospira*, as well as serovars from more than one serogroup. Serovar and serogroup designations will likely remain in use, therefore, as they are valuable in both the serologic diagnosis and epidemiologic characterization of leptospirosis. Current phenotypic and genotypic techniques for characterization of *Leptospira* are problematic, especially for clinical microbiology laboratories. Among molecular typing methods applied to leptospire, pulsed-field gel electrophoresis (PFGE) has yet to be thoroughly evaluated, but holds promise as a clinically relevant technique for identification and subtyping of leptospiral strains.⁸⁻¹⁰

Leptospirosis is definitively diagnosed by isolation of leptospire in culture from clinical or autopsy specimens. Leptospiremia precedes symptom onset and generally lasts through the first week of illness (Fig. 16-2). Leptospire survive in blood culture media for several days, though blood should be inoculated into semisolid media as soon as possible to increase the likelihood of isolating the bacteria.^{11,12} Culture of CSF during the first week of illness may also yield leptospire. Leptospiruria generally begins during the second week of illness and may be prolonged, lasting several weeks. Survival of leptospire in voided urine is limited, and urine should be processed and inoculated into semisolid media as quickly as possible. Leptospire grow slowly, so cultures should be incubated and examined weekly for up to 13 weeks before discarding. Isolation of pathogenic leptospire

from environmental sources is problematic, due to the variety and prevalence of saprophytic serovars.

In practice, the mainstay of leptospirosis diagnosis is serology. Microscopic agglutination testing (MAT) remains the reference serologic method, in which sera from patients are reacted with a panel of live antigen suspensions using a variety of leptospiral serovars.¹³ Serial dilution of sera is performed, and the serum-antigen mixtures incubated and examined by darkfield microscopy for agglutination. The highest titer at which 50% agglutination occurs is the end-point. Agglutinating antibodies consist of IgM, IgG, and IgA, and become detectable approximately 5–7 days after symptom onset, though the sensitivity is highest after 10–14 days (Fig. 16-2). Due to cross-reactivity of antibodies among antigenically related serovars, MAT is considered a serogroup-specific test. In general, at least one serovar from a wide range of serogroups is included on an MAT panel, as are all locally important serovars. A large and diverse antigen panel increases the likelihood of detecting infections with rare or new serovars, but adds to the complexity of interpreting the assay as it increases the likelihood of detecting cross-reacting antibodies. MAT requires technical expertise, maintenance and weekly subculturing of live antigen stocks, and considerable effort to minimize inter- and intra-observer variation in interpretation of results. Reference laboratory services, including MAT, are available at several World Health Organization (WHO) Collaborating Centers for Leptospirosis around the world, including at the U.S. Centers for Disease Control and Prevention.

While a single high titer by MAT in the context of a compatible febrile illness suggests acute leptospirosis, demonstration of a four-fold or greater rise in titer between acute and convalescent sera is required to confirm the diagnosis.¹⁴ Patient sera may demonstrate elevated titers to more than one serovar, resulting from cross reactivity of antibodies among serovars. The serovar to which the highest antibody titer is detected is generally considered to represent the most likely infecting serogroup. Patients who have past infection with a different leptospiral serovar may demonstrate an anamnestic response, in which the initial rising antibody titer resulting from the current infection is directed toward the previously infecting serovar.¹⁵ Antibody titers specific to the current infecting serovar subsequently develop. Even in the absence of antibody cross reactions and paradoxical responses, MAT results correlate only moderately with definitive determination of infecting serovars by isolation in culture and identification by cross-agglutinin absorption.^{16,17} In practice, definitive conclusions about the infecting serogroup and serovar in individual cases require isolation of leptospire in culture. In the aggregate, MAT results may give an impression of important serogroups, and therefore animal reservoirs, in populations. Moreover, patient titers may be very high and take months or years to fall following infection.^{18,19} MAT is therefore currently the most useful tool for epidemiologic serosurveys.

Rapid screening serologic tests are available, most of which use enzyme-linked immunosorbent assay (ELISA) methods to detect IgM. IgM antibodies are produced and become detectable as early as day 3 of illness.²⁰⁻²³ IgM detection is more sensitive than MAT when employed on specimens obtained in the acute phase of illness, making these tests useful for diagnosing leptospirosis and initiating treatment when it is most likely to be effective. However, IgM antibodies may persist for many months following onset of illness, making interpretation of positive IgM assay results problematic in endemic areas, especially when single specimens are tested.²¹ Confirmation of positive results by MAT on paired sera is recommended. IgM assays have many forms, including a dot-ELISA dipstick test, and are broadly reactive and genus specific, in contrast to MAT. Polymerase chain

Figure 16-2. Biphasic nature and relevant investigations at different stages of disease. Specimens 1 and 2 for serology are acute-phase specimens, 3 is a convalescent-phase sample which may facilitate detection of a delayed immune response, and 4 and 5 are follow-up samples which can provide epidemiologic information, such as the presumptive infecting serovar. (Source: Turner LH. *Leptospirosis I*. Trans R Soc Trop Med Hyg. 1967;61(6):842-854, with permission.)

reaction (PCR) techniques have been applied to detection of leptospires, using a variety of primers and clinical specimen sources.²⁴⁻²⁶ Though currently not commonly available in clinical laboratories, in the future PCR may provide a sensitive, specific, and rapid means of detecting leptospires in clinical specimens, before the development of antileptospiral antibodies (Fig. 16-2). Other detection methods include immunohistochemical staining of tissue, and visualization by direct microscopy, though the latter is difficult and prone to both false positive and false negative readings.

The Disease

Like many other infectious diseases that are characterized as “influenza-like,” the spectrum of symptoms and clinical presentations in leptospirosis is broad and nonspecific. The clinical course of infection is classically biphasic and follows a 2–20 day incubation period. The acute, leptospiremic phase lasts about one week, followed by an immune phase of up to 30 days or more that coincides with localization of leptospires in the kidneys and development of leptospiruria (Fig. 16-2). The immune phase is characterized by increased antibody production and resolution of symptoms in most cases. Localization of leptospires in tissues can result in severe multiorgan dysfunction.

Leptospirosis is categorized into anicteric and icteric forms. The great majority of infections with leptospires are anicteric, and usually subclinical or mildly symptomatic and self-limited.²⁷ Symptomatic infections present with an acute febrile illness of sudden onset. Headache, myalgias, and conjunctival suffusion are generally reported in more than 50% of cases in most published series.²⁸⁻³⁰ Myalgias are often prominent and frequently affect the legs and lower back. The headache may be severe, with retro-orbital pain and photophobia. Nausea, abdominal pain, diarrhea, and arthralgias occur less frequently, reported in less than 50% of cases in most published series. In the absence of jaundice, mortality is very low.

In 5–10% of cases, more severe and sometimes rapidly fatal icteric leptospirosis develops.¹ Acute renal failure may occur, and oliguria is associated with increased mortality.³¹ A pulmonary syndrome consisting of cough, dyspnea and hemoptysis associated with intra-alveolar hemorrhage has been increasingly recognized in both outbreaks and sporadic cases.^{32,33} It occurs in up to two-thirds of severe cases, and may progress to acute respiratory distress syndrome (ARDS). Cardiac involvement is probably more common than has been traditionally described. In some series, EKG abnormalities are present in up to 40% of patients in whom cardiac monitoring is performed.^{34,35} Arrhythmias and repolarization abnormalities are associated with poor prognosis.³¹ Severe myocarditis associated with the pulmonary syndrome resulted in a mortality rate of 54% in one series.³⁶ Other manifestations of leptospirosis include abortion or fetal death during pregnancy, aseptic meningitis, cerebrovascular accident, cranial nerve palsies, and reactive arthritis. Ocular manifestations are present in the majority of cases of icteric leptospirosis, and conjunctival suffusion with scleral icterus is highly suggestive of Weil’s disease. Rarely, recurrent anterior uveitis may occur during recovery.³⁷

The differential diagnosis of leptospirosis is broad, and includes other viral, bacterial, mycotic, rickettsial, and parasitic infections of the tropics.³⁸ These include dengue fever, yellow fever, viral hemorrhagic fevers, typhoid fever, disseminated histoplasmosis, louse- or tick-borne relapsing fever, malaria, and other vector-borne disease. Nonspecific signs and symptoms, a paucity of diagnostic testing options, especially in developing countries, and a low index of suspicion in temperate climates make misdiagnosis of leptospirosis common. Misdiagnosis may result in delayed administration of appropriate antibiotics and worse outcomes in individual cases, as well as to delayed recognition of and response to outbreaks.³²

Treatment of leptospirosis differs based on clinical presentation. While many patients with mildly symptomatic anicteric leptospirosis recover without specific antibiotic treatment, worsening symptoms or the development of jaundice may herald severe, multi-system

involvement. Doxycycline (100 mg twice daily for 7 days) was shown in one study to reduce the duration and severity of anicteric leptospirosis by an average of two days.³⁹ Two randomized studies of intravenous penicillin produced conflicting results. In the first study, which included both icteric and anicteric cases, six millions units per day for seven days reduced the duration of fever by half.⁴⁰ In a second study of icteric leptospirosis cases, no difference in outcome or duration was observed between control patients and patients who received eight million units per day for five days.⁴¹ No treatment trials have compared doxycycline and penicillin. Differences in response to penicillin treatment between studies may have resulted in part from the late presentation of patients with severe icteric leptospirosis, after leptospires have localized in tissues. For this reason, specific antibiotic treatment should be initiated as soon as possible in the course of illness. Treatment should be initiated based on clinical suspicion if timely diagnostic testing is unavailable or inconclusive. Severe icteric leptospirosis requires supportive care, often in an intensive care unit. Dialysis may be needed for renal failure, which can last several weeks, and cardiac monitoring, at least initially, is encouraged.

Mode of Transmission

Pathogenic leptospires have their reservoirs primarily in wild, domestic, and peridomestic mammals, referred to as maintenance hosts. Many leptospires are highly adapted to their maintenance hosts, such as icterohaemorrhagiae with rats and mice, and pomona with cattle and swine.⁶⁴² Infection in these animals by host-adapted serovars is usually endemic and asymptomatic. Maintenance hosts typically acquire leptospirosis early in life through animal-to-animal contact, and develop chronic infection of the renal tubules with shedding of leptospires into the environment. Accidental hosts, in contrast, may develop symptomatic and sometimes severe leptospirosis without persistent renal infection and shedding. Humans are accidental hosts of leptospires, and do not contribute significantly to their transmission. Animals may be maintenance hosts for some serovars and accidental hosts for others, and geographic variations in maintenance hosts and their associated serovars are observed throughout the world. The degree to which accidental hosts are exposed to and infected with pathogenic leptospires results from multiple factors, including climate, population density, and the degree to which they interact with maintenance hosts. Understanding the prevalent serovars and their maintenance hosts is essential in understanding the local epidemiology of leptospirosis and its prevention.

Humans acquire infection with leptospires primarily through contact with the urine of leptospiuric animals. Infection may also be acquired through direct contact with infected animal tissues or body fluids. Infections may be sporadic or outbreak-associated, and can result from occupational, recreational, or avocational exposures.¹ Occupational groups who work with animals are at increased risk of leptospirosis from direct exposure to animals or animal urine. Infection can also occur indirectly, through exposure to leptospires in urine-contaminated soil and surface water. Sewer workers, gardeners, or those who swim or raft in contaminated rivers are at increased risk of infection through indirect exposure. The route of entry is usually through breaks in the skin, though mucous membrane contact, inhalation, and perhaps prolonged immersion or ingestion can lead to infection. Infection has also occurred following animal bites, and consumption of contaminated food and water.^{43,44} Human-to-human and sexual transmission of leptospires has been documented, though the risk is very low.

Occurrence

Leptospirosis is found worldwide. While attempts have been made to compile leptospirosis incidence data, accurate figures on the true burden of morbidity and mortality are lacking for this often overlooked and underreported infection.⁴⁵ It occurs with higher incidence in

warmer climates, relating to increased numbers of maintenance hosts and leptospiral serovars, increased survival of leptospires in the environment, and the frequency of exposure to environmental leptospires during activities of daily living.⁴⁶⁻⁴⁸ In temperate climates, disease is more common during late summer and early fall, while infections in tropical areas tend to increase in number during rainy seasons. Urban, primarily rat-associated leptospirosis, has also been described.^{49,50} Large leptospirosis outbreaks have occurred following flooding or exposures of large numbers of persons to contaminated surface water sources.^{32,51} Outbreaks related to recreational water exposures, such as occur during adventure travel, are reported with increasing frequency.⁵²⁻⁵⁴ Historically, a male predominance has been noted, though this is likely to be a result of the association of leptospirosis with many traditionally male occupations, such as farming and mining.⁵⁵ More recently, cases associated with recreational exposures and among females and younger age groups are increasingly recognized.⁵⁶⁻⁵⁹

Prevention and Control

Efforts to control and prevent leptospirosis may be divided into three broad categories based on the target of the intervention: the source or reservoir of infection, the route of transmission, or the human host. An understanding of the locally relevant serovars, animal reservoirs, and environmental conditions that promote infection is necessary to find specific means of controlling leptospirosis in endemic areas. Furthermore, careful investigation of occupational, avocational, and recreational pursuits and exposure histories may point to the likely source of infection in human cases, and therefore a potential target for intervention. Of critical importance, then, are thorough epidemiologic characterizations of incident human cases and prompt recognition of outbreaks.

Humans acquire infection primarily from animals shedding leptospires in their urine. Domestic, agricultural, feral, or nuisance animals all may serve as reservoirs for leptospires. In small or well-defined animal populations such as dogs or farm herds, infected animals may be treated with antibiotics to control leptospiral shedding. Animal vaccines are available and may be useful, but vaccine-induced immunity is serovar specific, requires frequent revaccination, and protects against symptomatic disease but not necessarily against infection or urinary shedding.¹ When rodents or feral animals are known or suspected to be reservoirs, they may be trapped, poisoned, or excluded from human living spaces through fences or other engineering controls. Access of these animals to food and water sources should be limited, and strict environmental hygiene employed.

Interventions may also attempt to prevent transmission. Exposures to infected animals, tissues, or body fluids should be minimized or personal protective equipment worn when exposures are unavoidable. Contact with water sources known or suspected to be contaminated with leptospires should be avoided, but if contact is unavoidable, any open wounds present on the skin should be covered with occlusive dressings. Care should be taken to prevent submersion of the face, and washing or showering is recommended following exposure.

Finally, interventions may be aimed at the level of the human host. In endemic areas, educational campaigns may be conducted to promote awareness of the clinical manifestations and prevention of leptospirosis. Members of at-risk groups or the general public should be made aware of risk avoidance measures. Health care professionals should maintain an index of suspicion for leptospirosis, and should inquire into occupational, avocational and recreational exposures, animal contacts, and travel histories. Health care providers may consider recommending antibiotic prophylaxis for travelers to endemic areas for whom exposure to infected animals or contaminated environments is unavoidable. Two studies have suggested that doxycycline 200 mg in one dose or once weekly may prevent symptomatic infection when used during brief, high-risk exposures such as military training exercises conducted in wet environments or floods.^{60,61} Doxycycline 200 mg once weekly also reduced clinical illness and mortality, but not infection as determined by seroconversion or leptospiral isolation, in an endemic area.⁶²

Though leptospirosis is no longer nationally reportable in the United States, prompt reporting of leptospirosis cases to public health officials can facilitate recognition of the source of infection and amelioration of ongoing risk to the population. Thorough characterization

of outbreaks, improved understanding of the epidemiology of endemic disease, and the development of simple, rapid, and clinically useful strain typing methods will further our understanding of leptospirosis and increase the effectiveness of our prevention strategies.

Nontyphoidal Salmonellosis

John A. Painter • Michael Perch • Andrew C. Voetsch

Salmonellosis is a convenient etiological term to describe a variety of conditions that affect humans and many animal species. In humans, the clinical manifestations of *Salmonella* infection range from asymptomatic carriage to invasive illness, and infection is primarily the result of consuming contaminated foods. Except for *Salmonella* Typhi, which only infects humans and is the causative agent of typhoid fever, animals are the main reservoir of *Salmonella*. In the early twentieth century, public health interventions such as sewage treatment, drinking water chlorination, and pasteurization resulted in a dramatic decline in *Salmonella* Typhi infections (Fig. 16-3). Infection and illness with the nontyphoidal strains of *Salmonella*, increased in many areas with adequate sanitation and are now an important cause of morbidity and expense in many developed and developing countries.

Taxonomy

Bacteria of the genus *Salmonella* are Gram-negative bacilli that have many microbiological properties and antigens in common with other members of the family Enterobacteriaceae. There are two *Salmonella* species, *S. enterica*—which is divided into six subspecies—and *S. bongori*. Nearly all clinically important isolates of *Salmonella* are *S. enterica* and all named serotypes belong to *S. enterica* subspecies I. Thus, the species name is often dropped; for example, *S. enterica* serotype Enteritidis is referred to as *Salmonella* Enteritidis (serotype names are capitalized without italics).² Individual serotypes are identified by their somatic (O) and flagellar (H) antigens. *Salmonellae* are grouped by O antigens (Group A, B, C₁, C₂, D, E₁, E₄, and so on). Within each O group, individual serotypes are distinguished by their H antigens. *S. Enteritidis*, for example, belongs to group D (O₉), and is characterized by its O (9,12) and H (g, m) antigen. Unlike other enteric bacteria, *Salmonella* serotypes often express two antigenically different flagellae, referred to as Phase 1 and Phase 2 H antigens. An individual salmonellae cell expresses either Phase 1 or Phase 2, but not both. The format for writing a serotype formula is: Subspecies [space] O antigens [colon] Phase 1 H antigen [colon] Phase 2 H antigen. All serotypes can be referred to by their antigenic formula but certain serotypes are referred to by name for historical reasons. *S. Typhimurium*, for example, belongs to subspecies I, group B(O₄), has three O antigens (4, 5, 12), and two flagellar antigens (i) and (1,2); the antigenic formula is I 4, 5, 12:i:1, 2. Individual serotypes can be subdivided for surveillance and investigative purposes using pulsed-field gel electrophoresis (PFGE)³, as well as by phage typing, and antibiotic resistance patterns.⁴

Environmental Characteristics of the Bacteria

Temperatures used in routine pasteurization of milk destroy salmonellae. However, salmonellae within meat or other products may

survive if cooking temperatures and time of cooking are adequate only to cook the surface of the food. Refrigeration does not destroy this bacterium and growth has been recorded at as low as 10°C (50°F). In the environment, salmonellae survive for long periods in water and soil and on or within foods.

Clinical Characteristics

The most frequent symptoms of *Salmonella* gastroenteritis—diarrhea, abdominal cramps, fever, headache, nausea, and vomiting—resemble those of many other causes of gastroenteritis. The bacteria invade the gut wall, particularly in the ileum, producing fever and generalized symptoms. The incubation period is most often between 12–48 hours, although longer incubation periods (over 10 days) have been documented. Many infections are asymptomatic. Following gastrointestinal infection, the median duration of enteric carriage is approximately five weeks; carriage lasts for one year or more in 1% of infected persons.⁵ Young children have longer periods of carriage than other age groups. Practice guidelines that address the diagnosis, treatment, and public health control of this and other infectious diarrheas exist.⁶

In persons who are very old, very young, have underlying immunodeficiencies, or who receive an overwhelming dose, *Salmonella* can invade the bloodstream, producing a septicemic illness resembling typhoid fever, and cause infections in sites remote from the gut. Persons with human immunodeficiency virus (HIV) infections are particularly prone to bloodstream infections, which may recur after apparently adequate therapy.⁷ When salmonellae localize in extraintestinal sites, they can cause an abscess, meningitis, osteomyelitis, and other focal infections.

For severe salmonellosis, fluoroquinolones, such as ciprofloxacin, are the most effective antibiotics for adults and cephalosporins, such as ceftriaxone, are effective for children. Antimicrobials are indicated in the treatment of systemic illness; however, antimicrobial agents are not indicated for uncomplicated gastroenteritis because they do not shorten the illness and have been shown to prolong bacterial shedding.⁸ Approximately 20% of patients with laboratory-confirmed infection are hospitalized and the case fatality rate for reported infections is <1%.⁹

Diagnosis

Laboratory diagnosis of *Salmonella* infection is made by culture of feces, blood, or other clinical specimens, followed by determination of biochemical reactions and by specific agglutination with polyvalent and monovalent typing sera.¹⁰ Although serological response may occur to the O and H antigens of the infecting *Salmonella*, serologic diagnosis is not useful routinely because of nonspecific cross-reaction with other agents.

Transmission

Salmonellosis is predominantly a foodborne illness. Cattle, swine, fowl, and other food animals are reservoirs for *Salmonella*. Infections in food animals are primarily in the intestinal tract, but occasionally involve lymph nodes. Infections in animals may be initiated when animal feed or feed supplements are contaminated with *Salmonella*.

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Figure 16-3. Reported combined incidence of typhoid fever and nontyphoid salmonellosis in the United States from 1920 to 2003.

Infections may be amplified when animals are moved or held before slaughter.¹¹ *Salmonella* enter the human food chain on raw meat brought into the kitchen and lead to human infection if the meat is cooked only superficially or contaminates other food. Several common serotypes (Enteritidis, Typhimurium, and Heidelberg) can cause a chronic ovarian infection in hens and can invade the egg contents before the shell is formed.¹² Consumption of raw and undercooked shell eggs is currently the predominant source of *Salmonella* Enteritidis infections.^{13,14} More recently, sporadic *S. Heidelberg* infections were associated with consumption of undercooked eggs.¹⁵

Although the great majority of *Salmonella* infections are sporadic, without an identified link to other cases, *Salmonella* are a common cause of outbreaks, or clusters of illness related to the same exposure. A mean of 113 foodborne outbreaks of salmonellosis was reported to the Centers for Disease Control and Prevention (CDC) each year during the period 1998–2003; 45% occurred in restaurants or delicatessens.¹⁶ Eggs, poultry, meat, and dairy products were the most commonly reported food vehicles. Outbreaks due to produce, including alfalfa sprouts, mangoes, cantaloupe, and tomatoes, increased significantly between 1973–1997.¹⁷ Outbreaks of salmonellosis typically resulted from foods of animal origin. Contamination at the source, inadequate cooking, cross-contamination, and prolonged holding at inappropriate temperatures were the usual contributing errors. Although foodhandlers may be found to be infected in the course of an investigation, this is often because they ate the contaminated foods; they are more likely to be victims than sources of the contamination.¹⁸

Antimicrobial resistant salmonellae transmitted through the food supply are an increasing public health problem. Patients infected with antimicrobial resistant *Salmonella* strains are more likely to have *Salmonella* bacteremia and are hospitalized at a greater frequency and duration compared to patients with susceptible strains.¹⁹ Two multiple-resistant strains account for 9% of all salmonellosis.²⁰ A particular phage type of *Salmonella* Typhimurium called definitive type 104 (DT104) is resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. It increased from <1% of *S. Typhimurium* in 1979–1980 to 34% in 1996 and accounted for 22% of isolates in 2003.²¹ In the United States, outbreaks of DT104 infection have been associated with consumption of ground beef and cheese made from raw milk.^{22,23} *Salmonella* Typhimurium DT104 has been isolated from retail ground beef, pork and chicken.²⁴ Beginning in 1999 a *S. Newport* strain (Newport-MDRampC) emerged that was resistant to amoxicillin/clavulanic acid, cephalothin, cefoxitin, and ceftiofur (a cephalosporin used in animals) in addition to the five antimicrobial agents to which DT104 is resistant. By 2001 Newport-MDRampC represented 25% of all *S. Newport* isolates.²⁵ In 2002, a multistate outbreak of *S. Newport*-MDRampC infections was

associated with consumption of undercooked ground beef.²⁶ There is strong evidence that use of antimicrobial agents in food animals is responsible for the emergence of these strains, which are transmitted to humans generally through the food supply.²⁷

Salmonella is also transmitted by routes other than food. Many infections are related to direct or indirect contact with animals, especially reptiles and birds. Before their distribution was banned in 1975, small pet turtles were the single most commonly identified source of salmonellosis in the United States.²⁸ In recent years, many serotypes of *Salmonella* have caused illness in children exposed to pet iguanas, snakes and other reptiles.^{29,30} An infant in the same house with a reptile can become infected without direct contact.³¹ Pet baby chicks and ducklings have also been associated with salmonellosis.^{32,33} Direct person-to-person transmission of *Salmonella* can occur, although this is not common, and transmissibility varies by serotype.³⁴ Waterborne transmission of *Salmonella* is uncommon but possible when municipal water treatment fails. Of the 416 waterborne outbreaks reported to CDC between 1991 and 2001, *Salmonella* was the confirmed etiology in only three (two *S. Typhimurium* outbreaks and one *S. Bareilly* outbreak) of the 173 drinking water outbreaks and none of the 243 recreational water outbreaks.

Volunteer studies have suggested that a large dose (>10⁶ organisms) of *Salmonella* is necessary to initiate infection in most persons.³⁵ This high dose may explain the low frequency of secondary illnesses in households where a primary case is identified. However, in some circumstances the infectious dose can be substantially smaller.³⁵ For example, in a large outbreak of *S. Enteritidis* infections associated with ice cream, the infective dose was estimated to be as few as 10 organisms per 100 g of ice cream.³⁶ The virulence of the organism, the nature of the food vehicle, and host factors, such as underlying disease and reduced gastric acidity in infants and the elderly, may increase the risk of infection with a low infectious dose. Use of antibiotics for other reasons shortly before or during exposure increases the susceptibility of the host to infection with resistant strains by reducing competitive flora and thereby lowering the infectious dose.³⁷

Institutional Salmonellosis

Outbreaks of salmonellosis in hospital nurseries were common and severe in the decade after the Second World War, but virtually disappeared as infection control practices improved. Outbreaks of salmonellosis in hospitals and nursing homes are associated with especially high mortality.^{38–40} Nosocomial *Salmonella* transmission may be foodborne, but can also spread among patients in a ward, either by person-to-person contact or occasionally by fomites. Fomites have included dust, delivery room resuscitators, bedside tables and cribs, thermometers, waterbaths, suction tubing, and endoscopes. The vehicles identified in institutional outbreaks are most often foods. For example, an outbreak of *S. Saintpaul* infections in a nursery was associated with enteral feedings of formula mixed in the hospital.⁴¹ Occasionally, medicinal and pharmaceutical products of animal origin, such as carmine dye, pancreatin, pepsin, bile salts, gelatin, vitamins, extracts of various tissues, and transfused platelets have been responsible for institutional outbreaks. *Salmonella* are also common causes of outbreaks reported in institutional settings: 36% of foodborne outbreaks of known etiology that occurred in schools from 1973 through 1997 and 37% of foodborne outbreaks that occurred in prisons from 1974 through 1991 were caused by *Salmonella*.^{42,43} Because of the susceptibility of newborns, intensive care patients, children and those with immunosuppressive conditions, special precautions are warranted to prevent transmission of *Salmonella* in these populations.

Occurrence

Approximately 33,000 laboratory-confirmed *Salmonella* cases are reported annually through national surveillance.⁴⁴ Similar to other foodborne pathogens, a low proportion of *Salmonella* cases are confirmed

by a laboratory. CDC estimates that for each case reported through laboratory-based surveillance, 39 cases are undiagnosed in the community. Therefore, an estimated 1.4 million cases of salmonellosis occur in the United States each year, resulting in 15,000 hospitalizations and 400 deaths.⁴⁵ Among foodborne illnesses due to known pathogens, *Salmonella* is estimated to represent 10% of total cases, 26% of hospitalizations, and 31% of deaths.⁴⁶ Among foodborne outbreaks in the United States between 1998 and 2003, *Salmonella* represented 28% of outbreaks with a confirmed etiology.¹⁶

The highest reported infection rates occur in infants and children up to four years of age, accounting for approximately 25% of isolates.^{44,47} The age-specific incidence varies considerably by serotype, probably because different serotypes contaminate different vehicles.

Of the more than 2500 identified *Salmonella* serotypes, the three most common serotypes (Typhimurium, Enteritidis, and Newport) accounted for approximately 50% of isolates and the top 20 serotypes accounted for approximately 78% of the total human isolates reported to the CDC in 2003 (Table 16-4).⁴⁴

The annual frequency of individual serotypes is not stable (Fig. 16-4) and may reflect changes in the vehicles of transmission, changes in surveillance, and recognized outbreaks.⁴⁷ For example, the incidence of *Salmonella* Enteritidis infections rose from less than 1 case per 100,000 in the early 1980s to 3.9 cases per 100,000 in 1995 as a result of widespread infection in egg laying poultry flocks.¹⁴ The incidence of salmonellosis shows strong seasonality, though the specific pattern varies with the serotype, vehicle, mode of spread, and local circumstances.⁴⁸ The reasons for seasonality may include increased warm season transmission among food or other reservoir animals, heavier contamination at slaughter plants, and greater opportunity for rapid bacterial growth should refrigeration be inadequate in the warmer months. The age-specific incidence varies considerably by serotype, perhaps because different serotypes contaminate different food vehicles.⁴⁸

Some *Salmonella* serotypes have specific reservoirs (*Salmonella* Dublin in cattle, *Salmonella* Choleraesuis in pigs, *Salmonella* Pullorum in poultry, and *Salmonella* Typhi in humans), whereas others have broad host ranges. Some serotypes are globally distributed while others are restricted to certain geographical areas, for example, *Salmonella* Javiana in the Southeastern region of the

United States, and *Salmonella* Weltevreden in the South Pacific and Southeast Asia.

Prevention

Because lapses in hygiene can occur at any point in production, control measures need to be applied at multiple points along the food chain from “farm to fork.” Milk pasteurization, and the regulation of precooked beef have reduced salmonellosis in the United States, but a better understanding of the ecology of *Salmonella* in animals and plants is needed to improve current prevention strategies. Studies to determine risk factors for *Salmonella* infection in farm animals and to characterize farms where infected herds are found would be helpful in formulating effective farm-based prevention measures. *Salmonella* are frequent contaminants of the feeds that farm animals themselves eat, so efforts are needed to prevent *Salmonella* from infecting food animals from this and other routes.⁴⁹ Good agricultural practices, including using chlorinated water for processing and minimizing contamination from nearby animals, are necessary to reduce contamination of produce. Although not currently in widespread use, irradiation of half of meat and poultry products could reduce the total burden of salmonellosis by an estimated 300,000 cases per year.⁵⁰

To reduce contamination of meat and poultry products at slaughter, the United States Department of Agriculture’s Food Safety Inspection Service (USDA-FSIS) issued the Pathogen Reduction: Hazard Analysis and Critical Control Point (HACCP) systems final rule in 1996.⁵¹ The HACCP approach to engineering safety means addressing the likely sources of contamination and cross-contamination with strategies to reduce or eliminate them. Preliminary evidence suggests that the prevalence of *Salmonella* on meat and poultry products has a decrease concurrent with the implementation of these programs. For example, the prevalence of *Salmonella* on broiler carcasses declined from 20% in pre-HACCP baseline surveys to 11.5% in 2002.⁵² Concurrent declines in the incidence of human salmonellosis by 17% between 1996–2003 were reported in the Foodborne Diseases Active Surveillance Network (FoodNet).⁹

The World Health Organization advocates restricting the use of antimicrobials in animal feed to reduce the frequency of antimicrobial-resistant *Salmonella*.⁵³ The experience of several European countries demonstrates the effectiveness of controlling antimicrobial-resistant pathogens by banning the use of certain antimicrobial in animals.⁵⁴

In restaurants, inspecting food service areas to ensure that safe food handling procedures are well understood, refrigeration is

adequate, storage facilities are appropriate, and hand washing is frequent are critical to preventing salmonellosis outbreaks. Control of *Salmonella* in food handlers is difficult to achieve because excretion of *Salmonella* may be prolonged, and no treatment regimen has been shown to reduce carriage. Although many health departments recommend particular

prevention measures, the most common measures directed at foodhandlers to control salmonellosis are educating them in good personal hygiene and proper food handling practices. Consumers who prepare food in their homes should be aware of basic food safety practices, such as those outlined in the *Fight Bac!* program (clean, cook, chill, separate).⁵⁵

Toxoplasmosis

Jeffrey L. Jones • Jacob K. Frenkel

► INTRODUCTION

Toxoplasma gondii, the etiologic agent of toxoplasmosis, is one of the most common protozoan parasites of man. *T. gondii* was described in 1908 both by Nicolle and Manceaux at the Pasteur Institute in Tunis from gonds used as laboratory animals in typhus research, and by Splendore at the Hygiene Institute in Sao Paulo, Brazil, from a laboratory rabbit. Human infection was first discovered in 1924 in the eye of an infant by Janku in Czechoslovakia. This was followed, starting in 1937, by several diagnoses in infants by Wolf, Cowan, and Paige at Colombia University in New York City. After the development of a serologic test, the dye test by Sabin and Feldman in 1948, it became clear that infections in humans and animals were found worldwide and were highly prevalent in many areas. The identification of the sexual cycle of *Toxoplasma* in cats led to its classification as a coccidian.¹ Only then it became clear that the infections of gonds and rabbits were linked to cats, which at the time were kept in laboratories to catch wild rodents and laboratory animals that had escaped.

Life Cycle and Modes of Transmission

The three forms of the protozoan—the tachyzoite, the bradyzoite, and the sporozoite—are similar in appearance, being crescent shaped and 4- to 8- μ m long. The tachyzoites (Fig. 16-5) are the rapidly proliferating intracellular forms seen in many tissues and organs during the acute phase of infection. Bradyzoites occur in cysts (Fig. 16-6) and are formed primarily in brain, eye, heart muscle, and skeletal muscle. Bradyzoites multiply slowly and persist in tissues for many years, possibly for the life of the host. The sporozoite occurs in the mature oocyst (Fig. 16-7). It is the stage resulting from the sexual reproduction phase, which takes place in the small intestine of cats. Tachyzoites and bradyzoites occur in all hosts susceptible to this infection, but oocysts occur only in felines, where they develop during the sexual phase of the enteroepithelial cycle.

Cats usually acquire infection by ingesting bradyzoites in fresh tissues and rarely from tachyzoites or sporulated oocysts. Kittens are more susceptible than older cats. The prepatent period of infection, that is, the time between ingestion of infective stages and the passage of oocysts in the feces, may be as short as 3–10 days when bradyzoites were ingested, or 21–40 days after either tachyzoites or mature oocysts were ingested. Cats that have recovered from toxoplasmosis may become reinfected if exposed, but their immunity either arrests the infection before oocyst formation or greatly reduces oocyst shedding.

Hosts other than cats usually become infected in the same manner—by ingestion of infective stages, most frequently from undercooked meat, cat feces/soil exposure, or untreated water. After initial infection of the intestinal wall, the parasites spread to extraintestinal sites, where intracellular multiplication of tachyzoites takes place. Disintegration of infected cells releases tachyzoites, which

infect nearby cells or are carried to other sites by body fluids to continue the cycle. Hosts whose immune system has not been compromised usually survive the acute phase without specific therapy, whereupon tachyzoites disappear and bradyzoite-containing cysts form in the tissues, mainly the brain and muscle.

Although ingestion of infective material is the principal mode of transmission for *Toxoplasma* in humans, others are known. In fact, the disease was first recognized in transplacentally infected babies, where it may have serious consequences. Parasitemia (with tachyzoites) occurs primarily during the acute stage of toxoplasmosis, and although transmission via blood transfusion can be considered possible, the risk from normal donors apparently is slight.¹ Acquisition of *T. gondii* infection from donor organs has been reported in transplant recipients and probably resulted from persistent tissue cysts.²

T. gondii is one of the most common protozoan parasites of animals and humans. Survival of the species is assured because: (a) it infects a wide range of hosts; (b) many hosts survive infection; (c) it can persist in its host for many years so that predators can acquire infection; (d) its natural hosts, several members of the cat family, produce millions of oocysts, which remain infective in the environment for long periods; and although of lesser epidemiological importance, (e) it can be transmitted transplacentally in certain hosts (see lifecycle, Fig. 16-8).

Clinical Characteristics

In humans, postnatally acquired infection usually is asymptomatic or has such mild transient manifestations that it goes unrecognized. This is evident from the high prevalence of seropositive individuals with no history of a diagnosed infection. The most common feature in the immunocompetent host is local or generalized lymphadenopathy. Tender cervical nodes often are accompanied by fever, sore throat, myalgia, a maculopapular rash sparing the palms and soles, abdominal pain from enlarged retroperitoneal nodes, hepatosplenomegaly, and atypical lymphocytosis suggestive of infectious mononucleosis. With rare exceptions, symptoms resolve over a period of several weeks without chemotherapy, although lymphadenopathy may persist for many months, often raising the suspicion of a lymphoma, such as Hodgkin's disease.³ Studies in laboratory animals have demonstrated the persistence of cysts in brain and skeletal muscle for long periods after the initial mild acute stage, but data on the proportion of recovered human cases with persistent cysts are not available. In a few instances the acute infection was accompanied by pneumonitis, myocarditis, pericarditis, hepatitis, polymyositis, encephalitis, and meningoencephalitis. Whether or not these patients with illness were immunocompetent was not reported in most of these cases. It has been estimated that only 10–20% of immunocompetent individuals are symptomatic during mild acute infections. In adolescents and adults, retinochoroiditis may be the only manifestation of toxoplasmosis, and the majority of these infections are now thought to be acquired postnatally.⁴ The lesions, which may be unilateral or bilateral, and may be recurrent, consist of active lesions without a scar, old scars with active satellite lesions, or inactive scars.

Note: The findings and conclusions in this chapter are those of the author and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Figure 16-7. Sporulated oocyst of *Toxoplasma gondii* containing two sporocysts, each with four sporozoites. ($\times 1200$)

Congenital toxoplasmosis can occur when a woman acquires her initial infection during pregnancy. Although the infection is usually inapparent in the woman, the lesions in the fetus show a wide degree of severity, depending on the gestational age at which transplacental transmission occurred. Although congenital transmission is less likely to occur earlier in gestation, fetal damage is usually more severe the earlier during gestation transmission occurs. Results can be (a) a spontaneous abortion of a severely damaged fetus, (b) a fully developed stillborn infant with evidence of severe lesions, (c) a live infant with classic signs, such as hydrocephalus or microcephalus, cerebral calcifications, and retinochoroiditis, (d) a premature infant who fails to thrive or in whom retinochoroiditis or other symptoms of central nervous system involvement may be found, or (e) a seemingly normal infant in whom retinochoroiditis or symptoms of central nervous system involvement develop later.⁵ Evidence suggests that if a woman becomes infected a few weeks before conception, it is unlikely that the infant will be born infected. Since physical examinations and antibody titers of infants born to women who acquired *Toxoplasma* infection during pregnancy may be inconclusive, these infants should be observed over a period of one year for the development of antibody,

Figure 16-6. Section of mouse brain showing a cyst of *Toxoplasma gondii* containing hundreds of bradyzoites. (Hematoxylin and Eosin stain, $\times 480$)

or the development of lesions such as retinochoroiditis or cerebral calcifications. If found, or suspected to be, infected, prompt therapy should be given in an attempt to prevent more serious injury to the brain and retina.^{6,7}

The persistence of *T. gondii* in the tissues of individuals who have recovered from a primary infection, and the high percentage of such individuals in many populations, are problematic when HIV infection is contracted. The development of immunodeficiency in these individuals may result in a recrudescence of the latent or

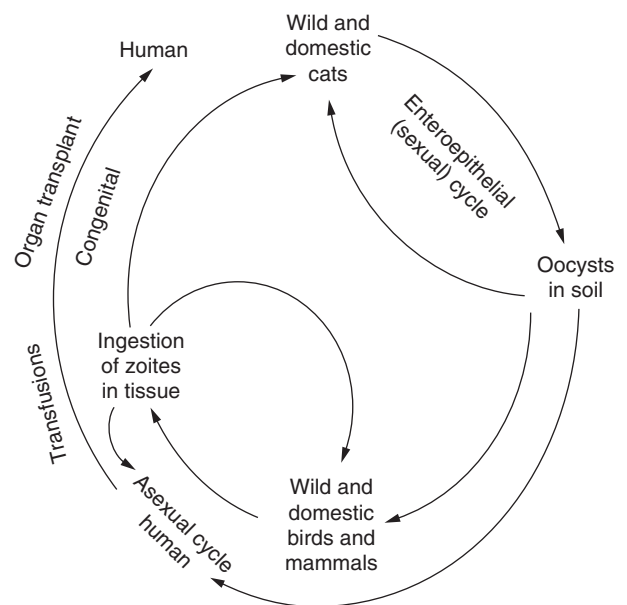

Figure 16-8. Transmission of *Toxoplasma gondii* in nature involves two main cycles: (a) from cats to intermediate hosts and back to cats and to humans through fecal contamination of the environment with oocysts that are generated during the enteroepithelial cycle in the cat, mature in the outside environment, and are taken up in contaminated foods or water, and (b) from intermediate hosts to cats and to intermediate hosts (and humans) when zites (tachyzoites and bradyzoites, generally the latter) that are generated in extraintestinal tissues by asexual reproduction (endodyogeny) are ingested. Except for congenital transmission, blood or cell transfusion, or organ transplant, the place of humans in either of these two cycles is that of a dead-end intermediate host. Predation and cannibalism among intermediate hosts, though not essential to enzooticity, are factors of great significance.

chronic *Toxoplasma* infection. It has been estimated that toxoplasmic encephalitis will develop in about 30% of persons with AIDS in the United States who are seropositive for *Toxoplasma*.⁸ Furthermore, individuals who acquire HIV infection and who have not been infected previously with *Toxoplasma* are more likely to develop a severe primary infection with this organism. Toxoplasmic encephalitis is life-threatening in persons with AIDS⁸; however, with the advent of prophylactic medication and highly active antiretroviral therapy in the mid-1990s, the frequency of toxoplasmic encephalitis among persons with AIDS has been reduced in countries with good access to these medications.^{9,10} In some instances the CNS symptoms occur before a diagnosis of HIV infection is made, which emphasizes the need for early HIV testing and appropriate initiation of prophylactic therapy. The prognosis is poor if the patient is in a coma when first seen. Ocular lesions are less common than encephalitis in HIV infected persons, but can lead to blindness. Involvement of other organs has also been described occasionally. Patients who receive organ transplants may acquire *T. gondii* infection from the donor organ, or they may suffer from recrudescence of their latent infection as a result of antirejection immunosuppressive therapy.¹¹

Epidemiology

Most *T. gondii* infections are acquired by the ingestion of tissue forms in undercooked meat or oocysts passed into the environment by felines. Cats usually cover their feces with sand or soil, thus protecting the oocysts, which measure 10 μm by 13 μm and may remain viable for up to a year or more in moist soil. An area where cats abound may be contaminated continually with infective oocysts as generations of cats inhabit the area. Where domestic water supplies are not filtered, *Toxoplasma* oocysts may contaminate drinking water.¹²

A population-based study conducted in the United States from 1988–1994 showed that 22.5% of the population ≥ 12 years old, and 15% of women 15–44 years old, were infected with *T. gondii* as determined by the presence of IgG antibodies.¹³ Other serologic surveys have shown that up to 95% of various populations throughout the world have been infected with *Toxoplasma*. Such studies have shown that the percentage of seropositive individuals increases with age, indicating continued exposure throughout life. The presence of cats has also been associated with a higher percentage of seropositive individuals. Prevalence of infection is highest in hot, humid climates and lowest in dry or cold climates, as well as at high altitudes. A 10-year study in Panama showed that antibody prevalence rose from 25% at five years of age to 50% at 10 years and increased gradually, reaching 90% by 60 years of age.¹⁴ In a collaborative project involving 12 university medical centers located throughout the United States an analysis of antibody titers to *Toxoplasma* in 22,845 pregnant women was conducted in relation to clinical and laboratory findings in the mothers and children through seven years of age.¹⁵ Based on more than 900 observations considered for each mother and child, the major findings were in children and included a doubling in predicted frequency of deafness and a 60% increase in microcephaly among children born to women with antibody to *Toxoplasma*. A high antibody titer (1:256 to 512) in the mothers was associated with 30% increase in low IQ (< 70) in their offspring.

Diagnosis

A diagnosis can be made by demonstrating the characteristic crescent-shaped zoites in CSF or tissue imprints made from patient material and stained with Giemsa (Fig. 16-5). Biopsies of bone marrow, lymph nodes, brain, placenta, and other involved tissues can be sectioned and stained with hematoxylin to identify the spherical nuclei of *Toxoplasma*. Material from patients can be inoculated into cell cultures or weanling mice in an effort to isolate the protozoa. However, in most instances serological tests are employed because of the difficulty of obtaining patient specimens (often requiring biopsy), the difficulty of locating a laboratory equipped to isolate the organism, and the time that may be required to accomplish this task. The diagnosis is generally made by detection of *Toxoplasma*-specific IgG, IgM, or IgA antibodies. The dye test (DT), indirect fluorescent antibody test (IFA), and

enzyme immunoassays (ELISA, immunoblots) detect specific IgG, IgM, or IgA titers within several weeks of infection. IgM and IgA levels will decline to nil within 1–2 years, but IgG titers slowly decline and remain detectable at low levels for the patient's lifetime.

If acute *Toxoplasma* infection is suspected, the patient's serum specimen should be tested for the presence of *Toxoplasma*-specific IgG and IgM antibodies.¹⁶ If the results are negative, the patient is probably not infected. If the IgG is positive and IgM is negative, the patient was most likely infected more than six months ago. If both IgG and IgM are positive, the results may indicate acute infection or a false-positive IgM result. In this case, the specimen should be submitted for *Toxoplasma*-specific IgG avidity status. If the IgG avidity is high, acute infection may be ruled out (depending on the specific test with the high avidity result, infection may have occurred 12 or more weeks previously). If the IgG avidity is low, recent infection is possible, but low avidity may be present for a year after infection. If the patient with low IgG avidity is pregnant, a second sample should be obtained three weeks after the first and both samples should be sent to a *Toxoplasma* reference laboratory for confirmation of results and additional testing by differential agglutination and other tests before any clinical intervention is undertaken. A toxoplasmosis reference laboratory is essential for provision of a serologic profile to assist with the diagnosis, particularly in pregnant patients.^{17,18}

Serologic tests are sometimes unreliable in immunosuppressed patients; tests for *Toxoplasma* DNA are available at some labs and may be useful in some patients. However, in immunosuppressed patients both positive PCR and serologic results need to be linked to the presence of active infection because of the persistence of *Toxoplasma* cysts and antibody in asymptomatic chronic latent infections. Histologic study of a tissue biopsy can often help to distinguish active from latent toxoplasmosis. In addition to the applications above, *Toxoplasma* PCR performed on amniotic fluid has been shown to be helpful in determining fetal infection following acute acquired infection in the mother.

Treatment

Most immunologically competent individuals recover from the acute phase of toxoplasmosis without chemotherapy. In the presence of illness, combinations of pyrimethamine with either sulfadiazine or trisulfapyrimidines have been shown to be effective. Where unavailable, the fixed combination of trimethoprim with sulfamethoxazole has been used. Specific inhibition of the parasite's folate-metabolizing enzymes is the mode of action of these combinations. Frequent differential blood and platelet counts are required to check for bone marrow toxicity. Folinic acid (not folic acid) has been employed to counteract toxicity without impairing the chemotherapeutic effect.^{5,19} If the patient has a hypersensitivity reaction to the pyrimethamine-sulfonamide combination, most often it is to the sulfonamide component; pyrimethamine plus clindamycin can be substituted.²⁰ Treatment during pregnancy, and of the newborn and infant, has been successfully carried out in immunocompetent individuals, although this treatment does not eliminate the parasite completely.^{5,21,22} Women who are acutely infected with *T. gondii* during pregnancy usually receive an amniocentesis and PCR test of amniotic fluid at ≥ 18 weeks gestation to determine if the infant is infected with *T. gondii*. When a pregnant woman is found to be acutely infected with toxoplasmosis, spiramycin is given prior to the amniocentesis in an effort to prevent infection of the fetus, and if the fetus is not found to be infected at the time of amniocentesis, throughout the pregnancy.^{18,19}

In a patient with AIDS, recrudescence or a newly acquired active toxoplasmic infection generally requires chemotherapy until significant clinical improvement has been achieved. Thereafter, maintenance therapy in lower doses is necessary for the life of an AIDS patient, or as long as the patient remains immunosuppressed. Reactivation and progression of ocular or cerebral toxoplasmic lesions in AIDS patients after therapy is discontinued has been reported.²³ Empirical treatment of suspected *Toxoplasma* encephalitis based on radiographic findings has been satisfactory, thereby avoiding a brain biopsy.^{10,19,24,25} Severely immunosuppressed HIV-infected

adults and adolescents who have never had an active *T. gondii* infection, but are *T. gondii* antibody seropositive, should receive primary preventive therapy with trimethoprim-sulfamethoxazole or alternative medications.¹⁰

Preventive Measures

Even though clinical toxoplasmosis is likely to be more severe in the immunosuppressed patient, the preventive measures are identical for both immunosuppressed and immunocompetent individuals (including pregnant women). Although hard freezing of meat kills most *Toxoplasma* stages, there is no assurance that an occasional organism does not survive. Meat can be safe only if it has been thoroughly heated during cooking, till the color changes and the juices are clear (160°F, 72°C). It is essential that meat is completely thawed and that the thicker cuts are sufficiently heated. Women who are seronegative to *Toxoplasma* should take precautions to avoid infection. Pregnant women in particular should not eat raw or undercooked meat. Pregnant women should be advised to wash their hands after contact with meat, soil, outdoor cats and their litter boxes, and before eating. Because some dogs have the habit of eating or rolling in cat feces, hand washing after contact with dogs should also be recommended.²⁶ Contact with soil should be avoided by wearing gloves when one is

working in the garden, and then afterwards thoroughly scrubbing one's hands, including under the nails. Cats do not recognize property lines and a neighbor's cats may use the yard of another, especially if the soil is well cultivated for flowers or vegetables. Children's sandboxes should be covered when not in use. Ideally, cat box litter should be bagged daily for disposal because *T. gondii* oocysts take more than one day to sporulate and become infectious. Only cooked meat, dried food, or canned food should be fed to cats. Stray cats should be controlled. If possible, house cats should be belled to diminish their chances of catching rodents and birds, becoming infected and leaving millions of infectious oocysts in yards, flower beds, or children's sandboxes. Transmission through blood transfusion or organ transplant should be of concern if the recipient is immunocompromised; the donor's and recipient's blood should be serologically tested.²⁷

Two types of vaccines have been developed; one to potentially immunize humans, such as seronegative transplant recipients, and meat animals; and another, to vaccinate cats against oocyst shedding.^{28,29} Both vaccines are live and need to be kept frozen until used. In New Zealand and England, a vaccine similar to the first one is used to immunize sheep against abortion from toxoplasmosis. Efforts are underway to develop stable recombinant vaccines.

Trichinellosis

Michael P. Stevens • Michael Edmond

► INTRODUCTION

Trichinellosis is human disease caused by infection with the nematode *Trichinella* spp, and occurs when improperly prepared meat that is contaminated with worm larvae is ingested. The disease has a worldwide distribution, being found on every continent save Antarctica and being present in numerous animal species, including mammals, reptiles, and birds.¹ The prevalence of human disease globally is estimated at 11 million.² To date, there have been eight individual species identified, as well as an additional three genetically distinct potential species that have not yet been fully classified (see Table 16-5). One of the principal differentiating characteristics between *Trichinella* species is the presence or absence of capsule formation in host tissue.¹ As clinical signs and symptoms are often nonspecific, diagnosis can be difficult. Definitive diagnosis relies on serological tests and occasionally on results from muscle biopsies. Treatment often involves the use of benzimidazoles and sometimes corticosteroids.²

Life Cycle

All stages of the *Trichinella* life cycle occur within a particular host.³ Contaminated skeletal muscle is ingested and the encysted larvae are released via the action of digestive juices, and these travel to the small intestine, where they invade columnar epithelial cells. The freed larvae (L1 stage) rapidly mature into adult worms, copulate, and the adult females begin producing newborn larvae (NBL) at approximately 6–7 days following initial infection. This process can continue for up to three more weeks before expulsion of the adult worms occurs.² The larvae gain access to the bloodstream via lymphatic channels and travel throughout the body and burrow into striated muscle. Although the NBL can transiently invade other tissues (including the retina, myocardium, brain, liver, and lungs) they can only complete their life cycle from within striated muscle cells. They continue to develop for approximately two more weeks before they achieve their infective (L1) stage. Depending on the species of *Trichinella* involved, these larvae will then encyst

and are themselves infective around 17–21 days following initial infection. These larvae can remain viable for a number of years. The cycle ends when the infected muscle is eaten by another host. The body will eventually destroy the larvae and calcification occurs.³

Epidemiology

This is a worldwide disease, with species of *Trichinella* found on every continent except Antarctica.² The two major patterns for transmission include domestic and sylvatic animal reservoirs, and a large number of animals exist that are capable of hosting this organism. Human disease is most often due to *T. spiralis*, usually from infected domestic pork. Although single-source outbreaks from infected pork play a significant role in the epidemiology of this disease,³ many outbreaks have been secondary to sylvatic species of *Trichinella*,⁴ including such animals as bears, foxes, dogs, walruses, wild boars, and cougars.² Significantly, between the years of 1997 and 2001 in the United States there were 72 cases of trichinellosis reported, 31 of which were secondary to the ingestion of infected wild game.⁵ Herbivores such as horses, sheep and goats have been associated with disease, as well.⁴ Political, economic and cultural factors have significantly influenced the epidemiology of this disease. In the 1990s, political and economic turmoil led to the breakdown of infection control systems in some eastern European countries, leading to significant increases in the prevalence of *Trichinella* infection in swine.⁶ Additionally, infections in Italy and France have been associated with the importation of infected horse meat, and outbreaks have been associated with groups preparing traditional foods containing raw or undercooked pork, as well.⁴

► DISEASE

Disease expression is highly variable and is dependent on numerous factors, including the species of *Trichinella* involved, the total number of viable larvae ingested and the age, sex, ethnicity, and immune status of the host.³ Importantly, in many cases of infection patients may

TABLE 16-5. COMPARATIVE FEATURES OF *TRICHINELLA* SPP.^{1,2,26}

Species	Distribution	Cycles involved	Documented human infections	Presence of capsule	Resistance to freezing	Pathogenicity
<i>T. spiralis</i>	Cosmopolitan	Domestic, sylvatic	Yes	Yes	None	High
<i>T. nativa</i>	Subarctic and arctic areas of Europe, Asia, North America	Sylvatic	Yes	Yes	High	Moderate
<i>T. britovi</i>	Temperate regions of Asia, Europe	Sylvatic, rarely domestic	Yes	Yes	Moderate	Moderate
<i>T. murrelli</i>	North America	Sylvatic	Yes	Yes	None	Moderate to high
<i>T. nelsoni</i>	Sub-Saharan Africa	Sylvatic	Yes	Yes	None	Low
<i>T. pseudospiralis</i>	Cosmopolitan	Sylvatic, rarely domestic	Yes	No	None	High
<i>T. papuae</i>	Papua New Guinea	Sylvatic	Yes	No	None	Low to moderate
<i>T. zimbabwensis</i>	Zimbabwe, Ethiopia, Mozambique	Sylvatic	Yes	No	None	Uncertain

Additionally, there are three genetically distinct species (T6, T8, T9) that have been identified but which have not been fully classified yet.

have few or absent symptoms.⁷ Acute disease can be broken into the two distinct stages of enteral and parenteral illness.

The enteral stage is characterized by nonspecific gastrointestinal symptoms with diarrhea, nausea, vomiting, and abdominal pain. Mild fever and constipation can also occur.⁸ Symptoms can begin as early as two days following initial infection and can persist for weeks. Diarrhea can be seen as far out as 3 months from initial infection.³ Although death is uncommon during this phase, it can occur secondary to diarrhea or enteritis.⁹

Parenteral disease occurs with the dissemination of larvae throughout the body, and symptoms can be directly attributed to both their passage and to the immunological response to their presence.¹⁰ Notably, there can be an overlap between the enteral and parenteral phases of illness that can last from several days to weeks. The manifestations of clinical illness during this phase are myriad, with the key elements of disease including fever, periorbital edema and myalgia.² Fever is common, with temperatures occurring up to 40°C. With severe disease fever can continue for three weeks.¹¹ Symmetrical periorbital edema can occur, and edema often involves the face in its entirety. Edema of the eyelids is often seen with concurrent lacrimation, itching and conjunctival hyperemia. Additionally, patients frequently have pain with movement of the extraocular musculature.² Muscles of the neck, trunk, extremities, and less frequently the masseters can be involved.¹¹

Neurologic involvement is seen in 10–24% of patients.⁷ The neurologic manifestations that occur are mostly vascular in etiology.³ Headaches are common, and focal signs such as tinnitus, facial nerve paralysis, and transient hemiparesis can be seen, as well. Psychological disturbances, ranging from personality changes to psychosis, can occur.² Significantly, meningoencephalitic signs can be seen, as well.¹² Computed tomography (CT) imaging can reveal multiple brain lesions, variously described as 3–8 mm ring-like or nodular masses that usually enhance with contrast. Additionally, some of these lesions will also show ring calcifications.¹³ However, in some cases consistent with neurotrichinellosis, brain CT has revealed no pathologic changes.^{14,15} Magnetic resonance imaging (MRI) has also been utilized and can reveal multifocal lesions in the white matter and cerebral cortex.¹⁶

Larvae can infiltrate the myocardium and myocarditis can ensue. Additionally, arrhythmias and heart failure can be seen. EKG changes can occur and usually do so in the second week of infection and can persist into the third and fourth weeks of infection.³

Dyspnea, cough, and hoarseness are also possible, with the dyspnea sometimes related to larval infiltration into the muscles of respiration.⁹ A macular or maculopapular rash may develop, and conjunctival, subungual, and nail bed hemorrhages can be seen, as well.^{9,3,11} Additionally, thromboembolic phenomena such as pulmonary embolism, deep thrombophlebitis, and intraventricular thrombi can occur.²

The stage of convalescence occurs once there are no more larvae being produced in the small intestine and the larvae embedded in the skeletal musculature have fully developed. This usually occurs at 6–8 weeks following initial infection, and is associated with clinical improvement. Importantly, patients can continue to have muscle pain as late as six months following infection.¹⁰ However, ultimate recovery is usually complete.³ The phenomenon of chronic trichinellosis, characterized by chronic pain and psychiatric symptoms, has been described, but the diagnosis is contentious.¹⁰

Diagnosis

In sporadic cases the diagnosis can be difficult to make, as the symptoms are fairly nonspecific and can be attributed to numerous other illnesses. In outbreaks, the disease is easier to identify. The ingestion of possibly contaminated meat, gastrointestinal symptoms, facial edema, myalgia, and an associated eosinophilia should heighten suspicion for disease with *Trichinella*.³

Characteristic laboratory findings associated with this illness include eosinophilia, leukocytosis, elevated muscle enzymes and an increased total IgE level.³ Leukocytosis is commonly seen with levels as high as 18,000 cells per mm³ with an associated eosinophilia with levels as high as approximately 8700 cells per mm³.⁸ Some degree of eosinophilia is present in nearly every patient.¹⁰ It is possible that eosinopenia can occur with very severe disease, and this can be a poor prognostic indicator.⁸ Additionally, eosinophilia can be absent with concurrent bacterial infections and decreases following corticosteroid administration.³ Creatine phosphokinase (CPK), aspartate aminotransferase (AspAT) and lactic acid dehydrogenase (LDH) levels can be elevated, reflecting skeletal muscle involvement.¹¹ The total IgE level can be elevated, although this is not seen in all cases.³

There are a number of serologic tests available to aid in diagnosis. The most frequently used tests for human disease detection include enzyme-linked immunosorbent assay (ELISA), indirect hemagglutination (IHA), latex agglutination, bentonite flocculation and indirect immunofluorescence assay (IFA). Of these, ELISA is the most frequently used modality and is the most sensitive. Seroconversion usually will occur between weeks 2 and 5 after initial infection, and antibodies can be positive for a year or longer.¹⁷ Importantly, there is no direct association between antibody levels and disease severity.¹⁸ Polymerase chain reaction (PCR) technology has been used to detect *Trichinella* DNA in mouse blood, and this technology has potential utility for human serologic diagnosis.¹⁹

Conduction changes are often seen with electromyography (EMG) during the parenteral phase of illness, although these findings

are not disease specific.² The changes seen on EMG often disappear by 3–4 months, although they can persist for years.^{20,21}

Although the diagnosis can be made via muscle biopsy, this only is recommended for difficult cases. Biopsy, when performed, is usually from the deltoid muscle.³ The biopsy tissue can be examined directly via microscopy, and will often reveal larvae when severe infection is present.⁸ Histologic evaluation of the muscle biopsy tissue may also reveal basophilic changes, which is a useful finding even when larvae are not directly identified. Additionally, muscle digestion with a 1% hydrochloric acid and 1% pepsin solution is a useful method to isolate larvae. However, this method is only useful for larvae harvested 2–3 weeks from the time of initial infection, as younger larvae may not manifest sufficient resistance to the digestion process.¹⁰

Treatment and Prognosis

Therapy in this disease is controversial, and there is little evidence-based literature available to guide management decisions. Mebendazole and thiabendazole have been shown to be effective in treating systemic trichinellosis, and albendazole has shown some efficacy, as well. Importantly, thiabendazole is poorly tolerated and therefore is not used anymore in this disease. Although the optimal dosing for these drugs has yet to be determined, animal experimentation has revealed that extended regimens with overall low drug levels have been most efficacious. As disease severity is directly related to how many viable larvae are produced in the small intestine, there is general consensus that treatment during the enteral phase is essential. In this stage of illness mebendazole appears to be the best drug. Pyrantel pamoate has some reported success against intestinal trichinellosis but is not effectively absorbed and therefore can not be used for parenteral illness.

The optimal use of corticosteroids is uncertain, as experiments have shown they can prolong the intestinal phase of illness. However, many experts still recommend their use with severe disease. For systemic disease mebendazole appears to be the drug of choice, but albendazole has shown some efficacy, as well. Further studies are needed to determine the optimal dosing and schedule for these medications, and their efficacy relative to each other.²² Significantly, both albendazole and mebendazole are teratogenic in animals, and are not recommended for pregnant women and children under two years of age. Optimal therapy for these groups is unclear.

Death is an uncommon occurrence with this disease process. When it does occur, it is usually secondary to myocarditis related heart failure, pneumonitis, encephalitis, or from thromboembolic complications.^{2,3} Significantly, between 1997 and 2001 in the United States there were 72 reported cases of infection with *Trichinella*, with no deaths reported.⁵

Prevention and Control

Control of *Trichinella* at the animal reservoir level is essential in preventing human illness. This includes measures to prevent disease transmission to domestic swine. Such control practices minimize swine exposure to potentially infected rodents and prevent the use of meat scraps and animal carcasses as food sources.⁸ As well, hunters should be educated about both the appropriate processing of wild game meat and the disposal of animal remains.⁴ Although the inspection of slaughtered pork is a common practice in many developed countries, in the United States it is not mandated.⁸ The United States Department of Agriculture has put forth regulations regarding the safe processing of meat to prevent human infection with *Trichinella*. These include specific guidelines for rendering meat safe via both heating and freezing. For example, they recommend that pork be cooked to an internal temperature of at least 52.2°C for a minimum time period of two hours, and, for sections of pork not greater than six inches in thickness, they recommend freezing at –23°C for at least 10 days. When the technology is not available to fully monitor the heating process, it is recommended that meat be cooked until it is gray throughout and individual muscle fibers can be separated from one another easily. Additionally, when it is not possible to fully monitor the freezing process it is recommended that meat should be frozen solid (at a temperature at least as low as –15°C) for 3–4 weeks, depending on the thickness of the cut of meat involved.²³ Importantly, recommendations for freezing should only be applied to pork, and not to meat from wild game or horses, as these may harbor *Trichinella* species resistant to freezing.²⁴ Additionally, consumer education is also important, and should include information on the appropriate handling of meat from both domestic and wild animals.²³ Of note, an experimental vaccine utilizing antigens from the NBL of *T. spiralis* has shown efficacy in pigs.²⁵ However, the ultimate costs of producing a vaccine to eliminate *Trichinella* in populations of swine may be prohibitive.⁴

Clonorchiasis and Opisthorchiasis

Kenrad E. Nelson

Three parasitic trematodes of the family Opisthorchiidae—*Clonorchis sinensis*, *Opisthorchis viverrini*, and *Opisthorchis felinus*—are responsible for chronic disease of the liver and bile ducts in humans. Infections with these similar trematodes are widely distributed in countries in the Far East and Southeast Asia and countries of the former Soviet Union. They present serious public health problems in certain localized areas of China, Korea, Thailand, Laos, Cambodia, Vietnam, and several countries of the former Soviet Union. The World Health Organization has estimated recently that at least 7 million persons are infected with *C. sinensis* in China and Korea, 2 million persons are infected with *O. felinus* in Russia, and 6 million persons are infected with *O. viverrini* in Southeast Asia.¹ With increased travel and migration of populations at risk and importation of indigenous uncooked foods contaminated with these parasites, infections have also occurred on occasion in nonendemic areas.²

Life Cycle

The parasites *C. sinensis*, *O. viverrini*, and *O. felinus* require two intermediate hosts and a definitive host to complete their life cycle. In addition to humans, dogs, cats, rats, and other fish-eating mammals can serve as reservoir hosts. When the eggs are passed with the stools of humans or infected carnivores, they are fully embryonated. However, they do not hatch spontaneously when they reach fresh water. The miracidium is set free only after the eggs are ingested by an operculate snail, the first intermediate host. Species of these snails that can serve as intermediate hosts are from the genera *Parafossarulus*, *Bulinus*, *Semisulcospina*, *Alocinma*, and *Thiara*. In these intermediate hosts, further development from the stage of miracidium to cercariae takes place. The cercariae emerge into water, and on contact with a suitable fresh-water fish of the minnow and carp family (Cyprinidae), they penetrate the skin of the fish, discard their tails, and encyst in the flesh as metacercariae. When infected raw fresh-water fish containing

the encysted stages of the parasite are eaten, the larvae are set free in the duodenum of the final host and enter the bile ducts within a few hours after being ingested. In about four weeks, the flukes reach maturity and begin to shed eggs into the bile ducts. When the embryonated eggs are passed in the stool and reach fresh water, the life cycle of the parasite is completed. The complete life cycle, from one infected person to another, requires at least three months.

Geographic Distribution

The geographic distribution of endemic clonorchiasis or opisthorchiasis is determined by three factors: (a) the presence of suitable intermediate hosts, (b) the preference of the people in these areas to eat raw fish, and (c) exposure of these aquatic environments to sewage containing parasite eggs. Infections with *C. sinensis* are common in populations in Korea, China, parts of Japan and Taiwan, and among refugees from Vietnam and Cambodia. Infections with *O. viverrini* are endemic in Thailand, Laos, Cambodia, and the Philippines; *O. felinus* infections occur among populations in Siberia and other areas of Central Russia and the Ukraine. Clonorchiasis or opisthorchiasis in humans can be long-lived (up to 25 years) if left untreated. The infection affects Asians worldwide; nevertheless there is no evidence that Asian migrants have introduced the parasite into new environments, likely due to the absence of suitable intermediate hosts.

Clinical Illness

The flukes injure the bile ducts and produce chronic cholangitis characterized by marked hyperplasia of the cylindrical epithelium, frequently associated with numerous mitoses. Eventually, nonspecific changes caused by chronic inflammation and subsequent reinfections lead to a progressive fibrous thickening of the walls, causing partial or complete obstruction of terminal bile ducts, pressure necrosis of the surrounding parenchyma, and in severe cases, biliary cirrhosis. Development of cholangitic cirrhosis is enhanced by intermittent acute episodes of complicating bacterial cholangitis, especially from *Escherichia coli* and other gut flora, which produces abscesses that lead to chronic cholecystitis. A causal relationship between chronic clonorchiasis or opisthorchiasis and biliary tract carcinoma (cholangiocarcinoma) has been established.²⁻⁵ Approximately two-thirds of patients from northeastern Thailand having obstructive jaundice secondary to malignant disease have cholangiocarcinoma related to liver flukes.¹ In contrast in persons living in Western nations, carcinoma of the head of the pancreas is by far the most frequent cause of obstructive jaundice secondary to malignant disease.

The signs and symptoms of clonorchiasis and opisthorchiasis are nonspecific. Most infected persons are asymptomatic; only about one-third of chronic infections are symptomatic. In patients who do have symptoms, gradual onset of discomfort in the upper abdomen, anorexia, indigestion, and abdominal pain or distention can occur. In the late stages obstructive jaundice, portal hypertension, ascites, and gastrointestinal bleeding can occur. Recurrent pyogenic cholangitis is the most frequent serious acute complication of clonorchiasis. These episodes can be followed by the formation of biliary stones in the gallbladder and bile ducts.¹

Diagnosis

Diagnosis is based on recovery of the typical eggs from stool specimens. Field surveys for the eggs in the stool can be made using standard fecal examination techniques, such as the sedimentation or the modified cellophane fecal thick-smear technique (Kato-Katz technique); these are simple and reproducible methods for the detection of trematode eggs. The Kato technique also permits storage of slides for later reexamination for quality control. Sometimes, eggs may be found only in the bile or duodenal contents after intubation and aspiration. The eggs of *C. sinensis* are among the smallest produced by trematodes that are pathogenic for humans, and measure only 27 by 16 μm . They are yellow-brown and have a characteristic operculum that fits into the rim of the shell, like a lid on a sugar bowl, and a small knoblike protuberance located at the opposite pole.

Intradermal and complement-fixation tests, with purified antigens prepared from *C. sinensis* or *O. viverrini*, are helpful in establishing the diagnosis. Among the modern immunodiagnostic tests, an enzyme-linked immunosorbent assay (ELISA) gives highly predictive results. The test combines a high degree of sensitivity with specificity and is a good tool for epidemiologic investigations.^{6,7}

Community Patterns of Infection and Disease

In hyperendemic areas, there is a rapid increase in the prevalence of infection from the age of 1 to about 20 years. Thereafter, the prevalence stabilizes and may fall among persons over 40 years of age. In rural areas of the Republic of Korea, along the Naktong river, it is not unusual to find as many as 80% of the villagers infected with *C. sinensis*. Although raw fish is eaten by both sexes, males are more often infected. This sex difference is probably related to local customs of serving raw fish with alcoholic beverages at the many social gatherings, which are attended exclusively by males.

Community studies in rural areas of China, Korea, and Indochina may yield age-specific prevalence rates close to 100%. In rural areas of northeastern Thailand and Laos the prevalence of *O. viverrini* infection can be over 80% in some populations. The disease has a pronounced focal distribution, depending on the availability and the habit of eating uncooked fish containing the metacercariae of the fluke. Spread of infection has been related to the use of aquaculture to develop sources of fish protein for consumption in areas where sanitary disposal of human waste is not available and consumption of uncooked fish is common.

Liver cancer is one of the most common malignancies in Southeast Asia. In many areas hepatocellular liver cancer, associated with chronic hepatitis B virus infection, is most common. However, in some areas the types and causes of liver cancer differ. Khon Kaen, in northeastern Thailand, has one of the world's highest incidence rates of liver cancer.¹ The high incidence of cholangiocarcinoma, which in many other populations accounts for only a minority of liver cancer cases, is particularly striking. In 1988 in Khon Kaen, 89% of liver cancers were cholangiocarcinomas. The age-standardized incidence rates for 1988 were 89.2 per 100,000 males and 35.5 per 100,000 females. In contrast, a cancer registry established in the province of Chiang Mai in northern Thailand, where the prevalence of *O. viverrini* infection is much lower, reported rates of cholangiocarcinoma of 5 per 100,000 males and 3 per 100,000 females. A retrospective study of hospital records in Khon Kaen yielded estimated annual age-standardized incidences of cholangiocarcinoma of 135.4 per 100,000 males and 43.0 per 100,000 females. Nearly all patients with diagnosed cholangiocarcinoma had heavy egg burdens of *O. viverrini* in their stools.

In the central part of the Tyumen region in Russia, where the prevalence of *O. felinus* infection was 45%, the rate of cholangiocarcinoma was 49.8 per 100,000 population.¹ In contrast, in the southern part of the Tyumen region only 0.5% of the population were infected with *O. felinus*, and the average prevalence of cholangiocarcinoma was reported to be 4.4 per 100,000.¹

The full public health importance of *C. sinensis* infection has not been adequately evaluated in relation to the prevalence and intensity of infection, the frequency of reinfections, and the risks of developing chronic liver disease or cancer of the bile ducts. Although *C. sinensis* infections and cholangiocarcinoma have been associated, fewer studies of the public health importance of *C. sinensis* infection have been reported.

Treatment and Control

Praziquantel—2-(cyclohexylcarbonyl)-1,2,3,6,7,11b-hexahydro-4H-pyrazino(2,1-a) isoquinolin-4-one—is the most effective drug for the treatment of human clonorchiasis or opisthorchiasis. The recommended doses are 25 mg/kg body weight of praziquantel three times daily (i.e., 75 mg/kg given in three doses on a single day).⁸ Mass treatment with a single dose of 40 mg/kg has been used in public health campaigns in northern Thailand.¹ Cure rates as high as 90% have been reported in mass treatment campaigns. Of course,

reinfection with the organism can occur readily unless public health practices are instituted that change the preparation and consumption of fish and/or the disposal of contaminated fecal material in endemic areas.

Poverty, pollution, and population growth are the triad of underlying determinants that directly influence the incidence of food-borne trematode infections. Although thorough cooking of all fish in endemic areas is an effective safeguard against infection, shortage of fuel in some poor homes may mandate the consumption of uncooked fish products. Traditional dishes in Southeast Asia that contain fermented freshwater fish may promote the transmission of food-borne trematodes.

Sanitary disposal of contaminated feces using latrines is another important method of public health control of the infection. In areas where night soil is used as a fertilizer in fish ponds, treatment of the

feces with a 0.7% solution of ammonium sulfate can be used to kill the miracidia in the eggs and interrupt the chain of infection. In Thailand public health efforts, which involve annual mass treatment of populations with praziquantel and distribution of cooking pots, have been successful in dramatically reducing the high prevalence of infection in some populations.¹

The recent and future exponential growth of aquaculture required to meet the growing need for human food may increase the risk of infection, especially in Asian areas endemic for food-borne trematode disease.^{9,10} Also increased travel to endemic areas and consumption of exotic foods containing uncooked fish (e.g. sushi) from these areas poses a potential risk of human infection. Dried or pickled fish shipped from endemic areas may be sources of infection in nonendemic areas. Therefore, more effective control of these imported food products is needed.

Cestode Infections

Taeniasis and Cysticercosis

Kenrad E. Nelson

Taeniasis refers to an intestinal infection with the adult stage of the beef tapeworm (*Taenia saginata*) or the pork tapeworm (*Taenia solium*). Cysticercosis is the somatic infection with the larval stage of the pork tapeworm. Neurocysticercosis is central nervous system infection with *T. solium* larvae. Both beef and pork tapeworms have been known as parasites of humans since ancient times, but infection of humans by the larval stage of the pork tapeworm was not recognized until the sixteenth century.¹

Life Cycle

Cestodes of the family Taeniidae complete their cycle in two mammalian hosts, typically a carnivore and a herbivore between which a well-defined predator-prey relationship exists.^{1,2} Humans are the definitive hosts for two species of *Taenia*: *Taenia saginata* and *Taenia solium*. The larval stages of the species occur in cattle (*T. saginata*) and in swine (*T. solium*). The larvae of *T. solium* can develop in dogs and humans also. Humans contract taeniasis through the ingestion of infective cysticerci in raw or undercooked beef, pork, or dog meat.² In the small intestine, the cysticercus inserts its scolex to attach to the mucosa and develops into the adult worm. Adult *T. saginata* can measure 4–12 m in length and can survive up to 30 years in the human intestine. Release of segments containing eggs infective for the intermediate host begins in the human intestine after 8–10 weeks for *T. saginata* and 9–13 weeks for *T. solium*. A tapeworm carrier releases between 6 and 9 proglottids daily, each containing about 50,000 fertile eggs. Humans acquire cysticercosis by ingestion of *T. solium* eggs, either from exogenous surroundings or from their own stool. Internal autoinfection, in which the eggs of *T. solium* are swept back into the stomach by reverse peristalsis, is also possible.

Distribution

According to recent estimates, about 45 million people worldwide are infected by *T. saginata* and about 3.5 million by *T. solium*. *Taenia saginata* is common in some regions of the former Soviet Union,

Southeast Asia, Africa, and some South American countries. The highest rates of human infection have been reported in Africa among nomadic cattle herders.^{2,3} *T. saginata* is uncommon in North America, north of Mexico, but its prevalence seems to have increased locally in the southwestern United States. In that region, workers harboring the adult worms may contaminate sewage used in irrigation, which are the sources of infection for cattle.^{4,5} *T. solium* is uncommon in most developed countries, but it is relatively common in some regions of Africa, southern Asia, Mexico, and Central and South America.

Clinical Picture

The presence of these cestodes in the human intestine is often asymptomatic. The symptoms, when present, are vague and include abdominal pain, nausea, flatulence, diarrhea, and weight loss. Patients, especially those infected with *T. saginata*, may sense the active migration of proglottids through the anus. *T. solium* proglottids do not migrate spontaneously.

In humans, systemic infection with *T. solium* larvae causes cysticercosis. This cestode is unique in the Taeniidae family in that both stages of its life cycle can develop in a single mammalian host; but larvae in skeletal muscle do not usually develop into mature cysts and generally are not symptomatic unless present in large numbers. However, significant functional disturbances may result when cysticerci localize in tissues of the central nervous system. Neurocysticercosis can be associated with a variety of clinical symptoms. Seizures are by far the most common clinical manifestation and occur in about 80–90% of cases.⁶ Neurocysticercosis is the most frequent cause of adult onset epilepsy worldwide.⁷ Less commonly, patients can present with headache, symptoms of elevated intracranial pressure, depressed mental status (including coma), stiff neck, or focal neurologic findings. The clinical presentation depends on the location, number, and viability of the cysts as well as the host response to their presence.^{6,8,9}

Diagnosis

The diagnosis of taeniasis is based on the characteristic eggs or proglottids found in the stool. The eggs of *T. solium* and *T. saginata* are indistinguishable, but the species can be differentiated by examination of the gravid proglottids. The number of main uterine branches of *T. saginata* is 15–20, and that of *T. solium* is 7–13.

The diagnosis of cysticercosis involving the central nervous system is sometimes difficult. Cysticercosis should be considered in the differential diagnosis of epilepsy, basilar meningitis, obstructive hydrocephalus, and other neurologic disorders in patients with a history of residence or travel in regions where *T. solium* is endemic.⁸ The cysts are sometimes seen radiologically in skull films after the death and calcification of the larvae. Imaging techniques such as computed tomographic (CT) scanning and nuclear magnetic resonance imaging (MRI) are the main diagnostic tools in neurocysticercosis.^{7,8} CT is the best method for detecting the calcification associated with a previous infection. Most parenchymal cysts will appear as low-density cysts, with enhancement of the cyst wall or surrounding tissues, usually accompanied by surrounding edema. MRI is more sensitive than CT for revealing cysts in the brain parenchyma or extraparenchymal sites and in basilar cisterns.⁹ Cysticerci localized in subcutaneous tissues or skin can form palpable nodules that are readily identified by biopsy. Rarely, patients with massive deposition of cysts in their muscle will develop muscular pseudohypertrophy.² Ophthalmic cysticercosis occurs in 1–3% of patients with cysticercosis.²

Immunodiagnostic tests for cysticercosis are available. Both antibody and antigen have been detected in serum or cerebrospinal fluid by enzyme-linked immunosorbent assay (ELISA) or a combination of other immunochemical techniques based on ELISA.^{10–12} Highly purified specific antigens are required for reliable results. The enzyme-linked immunoelectrotransfer blot (EITB) method, using lentil-lectin affinity-purified glycoprotein antigens for immunodiagnosing human cysticercosis, has been reported to be nearly 100% sensitive and specific.^{13,14} The test is more sensitive with serum than CSF samples.¹⁴ However, the sensitivity is lower in patients with only calcified lesions.¹⁴ The best available diagnostic assay for intestinal taeniasis is a coproantigen ELISA, which has about 95% sensitivity and 97% specificity. In contrast, microscopy has a sensitivity of 60–70% compared to the coproantigen ELISA. Cysticercosis appears to have increased in frequency recently.^{2,8} However, some of this increase in prevalence may be related to more sensitive methods of diagnosis, using ELISA or EITB, coupled with neuroradiologic techniques such as CT scanning and MRI.

Since humans can acquire cysticercosis through fecal-oral contamination with *T. solium* eggs from tapeworm carriers, vegetarians and people who do not eat pork can acquire cysticercosis. In fact, neurocysticercosis has been described among members of an orthodox

Jewish community due to transmission from a person from Latin American with Taeniasis.^{15,16} Also, increased travel from areas of the world where *T. solium* is endemic may have increased the frequency of the disease in the United States and Europe.⁶

Treatment

In treating taeniasis, good results have been obtained with niclosamide and dichlorophen, both of which cause some disintegration of the strobilae. Niclosamide is the drug of choice for the treatment of intestinal Taeniasis, because the drug is not absorbed. Praziquantel is 100% effective against *T. saginata* and other cestodes when administered in a single dose of 10 mg/kg. Side effects of treatment are minimal in patients with taeniasis. However, praziquantel can induce an inflammatory response in some persons with neurocysticercosis when organisms degenerate.¹⁸

Treatment of parenchymal neurologic cysticercosis has relied on the use of anticonvulsive drugs to control epileptiform attacks. Treatment has been advocated with praziquantel in doses of 50 mg/kg per day in three daily doses for 15 days or albendazole in doses of 15 mg/kg per day for 8 days.^{2,17} Some investigators recommend that corticosteroids be used routinely as an adjunct to the antiparasitic therapy.^{2,8,19} Others use steroids only in patients who develop symptoms.¹⁸ Controlled trials suggested that treatment with these antiparasitic drugs is associated with only modest improvement in the rate of resolution of cysts.^{19,20,21} Disorders attributable to interference with the flow of cerebrospinal fluid due to extraparenchymal racemose cysticerci can sometimes be alleviated surgically by removing the cysts or by performing shunting procedures.

Prevention and Control

Requisite conditions for the infection of humans by *T. saginata* and *T. solium* are poor sanitation and consumption of beef and pork insufficiently cooked to kill the cysticerci. The use of raw sewage containing human feces to fertilize crops completes the life cycle of these organisms. The best preventive measures include maintaining strict personal hygiene and environmental sanitation, and protecting cattle and hogs from contact with human excretions. Individual infection is prevented by thorough cooking of beef and pork to 55°C or freezing at –17°C for five days or irradiating the meat. In endemic regions, educational programs are needed to alert the public to the risks of eating inadequately cooked beef and pork. In the United States, federal meat inspection includes direct examination for the presence of cysticerci (i.e., looking for “measly” meat). However, interrupting the infection cycle in animals by good sanitation is the preferred public health approach to prevention.

Hydatid Disease (Echinococcosis)

Pedro L. Moro • Peter M. Schantz

Hydatid disease (echinococcosis) is the infection of humans by the larval stages of taeniid cestodes of the genus *Echinococcus*. Four species of *Echinococcus* are currently recognized, of which three

cause distinctive forms of disease: *Echinococcus granulosus* (cystic hydatid disease), *Echinococcus multilocularis* (alveolar hydatid disease), and *Echinococcus vogeli* (polycystic hydatid disease). The fourth species, *E. oligarthrus*, has only rarely (<5 cases) been identified as a cause of human disease. Diverse subpopulations of *E. granulosus*, distinguished by morphologic and biologic characteristics, have long been recognized; the taxonomic significance of these differences remain unresolved and controversial. However, recent demonstrations

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

of consistent genetic differences has prompted calls for splitting this species.¹ As a cause of morbidity in humans, *Echinococcus* species rank high among the helminths.

Life Cycle

The life cycles of *Echinococcus* species involve carnivores as final hosts and herbivores or omnivores as intermediate hosts. In their adult stage, these cestodes are small, ranging from about 2–12 mm in length, with three to six segments. They typically localize in the lower duodenum and jejunum of the final host. Embryophores containing infective embryos are expelled in large numbers in the feces of the final carnivorous host. After ingestion by the intermediate host, the embryo is released into the small intestine, which it penetrates, and soon enters the portal circulation. The site of localization and development of the embryo to the larval or hydatid stage differs with species of *Echinococcus* and may be influenced as well by species of the intermediate host. Humans are an incidental intermediate host, since further development of these cestodes depends on ingestion of their larvae (hydatids) by a carnivore.

Distribution and Transmission Patterns

Cystic hydatid disease (CHD) is caused by the larval stage of *E. granulosus*. Molecular studies using mitochondrial DNA sequences have identified nine distinct genetic types (G1–9) within *E. granulosus*.^{2,3} These include two sheep strains (G1, G2), two bovid strains (G3, G5), a horse strain (G4), the camelid strain (G6), a pig strain (G7), and the cervid strain (G8). A ninth genotype (G9) has been described in swine in Poland.² The sheep strain (G1) is the most cosmopolitan form that is most commonly associated with human infections. The other strains appear to be genetically distinct, suggesting that the taxon *E. granulosus* is paraphyletic and may require taxonomic revision.^{2,3} The “cervid,” or northern sylvatic genotype (G8), is maintained in cycles involving wolves and dogs and moose and reindeer in northern North America and Eurasia. Human infection with this strain is characterized by predominantly pulmonary localization, slower and more benign growth, and less frequent occurrence of clinical complications than reported for other forms.² The presence of distinct strains of *E. granulosus* has important implications for public health. The shortened maturation time of the adult form of the parasite in the intestine of dogs suggests that the period for administering antiparasite drugs to infected dogs will have to be shortened in those areas where the G2, G5, and G6 strains occur.⁴

E. granulosus is prevalent in broad regions of Eurasia, in several South American countries, and in Africa. Humans become infected through association with dogs that have been fed viscera from slaughtered animals or have had access to carcasses or discarded offal of domestic ungulates in which the larvae are present. Populations at risk in the United States include Basque Americans in California, Mormons in central Utah, and Navajo and Zuni Indians in New Mexico. However, the number of autochthonous cases appears to have declined substantially in the last 30 years.⁵ Most cases are diagnosed in immigrants from endemic countries.⁶

Alveolar hydatid disease is caused by *E. multilocularis*, which has an extensive geographical range in the northern hemisphere. The natural cycle involves foxes and small rodents as final and intermediate hosts, respectively. *E. multilocularis* is endemic in the central part of Europe, parts of the near East, Russia, and the central Asian Republics, China, northern Japan and Alaska.⁷ Recent surveys in central Europe have extended the known distribution of *E. multilocularis* from four countries at the end of the 1980s to 11 countries in 1999, although the annual incidence of disease in humans remains low.⁸ There is evidence of parasites spreading from endemic to previously nonendemic areas in North America and north Island, Hokkaido, Japan, due principally to the movement or relocation of foxes. In North America, the parasite has been recorded in two distinct geographic regions: the north Tundra zone (western Alaska) and central North America.^{8,9} Despite the presence of infected definitive and intermediate hosts in 12 of the states in central North America, only one human case of alveolar echinococcosis (AE) has been described in Minnesota.¹⁰

China is a newly recognized focus of AE in Asia. *E. multilocularis* occurs in three areas: Northeastern China including Inner Mongolia Autonomous Region and Helongjiang Province; Central China including Gansu Province, Ningxia Hui Autonomous Region, Sichuan Province, Qinghai Province and Tibet Autonomous Region; Northwestern China including Xingjian Uygur Autonomous Region.¹¹ The highest prevalence of AE in the world was found in Qinghai Province with 800 per 100,000 inhabitants.¹²

The infection of humans by the larval *E. multilocularis* is often the result of association with dogs and perhaps cats that have eaten infected rodents. Villages within the zone of Tundra may constitute hyperendemic foci because of the interaction between dogs and wild rodents that live as commensals in and around dwellings. In central Europe, rodents inhabiting cultivated fields and gardens become infected by ingesting embryophores expelled by foxes and, in turn, may be a source of infection for dogs and cats. A recent case-control study demonstrated a higher risk of alveolar hydatidosis among individuals who owned dogs that killed game, dogs that roamed outdoors unattended, individuals who were farmers, and individuals who owned cats.¹³ In rural regions of central North America, the cycle involves foxes and rodents of the genera *Peromyscus* and *Microtus*. Keeping uncontrolled dogs and cats in these regions may be hazardous.

Polycystic hydatid disease, caused by *E. vogeli*, has been reported infrequently from Central and South America. The natural hosts of this cestode are the bush dog, *Speothos venaticus*, and the paca, *Cuniculus paca*.¹ The larval stage occurs occasionally in rodents of other species. Little is known of the epidemiology of polycystic hydatid disease. The natural final host of *E. vogeli*, the bush dog, is a wary and rarely seen animal that is an unlikely source of infection for humans. The intermediate host, the paca, is widely hunted for food in northern South America and local hunters routinely feed the viscera of pacas to their dogs; thus, infected dogs may be the primary source of infection for humans.¹⁴

Clinical Picture

Cystic Hydatid Disease. In humans, hydatid cysts of *E. granulosus* are slowly enlarging masses comparable to benign neoplasms; most human infections remain asymptomatic. Hydatid cysts are frequently observed as incidental findings at autopsy at rates much higher than the reported local morbidity rates. The clinical manifestations are variable and are determined by the site, size, and condition of the cysts.¹⁵ Hydatid cysts in the liver and the lungs together account for 90% of affected localizations. The average liver-to-lung infection ratio varies from 2.1:1 in clinical cases to 6:1 and 12:1 in asymptomatic individuals with hydatid disease.¹⁶ The chronic signs of hepatic cystic echinococcosis include hepatomegaly with or without the presence of a mass in the upper right quadrant. Obstructive jaundice accompanied by symptoms such as mild epigastric pain, indigestion, and nausea may occur occasionally. Cysts may also become secondarily infected with bacteria and manifest as an abscess. Features of lung involvement include coughing, hemoptysis, dyspnea, and fever. In about 10% of cases the cysts occur in organs other than the lungs and liver. Other known complications include anaphylaxis, secondary spread following rupture, pathological fracture of bones and formation of hepatopulmonary fistulae.¹⁷ The northern form (G7 genotype) causes a milder form of the disease with smaller lung cysts.

Alveolar Hydatid Disease. The embryo of *E. multilocularis* seems to localize invariably in the liver of the intermediate host. Development of the larval *E. multilocularis* is inhibited in humans, so that it persists indefinitely in the proliferative phase. As a result, the hepatic parenchyma is gradually invaded and replaced by fibrous tissue in which great numbers of vesicles, many microscopic, are embedded. Proliferation continues peripherally, with the result that an entire hepatic lobe may be replaced over a period of years. As the lesion enlarges, it usually undergoes degenerative changes that lead to central necrosis, often with liquefaction, and abscesses with a volume of several liters may be produced. Uneven calcification of necrotic tissues is typical in lesions of long standing. Hepatomegaly

is characteristic and maybe extreme. The disease takes a chronic course, with deterioration of health often occurring around middle age. Patients eventually succumb to hepatic failure, invasion of contiguous structures, or, less frequently, metastases to the brain.¹⁸ However, instances of spontaneous death of the cyst during its early stage of development have been reported in people with asymptomatic infection.¹⁹

Polycystic Hydatid Disease. In human cases, hepatomegaly or tumorlike masses in the liver have been typical findings. Proliferation of vesicles may lead to destruction of much of the liver, and involvement of adjacent structures by extension does not appear to be unusual. The prognosis in polycystic hydatid disease is poor. The known cases have been described by D'Alessandro and associates.¹⁴

Diagnosis. The presence of a cystlike mass in liver or lungs of a person with a history of exposure to sheepdogs in areas in which *E. granulosus* is endemic supports the diagnosis of cystic hydatid disease.¹⁶ However, echinococcal cysts must be differentiated from benign cysts, cavitary tuberculosis, mycoses, abscesses, and benign or malignant neoplasms. A noninvasive confirmation of the diagnosis can usually be accomplished with the combined use of radiologic imaging and immunodiagnostic techniques. Chest roentgenography permits the detection of echinococcal cysts in the lungs; this is the most common means of diagnosis of the northern form that most commonly localizes in the lungs. In other sites, calcification is necessary for roentgenographic visualization by x-ray. Computerized axial tomography (CT), magnetic resonance, and ultrasound imaging are useful for diagnosing deep-seated lesions in the liver and other organs and are further useful for defining the extent and condition of avascular fluid-filled cyst(s). The CT image of *E. granulosus* larval cysts typically shows sharply contoured cysts (sometimes with internal daughter cysts) and marginal calcifications.²⁰ Portable ultrasonography machines have been applied for field surveys with excellent results.^{21,22}

Serologic tests are useful to confirm presumptive radiologic diagnoses, although some patients with cystic echinococcosis (CE) do not develop a detectable immune response.¹⁵ Hepatic cysts are more likely to elicit an immune response than pulmonary cysts; however, it appears that, regardless of location, the sensitivity of serologic tests is inversely related to the degree of sequestration of the echinococcal antigens inside cysts. Enzyme-linked immunosorbent assay (ELISA) or the indirect hemagglutination test are highly sensitive procedures for the initial screening of sera; specific confirmation of reactivity can be obtained by immunodiffusion (arc 5) procedures or immunoblot assays (8/12 kD band).²³ Eosinophilia is present in fewer than 25% of infected persons.

In seronegative patients, a presumptive diagnosis may be confirmed by demonstrating protoscoleces or hydatid membranes in the liquid obtained by percutaneous aspiration of the cyst. Although previously considered taboo because of the potential for anaphylaxis or dissemination of protoscoleces, with certain precautions percutaneous aspiration for purposes of diagnosis or treatment is now standard procedure. Ultrasound guidance of the puncture, anthelmintic coverage, and anticipation of the possible need to treat an allergic reaction now minimize risks.²⁴ Protoscoleces can sometimes be demonstrated in sputum or bronchial washings; identification of hooklets is facilitated by acid-fast stains.

Diagnosis of AE may be difficult, particularly in regions where its possible occurrence is not known to clinicians and pathologists, as in central North America; the disease is typically seen in persons of advanced age in whom it closely mimics hepatic carcinoma or cirrhosis. Plain roentgenography shows hepatomegaly and characteristic scattered areas of radiolucency outlined by calcified rings 2–4 mm in diameter. The usual CT image of *E. multilocularis* infection is that of indistinct solid tumors with central necrotic areas and perinecrotic plaque-like calcifications.²⁵ Serologic tests are usually positive at high titers; highly specific antigens have been identified and synthesized that, when used in serologic assays, are highly sensitive and specific for diagnosis of AE and can distinguish this infection from

CE (*E. granulosus*) and other forms of echinococcosis.²⁶ Needle biopsy of the liver may confirm the diagnosis if larval elements are demonstrated. Exploratory laparotomy is often done for diagnosis and delineation of the size and extent of the invasion.

Polycystic echinococcosis has characteristics intermediate between those of the cystic and alveolar forms.¹⁴ The relatively large cysts are filled with liquid and contain brood capsules with numerous protoscoleces. The primary localization is the liver, but cysts may spread to contiguous sites or occur in other primary localizations. Immunodiagnostic and other techniques useful for diagnosing cystic or alveolar hydatid disease are also of value in diagnosing polycystic hydatid disease. The hydatid cysts of *E. vogeli* can be differentiated from those of other species based on differences in the dimensions of the hooks of the protoscoleces.¹⁴

Treatment. Until recently, surgery was the only option for treatment of hydatid cysts; however, in the past 15 years chemotherapy has been introduced and evaluated and, more recently, combinations of cyst puncture, aspiration, and drainage, with or without injection of chemicals—called percutaneous aspiration, injection, reaspiration (PAIR)—have been evaluated and, increasingly, are seen to supplement or even replace surgery as the preferred treatment.²⁷ Surgery remains the preferred treatment when cysts are large (>10cm diameter), secondarily infected, or located in certain organs, that is, the brain or heart. The aim of surgery is total removal of the cyst while avoiding the adverse consequences of spilling its contents. Pericystectomy is the usual procedure, but simple drainage, capitonnage, marsupialization, and resection of the involved organ may be used, depending on the location and condition of the cyst(s). At times, surgery may be impossible because of the patient's general condition and the extent and location of the cysts. Under such conditions, treatment with benzimidazole drugs may be tried; approximately one-third of patients treated with benzimidazole drugs have been cured of their disease (e.g., complete and permanent disappearance of cysts), and an even higher proportion have responded with significant regression of cyst size and alleviation of symptoms.^{28,29} Both albendazole (10–15 mg per kg body weight per day) and mebendazole (40–50 mg/kg) have demonstrated efficacy; however, albendazole, because of its superior pharmacokinetic profile which favors intestinal absorption and penetration into the cyst(s), is slightly more efficacious. Similar adverse reactions (neutropenia, liver toxicity, alopecia, and others), reversible upon cessation of treatment, have been noted in most patients treated with both drugs. A minimum of treatment is three months. The long-term prognosis in individual patients is difficult to predict; therefore, prolonged follow-up with ultrasound or other imaging procedures is needed to determine the eventual outcome. The combination of praziquantel and albendazole has been used successfully in the treatment of hydatid disease.^{30–32} Praziquantel used at 50 mg/kg in different regimens (once daily, once weekly, or once every two weeks) in combination with albendazole produced very effective and rapid results compared with albendazole therapy alone.³¹ Further research is needed to determine the optimum dosage and length for this form of therapy. A third option for the treatment of echinococcosis cysts in the liver is PAIR which is based on percutaneous puncture using ultrasound guidance; aspiration of cyst fluid; injection of protoscolicidal substances (20% sodium chloride or 95% ethanol) for at least 15 minutes; and reaspiration of the cyst fluid content. PAIR is indicated for univesicular hepatic cysts of >5 cm in diameter, for cysts with daughter cysts, for cysts with detached membranes, and for multiple cysts if accessible to puncture.³³ PAIR is contraindicated for inaccessible or superficially located liver cysts and lung cysts. It is also contraindicated for honeycomb-like cysts; and cysts with echogenic lesions; inactive cysts or calcified lesions; and cysts communicating with the biliary tree. To avoid sclerosing cholangitis cysts should be inspected for bilirubin prior to injection of protoscolicidal substances. Presence of bile indicates direct communication between cyst contents and biliary ducts. Concomitant drug treatment should be provided in the form of benzimidazoles before the procedure and should last for one month

(albendazole) or three months (mebendazole) after the procedure. Risks include those associated with any puncture; anaphylactic shock or allergic reactions caused by leakage of cyst fluid; and secondary echinococcosis due to spillage.

Favorable results have been reported from more than 2000 PAIR interventions. A meta-analysis comparing the clinical outcomes for 769 patients with hepatic cystic echinococcosis treated with PAIR plus albendazole or mebendazole with 952 era-matched historical control subjects undergoing surgical intervention found greater clinical and parasitological efficacy, lower rates of morbidity and mortality and disease recurrence, and shorter hospital stays than surgical treatment.³⁴ A policy of conservative management has been adopted generally in the treatment of infections by the relatively benign northern form of *E. granulosus*, and surgical intervention is considered only in cases of uncertain diagnosis (i.e., possible neoplasms) or in rare cases of symptomatic disease.

Until recently, surgery has offered the only possibility for treatment of AE. The usual procedure has involved removal of the lesion with part or the entire affected hepatic lobe. Cases of advanced disease and those involving multiple lesions often are inoperable. With or without surgery, alveolar hydatid disease has a very high mortality rate. With metastases to the brain, death occurs within a few months after onset of neurologic disorders. Long-term treatment with mebendazole (50 mg/kg per day) or albendazole (10 mg/kg) inhibits growth of larval *E. multilocularis*, reduces metastasis, and enhances both the quality and length of survival; prolonged therapy may eventually be larvicidal in some patients.²⁷ Liver transplantation has been employed successfully on otherwise terminal cases.³⁵ In a Swiss study, therapy for nonresectable AE with mebendazole and albendazole resulted in an increased 10-year survival rate of approximately 80% (versus 29% in untreated historical controls) and a 16- to 20-year survival rate of approximately 70% (versus 0% in historical controls).⁸

Experience in treatment of polycystic echinococcosis is limited.¹⁴ Because the lesions are so extensive, surgical resection may be difficult and usually incomplete. A combination of surgery with albendazole is most likely to be successful.

Prevention and Control. Infection of humans by larval cestodes of the genus *Echinococcus* is contingent on ingestion of eggs distributed in the feces of dogs and perhaps other carnivores that harbor the adult worms. Control of hydatid disease in humans depends on the means to prevent or to eliminate infection of dogs. These objectives, so simple in concept, generally have been unattainable and will probably remain so in many regions because of human attitudes and other factors that defy change.

Little effort has been made to control the northern form of *E. granulosus*, in part because of the benign nature of the infection and perhaps also because the disease affects mainly scattered indigenous peoples. The significant decrease in incidence observed in recent years in Alaskan Eskimos and Indians has been attributable mainly to replacement of dogs by mechanized vehicles for winter travel. Some advantage, however, is being lost with the growing tendency of these people to adopt the European practice of keeping dogs as pets.

Few countries have shown significant accomplishment in attempts to control *E. granulosus* in life cycles involving synanthropic animal hosts. In most regions where hydatid disease is a serious medical and economic problem, the combination of uncontrolled slaughter, indiscriminate disposal of carcasses and offal, and an abundance of free-ranging dogs provides near-optimal conditions for the completion of the life cycle of this cestode. Large-scale programs of control have had noteworthy success only in Iceland, New Zealand, Australia, Tasmania, and Cyprus, which have in common the features of insularity, literate populations, satisfactory economies, and effective political organizations.³⁶ In these countries, the programs have been based on public education combined with strict regulations directed particularly toward control of dogs. Nearly complete control of *E. granulosus* in the Greek-controlled area of Cyprus was accomplished during the period between

1971 and 1975 through elimination of excess dogs, destruction of all dogs found to be infected, and regulation of slaughter. Development of the effective echinococcicidal drug, praziquantel, permitted the effective use of an anthelmintic in conjunction with other measures for the control of hydatid disease. The mass treatment of dogs and strict control of slaughter is effective under some conditions but of little value where early reinfection is probable. A promising advance has been the development of a recombinant vaccine (EG95) which seems to confer 96–98 % protection against challenge infection. Recent trials in Australia and Argentina using EG95 have reported that 86% of vaccinated sheep were completely free of viable hydatid cysts when examined one year after immunization. Vaccination reduced the number of viable cysts by 99.3%.^{37,38} Further research is needed to assess the cost-benefit of this intervention as part of control programs.

Control of *E. multilocularis* presents a difficult problem of potentially increasing importance. Measures for control of the cestode have involved anthelmintic treatment of dogs and destruction of stray animals. In Alaska, the general reduction of numbers of dogs and improvements in housing probably have had some effect on the prevalence of *E. multilocularis*. The implications of the spread of *E. multilocularis* in central North America are not now predictable. In some endemic areas in Central Europe, mass treatments of red foxes with baits containing praziquantel have demonstrated a significant reduction in the prevalence of *E. multilocularis* in the fox population.³⁹ However other studies suggest this form of treatment may be too difficult and costly.⁴⁰

Since the control of this cestode in its natural hosts does not appear to be possible, preventive measures must be directed toward domestic carnivores. In endemic areas, strict controls on the movement of pet dogs and cats as pets is necessary to prevent ingestion of infected rodents. Regular anthelmintic treatment of such animals might be practicable under some conditions.⁴¹

Opportunistic Fungal Infections

Michael A. Pfaller

Fungal infections, or mycoses, may be broken into two broad categories: (a) endemic and (b) opportunistic. The endemic mycoses are those in which susceptibility to the infection is acquired by living in a geographic area constituting the natural habitat of the particular fungus. The most commonly encountered endemic mycoses in North America are due to *Histoplasma capsulatum*, *Coccidioides immitis/posadasii*, *Blastomyces dermatitidis*, and *Sporothrix schenckii*. Infection due to these agents is usually acquired by inhalation of conidia from an environmental source. Although infections with these fungal pathogens are clearly important, a more pressing problem now is that of the opportunistic mycoses, which carry a particularly high mortality and appear to be increasing significantly.

The opportunistic mycoses occur primarily in immunocompromised patients, particularly those with malignancies and acquired immunodeficiency syndrome (AIDS) and after major surgery, severe burn injury, blood and marrow (BMT) and solid organ (SOT) transplantation. Contributing factors include exposure to broad-spectrum antibacterial agents, adrenal corticosteroids, and cytotoxic chemotherapeutic agents and prolonged use of indwelling catheters. The most important agents of the opportunistic mycoses are *Candida* spp., *Cryptococcus neoformans*, *Aspergillus* spp., and the Zygomycetes.

The prevention, diagnosis, and therapy of opportunistic mycoses remain extremely difficult. Increased recognition of the importance of these infections has spurred efforts to develop new diagnostic and therapeutic approaches, as well as to expand our knowledge of the epidemiology and pathogenesis of the mycoses.

► CANDIDIASIS

Clinical and Epidemiologic Features

Candida species are commonly found as part of the endogenous microbial flora of the oropharynx, gastrointestinal tract, and vagina of a variable proportion of normal persons. Although *Candida albicans* remains the most common cause of local and disseminated infection, there has been an increase in infections caused by *Candida tropicalis*, *Candida parapsilosis*, *Candida krusei*, *Candida glabrata*, and *Candida lusitanae* among others.¹⁻⁸

The clinical manifestations of candidiasis include local mucocutaneous infection and hematogenously disseminated candidiasis. Local mucocutaneous candidiasis is most commonly caused by *C. albicans* and may involve the oropharynx (thrush) and the entire gastrointestinal tract, including the esophagus, stomach, and large and small bowel. Genitourinary tract involvement includes cystitis and vulvovaginal candidiasis. Superficial infections of the skin are less common but may involve the axillae, groin, inframammary folds, perianal region, and other warm moist areas, particularly following antimicrobial therapy. Although vulvovaginitis commonly occurs in otherwise normal, healthy women, mucocutaneous candidiasis most commonly

occurs in immunocompromised patients: neonates, the elderly, patients with AIDS, and patients hospitalized with various malignancies and following organ transplantation and major surgery. Prolonged exposure to multiple broad-spectrum antibiotics may promote mucosal overgrowth of *Candida* spp. and thus predispose these patients to superficial candidiasis.^{1,9}

Chronic mucocutaneous candidiasis is a rare syndrome associated with defects in T cell-mediated immunity. These patients have persistent superficial *Candida* infection of skin, scalp, nails, and mucous membranes.⁹ Disease onset may begin at any age and may be associated with various endocrinopathies (diabetes mellitus, hypoparathyroidism, hypothyroidism, or hypoadrenalism), and the clinical manifestations may be limited or quite extensive.

Hematogenously disseminated candidiasis is a serious infection of hospitalized and immunocompromised patients that has increased markedly over the past 10–15 years.¹⁻⁸ Candidemia and disseminated candidiasis occur most commonly in hospitalized patients with neutropenia, malignancies, and following major surgical procedures.¹⁻⁸ Disseminated candidiasis is also a frequent, serious problem in infants hospitalized in neonatal intensive care units. Hematogenously disseminated candidiasis is generally thought to originate from an endogenous, usually gastrointestinal, source and is most commonly caused by *C. albicans* followed by *C. glabrata*, *C. tropicalis*, *C. parapsilosis*, and *C. krusei*.¹ Infection of peripheral and central venous catheters may result from endogenous or exogenous contamination of the catheter surface. The infected catheter may serve as a nidus for subsequent hematogenous dissemination. The clinical manifestations of hematogenously disseminated candidiasis are nonspecific, and infection may present with candidemia or focal involvement of specific “target organs” such as skin, liver, lung, bone, eye, or central nervous system.^{3,7,8}

Crude mortality rates reported for patients with candidemia and disseminated candidiasis have been as high as 90%;^{1,7} however, because these infections occur in patients with serious underlying disease, the actual contribution of the infection to the death of the patients has been difficult to estimate. Case-control studies have estimated the mortality directly attributable to nosocomial candidemia to range from 10–49%.^{8,10,11} These estimates of attributable mortality are comparable to data reported for primary aerobic gram-negative bacteria and are generally higher than the 13.6% reported for nosocomial bloodstream infections due to another opportunistic pathogen, *Staphylococcus epidermidis*.⁷

The identification of risk factors for disseminated candidiasis has been difficult because of the complex nature of the patients at risk for these infections. Significant independent risk factors for disseminated candidiasis identified by multivariate analysis include prior colonization by *Candida* spp., central catheterization (including Hickman catheters), neutropenia, hemodialysis, and chemotherapy for hematologic malignancies.^{12,13} These factors may be important in

the development of serious candidal infection independent of the underlying disease state or other confounding factors and should serve as the focus for future studies concerning methods of prevention, diagnosis, and therapy.

Microbiology

Candida organisms are small (4–6 µm), oval, thin-walled cells that reproduce by budding and may also form pseudohyphae and hyphae in tissue. Although over 80 species of *Candida* have been identified, only a few have been isolated from humans, including *C. albicans*, *C. tropicalis*, *C. glabrata*, *C. parapsilosis*, *C. krusei*, *Candida guilliermondii*, *Candida rugosa*, and *C. lusitanae*. *Candida* species grow well on most laboratory media and appear as white, creamy colonies and may be smooth, wrinkled, or fuzzy in appearance. Blastospores (yeasts), hyphae, or pseudohyphae may be seen directly in Gram-stained (gram-positive) or Calcofluor-KOH (potassium hydroxide)-treated preparations of clinical material. Special stains, such as the Gomori methenamine silver stain, may be used to visualize the organisms in tissue sections. Identification of *Candida* isolates to species level is accomplished by employing a series of biochemical and physiological tests. A number of prepackaged identification kits are commercially available that allow species identification within 48–72 hours. The germ tube test is a simple and rapid means of presumptively identifying isolates of *C. albicans*. This test takes advantage of the fact that most *C. albicans*, but not other species of *Candida*, will form germ tubes (hyphal evaginations) within 2 hours in the presence of serum.

Diagnosis

One of the major problems in the prevention and therapy of candidiasis in hospitalized patients is the difficulty in diagnosing infection versus colonization in these frequently complex patients.^{9,14} The clinical signs and symptoms associated with both local and disseminated candidiasis are nonspecific and are generally not helpful in distinguishing bacterial from candidal infection. The most common clinical presentation of superficial candidiasis is that of white or gray pseudomembranous plaques overlying the mucosal surface. Removal of the plaques reveals a red, painful base with ulcerations and necrosis. Oropharyngeal and esophageal involvement may be quite painful with considerable dysphagia and pain on swallowing. Vaginal and cutaneous involvement may be both painful and pruritic. Two major clues to diagnosis of hematogenously disseminated candidiasis are the presence of endophthalmitis and macronodular skin lesions. *Candida* endophthalmitis is marked by single or multiple raised, white fluffy chorioretinal lesions, with or without an overlying vitreous haze. The lesions are usually in the macular area and are easily detected by ophthalmoscopic examination. Unfortunately they are rarely observed in neutropenic patients. In addition to endophthalmitis and macronodular skin lesions, several additional clinical presentations of disseminated candidiasis have been described in recent years, including suppurative thrombophlebitis, hepatitis, purpura fulminans, and bullous dermatitis, epiglottitis, and osteomyelitis.^{1–3,8}

The laboratory diagnosis of candidiasis has been limited because available methods are insensitive and nonspecific.¹⁴ Superficial infection may be diagnosed by direct microscopic examination of Calcofluor-KOH-treated or Gram-stained material obtained from infected lesions. The most reliable means of documenting disseminated candidiasis is by histopathologic demonstration of tissue invasion on biopsy or recovery of *Candida* spp. from normally sterile body fluids such as pleural fluid, peritoneal fluid, or cerebrospinal fluid. Isolation of *Candida* spp. from urine or sputum may be helpful but frequently only represents colonization or contamination of the specimen. Isolation of *Candida* spp. from blood is also helpful and should always be considered to be important clinically. Conventional broth blood cultures are positive for *Candida* spp. in approximately 60% of patients with documented disseminated candidiasis although they may be negative despite visceral involvement.¹⁴ Therefore, they are not always helpful in making

diagnostic and therapeutic decisions. The usefulness of blood cultures in diagnosing disseminated candidiasis has been improved with the newer instrument-based continuous monitoring blood culture systems.¹⁴ Serologic methods have been disappointing. Measurement of antibody titers has been unsuccessful in delineating colonization and local infection from disseminated candidiasis. Detection of (1,3)-β-glucan in serum is promising as a noninvasive and rapid means of diagnosing invasive candidiasis as well as other opportunistic fungal infections.¹⁵

Therapy

Deeply invasive infection such as severe esophagitis and disseminated candidiasis requires systemic therapy with one of several agents including amphotericin B, fluconazole, voriconazole, and caspofungin.¹⁶ Prompt removal of potentially contaminated devices such as intravenous catheters is important. The addition of 5-fluorocytosine may provide synergistic candidicidal activity; however, improved clinical efficacy has not been proved in properly designed clinical trials. Currently amphotericin B, fluconazole, and caspofungin are all considered acceptable alternatives for the primary treatment of invasive candidiasis.¹⁶ Voriconazole has recently been approved for the treatment of candidemia in non-neutropenic patients.¹⁶ Topical antifungal agents such as nystatin, clotrimazole, or miconazole may be useful in the treatment of superficial mucocutaneous infections. Oral therapy with fluconazole has proved extremely useful in the treatment of oral candidiasis in AIDS patients and other immunocompromised individuals. Prophylaxis with fluconazole has been shown to be efficacious in preventing invasive candidiasis in BMT patients and in liver transplant recipients.¹⁶ Its role as prophylaxis in other patient populations is not well defined.¹⁶

► CRYPTOCOCCOSIS

Clinical and Epidemiologic Features

Cryptococcosis is a systemic mycosis caused by the encapsulated, basidiomycetous, yeast-like fungus, *C. neoformans*. The fungus is worldwide in distribution and is found as a ubiquitous saprophyte of soil, especially that enriched with pigeon droppings.¹⁷ At least four serotypes of *C. neoformans* have been identified: A, B, C, and D. Serotype A has recently been classified as *C. neoformans* variety *grubii* and serotype D is classified as *C. neoformans* var. *neoformans*.¹⁸ Serotypes B and C are classified as *C. neoformans* var. *gattii*.

C. neoformans serotypes A and D are common worldwide and may be recovered in large numbers from environmental sources contaminated with the droppings of pigeons and other birds. Serotypes B and C (var. *gattii*) are found in tropical and subtropical regions in association with *Eucalyptus* trees; however, recently an endemic focus of var. *gattii* has been identified in Vancouver Island, British Columbia.^{19–21}

Cryptococcosis is usually acquired by inhaling aerosolized cells of *C. neoformans* from the environment. Subsequent dissemination from the lungs, usually to the central nervous system (CNS), produces clinical disease in susceptible individuals. Primary cutaneous cryptococcosis may occur rarely following transcutaneous inoculation.

Cryptococcosis, particularly meningitis, commonly occurs in patients with underlying immunodeficiency;¹ however, both local and disseminated infections are observed in patients with no known immunologic defect.^{22–24} Immunosuppressed patients at particular risk for cryptococcal infection include those with lymphoreticular malignancies or sarcoid and those receiving corticosteroid therapy, organ transplants, or immunosuppressive therapy. The most common immunologic defect in patients with cryptococcal infection is a defect in cell-mediated immunity. The importance of cell-mediated immunity as a host defense mechanism is underscored by the fact that cryptococcosis is a major opportunistic pathogen of patients with AIDS.¹⁶ Those individuals with CD4 + lymphocyte counts of less than 100 per cubic mm are at high risk for CNS and disseminated cryptococcosis. The incidence of cryptococcosis seems to have peaked in the United

States in the early 1990s (65.5 infections per million per year) and has progressively declined since due to the widespread use of fluconazole and the successful treatment of the HIV infection with new antiretroviral drugs.²⁵

Cryptococcosis may present as a pneumonic process or, more often, as a CNS infection secondary to hematogenous and lymphatic spread from a primary pulmonary focus. A more widely disseminated form of the infection may also occur with cutaneous, mucocutaneous, osseous, and visceral involvement.

Pulmonary cryptococcosis is variable in presentation ranging from an asymptomatic process to a more fulminant bilateral pneumonia. Nodular infiltrates, usually without cavitation, may be either unilateral or bilateral becoming more diffuse in severe infections.

C. neoformans is highly neurotropic and the most common form of the disease is cerebromeningeal. The course of the disease is variable and may be quite chronic; however, it is inevitably fatal if untreated. Both meninges and the underlying brain tissue are involved and the presentation clinically is that of fever, headache, meningismus, visual disturbances, altered mental status, and seizures. The clinical picture is highly dependent upon the patient's immune status and tends to be very severe in AIDS patients and other severely compromised patients treated with steroids or other immunosuppressive agents.²³

Although both *C. neoformans* var. *neoformans* (and var. *grubii*) and var. *gattii* can cause meningoencephalitis, var. *neoformans* (and var. *grubii*) causes infection primarily in immunocompromised patients (e.g. AIDS), whereas var. *gattii* infections tend to occur in normal healthy hosts.^{19–22} Worse prognosis is usually associated with var. *gattii*.^{22,26} When compared with var. *neoformans*, infections caused by var. *gattii* are associated with cerebral or pulmonary cryptococcomas, papilledema, and high serum/CSF antigen titers.

Microbiology

C. neoformans is a ubiquitous encapsulated soil yeast that reproduces asexually by budding. The perfect or sexual stage of *C. neoformans* can be produced by mating the fungus *in vitro*; however, the role of this stage in infectivity and pathogenesis is unknown. The yeast cell may vary from 4–20 µm in diameter and is surrounded by a polysaccharide capsule ranging from 1–30 µm. The narrow-based buds are usually single. The capsule may be visualized indirectly by the India ink or nigrosin technique and more specifically in clinical material with mucicarmine, which stains capsular mucopolysaccharide. In tissue, cryptococci stain poorly with hematoxylin and eosin but well with methenamine silver and periodic acid-Schiff.

C. neoformans grows well on most bacterial and fungal media used in the routine clinical microbiology laboratory. A rapid presumptive identification of an encapsulated yeast as *C. neoformans* may be accomplished by demonstration of urease and phenoloxidase enzyme activity.¹⁷ *C. neoformans* is strongly urease positive and possesses a membrane-bound phenoloxidase enzyme that converts phenolic compounds to melanin. Phenoloxidase activity is readily demonstrated on media such as birdseed agar or caffeic acid agar, which contains 3,4-dihydroxycinnamic acid. Oxidation of the *O*-diphenol in medium produces dark colonies suggestive of *C. neoformans*. Confirmatory identification is accomplished by employing standard biochemical and physiological tests. Standard laboratory tests do not differentiate among the different serotypes. Media have been proposed for separating serotypes A and D from B and C but are not available commercially.

Diagnosis

The clinical presentation of pulmonary cryptococcosis may mimic a number of acute and chronic infectious processes as well as malignancies. Signs and symptoms include fever, malaise, pleuritic pain, cough, scanty sputum, and hemoptysis. Chest roentgenograms may reveal lobar infiltrates, single or multiple nodules, or tumor-like masses. Sputum cultures are positive in only 20% of cases, and the diagnosis is frequently made at thoracotomy for suspected malignancy. Patients with pulmonary cryptococcosis should be thoroughly

evaluated for systemic infection, with cultures of blood, urine, and cerebrospinal fluid (CSF).

Central nervous system cryptococcosis may present as either meningitis (most common), encephalitis, or a more focal process suggestive of malignancy. Signs and symptoms in patients without AIDS include fever, headache, mental status changes, ocular symptoms, meningismus, nausea, vomiting, cranial nerve palsies, and seizures. Aside from fever and headache these signs and symptoms may be significantly less common in patients with AIDS. The chest roentgenogram may or may not be abnormal in patients with central nervous system or systemic cryptococcosis. Extranural dissemination may present as cryptococemia or focal involvement of one of several target organs.

The laboratory diagnosis of cryptococcosis requires the isolation of cryptococci from normally sterile body fluids, histopathology showing encapsulated organisms, or detection of cryptococcal antigen in serum or CSF. A rapid diagnosis of extraneural infection may be facilitated by biopsy and staining with methenamine silver and mucicarmine. Examination of the CSF in patients with meningitis usually suggests a chronic lymphocytic meningitis with a low-grade (less than 500/mm³) lymphocytic pleocytosis, elevated protein, and low glucose. Microscopic examination of CSF mixed with India ink or nigrosin may reveal encapsulated organisms in approximately 50% of cases. Cultures of CSF and other clinical material are usually positive. Occasionally repeated lumbar punctures, cisternal taps, or sampling of large volumes (up to 10 mL) of CSF may be necessary to establish the diagnosis. In patients with AIDS, cryptococci are present in large numbers, but the CSF shows fewer abnormalities.

Detection of cryptococcal antigen in serum and CSF is extremely valuable in the diagnosis of cryptococcal infection. Antigen titers are particularly high in patients with AIDS. Both latex agglutination (LA) and enzyme immunoassays (EIA) are commercially available and are rapid, sensitive, and specific.²⁷ Antigen is detected in the serum in approximately 50% and in CSF in more than 90% of patients with cryptococcal meningitis. High titers of cryptococcal antigen in CSF or serum are associated with a poor prognosis. False-positive results are rare but may be due to rheumatoid factor or cross-reactivity in patients infected with *Trichosporon beigeli*. The newer EIA methods lack reaction with rheumatoid factor and are more specific than the LA methods.²⁷

Therapy

Pulmonary cryptococcosis may not require therapy as long as the process appears to be resolving and the patient is intact immunologically. Long-term follow-up is necessary in patients whose infection is diagnosed at thoracotomy, because there is a 3–10 risk of meningitis for up to three years after surgery. Patients with progressive pulmonary infection, particularly those who are immunocompromised, and all patients with extrapulmonary infection require systemic antifungal therapy. At present, such therapy consists of intravenous amphotericin B. Fluconazole may also be used although the efficacy of this agent in the treatment of pulmonary cryptococcosis has not been documented in clinical trials.

Cryptococcal meningitis and extrapulmonary cryptococcosis always require systemic antifungal therapy.²⁸ Cryptococcal meningitis is almost universally fatal without therapy, but approximately 80–90% of patients (non-AIDS) can be cured with current therapeutic regimens. Current therapeutic recommendations are amphotericin B plus 5-fluorocytosine acutely for two weeks (induction therapy), followed by 8-week consolidation with oral fluconazole.²⁸ AIDS patients generally require life-long therapy with fluconazole. In patients without AIDS, treatment may be discontinued after the consolidation therapy; however, relapse may be seen in up to 26% of these patients within 3–6 months after discontinuation of therapy.^{23,28} Thus, a prolonged consolidation treatment with an azole for up to one year may be advisable even with patients without AIDS.

Infections caused by *C. neoformans* var. *gattii* demonstrate slower response to antifungal therapy than those caused by var. *neoformans*. Neurological and visual sequelae are often present despite prolonged amphotericin B therapy and placement of intraventricular shunts.²⁶

► ASPERGILLOSIS

Clinical and Epidemiologic Features

The term aspergillosis refers to any one of a number of disease states caused by members of the genus *Aspergillus*. *Aspergillus* species are ubiquitous fungi that may be isolated from a variety of environmental sources, including insulation and fireproofing materials, soil, grain, leaves, grass, and air.²⁹ The aerosolized conidia are present in large numbers and are constantly being inhaled. Although several hundred species of *Aspergillus* have been described, relatively few are known to cause disease in humans. *Aspergillus fumigatus* remains the most common cause of aspergillosis, followed by *Aspergillus flavus*, *Aspergillus niger*, *Aspergillus terreus*, and *Aspergillus versicolor*.^{30,31}

Aspergillus infections occur worldwide and appear to be increasing in prevalence, particularly among patients with chronic pulmonary disease and among the immunocompromised populations.^{29–31} *Aspergillus* species are particularly important causes of nosocomial infections in patients who are immunocompromised secondary to burn injury, malignancy, leukemia, and bone marrow and other organ transplantation. Several major outbreaks of invasive nosocomial aspergillosis have been described in association with exposure to *Aspergillus* conidia aerosolized by hospital construction, contaminated air handling systems, and insulation or fireproofing materials within walls or ceilings of hospital bed units.^{29,30} The crude mortality associated with these infections is high, approximately 90% in most series.^{29,31}

The clinical manifestations of aspergillosis include pulmonary colonization with bronchitis and aspergilloma formation, allergic syndromes such as allergic bronchopulmonary aspergillosis (ABPA), and invasive aspergillosis.²⁹ Intoxication or neoplasm secondary to ingestion of aflatoxin or other toxins produced by *Aspergillus* spp. contaminating grain and other foods is also a serious problem worldwide.

Pulmonary colonization by *Aspergillus* spp. may involve the bronchial mucosa or may become localized in a preexisting cavity, resulting in the formation of an aspergilloma. Superficial colonization of the tracheobronchial mucosa produces little inflammation and is not associated with tissue invasion. The expectoration of bronchial casts containing mucus and hyphal elements may be observed. Patients in whom mucosal colonization is observed are those with preexisting pulmonary disease, including cystic fibrosis, chronic obstructive pulmonary disease, and chronic asthma requiring administration of corticosteroids.

Aspergillomas are masses of mycelia and amorphous debris localized in preexisting pulmonary cavities, usually in the upper lobes. The cavities are usually lined with modified bronchial epithelium and have been formed secondary to other disease processes such as tuberculosis, infarcts, or neoplasms. There is little surrounding inflammation, and invasion of the pulmonary parenchyma by *Aspergillus* spp. is rare. Aspergillomas may be clinically silent; however, hemoptysis secondary to ulceration of the epithelial lining of the cavity is observed in 50–80% of cases.²⁹ The lesions may be stable, grow, or shrink with the surrounding cavity. Spontaneous lysis occurs in approximately 10% of cases within 3 years.

The allergic manifestations of aspergillosis are the result of tissue hypersensitivity to conidia or other antigens of *Aspergillus* spp. (almost always *A. fumigatus*). The clinical picture may vary from mild asthma to fibrosis and bronchiectasis secondary to allergic bronchopulmonary aspergillosis. Exposure to aerosolized *Aspergillus* conidia may produce bronchospasm in individuals with atopic asthma. Repeated and heavy inhalation of *Aspergillus* conidia and other antigens may result in extrinsic allergic alveolitis in nonatopic patients. Prolonged exposure may lead to micronodular changes and fibrosis. ABPA is the result of type I (IgE-mediated), type III (immune complex-mediated), and possibly type IV (cell-mediated) hypersensitivity reactions to *Aspergillus* antigens. This condition occurs in up to 20% of individuals with asthma and is associated with colonization of the bronchial mucosa by *Aspergillus* spp. These patients experience recurrent bouts of severe asthma, wheezing, fever, weight loss, chest pain, and cough productive of blood-tinged sputum. Eventually the disease becomes chronic, with the

development of fibrosis, bronchiectasis, and mucus plugging with subsequent atelectasis or cavitation. This condition may be associated with nasal polyps and chronic sinusitis.

Invasive aspergillosis occurs most commonly in patients who are severely immunocompromised secondary to hematologic and lymphoreticular malignancies. Major risk factors include neutropenia, broad-spectrum antibacterial therapy, and administration of corticosteroids.^{29–32} Patients undergoing bone marrow transplantation are at particularly high risk, both during neutropenia and following engraftment during episodes of graft versus host disease (GVHD). The disease process is most commonly localized to the lungs, followed by the paranasal sinuses. The infectious process is typified by mucosal ulceration and direct extension of hyphae into surrounding tissues. Vascular invasion results in thrombosis, embolization, and infarction. Hematogenous dissemination occurs in 35–40% of cases of invasive pulmonary aspergillosis and may involve brain, liver, kidneys, gastrointestinal tract, thyroid, heart, skin, and other sites.^{29–32} Extension of paranasal infection into the orbit and brain may mimic rhinocerebral zygomycosis. Although the pulmonary process may occasionally be inapparent, it most commonly presents as a necrotizing, patchy bronchopneumonia with or without hemorrhagic infarction. In all infected foci, the infection is characterized by vascular invasion, tissue infarction, and necrosis. Massive hemoptysis, gastrointestinal bleeding, and cerebral infarcts and abscesses may occur.

Chronic necrotizing aspergillosis, a more indolent pulmonary infectious process, occurs predominantly in middle-aged patients with mildly compromised host defenses or preexisting pulmonary parenchymal damage. The locally invasive infection is slowly progressive and results in cavitation and aspergilloma formation. The infectious process is usually confined to the upper lobes but occasionally may involve an entire lung.

Microbiology

Aspergillus species are molds that reproduce by means of spores or conidia. The conidia germinate to form hyphae, which are the forms most commonly found in infected tissue. *Aspergillus* species grow well on most media and are identified to species level based on the microscopic identification of specific morphologic features. Over 600 different species of *Aspergillus* have been described; however, most clinical infections are due to *A. fumigatus*, *A. flavus* and *A. terreus*.^{30–35} *A. niger* is the most common cause of otomycosis. At present, there are no commercially available kits to aid in the identification of *Aspergillus* spp. In tissue, *Aspergillus* hyphae stain well with Gomori methenamine silver stain and are uniform, 2–7 µm in diameter, septate, and dichotomously branched with angles of approximately 45°. These features are not diagnostic and are shared by several other opportunistic fungal pathogens.

Diagnosis

The clinical signs and symptoms of pulmonary aspergillosis are nonspecific and range from mild asthma to severe hemoptysis, acute bronchopneumonia, and pulmonary infarction. Extrapulmonary involvement may present as cellulitis, hemorrhage, or infarction depending on the specific site of infection. Chest radiographs may be useful in the diagnosis of aspergilloma with the appearance of a freely movable intracavitary mass surrounded by a crescent of air (Monod's sign). The radiographic appearance of allergic bronchopulmonary aspergillosis varies with the stage and chronicity of the disease but may appear as bronchiectasis with bronchial thickening or dilation, consolidation, and atelectasis. The most common radiographic picture of invasive pulmonary aspergillosis is that of a patchy density or well-defined nodule, which may be single or multifocal with progression to diffuse consolidation or cavitation. However, invasive pulmonary aspergillosis is often inapparent on routine chest radiographs. Thus, high resolution CT (HRCT) scans play an important role in the early diagnosis of the disease.³⁶ Early lesions in the lungs of neutropenic patients appear as small nodules with a surrounding area of low attenuation, the so-called halo sign. These nodules eventually

become larger with the disappearance of the halo sign, and eventually cavitate (the air crescent sign).^{30,36}

The laboratory diagnosis of aspergillosis is generally unsatisfactory. Definitive diagnosis of invasive aspergillosis usually requires biopsy of the involved tissue. Unfortunately the severe underlying diseases and associated bleeding diatheses commonly seen in these patients often preclude such an invasive approach.

Isolation of *Aspergillus* spp. in cultures from the respiratory tract is problematic as this organism is common in the environment and may colonize the airways of individuals. Several investigators have shown that the interpretation of respiratory tract cultures yielding *Aspergillus* is aided by considering the risk group of the patient.^{37–39} Thus, it is clear that for high-risk patients, such as allogeneic BMT recipients, individuals with hematologic malignancies, those with neutropenia, and in liver transplant recipients, a positive culture alone that yields *Aspergillus* spp. is associated with invasive disease. Identification of fungi isolated from culture to the species level is also helpful: *A. niger* is rarely a pathogen, whereas *A. flavus* and *A. terreus* have been shown to be statistically associated with invasive aspergillosis when isolated from respiratory tract cultures.³⁸

The rapid diagnosis of invasive aspergillosis has been advanced by the development of immunoassays for detection of *Aspergillus* glactomannan (GM) in serum.^{36,40} This test employs an EIA format and is available as a commercial kit, or from reference laboratories. The GM test appears to be reasonably specific but exhibits variable sensitivity. It is best used on serial specimens from high-risk (primarily neutropenic and BMT) patients, often in tandem with HRCT scans, as an early indication to begin empiric or preemptive antifungal therapy and to more aggressively pursue a definitive diagnosis.³⁶ Skin tests and demonstration of serum precipitins have been useful in diagnosing ABPA; however, they are of no use in diagnosing invasive infection. Additional laboratory features of ABPA include elevated serum IgE and peripheral blood eosinophilia.

Therapy

Treatment of aspergillosis is difficult and is probably not indicated for aspergilloma unless life-threatening hemoptysis occurs, in which case segmental resection or lobectomy is indicated. Systemic antifungal therapy has been of no value. Likewise, neither systemic nor aerosolized antifungal therapy has been effective in treatment of the allergic syndromes such as ABPA. Corticosteroids are considered the treatment of choice.

Given the high mortality associated with invasive aspergillosis, an aggressive approach to diagnosis and treatment is required.^{30,31} In addition, return of bone marrow function or reversal of neutropenia is essential for survival. Specific antifungal therapy of aspergillosis usually involves the administration of amphotericin B or one of its lipid-based formulations.³⁰ It is important to realize that *A. terreus* is considered resistant to amphotericin B and should be treated with an alternative agent such as voriconazole.³³ The recent introduction of voriconazole provides a treatment option that is more efficacious and less toxic than amphotericin B.⁴¹ Concomitant efforts to decrease immunosuppression and/or reconstitute host immune defenses are important. Likewise, surgical resection of the involved areas, if possible, is recommended.

Prevention of aspergillosis in high-risk patients is paramount.³⁰ Neutropenic and other high-risk patients are generally housed in facilities where air is filtered so as to minimize exposure to *Aspergillus* conidia. Prophylaxis with an echinocandin or an azole may also be beneficial.

► ZYGOMYCOSIS

Clinical and Epidemiologic Features

Zygomycosis is a general term that includes infections caused by fungi in the order Mucorales and order Entomophthorales (class Zygomycetes). The Zygomycetes are ubiquitous worldwide in soil and decaying vegetation. Zygomycosis is not communicable and is

acquired by inhalation, ingestion, or contamination of wounds with spores from the environment. Although *Rhizopus oryzae* (*arrhizus*) is the most common agent of human zygomycosis, additional species of *Rhizopus*, *Mucor*, *Absidia*, *Rhizomucor*, *Cunninghamella*, *Saksenaia*, and others have been causing infection with increasing frequency.^{42–44}

Clinically zygomycosis is a fulminant infectious process that produces rhinocerebral disease in patients with diabetic ketoacidosis; rhinocerebral, pulmonary, or disseminated disease in immunocompromised patients; local or disseminated disease in patients with burns or open wounds; and gastrointestinal disease in patients with malnutrition or preexisting gastrointestinal disorders.^{42–47} In each case, the progression of disease may be rapid, with invasion and destruction of key anatomic structures in a matter of days. This is particularly true with rhinocerebral infection, wherein death may occur within 3–10 days in untreated patients.^{42,45–47} Although classically the major risk factor for zygomycosis is diabetic acidosis, it is now clear that neutropenia, hematologic malignancy, and cytotoxic or immunosuppressive therapy place patients at risk for these infections.^{42–47}

The hallmark of zygomycosis is vascular invasion with thrombosis, hemorrhage, infarction, and tissue necrosis. The disease usually extends locally across tissue planes; however, hematogenous dissemination may also occur. Mortality is directly related to rapidity of diagnosis (extent of disease), aggressiveness of therapy, and underlying disease state. Estimates of crude mortality in patients with rhinocerebral zygomycosis are 40% in patients with diabetes and at least 80% in patients with other underlying diseases (malignancy, organ transplantation, neutropenia).^{42,46} The prognosis is poor in cases of disseminated zygomycosis: only about 4% of patients have been reported to have survived the infectious process.⁴⁶

Focal outbreaks of zygomycosis have been related to the use of certain adhesive bandages or tape on open wounds. The resulting cutaneous infections were due to *Rhizopus* species, which were also isolated from the bandage material.^{42,46,47} Recently, zygomycosis has been seen following blood and marrow transplantation in patients receiving antifungal treatment or prophylaxis with either voriconazole or caspofungin, two agents that are not active against the Zygomycetes.^{45,48–51}

Microbiology

The agents of zygomycosis are molds that reproduce asexually by means of spores. All of the Zygomycetes appear identical in tissue and are seen microscopically following staining with hematoxylin and eosin or Gomori methenamine silver as broad (6–50 μm), irregular, branching, usually aseptate (pausiseptate) hyphae. Definitive identification requires isolation on agar medium and subsequent microscopic examination. Following primary isolation the Zygomycetes grow well on most media; however, primary isolation from clinical material is frequently difficult. Isolates are identified to genus and species level based on the microscopic identification of specific morphologic features.

Diagnosis

The clinical signs and symptoms of zygomycosis are dependent on the site of infection. Rhinocerebral disease may present with nasal stuffiness, blood-tinged nasal discharge, facial swelling, and facial or orbital pain. Major diagnostic clues are the presence of a black eschar on the nasal or palatine mucosa and drainage of “black pus” from the eye.^{42,46–48} Radiographic examination of the sinuses may reveal clouding, thickening of the mucous membranes, and bone destruction. Progression of disease is manifested by orbital cellulitis, proptosis, and cranial nerve defects. Cerebral infarction caused by vascular compromise is common. Examination of the CSF may reveal elevated protein, normal glucose, and a modest pleocytosis. Culture and microscopic examination of CSF is uniformly negative. Pulmonary zygomycosis may resemble invasive pulmonary aspergillosis presenting as an acute bronchopneumonia or pulmonary infarction. Radiographic findings are nonspecific and include a patchy, nonhomogeneous infiltrate

progressing to consolidation and cavitation. Life-threatening hemoptysis may occur. Gastrointestinal infection may present with abdominal pain, diarrhea, and bleeding. Vascular invasion results in infarction and perforation of the bowel with subsequent hemorrhage and peritonitis. Cutaneous infection may present as chronic ulceration, papules, or black, necrotic areas of infarction.

The fulminant and life-threatening nature of these infections precludes the use of culture in the diagnosis of zygomycosis.⁴² Cultures are positive in only 20% of cases and are rarely positive antemortem. Serologic tests are not reliable, and microscopic examination of sputum or wound drainage is rarely positive for fungal elements. The key to diagnosis is the demonstration of the characteristic hyphae in tissue obtained on biopsy.⁴² A negative histopathologic examination does not rule out infection, and additional material should be obtained if clinically indicated.

Therapy

Successful therapy of zygomycosis requires early diagnosis, systemic antifungal therapy with amphotericin B, aggressive surgical débridement of the involved area, and control of the underlying disorder.^{42,46,47} Most of the Zygomycetes appear quite susceptible to amphotericin B and are generally not susceptible to azoles or echinocandins.⁴⁶ Among the extended-spectrum triazoles; however, posaconazole has documented utility in the treatment of infections in humans.⁴⁶ In contrast, voriconazole is inactive against these agents and breakthrough zygomycosis has been reported in BMT patients receiving voriconazole prophylaxis.^{45,48,49} Similarly, breakthrough zygomycosis is now appearing among patients receiving agents of the echinocandin class as they are becoming more widely used in immunocompromised patients.^{50,51}

Other Infection-Related Diseases of Public Health Import

Dermatophytes

Marta J. VanBeek

► DERMATOPHYTOSES

Superficial fungal infections are among the most common diseases of the skin, affecting millions worldwide. The high global prevalence and ease of communicability render such infections a public health concern.

Dermatophytosis is a general term used to describe superficial fungal infections of the skin, hair, and nails. The infectious agents, referred to as dermatophytes, are a group of closely related fungi equipped with the capacity to invade keratinized tissue of both humans and animals. Since fungi are generally incapable of penetrating deeper tissues, infections are typically restricted to the nonliving cornified layers of the hair, skin, and nails. The clinical presentation and severity of dermatophytosis varies widely according to the anatomic site of the infection, the specific dermatophyte, and the immunological defense of the host.

The clinical term “tinea” refers exclusively to dermatophyte infections. Tinea infections are classified according to their anatomic location (Table 18-1). While a single dermatophyte species can cause a variety of clinical manifestations in different parts of the body, the same clinical picture may be due to dermatophytes of different species or genera.

Clinically relevant dermatophytes are classified into three genera, *Epidermophyton*, *Microsporum*, and *Trichophyton*.¹ Depending on their habitat, dermatophytes are also classified as anthropophilic (human), zoophilic (animal), or geophilic (soil). Anthropophilic organisms are responsible for most human cutaneous fungal infections and rarely infect other animals. Zoophilic dermatophytes are associated with animal fungal infections but occasionally infect humans. Geophilic dermatophytes are primarily associated with keratinous materials such as hair, feathers, hooves, and horns after these materials have been dissociated from living animals and are in the process of decomposition. These species may cause human and animal infection.¹ Dermatophytes are spread by direct contact from other people (anthropophilic fungi), animals (zoophilic fungi), soil (geophilic fungi), or indirectly from fomites. Fomites such as combs, towels, blankets, and pillows can disseminate fungus from a primary source to secondary contacts. However, person-to-person contact is the most common source of infection in the United States.²

The incidence of dermatophytosis varies by geographic distribution, climate, season, race, and cultural habitats. Dermatophyte infections are more common in warm, humid climates, and in dense populations. Up to 20% of the U.S. population harbors a dermatophytosis at any

time, with tinea pedis being the most common infection.² Overall, peak prevalence of dermatophytosis occurs after puberty.² In developed countries, it is estimated that 5% of patients with dermatological conditions have a dermatophytosis, and more than 90% of the male populations have experienced a transient fungal infection by the age of 40.³⁻⁵

The etiologic species, geographic distributions, and population characteristics of specific tinea infections have changed dramatically over the past 50 years. The following sections will review the epidemiology, clinical morphology, common etiologic species, diagnosis, and treatment for the most common types of tinea infection.

Tinea Capitis

Epidemiology

Almost a million children this year may be infected with the highly contagious disease called tinea capitis, also known as ringworm of the scalp. Tinea capitis accounts for over 90% of fungal infections in children under age 10 in the United States.⁶ Globally, *Microsporum canis* has been the most common species causing tinea capitis. It remains the predominant agent of tinea capitis in rural areas and in some parts of Europe, the eastern Mediterranean, and South America.^{7,8}

In recent decades *Trichophyton tonsurans* has become the most common species causing tinea capitis in the United States (80% of cases)⁹ and United Kingdom.¹⁰ The reason for this etiologic shift remains unclear. *T. tonsurans* is an anthropophilic fungus, which spreads from person to person or from infected fomites. It has been responsible for a progressive, continent-wide epidemic over the past 50 years.⁴ Urban areas and minority communities have been particularly affected.¹⁰ *M. canis*, a zoophilic species, can be acquired from infected cats or dogs. This same species can also be transferred from human-to-human, resulting in small outbreaks or clusters of infections among those living in close proximity.¹¹

Clinical Presentation and Diagnosis

Clinically, tinea capitis appears as an inflammatory erythematous, scaly plaque with central alopecia, or hair loss (Fig. 18-1). Unlike other tinea infections, tinea capitis is rarely pruritic. However, if left untreated or misdiagnosed, the plaques can evolve into an inflammatory nodule, referred to as a kerion (Fig. 18-2). This nodule may be

very painful and drain purulent material. Examination of the scalp hair under ultraviolet light (wood's filter) for yellow-green fluorescence is helpful in diagnosing tinea capitis caused by *M. canis* or *Microsporum audouinii*. However, tinea capitis caused by *Trichophyton* species does fluoresce.¹¹ Definitive diagnosis is made by scraping scale from scalp lesions onto a glass slide, applying 10–20% potassium hydroxide (KOH) to the collected scale, and examining the preparation under a microscope for the presence of arthrospores and/or segmented, branched filaments. Confirmation of the diagnosis and speciation is made by culture on Sabouraud's agar medium, a procedure requiring 2–6 weeks for growth and isolation.¹²

Figure 18-1. Tinea capitis.

Figure 18-2. Tinea capitis: kerion.

Prevention and Control

Tinea capitis is easily transmitted from person-to-person, or from animals to humans. Up to 30% of children can be asymptomatic carriers of *T. tonsurans*.¹³ Consequently, outbreaks of tinea capitis are frequent within families and among school children. Such outbreaks require the identification and treatment of all active infections and asymptomatic carriers. Specifically, it is important to inspect all contacts of cases, including family and intimate contacts in order to identify and eliminate all possible sources of infection. Some animals or pets may also be inapparent carriers.

Treatment of tinea capitis requires oral therapy for 6–12 weeks. Topical therapy is not adequate primary therapy; however, it may be added to deter or decrease transmission during treatment with oral antifungals.¹ In order to prevent reinfection, it is important to treat all infected family members and infected close contacts simultaneously.

Tinea Corporis

Epidemiology

Tinea corporis is a dermatophytosis of the glabrous skin of the trunk and extremities (excluding the scalp, beard, face, hands, feet, and groin). Tinea corporis may be caused by any of the dermatophytes of the genera *Trichophyton*, *Microsporum*, and *Epidermophyton*.¹⁴ Geography, race, and seasonality all seem to influence the etiologic dermatophyte in tinea corporis.⁶ In the United States, and throughout the world, *Trichophyton rubrum* is currently the predominant infecting dermatophyte of nonscalp skin infections.^{2,15} Other common pathogenic agents are *Trichophyton mentagrophytes*, and *M. canis*. Children are frequently infected with *Microsporum canis*, especially those exposed to infected animals.¹⁶ Unlike tinea pedis or tinea cruris, tinea corporis infections are more common in women.¹³

Clinical Presentation and Diagnosis

Tinea corporis, or ringworm, typically appears as single or multiple, annular, scaly lesions with central clearing, a slightly elevated, reddened edge, and sharp margination on the trunk or extremities (Figs. 18-3 and 18-4). The infection may range from mild to severe

Figure 18-3. Tinea corporis: neck.

with variable pruritus. When a zoophilic dermatophyte, such as *Trichophyton verrucosum*, is the responsible organism, an intense inflammatory reaction can occur, resulting in inflammatory papules and pustules. Fungal hyphae may also invade the follicle and hair shaft, causing perifolliculitis or an inflammatory nodule (Majocchi's granuloma).¹ The diagnosis of tinea corporis is based on clinical appearance and KOH examination of skin scrapings from the advancing edge of the lesion.

Prevention and Control

Tinea corporis is particularly common in areas of excessive heat and moisture. Risk factors include close body contact with infected humans, animals, or soil.¹ Considerable literature documents historical epidemics of tinea corporis among military recruits and athletes,

Figure 18-4. Tinea corporis: arm.

emphasizing the risk associated with dense populations in humid conditions.¹⁷ Consequently, a dry, cool environment may play a role in preventing infection.¹⁸ Avoiding contact with infected individuals will also minimize risk of infection. Once infected, scales may be transmitted through direct contact between individuals, or indirectly through contact with objects that carry the infected scales.¹⁹

Diagnosis is dependent on a positive KOH preparation. Scales for the preparation should be collected from the advancing edge of the lesion. Tinea corporis may be treated with topical antifungals in an immunocompetent patient with limited disease. When a large body surface area is affected, or the host is immunocompromised, oral therapy may be required.

Tinea Cruris

Epidemiology

Tinea cruris includes infections of the genitalia, pubic area, perineal skin, and perianal skin.¹ The condition is common throughout the world, with men being affected more frequently than women.^{13,20} Otherwise known as jock itch, the infection is most commonly caused by *T. rubrum* or *Epidermophyton floccosum*.¹³ Infection is more common in summer months, when ambient temperature and humidity are high. Occlusion from wet or tight-fitting clothing also provides an optimal environment for infection.¹⁷

Clinical Presentation and Diagnosis

Tinea cruris typically presents as annular lesions extending from the crural fold over the adjacent upper inner thigh (Fig. 18-5).²⁰ In addition to affecting the proximal medial thighs, lesions may extend to the buttocks and lower abdomen, typically sparing the scrotum. Pustules or vesicles may be present at the active edge of the infected area; maceration may ensue at the inguinal crease.¹⁷ Patients with tinea cruris frequently complain of burning and pruritus. Diagnosis is based on clinical signs and symptoms in addition to a positive KOH preparation or fungal culture.

Prevention and Control

Poor hygiene, hyperhidrosis, tight-fitting clothing, and immunosuppression are factors that contribute to the onset of this condition. Frequent outbreaks are common among people who use communal exercise or bathing facilities.¹⁷ Some have observed a higher prevalence of tinea cruris in patients with concomitant tinea pedis and

Figure 18-5. Tinea cruris.

onychomycosis (fungal infection of the toenails).^{21,22} Autoinoculation may occur when an individual brushes fungal organisms onto the underwear from infected feet and toenails. This may be ameliorated by covering the infected toenails with socks, before donning the undergarment. Alternatively, adequately treating the tinea pedis or onychomycosis eliminates the potential for autoinoculation. In an immunocompetent host, tinea cruris can be treated with a several week course of topical antifungal therapy.²³

Tinea Pedis

Epidemiology

Tinea pedis is the most common dermatophytosis, affecting up to 70% of adults worldwide.^{2,13} This is characteristically an infection of urbanized areas, occurring among people who wear shoes since heat and moisture are essential for the growth of the fungus.²⁴ Frequent exposure to communal locker rooms and shower stalls also predisposes to infection. Consequently, prevalence is high among people frequenting swimming pools and involved in sporting activities. Men between 20 and 40 years of age are most frequently affected.^{25,26} One report found that dermatophytes could be recovered from the plantar surface of up to 7% of the U.S. population.²⁷ In other studies, the incidence of tinea pedis has been estimated at 3% in the United States, but may be up to 5% in the elderly and in excess of 20% in populations who use communal showers or locker rooms.^{26,28} Tinea pedis in children is uncommon, with a frequency of 2.2% in children aged 7–10 years, and 8.2% in children aged 11–14 years.²⁹ Though many species can manifest as tinea pedis, *T. rubrum* and *T. mentagrophytes* var. *interdigitale* are thought to be the most common pathogens.³⁰

Clinical Presentation and Diagnosis

Tinea pedis, or athlete's foot, has three common presentations. The interdigital form is the most common and is characterized by fissuring, maceration, and scaling in the interdigital spaces of the fourth and fifth toes. Patients with this infection frequently complain of itching or burning. A second form, usually caused by *T. rubrum*, presents in a moccasin-like distribution with the plantar skin appearing scaly and thickened (Fig. 18-6). There is frequent hyperkeratosis and erythema of the soles, heels, and sides of the feet. The third form is vesiculobullous tinea pedis; it is characterized by the development of vesicles, pustules, or

Figure 18-6. Tinea pedis: moccasin distribution.

bullae on the soles.¹⁸ Diagnosis is based on clinical signs and symptoms in addition to a positive KOH preparation or fungal culture.

Prevention and Control

Many investigators suspect that the type and duration of exposure to a dermatophyte determine whether a person is likely to acquire tinea pedis. While tinea pedis is transmissible, not all people are equally at risk, likely due to a degree of innate resistance.³¹ Poor hygiene, hyperhidrosis, inadequate drying of the feet, and immunodeficiency are factors that contribute to disease.²⁴ Minimizing exposure to infected individuals and to areas known to be at high risk of fungal colonization (public exercise and bath facilities) will reduce a personal risk of infection. If left untreated, tinea pedis may remain throughout life and exhibit periods of exacerbation and remission.³²

Adequate treatment requires prolonged therapy with topical antifungal agents. Despite this, recurrence occurs in up to 70% of patients.² Such recurrence is often attributed to species persistence on fomites such as, socks and shoes.³³ These cases can be eradicated with the addition of a preventative maintenance program of topical antifungal use 1–2 times per week indefinitely.

Tinea Unguium/Onychomycosis

Epidemiology

Onychomycosis is the invasion of the nail plate by a dermatophyte, yeast or nondermatophyte mold. “Tinea unguium” refers to onychomycosis caused only by dermatophytes. The prevalence of onychomycosis increases with age, reaching nearly 20% in patients over 60 years old.²² Onychomycosis has been reported to occur at a rate of 5–15% in various populations,^{3–5} and represents 30% of all cases of dermatophyte infections.^{24,34} Onychomycosis in children is rare, with an estimated prevalence of 0.2%.³⁵

The incidence of onychomycosis has been increasing worldwide, and at present accounts for almost half of all nail disorders.³⁶ The increase is attributed to several factors, including the aging population, the growing number of immunocompromised patients, and the widespread use of occlusive clothing and shoes.³⁶

Ninety percent of all nail infections are caused by dermatophytes (*T. rubrum* 71%, *T. mentagrophytes* 20%); 8% by nondermatophyte molds (*Aspergillus*, *Fusarium*); and 2% by *Candida*.²² Among the dermatophytes, *T. rubrum* is the dominant organism in both the United States and in Europe, usually accounting for greater than 90% of the isolates.³⁵ Rarely, both yeasts and nondermatophytic molds can present as copathogens within the same infected nail.

Clinical Presentation and Diagnosis

Tinea unguium or onychomycosis is characterized by symptoms of pain, discoloration, thickening, onycholysis, accumulation of subungual debris, and brittleness of the nails (Fig. 18-7). Onychomycosis

Figure 18-7. Tinea unguium/onychomycosis.

Figure 18-8. Tinea unguium: white superficial onychomycosis.

can present as distal lateral subungual onychomycosis (DLSO), proximal subungual onychomycosis (PSO), total dystrophic onychomycosis (TDO), and white superficial onychomycosis (WSO).²⁶ DLSO is the most common presentation, manifest by thickening and discoloration of the distal nail bed which eventually progresses proximally. WSO (Fig. 18-8) type pathology affects the superficial nail plate and rarely penetrates to the nail bed; it accounts for 10% of onychomycosis cases.²⁶ PSO is the least common type of onychomycosis in healthy persons. It affects the nail plate in the area of the nail matrix, and progresses distally under the nail bed and plate. Total dystrophic onychomycosis may be the end result of any of the four main forms of onychomycosis. This condition is characterized by total destruction of the nail plate.

Since there are multiple potential causes of dystrophic nails (including vascular insufficiency, trauma, and psoriasis), the diagnosis of onychomycosis cannot be made clinically. Definitive diagnosis depends on a positive KOH preparation and fungal culture.¹

Hookworm Disease: Ancylostomiasis, Necatoriasis, Uncinariasis

Laverne K. Eveland

Hookworms are among the three most common soil-transmitted helminth infections,¹ and cause one of the most important diseases of humans in tropical and subtropical climates. Estimates of 700–800 million people are infected with hookworms, most of whom live in sub-Saharan Africa and eastern Asia.² Most human infections are caused by *Necator americanus*, with *Ancylostoma duodenale* infections scattered throughout the world.³ Investigations in rural West Bengal have shown marked aggregation of both hookworm species in individual villagers, with more than 60% of the infections found in less than 10% of the people, which theoretically should facilitate control.⁴ Although the prevalence of hookworm infection has decreased in areas such as the United States and Puerto Rico, where improvements in socioeconomic conditions have elevated living standards, hookworm disease results in enormous human misery and suffering, as well as economic loss in areas where overcrowding, poverty, and unsanitary living conditions combined with inadequate health care and education prevail.²

Prevention and Control

Onychomycosis presents with contiguous tinea pedis in 50% of cases.¹ In these cases it is impossible to pinpoint the initial infection. It is plausible that one could minimize risk of onychomycosis by treating an existing tinea pedis in a patient with unaffected toenails.¹ Groups of individuals such as the elderly, diabetics, and those with previous trauma to the nail unit may be predisposed to onychomycosis.²²

Treatment of onychomycosis requires at least 3 months of oral therapy. Since oral antifungal therapy only affects newly developed nail, it may take 12 months before the nail returns to normal. Even with apparently optimal diagnosis and treatment, one in five onychomycosis patients are not cured by current therapies.³⁷ The reasons for the 20% failure rate include inaccurate diagnosis; misidentification of the pathogen; and the presence of a second disorder, such as psoriasis.³⁸

► DERMATOPHYTOSIS: EXPECTED TRENDS

Over the past two decades, newer oral antifungals have improved the efficacy and rapidity of treatment. Despite this, dynamic changes in population susceptibility have contributed to a significant rise in the incidence of fungal infections. A weakened host defense and an impaired ability to complete activities of daily living, such as bathing, make the elderly patient especially susceptible to fungal infections.³⁹ Currently, fungal infections are among the most prevalent dermatologic conditions in the elderly, second only to benign and malignant tumors.⁴⁰

Similarly, immunosuppressed patients of any age are particularly susceptible to cutaneous fungal infections.¹ With rising numbers of organ and bone marrow transplants, our iatrogenically immunosuppressed population has increased markedly. Transplant patients on chronic immunosuppressant medications have a significant risk of frequent and recalcitrant dermatophytoses in addition to systemic fungal disease. Despite many advances in the treatment of HIV, these patients are also at increased risk for both cutaneous and systemic fungal infections. Currently, the prevalence of fungal infections is 20% in HIV positive patients with T-cell counts below 400/mL.⁴¹

It is clear that as the elderly and immunosuppressed populations swell, we will likely see increased numbers of infections and, perhaps changing trends in the most common offending dermatophytes. If properly anticipated, the public health community will be prepared to address these changes.

Immigration from developing countries has also changed the distribution of hookworms and other soil-transmitted helminth infections in developed countries. An analysis of 216,000 stool specimens examined in 1987 identified hookworms (1.5%), *Trichuris trichiura* (1.2%), and *Ascaris lumbricoides* (0.8%) as the leading causes of helminth infections in the United States, and the highest rates of hookworm infection were in California, Wisconsin, Rhode Island, Colorado, and Washington, all states lacking indigenous transmission.⁵ In fact, of the nine states reporting more than 2% rates of infection none were endemic for hookworm disease, suggesting that most infections were acquired outside the United States.

Hookworm disease is characterized by an iron-deficiency anemia and protein malnutrition, leading to higher infant mortality and lower birthweight,⁶ retarded growth, reduced worker productivity, and impaired learning and cognitive development.⁷ Disease manifestations are not dramatic, but silent and insidious, and have historically

been confused with innate shiftlessness.⁸ Although frank disease is usually not apparent in well-nourished persons with sufficient iron intake,⁹ significant protein is lost into the intestinal tract in the form of plasma,¹⁰ and the absorption rate of protein is significantly increased after deworming.¹¹

The Parasites

N. americanus and *A. duodenale* are often referred to as “new” and “old” world hookworms, respectively, but these designations are misleading. They are small nematodes, with males measuring 5–11 mm and females 9–13 mm. Hookworms have specialized mouthparts resembling one or more pairs of teeth in *A. duodenale* and a pair of curved cutting plates in *N. americanus* that bite into plugs of the intestinal mucosa which have been drawn into the large buccal capsule. *N. americanus* are bent dorsally at their anterior end. The two species are difficult to distinguish on the basis of egg morphology or size (60–70 × 40 μm). They are the only species that mature in humans, except for *A. ceylanicum* which causes rare human infections in South America and Asia. However, larvae of zoonotic hookworms that cannot develop to maturity in humans can cause dermatitis (Cutaneous Larva Migrans—see later on) when they migrate through human skin. In northeastern Australia sexually-immature stages of the canine hookworm *A. caninum* have been implicated as the cause of acute abdominal pain with peripheral blood eosinophilia and enteritis in humans.¹² *N. americanus* and *A. duodenale* also differ in their life cycles and biology, including modes of infection and survival, with implications for their control. *A. duodenale* is apparently not as well adapted to its host as *N. americanus*. It is relatively short-lived but more pathogenic as measured by the severity of symptoms, with increased blood loss and anemia,¹³ its relative resistance to expulsion with anthelmintics,⁸ and increased activity of proteases presumed to be involved in skin penetration, tissue migration, and feeding.¹⁴ *A. duodenale* increases the probability of contacting its host by producing a greater number of eggs, and synchronizing maximal egg output with the season most favorable for development of free-living larvae, which are robust and capable of surviving longer outside the host and infecting both orally and percutaneously.¹⁵

N. americanus has been the dominant species in southern China, southern India, Indochina, sub-Saharan Africa, southern United States, and Australia.¹⁵ *A. duodenale* predominates in southern Europe, northern coastal Africa, northern India, north China, and Japan. It has also been described in native Paraguayan Indians, in the hill tribes of Fukien, China, and in the aborigines of western Australia. Where the two species are sympatric, their relative abundance varies geographically with host age, gender, and other factors. *N. americanus* coexists with *A. duodenale* in southern India, Myanmar, Malaysia, Philippines, Indonesia, Micronesia, Polynesia, and Portuguese West Africa, although it is the predominant species in these areas. However, *A. duodenale* predominates in coastal Peru and Chile.¹⁶

The life cycles of the two species are similar, but differ in several important ways that influence their epidemiology, pathogenesis, diagnosis, treatment and control. Female *A. duodenale* lay up to 25,000 eggs per day, while *N. americanus* can only produce up to 10,000.¹⁵ The eggs are usually at the four-to eight-cell stage of development when they are passed in human feces and measure approximately 60 × 40 μm. If they are deposited in suitable moist, shady, sandy soil, they develop and hatch in 1 or 2 days into first-stage rhabditiform larvae (0.25–0.30 mm × 17 μm), which have characteristics that distinguish them from *Strongyloides stercoralis* larvae and free-living larvae such as those of *Rhabditis* species. The rhabditiform larvae grow for 2 or 3 days, feeding on bacteria and organic debris. They then molt into second-stage rhabditoid larvae (0.5–0.6 mm), which continue to feed for several days, and then into third-stage filariform larvae. The filariform larvae may remain viable in the soil for several weeks under favorable conditions. Eggs of *A. duodenale* are more resistant to temperature and other environmental variations than those of *N. americanus*, and its larvae can survive longer outside the host.¹⁵

Hookworms normally infect humans by penetrating the skin, after which the filariform larvae are carried in the blood to and through the right heart to the lungs, then up the respiratory tree and down the

digestive tract into the small intestine. After a final molt they attach to the mucosa of the jejunum and upper ileum and develop into sexually differentiated adults. The lung migration is essential for the development of *N. americanus* but not for *A. duodenale*. Eggs of *N. americanus* usually appear in host feces within 40–60 days after the worms reach the intestine, while *A. duodenale* has a much more variable prepatent period, ranging from 43 to 105 days.¹⁷

A. duodenale larvae can infect equally well by the oral route, developing into adults without lung passage.^{15,17} In a study in China many children showed clinical manifestations and eggs in their feces within 3 months of birth, suggesting transplacental transmission of infective larvae.¹⁸ Although the evidence is indirect, because hookworm larvae have never been demonstrated in breast milk, the facts that *A. duodenale* infects nursing infants with no apparent exposure to other routes of infection, and that in a number of endemic areas there is a predominance of *A. duodenale* in infants also strongly argue for transmammary transmission.¹⁰

The prepatent period for *A. duodenale* is long because before larvae that have penetrated the skin reach the intestine to become adults, they undergo arrested development for extended periods in deep tissues. Human patients dewormed as long as 200 days following infection have been reported positive for fourth- and fifth-stage *A. duodenale* larvae.¹⁹ *A. duodenale* larvae sequester in the viscera of experimental animals up to 36 days and in the muscles for 66 days,²⁰ and at least 27-day-old muscle larvae of *A. duodenale* from experimental animals develop into adult worms when fed to dogs.²¹ These observations indicate that meat-borne *A. duodenale* infection of humans is possible through the ingestion of larvae in food animals that can serve as paratenic hosts, although no work has been done to explore the actual epidemiological significance of this means of transmission. The duration of infections is highly variable; many worms are eliminated within a year, but records of longevity range from 4–20 years for *N. americanus* and 5–7 years for *A. duodenale*.¹⁶

Infection and Disease

The pathogenesis of hookworm disease usually begins when the larvae enter any portion of the skin with which they make contact, although it is also probable that in places where people have no direct contact with contaminated soil hookworms may also be acquired through the buccal mucosa and lower levels of the alimentary tract when people eat vegetables grown on soil containing hookworm larvae.²⁰ Skin penetration by the larvae results in a stinging sensation of minor or moderate intensity, depending upon the number of larvae penetrating and the sensitivity of the host. Skin reactions varying from erythematous papules to vesiculation last from 7 to 10 days.¹⁰ Secondary bacterial infections may also occur, especially if the itching lesions are abraded by scratching. This so-called “ground itch” or “dew itch” must be distinguished from the characteristic *Cutaneous Larva Migrans* (CLM) caused by the zoonotic *Ancylostoma braziliense* and other nematodes of the family Ancylostomidae. CLM is characterized by tortuous inflammatory areas in the dermis associated with swelling, erythema, papular dermatitis, and pruritus. *N. americanus* sometimes migrates in the skin and produces a mild CLM, which is of shorter duration than that caused by *A. braziliense*.¹⁶

Although migrating hookworm larvae do not usually produce pulmonary symptoms, they do produce minute focal hemorrhages when they break out of pulmonary capillaries, and may produce clinical pneumonitis in massive infections. Wakana disease, which has been described in Japan, sometimes results following the ingestion of *A. duodenale* larvae, penetration of the larvae into mucous membranes of the mouth and pharynx, and their migration to the lungs. The initial symptoms that occur shortly after the larvae are ingested are pharyngeal itching, hoarseness, salivation, nausea, and vomiting, followed by an illness of several days duration that includes coughing, dyspnea, wheezing, urticaria, nausea and vomiting. Chest roentgenograms may reveal pulmonary infiltrates, which presumably result from an allergic reaction to the larval antigens.²²

Although light infections are usually asymptomatic, acute, heavy hookworm infections can produce gastrointestinal symptoms similar

to those of acute peptic ulcers, which may include fatigue, nausea, vomiting, and burning and cramping abdominal pain. Peripheral blood eosinophilia occurs, and Charcot-Leyden crystals may be present in the feces. The acute disease occurs more frequently with *A. duodenale* than with *N. americanus*.

As the infection progresses, anemia from chronic blood loss may be accompanied by a loss of appetite and symptoms suggestive of congestive heart failure. Geophagy and pica may develop, with constipation resulting from the dietary change. The worms ingest blood that passes so rapidly through their bodies that they probably utilize simple diffusible substances rather than the ingested erythrocytes.²³ However, they also spill a significant amount of blood by lacerating the mucosa during feeding, and the bleeding continues for as long as 30 minutes.²⁴ Blood loss from mucosal damage increases disproportionately in heavy infections because the worms attach and reattach more frequently because of mating competition, especially early in the infection.¹⁶ Adult worms produce potent anticoagulants to facilitate blood feeding that may also enhance blood loss through mucosal bleeding,²⁵ and an inhibitor that blocks adhesion of activated neutrophils to vascular endothelial cells, thereby probably assisting the hookworm in evading the host's inflammatory response.²⁶

Classic hookworm disease is an iron-deficiency, microcytic, hypochromic anemia resulting directly from blood loss. Intestinal injury and changes in intestinal motility might contribute to malabsorption of nutrients in the host, but patients in general are no more malnourished than uninfected subjects.^{10,27,28} Good nutrition consisting of iron, other minerals, and animal protein mitigates the disease associated with light to moderate hookworm infections, even though it does not affect the existing hookworm population or protect an individual from infection. In heavy infections, disease cannot be ameliorated by diet alone. Although the disease is usually associated with heavy infections, it has long been a mystery why it occurs in some persons with only light infections while other persons with extremely heavy infections have no signs or symptoms. The answer appears to lie in the availability of dietary iron stores rather than diet per se,²⁷ because in hookworm endemic areas dietary intake of iron appears to be generally adequate.¹⁰ It is likely that those more susceptible to disease cannot absorb sufficient iron due to intestinal morphological or functional abnormalities for reasons unrelated to their hookworm infection, such as tropical enteropathy or protein malnutrition (kwashiorkor).²⁸

Remote organs such as the corneal epithelium,²⁹ central nervous system and heart³⁰ may also be adversely affected indirectly by hookworm infection. On the other hand, the chronic anemia of hookworm disease may also result in physiological compensations within the host, such as increased pulmonary vital capacity, increased tolerance of tissue cells to anoxia, and lowered systolic pressure. Also, the risk of myocardial infarction may be reduced due to dilatation of the heart and increased collateral circulation of coronary arteries.¹⁶ Changes may occur in bone marrow because of blood loss; retroperitoneal lymph nodes may become enlarged secondary to antigenic stimulation; and the anemia and hypoxia of hookworm disease are sometimes associated with fatty deterioration of the heart, liver and kidneys.^{27,31}

Infections that produce more than 5000 eggs per gram (EPG) of feces are considered heavy; 2000–5000 EPG, moderately heavy; 500–2000 EPG, moderately light, and less than 500 EPG, light.¹⁰ Light infections do not usually result in clinical disease, but moderate and heavy infections are often associated with significant anemia. Diagnosis is complicated in early infections because anemia may actually begin before hookworm eggs are detectable in feces, when larval and immature hookworms first reach the mucosa and begin to cause blood loss. Hookworm disease should be suspected in a person with a subnormal hemoglobin level, Charcot-Leyden crystals in feces, and a history of exposure. Specific immunoglobulin E has been reported to be highly specific (96%) and sensitive (100%) in the serodiagnosis of hookworm infections.³² Although heavy infections may be detected by direct fecal smears, in light infections concentration techniques are usually needed to demonstrate the eggs. Several excellent concentration methods are available, including zinc flotation and several modifications of formalin-ether and formalin-ethyl

acetate techniques. Hookworm eggs may develop and hatch in fecal specimens stored for more than 24 hours at room temperature or above. It is then necessary to distinguish the rhabditiform larvae from those of free-living nematodes and *S. stercoralis*.

Epidemiology

The most favorable conditions for the development of hookworm larvae and completion of the life cycle include loose, moist, shady, sandy humus, promiscuous defecation or the use of improperly treated human feces (night soil) as fertilizer, and the opportunity for humans to come into contact with the soil. An important epidemiological factor appears to be the presence of dung beetles that thrive in such soil and bury human feces efficiently, thereby maintaining defecation sites acceptable for repeated use and enhancing the infection potential of particular spots in which the larvae hatch, develop and migrate upward through the sandy soil.³³ Rainfall is required to provide adequate moisture for the larvae to migrate, aggregate, and reach human skin on grass or other moist surfaces. Temperature is an important factor in determining which species of hookworm is found, because *N. americanus* can tolerate higher temperatures than *A. duodenale*, while the latter can withstand low temperatures that retard or prevent development of the former.¹⁶ The infective larvae may remain viable in the soil for months during periods of drought or low temperatures. Eggs and infective third-stage hookworm larvae have also been found on the external body and in the gut of several fly species, some of which forage on human feces and moist skin³⁴ and remain infective when regurgitated by common houseflies for up to eight hours postingestion.³⁵

Observations in the American south that whites are much more susceptible to infection than nonwhites of similar socioeconomic status suggests a genetic predisposition to infection, and gender-associated effects have been attributed to differences in habits and exposure to infection.^{8, 10} It has been observed that approximately 10% of available hosts harbor 70% or more of the parasite population, further evidence suggesting that heavily infected persons may be genetically predisposed to such levels of infection.³⁶ For epidemiological purposes, the extent of hookworm disease in a community depends on both the prevalence and intensity of infection as measured by egg output. There can also be high prevalence with low intensity of infections or heavy infections in regions of low prevalence.¹⁰ However, people who contribute large numbers of eggs to the environment are not necessarily those who are the greatest source of infection for others, because infective larvae show a high degree of aggregation in the soil that depends on density independent factors influencing larval development and survival, such as moisture, shade and the vertical distribution of ova in the soil.³⁷

Prevention and Control

Theoretically, hookworm disease could be reduced by the sanitary disposal of human feces, wearing shoes and protective clothing, the use of ovicides or larvicides, vaccines, and adequate individual or mass chemotherapy. However, the mere availability of properly constructed sanitary latrines does not ensure their use, as local habits, customs, or beliefs regarding cleanliness and personal hygiene may be major obstacles.¹⁰ It has been demonstrated that children more often than adults tend to go barefoot, resulting in more contact with soil, and fail to use sanitary facilities even when they are present, but prefer the convenience of defecating among bushes in backyards or areas near their homes.³⁸ Even in adults, shoes and protective clothing are often not a reasonable expectation because they are expensive, difficult to clean, and can be extremely uncomfortable in hot weather. Health education encourages people to defecate where conditions are unfavorable for the development or survival of free-living stages, such as on saline soils, open, dry, fallow land, or in flooded fields.¹⁰ However, none of these control methods have been very successful in areas where soil pollution is the norm and poverty and unsanitary life styles promote the heaviest hookworm transmission. For this reason, more recent efforts are being made to eliminate worm burdens by the mass treatment of affected populations with anthelmintics, in an effort to lower the intensity of the infection, which will reduce

morbidity and gradually disrupt transmission.³⁹ To further this objective more research is also needed in (a) development of species- and stage-specific diagnostic tests, (b) investigation of the consequences of arrested development of hookworms, (c) study of hookworm transmission in various regions in the context of varied cultural factors, (d) quantification of the effects of morbidity on individuals and communities, (e) investigation of the relationships between hookworm disease and human nutrition, (f) elucidation of the human host response to infection, and (g) the search for potential vaccines.

At present no effective vaccines are available. Although a cDNA clone encoding a specific antigenic protease has been proposed as a candidate immunogen in human beings, there is no direct evidence that protective immunity to hookworm develops in humans.¹⁰ A study in Papua New Guinea following mass chemotherapy showed that infection with *N. americanus* returned to pretreatment levels after 2 years and that the predisposition to reinfection was independent of host age and sex.⁴⁰ It has also been noted that the intensity of hookworm infection steadily rises with age or plateaus in adults.^{3,41,42} However, a recent study in dogs with a *Ancylostoma caninum* aspartic protease vaccine resulted in significantly lowered worm burdens and fecal egg counts, and prevented anemia in animals following challenge with infective larvae.⁴³ A nonprofit partnership called the Human Hookworm Vaccine Initiative is currently attempting human vaccine trials using antigens derived from living L3 canine

hookworm larvae that can partially protect laboratory animals against hookworm challenge.^{44,45}

In general, only persons at highest risk for disease as determined by egg output and iron-deficiency anemia should be treated. Little benefit is gained from treating individuals with light infections in endemic areas, as reinfection commonly occurs in such foci within 4–6 months.⁴⁶ Persons who return from endemic areas to good sanitary conditions and adequate nutrition may not require treatment.¹⁰

Albendazole, mebendazole, or pyrantel pamoate are drugs of choice for treating hookworm infection.⁴⁷ Since thiabendazole was first introduced as an anthelmintic in 1961,⁴⁸ the benzimidazoles (BZ) drugs have become the current drugs of choice to treat hookworm infections. Although thiabendazole is larvicidal and mebendazole is ovicidal and larvicidal, albendazole kills both preintestinal and intestinal worms, but it is not known whether it affects arrested larvae of *A. duodenale*.¹⁰ Bephenium hydroxynaphthoate is effective against *A. duodenale*, and also against *N. americanus* when combined with tetrachloroethylene, although the latter is difficult to obtain for human use in the United States. Tetrachloroethylene is effective when used alone in higher doses but should not be used if *Ascaris* worms are present. Pyrantel pamoate is useful against both species and is useful for combined infections with *Ascaris*. Praziquantel has also been shown to reduce hookworm infections from 93.5 to 64.8% in boys, and from 70.9 to 23.7% in female patients treated for schistosomiasis.⁴⁹

Other Intestinal Nematodes

Mark R. Wallace • John W. Sanders • Shannon D. Putnam

Intestinal nematodes are the most common parasites in humans, infecting up to one-fourth of the world's population. Most infestations occur in the developing world where warm, moist climates, poverty, and poor sanitation favor transmission. Since most helminths do not multiply in the human host (*Strongyloides stercoralis* and *Capillaria philippinensis* being notable exceptions), the overall worm burden is usually light and symptoms minimal. Heavy worm burdens occur in a sizable minority of infected persons (often children) and may cause severe illness, impaired school or work performance, stunted growth, and a variety of unusual manifestations. Through autoinfection, *S. stercoralis* and *C. philippinensis* have the potential to cause life-threatening hyperinfections.

The intestinal nematodes vary greatly in size, life cycle, and disease manifestations. In this chapter we review the most common intestinal nematodes excluding the hookworms, which are discussed elsewhere. With the exception of *C. philippinensis*, all the intestinal nematodes discussed are primarily pathogens of humans.

Strongyloides Stercoralis

Though strongyloidiasis is less prevalent than the other common intestinal nematodes and is often only minimally symptomatic, its potential for autoinfection allows for unusually chronic and/or severe infections.

The Parasite

The life cycle of *S. stercoralis* is similar to that of the hookworms (Fig. 18-9). The adult worm, a parthenogenetic female, lives within the mucosal epithelium of the human small intestine and deposits eggs (usually less than 50 per day) in the mucosa. There they hatch

into noninfective rhabditiform larvae, migrate into the small intestinal lumen, and are discharged with human feces into the soil. The larvae then develop into either the infective filariform larvae (direct cycle) or adult worms capable of producing additional generations of rhabditiform larvae, which subsequently moult into infective filariform larvae (indirect cycle). Human infection is acquired through skin penetration or (less commonly) ingestion of filariform larvae, which then traverses the venous circulation to the lungs. Once in the lungs, the larvae penetrate capillary walls, enter the alveoli, ascend the trachea to the epiglottis, are swallowed, and eventually reach the upper part of the small intestine where they develop into adult worms.

In the autoinfection cycle, the rhabditiform larvae mature to infective filariform larvae within the human gut and reinvade through the intestinal mucosa or perianal skin. This allows the infection to continue and the parasites to multiply without any additional exposure to soil-borne filariform larvae. Autoinfection accounts for the extremely long-lived infections (sometimes over 50 years) and the possible development of hyperinfection and disseminated strongyloidiasis in immunocompromised hosts.

Epidemiology

Strongyloidiasis is an infection of worldwide importance. It is endemic in the developing world, much of Europe, and the Appalachian region of the United States. The prevalence rates vary greatly between surveys with estimates of up to 100 million cases worldwide. Immigrants, travelers, and military personnel can acquire *S. stercoralis* in endemic areas and then harbor the parasite with few (if any) symptoms for decades through autoinfection. Residents of mental institutions are also at particularly high risk for strongyloidiasis due to fecal-oral transmission and geophagia.

Figure 18-9. Life cycle of *Strongyloides stercoralis*. (Source: Redrawn from Longworth DL, Weller P. Hyperinfection syndrome. In: Remington JS, Swartz S, eds. Current Clinical Topics in Infectious Disease, vol 7. New York, McGraw-Hill; 1986.)

Infection and Disease

The initial entry of the filariform larvae through the skin may produce a transient pruritus similar to that of the hookworms. Cough and wheezing, indistinguishable from that seen in hookworm or *Ascaris* infection, may occur as the larval forms migrate through the respiratory tree. The pulmonary symptoms are usually mild and short-lived, but may be severe in hyperinfection.

Established infection in the immunocompetent host may be asymptomatic or manifested by intermittent vague abdominal pain, indigestion, nausea, anorexia, or diarrhea. The autoinfection cycle may perpetuate strongyloidiasis infection for decades. Patients with ongoing autoinfection may develop larva currens: an urticarial, serpiginous rash. This rapidly moving eruption (up to 5–10 cm/h) is due to autoinfecting filariform larva migrating under the skin after penetrating the perianal surface. Larva currens may last days and recur over months or years; it is said to be pathognomonic of strongyloidiasis. Children with heavy worm burdens may have malabsorption and growth retardation. Severe strongyloidiasis may resemble inflammatory bowel disease and lead to the (disastrous) initiation of immunosuppressive therapy and subsequent hyperinfection.

Hyperinfection and disseminated strongyloidiasis occur when autoinfection is amplified by the presence of immunosuppression or chronic illness. Common predisposing factors include corticosteroid therapy, immunosuppressive chemotherapy, renal failure, malignancy, chronic pulmonary disease, alcoholism, tuberculosis, or malnutrition. Hyperinfection strongyloidiasis may present with severe pulmonary or gastrointestinal symptoms due to the massive parasite load and may also involve other organs as *S. stercoralis* larvae aberrantly migrate to the central nervous system, liver, heart, or other distant sites. Bacteremias may occur as the larvae penetrate the gastrointestinal mucosa and carry gastrointestinal flora into the bloodstream. Hyperinfection should

always be considered in immunosuppressed patients with unexplained gastrointestinal or pulmonary processes or recurrent Gram-negative bacteremias. Eosinophilia, prominent in uncomplicated strongyloidiasis, is often absent in these seriously ill patients. Overall mortality of the hyperinfection syndrome is high even with appropriate therapy.

Diagnosis

The diagnosis of *S. stercoralis* infection rests on identifying the larval forms; eggs hatch before exiting and are usually not seen in the stool. Because of the low rate of egg production, examination of a single stool detects only about 30% of infections; three or more fresh stools should be examined for the presence of rhabditiform larvae. Various stool concentration methods may improve the yield, and *Strongyloides* stool cultures are available in a few laboratories. Duodenal aspirates or sampling by the “string test” are positive in over 90% of infections. When pulmonary symptoms are present, a sputum examination for filariform larvae is indicated. In some cases where strongyloidiasis is suspected but no larval forms can be demonstrated, an enzyme-linked immunosorbent assay (ELISA) serology may be helpful; this is both sensitive and specific. Serologic testing may be used to screen patients from endemic areas prior to the initiation of immunosuppressive therapies.

Therapy

Eradication is the goal of strongyloidiasis therapy. Simply reducing worm burden is inadequate as it leaves the patient exposed to the risk of subsequent hyperinfection. Ivermectin (100 µg/kg per day for 1–2 days) is highly effective (>90%) against chronic intestinal strongyloidiasis and is generally well tolerated. For patients with underlying immunodeficiencies, including human T-lymphotropic virus (HTLV)-I infections, treatment should be repeated at two weeks. Although not

FDA-approved for disseminated strongyloides, it is the most effective and best tolerated drug, but some experts recommend dosing for 5–7 days, and repeating that in two weeks. Albendazole, dosed at 400 mg PO twice daily for 2–3 days, is another choice for treatment and is also well tolerated; but it is not as effective as ivermectin. Thiabendazole was the traditional therapy of choice for strongyloidiasis and is given for three days in uncomplicated cases and seven (or more) days in hyperinfection syndromes. It is effective, with 90% cure rates in uncomplicated cases, but virtually all patients treated with thiabendazole will develop some toxicity; disorientation, fatigue, and gastrointestinal complaints are the primary side effects.

Prevention and Control

The sanitary disposal of human feces is essential for the control of strongyloidiasis in endemic areas. Wearing appropriate footwear is a valuable adjunct to prevention, but may be impractical in warmer climates. Hyperinfection syndromes are prevented by the identification and eradication of strongyloidiasis infections.

Ascaris Lumbricoides

Ascaris lumbricoides is the largest and most common of all the intestinal geohelminths infecting humans. Though usually asymptomatic, severe clinical manifestations occur in a significant minority of patients. The fecundity of the female ascarid and the prolonged egg survival in the soil guarantee that ascariasis will continue to be among humankind's most prevalent infections for the foreseeable future.

The Parasite

The adult worms are 120–400 mm long and live in the small intestine for 1–2 years. The mature female produces approximately 200,000 unembryonated eggs daily. The eggs have a rough, mammillated coat and are discharged into the intestinal lumen and passed with the feces. Once deposited in soil, the eggs embryonate and become infectious, remaining viable for years despite extremes of temperature and moisture. After ingestion via contaminated soil or foods, the eggs hatch into rhabditiform larvae in the small intestine. The larvae penetrate the intestinal mucosa, invade the portal veins, pass through the liver, and continue to the lungs. Once in the lung, they penetrate into the alveoli, are coughed up, swallowed, and return to the small intestine where they develop into the adult worms.

Epidemiology

It is estimated that over one billion humans are infected with *Ascaris*. Ascariasis is most common in warmer climates with inadequate human waste facilities, but cases can occur in temperate climates with good sanitation; there are an estimated four million cases per year in the United States. Although the usual mode of transmission is usually fecal-soil-oral, egg-contaminated food or inhalation of airborne eggs may also produce infection.

Infection and Disease

Most infections with *A. lumbricoides* are asymptomatic. Clinical disease is most likely in heavily infected individuals, especially children. During the larval migration through the lungs in primary infection, a transient pneumonitis with eosinophilia may be seen, which is indistinguishable from the pulmonary phase of *Strongyloides* and hookworms. Gastrointestinal symptoms of ascariasis are often mild and vague, but wandering ascarids occasionally cause severe pancreatic or hepatobiliary disease. Children with heavy infections may develop bowel obstruction. The role of sustained heavy *Ascaris* burdens in childhood malnutrition and developmental delays is difficult to firmly establish but probably is a contributing factor.

Diagnosis

The diagnosis of ascariasis is easily made by identifying the large number of eggs in a single stool specimen. Pulmonary ascariasis is occasionally diagnosed by identifying the larvae in sputum. Adult worms may be found in the stools or emerging from the mouth or nose.

Treatment

There are many effective treatment choices for ascariasis. The primary drugs of choice are the benzimidazoles, mebendazole (100 mg twice daily for 3 days or 500 mg once), or albendazole (400 mg once), but as these are potentially teratogenic, pyrantel pamoate (11 mg/kg up to a maximum of 1 g once) should be used during pregnancy. Piperazine (50–75 mg/kg QD up to a maximum of 3.5 g for 2 days) should be used if intestinal obstruction or “wayward worms” are suspected, as it will paralyze the worms and reduce the risks of additional visceral injury. Ivermectin (200 µg/kg once) and nitazoxanide (adults: 500 mg twice daily for 3 days; children ages 4–11: 200 mg oral suspension twice daily for 3 days) are effective alternatives.

Prevention and Control

Proper human waste disposal is essential to control ascariasis. Targeted mass treatment aimed at groups at risk for heavy helminthic infections (usually children) are often conducted as a part of preventative medicine programs and may reduce overall morbidity and mortality.

Trichuris Trichiura

Trichuriasis is an extremely common infection, with approximately 800 million persons infected worldwide. Many are coinfecting with *Ascaris* or hookworm, which share a similar geographic and socioeconomic distribution. Like *Ascaris*, most infections are asymptomatic, but severe disease can occur with massive worm burdens.

The Parasite

Adult *T. trichiura* are approximately 30–50 mm long and live for years in the cecal and colonic mucosa. The posterior section of the adult worm appears thick and tapers to a long threadlike anterior structure, resembling a bull whip (hence the name whipworm). The adult male worm's tail is coiled while the female worm's tail is straight. The females are oviparous, producing 2000–10,000 eggs each day, which pass into the environment with the fecal stream. Once in the soil, the eggs mature over the next 2–4 weeks developing into infective first-stage larvae. After ingesting fecally contaminated material, the first-stage larvae hatch in the small intestine and migrate to the colon where they develop into mature worms. There is no tissue phase in the whipworm life cycle.

Epidemiology

Trichuris has a cosmopolitan geographic distribution with a preference for warm, moist regions where sanitation facilities are lacking. The use of human waste for fertilizer (“night soil”) facilitates *T. trichiura* transmission. Though more common in the developing world, trichuriasis is also found in the southeastern United States and Puerto Rico.

Infection and Disease

Most *T. trichiura* infections are asymptomatic, but abdominal pain, anorexia, and diarrhea can be seen. Heavy infections can produce the *Trichuris* dysentery syndrome when whipworm infiltrates the bowel from the cecum to the rectum. The dysentery syndrome may be so severe as to resemble inflammatory bowel disease and may result in anemia or rectal prolapse. As with other geohelminths, children are most often heavily infected with *Trichuris* and may suffer delayed development. *Trichuris* is usually not associated with eosinophilia.

Diagnosis

Diagnosis is made by identifying the eggs in the feces. The eggs have a thick, clear shell with distinctive bipolar plugs. More than 10,000 eggs per g of stool indicate heavy infection. The diagnosis is occasionally made endoscopically through direct visualization of adult worms in the colon.

Treatment

A 3-day course of mebendazole (100 mg twice daily for 3 days) is the optimal therapy for the individual patient as it is more effective than

single dose therapy; but single doses of either mebendazole (500 mg once) or albendazole (400 mg once) are often used in mass treatment eradication campaigns in heavily endemic areas. Single-dose therapy results in a 60–75% cure rate. Ivermectin also has activity against *Trichuris*, but the efficacy of single dose therapy has been disappointing. However, combining a single dose of albendazole and ivermectin was shown to be more effective than either drug alone, making this the best choice for mass treatment campaigns. Nitazoxanide has also shown promise as an effective therapy for trichuriasis.

Prevention and Control

As with most intestinal nematodes, the primary mode of prevention is to provide the proper disposal of human feces and to avoid ingestion of soil-contaminated material through careful hand washing and food preparation.

Capillaria Philippinensis

Unlike the more common intestinal nematodes infecting humans, capillariasis is not primarily a human disease and almost always results in severe infection.

The Parasite

C. philippinensis is believed to exist primarily in a fish-bird life cycle. Birds, the proposed reservoir host, harbor the adult worms and in turn defecate eggs, which are fed upon by freshwater fish. Larval forms of *C. philippinensis* develop within the fish, which are then consumed by birds to complete the cycle. Humans inadvertently become infected by ingesting raw fish or crustaceans infected with the larval forms; the eggs are not infectious to humans. Following raw fish ingestion, the adult worms develop and reside in the proximal small bowel. Like strongyloidiasis, eggs can hatch into infective larvae within the human gut and produce autoinfection with extremely high parasite burdens and serious illness.

Epidemiology

Since first discovered in the 1960s, most cases of *C. philippinensis* infections have been reported from the Philippines and Thailand. More recently, cases have been reported from Japan, Iran, Taiwan, Egypt, Indonesia, Korea, and India.

Infection and Disease

Infection with *C. philippinensis* usually (if not always) leads to a serious illness characterized by abdominal pain, nausea, vomiting, borborygmi, and voluminous diarrhea. Severe chronic infection can cause malabsorption, electrolyte abnormalities, wasting, and eventual death. The untreated mortality has been estimated at 10–30%.

Diagnosis

Diagnosis is based on the identification of thick-shelled, striated, bipolar eggs in the feces. The eggs (35–45 μm long by 20 μm wide) somewhat resemble those of the closely related *Trichuris*. In chronic cases, larvae and adult worms may also be seen in stool specimens. Examination of small bowel aspirates or biopsies may occasionally be helpful in making the diagnosis when stool examinations are negative.

Treatment

A 10-day course of albendazole is the preferred treatment, as it kills all forms of the parasite. A 20-day mebendazole regimen is the best alternative. The previously used 30-day course of thiabendazole is too toxic for routine therapy. Shorter courses of treatment lead to an unacceptably high relapse rate and should be avoided.

Prevention and Control

Human capillariasis is entirely prevented by avoiding the consumption of raw fish. When cases occur, prompt treatment is essential to prevent mortality and to limit possible contamination of local waters with feces, which could create local outbreaks. As with all other intestinal nematodes, proper disposal of human waste is essential to prevent the disease.

Enterobius vermicularis

Enterobius (human pinworm) is one of the most common parasitic intestinal infections, occurring in both temperate and tropical climates. The worldwide prevalence is difficult to estimate, as the infection is often asymptomatic, but some authorities have speculated that over a billion people are infected. Pinworm infection rarely results in serious illness, but frequently produces considerable morbidity and anxiety among school-age children and their parents.

The Parasite

Adult pinworms are small (females, 8–13 mm long with a long pointed tail; males, 2–3 mm in length with a blunt tail) and live in the ileum, cecum, colon, and appendix for 1–3 months. The typical infection involves a few to several hundred adult worms. The gravid adult female migrates out of the anus at night to lay thousands of eggs in the perianal region. The eggs are elongated, flattened on one side, with a thick clear shell. They are partially embryonated when laid and become infective within 4–6 hours at body temperature. Infection occurs when the eggs are ingested, hatch in the small intestine to produce larvae, and pass into the colon where they moult twice as they mature into adult worms.

Epidemiology

Enterobiasis occurs worldwide, affecting all socioeconomic classes. It is the most common nematode infection in the United States, usually involving school-aged children. The condition may spread rapidly within families, day care facilities, institutions, or other crowded situations. Ingesting infective eggs via contaminated fingers, fomites, or direct oral-anal sexual contact leads to infection.

Infection and Disease

Most infections are asymptomatic. Pruritus or dysesthesia of the perianal and perineal areas are the primary symptoms of infection. Vulvovaginitis and urinary tract infection due to migration of adult worms are sometimes reported in prepubescent girls. Rarely, adult worms may traverse the fallopian tubes or move across breaks in the gut mucosa to gain access to the peritoneum and form granulomas. The pinworm larval forms have been implicated in case reports as a rare cause of eosinophilic colitis resembling the trichuriasis dysentery syndrome. Pinworm infection does not cause eosinophilia or anemia.

Diagnosis

Enterobiasis diagnosis is best made by applying adhesive tape to the perianal region and microscopically examining the tape for *E. vermicularis* eggs or adults. For the highest diagnostic sensitivity, material should be collected in the early morning prior to bathing or defecation. Examination may need to be repeated six times before infection can be conclusively excluded, but three specimens are adequate in most cases. Standard “ova and parasite” stool examination is positive in only 5–15% of confirmed cases.

Treatment

Single doses of albendazole, mebendazole, or pyrantel pamoate are all highly effective and widely used; a second dose 1–2 weeks after initial therapy is often given. Reinfection, whether through self infection or infection from close contacts, is a major problem in *E. vermicularis* therapy. Attention to washing hands after defecation, keeping fingernails cut short and avoiding perianal scratching are the keys to avoiding reinfection. All family members may need to be simultaneously treated to avoid a circle of infection. Although not generally used for this purpose, ivermectin also has activity against *E. vermicularis* and should be effective.

Prevention and Control

Enterobiasis infection can be prevented through proper personal hygiene practices including washing hands after defecation and before eating or preparing foods, discouraging bare perianal scratching, changing undergarments and bedding regularly, and providing sanitary human waste disposal.

Schistosomiasis

Ettie M. Lipner • Amy D. Klion

Schistosomiasis, or bilharziasis, is a chronic debilitating disease with significant morbidity and mortality. It affects more than 200 million people in 74 countries worldwide and is second only to malaria in socioeconomic and public health importance in tropical and subtropical areas.¹ Human disease is caused by five species of blood flukes of the genus *Schistosoma*: *S. mansoni*, *S. haematobium*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*.

Biology and Life Cycles

The schistosome requires an intermediate and a definitive host to complete its life cycle. Asexual reproduction takes place in the molluscan intermediate host and sexual reproduction in the definitive vertebrate host. Briefly, free-swimming miracidia hatch from eggs deposited in freshwater during defecation or urination by an infected definitive host. These miracidia penetrate the appropriate snail host and develop into primary sporocysts, each of which produces multiple secondary sporocysts. Each of the secondary sporocysts produces a great number of cercariae, resulting in the production of hundreds to thousands of cercariae from an individual miracidium. The fork-tailed cercariae migrate out of the snail and propel themselves toward the surface of the water. Of note, both miracidia and cercariae have a limited life span in the absence of an appropriate host (6–24 hours under experimental conditions).² Sporocysts, on the other hand, remain dormant during adverse conditions, and are able to resume cercarial production with the return of a favorable environment.

When humans contact schistosome-infested water, cercariae penetrate the skin, lose their tails, and are transformed into schistosomula. After several days, the schistosomula enter a venule or lymphatic vessel and migrate to the right side of the heart, then to the lungs, and finally to the liver sinusoids, where they begin to mature. On reaching maturity, adult male and female worms pair and migrate to their final habitats. There, eggs are deposited in the venules of the intestine or urinary bladder, break through the submucosa and mucosa into the lumen, and are evacuated through the feces or urine completing the life cycle.

The mature female schistosome measures from 7.2 to 26 mm in length and 0.25 to 0.5 mm in width, whereas the mature male measures from 6.5 to 20 mm in length and 0.5 to 1 mm in width. They remain *in copula* for their entire lifespan, an average of 5–8 years, but sometimes for as long as 30 years.³ The preferred location of adult worms in the host is different among the schistosome species. *S. japonicum* and *S. mekongi* adult parasites are generally found in the superior mesenteric vein; *S. mansoni* and *S. intercalatum* in the inferior mesenteric vein; and *S. haematobium*, in the vesicular and pelvic venous plexuses. Daily egg production also varies with the species: from approximately 1500 to 3000 eggs per day per worm pair in *S. japonicum* infection to 250 eggs per day in *S. mansoni* and *S. intercalatum* infection and 50–100 eggs/day in *S. haematobium* infection. These biological differences between schistosome species are important in determining both the clinical manifestations and transmission rates of infection.

Distribution

Schistosomiasis is endemic in many tropical and subtropical countries and is a frequent cause of travel clinic visits, particularly in travelers to west Africa.^{1,4} The distribution of schistosomiasis is dependent on the existence of the appropriate snail host and necessary environmental conditions. *S. mansoni* (intermediate host: *Biomphalaria* spp.) has the most widespread distribution, ranging from the Arabian peninsula to

South America and the Caribbean. *S. japonicum* (intermediate host: *Oncomelania* spp.) is confined to the Far East, distributed in parts of China, Indonesia (*S. japonicum*-like), the Philippines, and until recently, Japan. A related species, *S. mekongi* (intermediate host: *Neotricula* spp.), is found in Laos, Cambodia and Thailand. *S. haematobium* (intermediate host: *Bulinus* spp.) is endemic in the Middle East, Africa, Turkey, and India. Transmitted by the same intermediate host as *S. haematobium*, *S. intercalatum* is found only in regions of Central and West Africa. Important reservoir hosts for *S. japonicum* include mice, dogs, goats, rabbits, cattle, sheep, rats, pigs, horses, and buffalo.⁵ Although natural infection of non-human primates with *S. mansoni* and *S. haematobium* has been described, animals other than humans do not appear to be major reservoirs of infection with these species.⁵

Pathological and Clinical Manifestations

Most of the pathological changes and clinical manifestations of schistosomiasis result from the host's immunological response to the eggs. The severity of the disease depends on the species, strain, location of parasites, intensity and duration of infection, frequency of reinfection, and the host's reactivity. Mild infections without symptoms often occur. The course of infection may be divided into four progressive stages: invasion, maturation, established infection, and chronic infection with its attendant complications.

In the invasion stage, exposure of the sensitized host to cercarial or schistosomular antigens may lead to transient allergic manifestations. Although most infected individuals have no symptoms during cercarial penetration, a localized papular dermatitis ("swimmer's itch") may occur with repeated exposures.⁶ A similar, but more intense, reaction is provoked when schistosome species that normally do not infect humans penetrate the skin and die in the dermis releasing large quantities of parasite antigen.⁷ Petechial hemorrhages, foci of eosinophilia, and leukocytic infiltration may be produced in the lung or in the liver when schistosomula migrate through the lungs and reach the liver. During this period, transitional symptoms of fever, malaise, cough, and a generalized allergic reaction may appear. When present, symptoms generally resolve in 5–15 days without treatment.

Active schistosomiasis starts with worm maturation and the beginning of egg production. Severe cases of acute schistosomiasis, or Katayama fever, are not uncommon and occur 35–40 days after *S. japonicum* or heavy *S. mansoni* infection, coincident with the first two weeks of egg production. The clinical manifestations are characterized by a serum sickness-like syndrome of fever, chills, cough, arthralgias and myalgias, diarrhea, eosinophilia, hepatosplenomegaly, and generalized lymphadenopathy. Recovery usually occurs within several weeks, but fatalities do occur. The syndrome most likely reflects the strong host immune response to egg antigens and the formation and deposition of circulating immune complexes.

In the established stage, intense egg deposition and excretion takes place. The intestinal schistosomes (*S. japonicum*, *S. mekongi*, *S. mansoni*, and *S. intercalatum*) release eggs into the mesenteric veins. Some of these become lodged in the intestinal submucosa, where they secrete proteolytic enzymes that erode the tissue, and break through the intestinal wall. In heavy infection, this may cause diarrhea and blood in the stool. Other eggs may be trapped at the original site or swept back into the portal blood flow and distributed to the liver, spleen, or other ectopic foci, where they provoke an inflammatory tissue response and granuloma formation. This may cause thrombosis of vessels, formation of polyps in the intestinal wall, or hepatosplenic schistosomiasis (see later on). In *S. mansoni* infection, the rectum and colon

are affected more frequently than other parts of the gastrointestinal tract. The severity of early disease is closely correlated with the number of eggs and their anatomic location. Consequently, *S. japonicum*, which has the highest capacity for egg production and the widest egg distribution, is a more common cause of severe, disseminated disease.

Adult *S. haematobium* in the veins surrounding the urinary bladder deposit eggs into the vesicular plexus. These commonly break through the bladder wall and cause dysuria, urinary frequency, proteinuria, and hematuria. Inflammatory polypoid masses in the bladder or ureteral walls are common early in infection and are a significant cause of obstructive uropathy. Eggs may also be carried by the venous system to the genital organs, gastrointestinal tract, lungs, and liver.

The chronic stage with its attendant complications is generally observed only in heavy infection, and is consequently very uncommon in travelers. The acute symptoms (if present) resolve, and the level of egg secretion becomes stable. Although most individuals with chronic infection are asymptomatic, egg-induced granuloma formation, fibrous proliferation and vascular obliteration lead to chronic pathology in others (see later on). Once initiated, schistosome-induced fibrosis may progress despite resolution of the initial infection.⁷

Chronic intestinal schistosomiasis is characterized by fibrous patches, inflammatory polyps, thickening of the intestinal wall and adhesions of the thickened mesentery and omentum to the intestine. Complications include secondary bacterial infection and intestinal obstruction. Recurrent Salmonella bacteremia is particularly common.⁸ In hepatosplenic schistosomiasis, granulomas develop around eggs in the portal venules. Hepatosplenomegaly may be pronounced. Over time, the liver gradually shrinks in size as a result of increasing fibrosis in a periportal distribution, called Symmers' pipestem fibrosis. This may result in blockage of presinusoidal blood flow, leading to portal hypertension, ascites, and esophageal varices. An association between hepatosplenic schistosomiasis and nephrotic syndrome secondary to immune complex glomerulonephritis has been well-documented.⁹

Pulmonary schistosomiasis has been reported in all five species of schistosome infection. Eggs may be carried to the lungs by venous shunting through systemic collateral vessels formed as a result of portal hypertension or because of aberrant migration of worms into the vena caval or vertebral venous systems. The resultant granulomatous arteritis of the pulmonary capillary bed may lead to obliterative arteriolitis, dilatation of the pulmonary arteries, and pulmonary hypertension. Rarely, this leads to cor pulmonale with right-sided heart failure.

Fibrosis and calcification of the eggs in the urinary bladder may impair bladder function. Fibrosis of the neck of the bladder and opening of the ureter result in obstruction of urine flow and may lead to the development of hydronephrosis, hydronephrosis, renal stones and, rarely, renal failure. Chronic ulceration and irritation of the bladder epithelium may in time lead to malignant transformation and the development of squamous cell carcinoma of the bladder.

Female genital schistosomiasis, as defined by the presence of schistosome eggs or worms in the upper or lower genital tract, is a recently recognized syndrome that is associated with the presence of visible lesions or "sandy patches" on the cervix on colposcopic examination.¹⁰ The potential role of these inflammatory lesions in enhancing the transmission of sexually transmitted infections, the development of malignancies of the genital tract and infertility rates remains controversial.

In cerebrospinal schistosomiasis, ectopic eggs may cause granuloma formation in the central nervous system, resulting in focal damage.¹¹ Brain involvement is most common in *S. japonicum* infection, and may present acutely as meningoencephalitis.¹¹ In chronic infection, seizures are the predominant manifestations. *S. mansoni* and *S. haematobium* more commonly affect the spinal cord, causing transverse myelitis.¹²

The immune response to helminth infections, including schistosomiasis, is characterized by a Th2 phenotype with eosinophilia, elevated serum IgE levels. In contrast, viruses and protozoa generally

induce a Th1 type immune response. The immunological and clinical effects of coinfection with schistosomiasis and such pathogens reflect the balance between these opposing responses.¹³⁻¹⁹ In some infections, such as viral hepatitis C, coinfection with schistosomiasis leads to more severe liver disease, with higher viral titers and increased mortality.¹⁵ In other infections, such as malaria, coinfection with schistosomiasis appears to afford a modest protective effect against malaria, with decreased parasitemia and milder clinical disease in coinfecting children.^{16,17} Finally, although the course of HIV infection does not appear to be altered by schistosomiasis,¹⁸ available data suggest that advanced HIV infection may decrease resistance to reinfection in schistosomiasis.¹⁹

Diagnosis

Definitive diagnosis is made by identifying characteristic eggs in the stool or urine sample, or by tissue biopsy.²⁰ Eggs of *S. japonicum* and *S. mekongi* are globular in shape without spines; *S. mansoni*, oval with a lateral spine; and *S. haematobium*, oval with a terminal spine. Concentration techniques should be employed for all urine and stool specimens, and multiple samples should be examined carefully before a negative report is given. The quantitative Kato-Katz (cellophane) thick fecal smear is a rapid, inexpensive method of detection of eggs in the stool. It has become a standard diagnostic tool in epidemiology for international comparison of data,⁴ and has largely replaced filtration and hatching techniques. Newer techniques, such as Visser filtration,²⁰ allow examination of larger amounts of stool and may be useful in documenting light infections. If eggs cannot be found in a chronic symptomatic case, rectal biopsy snips should be taken, pressed between two slides and examined by light microscopy for eggs.²¹ Colposcopic biopsy with histologic examination may also be useful in such instances.

In urinary schistosomiasis, concentration and quantification of eggs in urine samples may be accomplished by centrifugation or a variety of filtration techniques. Since *S. haematobium* eggs are shed into the urine following a circadian rhythm, samples should be obtained between 10 A.M. and 2 P.M. Large volumes (>3 liters) of urine may need to be examined to detect eggs in light infections. In epidemiological studies, hematuria is often used as an indirect indicator of *S. haematobium* infection; however, the diagnostic value of hematuria at the individual level is limited by large variations in the predictive value of the test between different populations.²²

The detection of antibodies against schistosomes may be helpful in documenting recent infection in visitors to endemic areas; however, the inability of such tests to distinguish between past and current infection limits their utility in endemic areas.²³ More recently, a variety of schistosome antigen detection tests have been developed, of which serum CAA (circulating anodic antigen) and urine CCA (circulating cathodic antigen) are the best characterized.²³ Since antigen titers become positive early in infection and are correlated with the intensity of infection, serum CAA and urine CCA may be useful in the diagnosis of acute schistosomiasis and in assessing cure after chemotherapy.

Although abdominal ultrasonography is sometimes helpful diagnostically, findings may be nonspecific early in infection. Consequently, it is most useful in assessing morbidity and monitoring the response to treatment in patients with chronic disease.⁷

Treatment

Praziquantel, a heterocyclic pyrazinoisoquinoline, is the drug of choice for all species of schistosomes, with cure rates from 60% to 98% in most series.²⁴ In patients with hepatosplenic involvement, periportal fibrosis may actually resolve with treatment.²⁵ The drug is well tolerated, with only mild transient side effects, including abdominal discomfort, nausea, diarrhea, headache, dizziness, drowsiness, and pruritus. Three doses of 20 mg/kg given at 4-hour intervals are recommended for treatment of *S. japonicum* infections.²⁴ In most cases, a single dose of 40 mg/kg is sufficient for treatment of infection with other schistosome species.²⁴ Of note, HIV status does not appear to play a role in the response of schistosomiasis to praziquantel therapy.²⁶

Resistance to praziquantel has been induced in laboratory strains of *S. mansoni* with repeated exposure to the drug.²⁷ Reports of decreased cure rates with praziquantel in epidemic foci in Senegal²⁸ and the Nile Delta Region of Egypt²⁹ coupled with decreased drug susceptibility of parasite isolates from individuals in these two regions in a murine infection model³⁰ initially raised concern that the same phenomenon would occur in humans. However, praziquantel resistance has not been detected in other endemic regions,³¹ and there is no evidence that the proportion of parasite-resistant strains has increased in these regions over time despite continued use of praziquantel.³²

Concern about reliance on a single drug has led nevertheless to renewed interest in alternatives to praziquantel therapy, including artemisinin derivatives. Metrifonate, an organophosphorus ester, and oxamniquine, a tetrahydroquinoline, used in the past as alternative therapies for the treatment of *S. haematobium* and *S. mansoni*, respectively, are no longer commercially available and will not be discussed.

Artemisinin derivatives, including artesunate and arthemether, are best known for their antimalarial properties; however, laboratory experiments and clinical trials have confirmed that these compounds also exhibit activity against all of the schistosome species that infect humans.^{33–35} Artemisinin derivatives are well-tolerated and may be administered orally or by intramuscular injection. Optimal regimens for artemisin treatment of schistosomiasis have not yet been determined. Unlike praziquantel, which is active only against adult worms, artemisinin compounds have activity against both the immature and adult stages of the schistosome life cycle and may be useful for chemoprophylaxis.³⁶

Control and Prevention

Control and prevention of schistosomiasis are among the most complex problems in public health. Success in control depends on having a well-organized program based on a profound understanding of the epidemiology of the disease, the biology, ecology, and distribution of the parasite intermediate snail host, and the geographic characteristics of the environment. It is also important to have sound knowledge of local socioeconomic conditions, support from health authorities, and cooperation of the communities.

The elimination of schistosomiasis through interruption of transmission has been attempted for the last five decades. It has been successful in some countries, such as Japan and large parts of China,³⁷ but has proved to be beyond the resources of many endemic areas. Furthermore, ecological changes, both natural (e.g., drought) and man-made (e.g., water resource development projects, relocation of populations for political reasons), have led to schistosomiasis outbreaks in some regions where disease transmission was previously controlled.³⁸ As a result, the World Health Organization has recommended the institution of integrated control programs targeted at reducing the morbidity and prevalence of the disease.³⁹ The availability of geographic information systems (GIS) and sophisticated epidemiologic models is likely to enhance the effectiveness of such programs.⁴⁰

Snail Control

Molluscicides provide a rapid and effective means of reducing the snail population and decreasing disease transmission;⁴¹ however, their application must take into account the focal and seasonal patterns of disease transmission. A suitable molluscicide must be safe and nontoxic to mammals and aquatic organisms, stable in storage, and simple to apply. Niclosamide, a synthetic amide that has been used since the 1960s, fulfills most of these criteria and remains the molluscicide of choice. The major limitations to its widespread use are cost (as much as \$100 per kg in some areas of the world) and the high incidence of drug-associated fish mortality. Natural molluscicides of plant origin provide the theoretical advantage of decreased cost, local production, and low toxicity, but to date have not been as effective as niclosamide in field trials.

Long-lasting effects in the reduction of snail populations can be achieved by environmental modifications, such as the installation of

overhead sprinklers and trickle-type irrigation systems, modification of canal design, alteration of water level, or lining of canals with cement. Simple methods, including weed control and drainage of unused standing water, can also reduce snail populations. Biological snail control methods are still in the experimental stages, and none has reached large-scale field trials. Preliminary studies using fish, insect, and molluscan competitors have met with only limited success.

Chemotherapy

Chemotherapy not only decreases the morbidity and prevalence of disease⁴² but also reduces transmission. Three basic strategies have been advocated: mass treatment, selective population-based therapy of infected individuals, and therapy targeted to subpopulations of infected individuals (e.g., those with high-intensity infection). The most appropriate treatment strategy depends on the endemicity of infection and the available resources. For example, in a highly endemic area, the cost of screening individuals for infection may exceed the cost of providing therapy for all persons living in the endemic area. Regardless of the strategy, reinfection generally occurs, especially in children where up to 40% may be reinfected one year after treatment. Even a small residual egg output can sustain disease transmission if the snail population is not controlled. Thus, a continuing schedule of screening and retreatment is required. The long-term side effects (if any) of repeated drug treatment and the potential effects on drug resistance also need to be considered.

Education

Health education is an integral part of any successful schistosomiasis control program and has been shown in several studies to have an effect on human behavior and ultimately on disease transmission and prevalence.⁴³ It is much more likely that people will minimize contact with infested water, avoid polluting water sources and cooperate with community control programs if they understand the basic mechanism of disease transmission. Furthermore, simple and inexpensive water disinfection procedures, such as boiling, filtering, or storing for 24 hours, after which contaminating cercariae become noninfective, can be instituted. Finally, people who must have contact with contaminated water can be taught personal protection measures, including the use of repellents, rubber boots, and other barrier methods (e.g., wrapping the feet with cloth or puttees smeared with powdered *Thea oleosa* fruits), which may provide partial protection against infection.

Sanitation and Water Supply

Although expensive, the provision of safe water and adequate sanitation is crucial to the long-term control of schistosomiasis. In St. Lucia, the installation of individual household water systems was associated with a 75% decrease in the incidence of new *S. mansoni* infections in children.⁴⁴ In theory, installation of latrines may protect snail-bearing waters from contamination with infectious human wastes; however, this has been less effective than provision of a safe water supply in decreasing transmission. The reason for this is likely multifactorial, and includes accessibility and social issues limiting the use of latrines in many communities. Finally, since water resource development programs may spread schistosomiasis to previously uninfected areas, such programs should be planned by multidisciplinary teams, including epidemiologists, ecologists, biologists, engineers, and public health officials.

Successful short-term control has been achieved with an integrated approach in some endemic areas.^{44–46} However, once prevalence has been reduced to the targeted level, a maintenance program is necessary to sustain it. This was highlighted by a recent study of community-based control of schistosomiasis in the Philippines, in which a marked increase in the incidence of hepatosplenomegaly was seen with suspension of antischistosomal chemotherapy for as little as two years.⁴⁶ The cost of such long-term, multi-faceted control programs is not insignificant and may be as high as US\$3 per *protected subject* per year (as compared to the less than US\$5 per capita total expenditure for health in sub-Saharan

Africa). Although integration of schistosomiasis control programs with other local health programs has been successful in decreasing costs and increasing efficacy in some countries, additional inexpensive and effective alternatives (such as a vaccine) are clearly needed.

Vaccine Development

The immune response to schistosome infection is extremely complex and likely depends on the intensity and timing of exposure as well as genetic factors.^{47,48} Nevertheless, epidemiological studies in areas endemic for schistosomiasis suggest that acquired resistance to reinfection occurs with age. Furthermore, although vaccination of experimental animals (including nonhuman primates) with live

attenuated schistosomes provides only partial immunity to reinfection (70–90% reduction in worm burden), such levels of immunity could have a significant effect on morbidity by reducing the prevalence of high intensity infections and could potentially reduce transmission.^{49,50} Since the use of a live vaccine would be unethical in humans, recent attention has focused on recombinant or synthetic peptides as potential vaccine candidates and on the use of novel delivery systems (e.g., BCG) and adjuvants (e.g., IL-12) to enhance their immunogenicity. One such vaccine, Sh28-GST, a recombinant from *S. haematobium*, has completed Phase I/II clinical trials in Africa with no evidence of local or systemic toxicity and may progress soon to Phase III human studies.⁵¹

Toxic Shock Syndrome (Staphylococcal)

Arthur L. Reingold

► INTRODUCTION

Staphylococcal toxic shock syndrome (TSS) is an acute, multisystem febrile illness caused by *Staphylococcus aureus*. A similar illness caused by group A streptococcal infections is discussed in Chap. 12. The accepted criteria for confirming a case of TSS include fever, hypotension, a diffuse erythematous macular rash, subsequent desquamation, evidence of multisystem involvement, and lack of evidence of another likely cause of the illness (Table 18-2).

► HISTORICAL BACKGROUND

TSS was first described as such in 1978 by Todd et al.¹ However, cases of what we now believe to have been TSS have been reported in the medical literature since at least 1927 as “staphylococcal scarlet fever” or “staphylococcal scarlatina.”^{2,3} In addition, a number of patients reported in the medical literature in the 1970s as having adult Kawasaki disease probably had TSS.⁴ The association between illness and focal infection with *S. aureus* was, by definition, apparent in early reports of staphylococcal scarlet fever, but was reinforced by the findings of Todd et al¹ and later by the findings of other investigators.^{5,6}

TSS achieved notoriety in 1980 when numerous cases were recognized and an association between illness (in women), menstruation, and tampon use was demonstrated.^{7,8} While the early case reports of staphylococcal scarlet fever and the report by Todd et al¹ clearly showed that TSS occurred in small children, men, and women who were not menstruating, most (but by no means all) of the cases initially recognized and reported in late 1979 and early 1980 were in menstruating women,^{8–10} leading to the frequent misperception among the general public and many physicians that TSS occurred only in association with tampon use (hence, “the tampon disease”). This misperception undoubtedly led to subsequent biases in the diagnosing (and probably reporting) of TSS cases. However, later studies designed to eliminate such biases have shown that TSS does, in fact, occur disproportionately in menstruating women,^{11,12} while case-control studies demonstrating an association between the risk of developing TSS during menstruation and tampon use preceded (indeed, led to) the introduction of bias concerning the relationship between tampon use and menstrual TSS.^{5,6}

Follow-up studies demonstrated that the risk of developing tampon-related menstrual TSS varies with the absorbency, chemical composition, and oxygen content of the tampon,^{13–16} although the relative importance of these and other tampon characteristics in determining that risk remains uncertain. As a result of both epidemiological and in vitro laboratory studies, the formulation of available tampons changed dramatically in the early 1980s, such that absorbencies were substantially lower and chemical composition was less varied across brands and styles. Studies in the late 1980s demonstrated that the incidence of TSS, particularly menstrual TSS, rose and fell in parallel with the absorbency of tampons,¹⁷ but that the risk of developing menstrual TSS continued to vary directly with tampon absorbency, despite the changes in tampon formulation.¹⁸

► METHODOLOGY

Sources of Mortality Data

Mortality rates for TSS have not been reported directly, but can be estimated from reported incidence rates and case-fatality ratios.

Sources of Morbidity Data

Surveillance for TSS began in a few states in late 1979 and in other states and nationally in early 1980. Since that time, TSS has been made a reportable disease in most states. However, the level of intensity of surveillance activities has varied markedly between and within states. Thus, a few states established active surveillance for TSS for brief periods of time, while others did little to stimulate the diagnosis and reporting of cases. As a result, the completeness of diagnosing and reporting TSS cases undoubtedly has been inconsistent between states and over time. However, data from a national hospital discharge survey indicated that reporting of cases in the 1980s, while incomplete and variable by region, was not biased dramatically insofar as the age, race, sex, or menstrual status of the patients is concerned.¹⁹ Hospital record review studies, in which both diagnosed and previously undiagnosed cases of TSS were ascertained in a consistent fashion, so as to minimize or eliminate both diagnostic and reporting biases, also have been conducted.^{11,12,17,20,21} These studies demonstrated that, by and large, the patient characteristics and temporal trends observed in

TABLE 18-2. CASE DEFINITION OF TOXIC SHOCK SYNDROME

Fever: temperature $\geq 38.9^{\circ}\text{C}$ (102°F)
 Rash: diffuse macular erythroderma
 Desquamation: 1–3 weeks after onset of illness
 Hypotension: systolic blood pressure ≤ 90 mm Hg for adults or below fifth percentile by age for children under 16 years of age, orthostatic drop in diastolic blood pressure ≥ 15 mm Hg from lying to sitting, orthostatic syncope, or orthostatic dizziness
 Multisystem involvement: three or more of the following:
 Gastrointestinal: vomiting or diarrhea at onset of illness
 Muscular: severe myalgia or creatine phosphokinase level at least twice the upper limit of normal for laboratory
 Renal: blood urea nitrogen or creatinine at least twice the upper limit of normal for laboratory or urinary sediment with pyuria (≥ 5 leukocytes per high-power field) in the absence of urinary tract infection
 Hepatic: total bilirubin, serum aspartate transaminase, or serum alanine transaminase at least twice the upper limit of normal for laboratory
 Hematologic: platelets $< 100,000$
 Central nervous system: disorientation or alterations in consciousness without focal neurological signs when fever and hypotension are absent

Negative results on the following tests, if obtained:
 Blood, throat, or cerebrospinal fluid cultures (cultures may be positive for *Staphylococcus aureus*)
 Rise in titer to Rocky Mountain spotted fever, leptospirosis, or rubeola

data collected through the largely passive network of TSS surveillance reflected true variation in the incidence of TSS by age, sex, race, and menstrual status. These same studies, taken together, demonstrated that at least some of the apparent geographic variation in the incidence of TSS in the United States in the 1980s was real. More recent information concerning the epidemiologic features of TSS comes almost entirely from the passive national surveillance system, as few epidemiologic studies of TSS have occurred since the 1980s.

Surveys

Numerous small surveys have demonstrated that many asymptomatic individuals carry in the nasopharynx and/or vagina strains of *S. aureus* that produce TSS toxin-1 (TSST-1), the toxin believed to be responsible for most TSS cases.^{22–26} Similarly, large serosurveys have shown that antibodies to TSST-1 or to a cross-reacting antigen are extremely common.^{22,25,27,28}

Laboratory Diagnosis

Isolation and Identification of the Organism

While recovery of *S. aureus* from the vagina or another site of infection is not one of the criteria of the TSS case definition, it is possible in most TSS cases if appropriate specimens are obtained before antimicrobial therapy is initiated.^{5,6,29,30} *S. aureus* grows readily on most standard culture media and is readily identifiable by any clinical microbiology laboratory within 2 or 3 days. Testing of *S. aureus* strains for production of TSST-1, however, is performed in only a few research laboratories. Hence, the results of such testing are not readily available during the acute illness and are not of value in treating patients suspected of having TSS. Furthermore, because both *S. aureus* in general and TSST-1-producing strains of *S. aureus* in particular can be recovered from many patients without the clinical features of TSS and from asymptomatic individuals, microbiological results cannot and do not prove that a given patient has TSS.

Serological and Immunologic Diagnostic Methods.

A variety of serological and immunologic techniques have been used to test *S. aureus* strains for production of TSST-1. As noted above,

these tests are not available outside a few research laboratories. It is possible to detect TSST-1 in clinical specimens,^{31,32} but these assays are not generally available. Antibodies to TSST-1 can be measured using solid-phase radioimmunoassay and other techniques. However, most healthy individuals have detectable anti-TSST-1 antibodies.^{22,25,27,28} Furthermore, some patients with TSS have demonstrable anti-TSST-1 antibodies at the time of onset, and many patients without such antibodies at the time of onset do not demonstrate an antibody rise in response to their illness.^{27,33} Thus, testing for anti-TSST-1 antibodies (which is not available except in one or two research laboratories, in any event) is of limited value in confirming the diagnosis of TSS, although it has been argued that the absence of detectable antibodies at the time of onset supports the diagnosis of TSS.

► BIOLOGICAL CHARACTERISTICS OF THE ORGANISM

As noted earlier, there is convincing evidence that *S. aureus* is the cause of TSS. In patients with menstrual TSS, *S. aureus* can be recovered from the vagina and/or cervix in 95–100% of cases (usually as a heavy growth), but in only 5–15% of healthy control women.^{5,24,34–39} In patients with nonmenstrual TSS associated with a focal wound, *S. aureus* is typically the only organism found in the lesion.^{29,30} Furthermore, experimental studies demonstrate that TSS-associated *S. aureus* strains can cause a similar illness in rabbits.

Similarly, there is strong evidence that the ability to make TSST-1, previously known as pyrogenic exotoxin C,⁴⁰ staphylococcal enterotoxin F,⁴¹ and several other names, is characteristic of, although not universal among, TSS-associated *S. aureus* strains. Thus, 90–100% of *S. aureus* isolates recovered from the vagina, cervix, or used tampon in menstrual TSS cases produce TSST-1, compared with only 10–20% of vaginal or nasopharyngeal isolates from healthy controls.^{26,40–43} On the other hand, only 60–70% of *S. aureus* strains recovered from normally sterile sites in patients with nonmenstrual TSS produce TSST-1,^{44–46} suggesting that other staphylococcal toxins, particularly staphylococcal enterotoxin B (SEB), are capable of inducing a clinically indistinguishable syndrome. Two studies of historical strains of *S. aureus* demonstrated that the proportion of strains capable of making TSST-1 has changed over time and was generally higher in the mid to late 1970s than in earlier time periods.^{42,47} Interestingly, that proportion appears to have declined somewhat in the early 1980s, when the incidence of TSS was peaking. More recent data concerning the proportion of *S. aureus* strains that make TSST-1 have not been published.

TSS-associated *S. aureus* strains have also been characterized phenotypically with respect to a number of other properties, including phage type, antimicrobial susceptibility, resistance to heavy metals, production or activity of various enzymes, and presence of plasmids and bacteriophages. The picture that emerges with regard to these characteristics, while consistent, is by no means invariable or unique. A higher proportion of TSS-related *S. aureus* strains are lysed by phase types 29 and/or 52 (58–82%), as compared to only 12–28% of control strains.^{42,43,48} Similarly, TSS-associated strains generally are resistant to penicillin (and ampicillin), arsenate, and cadmium, while being susceptible to β -lactamase resistant antimicrobial agents, most other commonly tested antimicrobial agents, bacteriocins, and mercury.^{6,49,50} Other characteristics that appear to distinguish these strains from other *S. aureus* strains include decreased production of hemolysin, lipase, and nuclease^{49,51}; tryptophan auxotrophy⁵²; decreased lethality in chick embryos⁴⁹; increased pigment production⁵³; and increased casein proteolysis.⁵³ TSS-associated strains also have been reported to be less likely to carry plasmids and more likely to carry lysogenic bacteriophage than control strains. There is controversy over whether or not the gene coding for TSST-1 can be transferred by lysogeny.^{54,55}

It should be noted that most of the strains examined in the above studies were recovered from the genital tract in menstrual TSS cases. Thus, the results are not necessarily applicable to *S. aureus* strains associated with nonmenstrual TSS, and there is some evidence to

suggest that such strains, recovered from normally sterile sites in patients with nonmenstrual TSS, are less likely to be lysed by phage types 29 and/or 52 than are strains from menstrual TSS cases.⁴⁴ At the same time, as noted above, they also are less likely to make TSST-1.

► DESCRIPTIVE EPIDEMIOLOGY

Prevalence and Incidence

Carriage of *S. aureus* on the skin and in the nasopharynx and vagina is very common. Numerous cross-sectional studies have demonstrated that 30–40% of individuals carry *S. aureus* in the nasopharynx and 5–15% of women carry *S. aureus* in the vagina.^{22–24,34–39} The corresponding figures for TSST-1 producing *S. aureus* are 5–15% (nasopharynx) and 1–5% (vagina). Thus, carriage of *S. aureus* strains believed to be capable of causing TSS is also very common.

In contrast, TSS is a rare disease. After it became a notifiable disease in 1983, the number of cases reported annually in the United States initially ranged from 400 to 500. More recently, approximately 100–150 cases have been reported annually to the Centers for Disease Control and Prevention (CDC).⁵⁶ The most reliable estimates of incidence rates come from hospital-based record review studies. In these studies, both diagnosed and previously undiagnosed cases of TSS were ascertained in an unbiased way by reviewing thousands of medical records of hospitalized patients with one of a long list of discharge diagnoses likely to be indicative of misdiagnosed cases of TSS. In one such study in Colorado, the annual incidence of TSS in women between the ages of 10 and 30 was 15.8 per 100,000 in 1980.¹² In a similar study in California, the incidence rate in women between the ages of 15 and 34 was only 2.4 per 100,000 in 1980.¹¹ The incidence rate in men of the same age group in the latter study was consistently less than 0.5 per 100,000 in all of the years studied.

Initial estimates of the incidence of diagnosed TSS were derived from statewide surveillance systems established in late 1979 or early 1980. The states with the most aggressive case-finding methods reported annual incidence rates at that time of 6.2 per 100,000 menstruating women (Wisconsin),⁵ 8.9 per 100,000 menstruating women (Minnesota),⁵⁷ and 14.4 per 100,000 females 10–49 years of age (Utah).⁵⁸ An overall estimate of 0.8 per 100,000 total population of hospitalized, diagnosed TSS in the United States in 1981 and 1982 was derived from a national hospital discharge survey.¹⁹ More recent estimates of the incidence of TSS, based on admittedly incomplete passive surveillance, are even lower.⁵⁶ While TSS has been documented in numerous other countries, no estimates of incidence rates for other countries are available.

The discrepancy between the frequency of colonization and/or infection with TSST-1-producing *S. aureus* and the rarity of TSS is thought to be due to the fact that most individuals have detectable anti-TSST-1 antibodies. By age 30, more than 95% of men and women have such antibodies.²⁸ The origin of these antibodies is unknown.

Epidemic Behavior and Contagiousness

Because TSS increased dramatically in incidence in the United States beginning in 1979 in comparison with previous years,^{11,12,20} it would be correct to say that an epidemic of TSS occurred at that time. TSS does not occur, however, in explosive epidemics in the same way that dengue and meningococcal disease do, although strains of *S. aureus* that produce TSST-1 are, like other *S. aureus* strains, transmitted readily by person-to-person spread.

Geographic Distribution

United States

Cases of TSS have been reported in all 50 states and the District of Columbia, but the incidence of reported cases has varied substantially between states and regions.^{9,10,56} Variation in the completeness of diagnosis and reporting of cases undoubtedly accounts for some of

the observed differences, but there is substantial evidence that at least some of the observed differences are real. For example, a study of hospital discharge data in which differences in the reporting of cases could not have been a factor showed that the overall annual incidence of hospitalized cases varied by region between 0.24 and 1.43 per 100,000 in 1981–1982.¹⁹ In this study, however, potentially large differences in the completeness with which TSS cases were diagnosed and different standards for hospitalizing patients suspected of having TSS could not be ruled out. More convincing evidence for true geographic differences in incidence rates comes from the virtually identical hospital record review studies conducted in Colorado and northern California, in which variation in the diagnosing and reporting of cases was largely or completely eliminated.^{11,12} As noted earlier, the incidence of TSS in 1980 in females 10–30 years of age was 15.8 per 100,000 in Colorado, but only 2.4/100,000 females 15–34 years of age in northern California. However, a prospective study employing active surveillance for TSS in five states (Missouri, New Jersey, Oklahoma, Tennessee, and Washington) and one large county (Los Angeles) showed that in 1986, the incidence of menstrual TSS was in the range of 1 per 100,000 females 15–44 years of age in all six study areas.⁵⁹

Studies of *S. aureus* strains from the United States show no geographic differences in what proportion make TSST-1.⁴⁷ Similarly, anti-TSST-1 antibodies are found in similar proportions of healthy individuals in different parts of the United States.

Other Countries

Documented cases of TSS have been reported from Canada, most of western Europe, Australia, New Zealand, Japan, Israel, South Africa, and elsewhere. No information concerning incidence rates of TSS outside of the United States is available. However, the proportion of cases in other countries associated with menstruation and tampon use appears to be substantially lower than in the United States, in keeping with the fact that tampon use in general is less frequent in other countries and superabsorbent tampons are less widely used.

Temporal Distribution

Substantial controversy has surrounded the interpretation of observed changes over time in the diagnosis and reporting of TSS cases. Data from the passive national surveillance system suggested that the number of cases began to rise in 1978, peaked in 1980, and then declined and leveled off, with virtually all of the observed differences being due to changes in the number of menstrual TSS cases reported.^{9,10} (Fig. 18-10). While this pattern also was observed in some individual states employing vigorous case-finding methods (e.g., Utah and Wisconsin), a different pattern was seen in Minnesota, where no decline in the number of cases was observed in 1981.⁶⁰ Because of the documented impact of publicity on reporting of TSS cases and the undoubted fluctuations over time in the likelihood that cases would

*FDA, food and drug administration; includes definite and probable toxic shock syndrome cases

Figure 18-10. Reported cases of toxic shock syndrome, United States, 1979–1994.

be diagnosed and/or reported, the results of studies that eliminate or minimize these influences are important in interpreting temporal trends.

While the three published hospital record review studies all suffer from having a relatively small number of cases of TSS to analyze statistically, the results of all three studies are consistent. In the California study, the incidence of TSS in women increased consistently through 1980, fell somewhat in 1981 and 1982, and then increased again in 1983, while the incidence in men remained consistently

low (Fig. 18-11). In the Colorado study, the results were similar except that the decrease in 1981 compared with 1980 was sharper (Fig. 18-12). The similarity of the pattern in Colorado is even more apparent, if cases meeting only the authors' proposed screening definition for TSS and not the more rigorous collaborative case definition are removed.⁶¹ Similar trends are seen in the study from Cincinnati, although incidence rates cannot be estimated in this study.²⁰

Thus, there is convincing evidence that hospitalized cases of TSS in females of menstrual age increased in the late 1970s, irrespective of

Figure 18-12. Annual incidence per 100,000 population of toxic shock syndrome in hospitalized patients ≤ 30 years of age meeting either the strict or the screening case definition in two Colorado counties, 1970–1981.

any changes in the recognition and reporting of the disease. A similar increase was not apparent among men. There is also some evidence that this upward trend in the incidence of TSS through 1980 was reversed in several geographic areas, at least temporarily, in 1981.

Age

TSS can occur in individuals of all ages and has been documented in a newborn baby and in patients up to 80 years of age. However, data from both passive and active surveillance systems and from the California record review study indicate that younger women are at greater risk of developing TSS than are older women. Of cases associated with menstruation reported nationally, almost 60% have been in women 15–24 years of age, compared with only 25% in women 25–34 years of age.^{9,10} Cases in women 35–44 years of age are even less common. Furthermore, the highest age-specific incidence rates consistently have been observed in women 15–19 or 15–24 years of age. Thus, in the California record review study, the annual incidence rate was 2.6 per 100,000 women 15–19 years of age compared with rates of 0.8 to 1.4 per 100,000 among women 20–24, 25–29, and 30–34 years of age.¹¹ Similarly, in Minnesota the annual incidence of menstrual TSS among women 15–24 years of age was 13.7 per 100,000 compared with rates of 2.3 in those <15 years of age and 6.6 in those ≥25 years of age.⁵⁷ The age distribution of TSS cases unassociated with menstruation is more uniform, especially if cases in postpartum women are excluded.³⁰

Sex

All available evidence clearly indicates that TSS is much more common among women of menstrual age than among men of the same age. Of U.S. cases reported through passive surveillance, 95% have been in women and 5% in men.^{9,10} In the California record review study, the overall incidence of TSS in women 15–34 years of age during the time period 1972–1983 was 15 times that in men of the same age (1.5 vs. 0.1 per 100,000 person years).¹¹ This marked difference in incidence rates between men and women undoubtedly relates primarily to the fact that most cases of TSS are associated with menstruation and tampon use. What appears to be an increased risk of TSS during the postpartum interval and the apparent association between TSS and the use of barrier contraception probably contribute further to this pattern.^{29,30,62} The incidence of TSS associated with other types of staphylococcal infections (e.g., surgical wound infections, cutaneous, and subcutaneous lesions) appears to be similar in men and women.^{29,30,59}

Race

Although it has been apparent since at least 1980 that TSS occurs in individuals of all racial groups,⁸ the over-whelming majority (93–97%) of reported cases have been in whites, who make up only 80–85% of the U.S. population.^{9,10} Likely explanations for this discrepancy fall into two categories: biases in the diagnosis and reporting of cases on the one hand and true racial differences in either susceptibility to TSS or exposure to risk factors on the other. It has been postulated that increased difficulty in recognizing the rash on dark-skinned individuals, poorer access of minority groups to medical care, and the relative paucity of individuals of races other than white in areas with active TSS research efforts have all contributed to the observed racial distribution of cases. However, data from the California record review study indicate that in the 15–34 age group TSS does indeed disproportionately affect whites.¹¹ All of the 54 definite cases (most of which are related to menstruation) found in that study were in whites, while only 81% of the population at risk was white ($p < 0.05$; Fisher's exact test, two-tailed).

It has been noted that the racial distribution of patients with non-menstrual TSS (87% white) more closely resembles the racial distribution of the U.S. population than does the racial distribution of patients with menstrual TSS (98% white).^{10,59} Taken together with

studies demonstrating that young white women use tampons far more often than do comparably aged women of other racial groups,^{63–66} these results suggest that observed race-specific differences in incidence rates are due, at least in part, to different levels of exposure to an important risk factor for developing TSS during menstruation.

Occupation

There is no evidence to suggest that any given occupational group, including health-care providers, is at increased risk of developing TSS.

Occurrence in Different Settings

As noted below, transmission of strains of *S. aureus* capable of causing TSS has been demonstrated in the hospital setting.^{67–69} There is also evidence of spread of these strains and occasional clustering of cases in households and in military installations (CDC, unpublished observations).

Socioeconomic Factors

It is unclear to what extent the marked racial variation in tampon use, especially among adolescents, reflects socioeconomic rather than racial differences. Other socioeconomic factors have not been noted to play a role in TSS.

Other Factors

Menstrual TSS

Numerous case-control studies conducted in 1980–1981 examined risk factors for developing TSS during menstruation (Table 18-3). These studies consistently found that tampon use increased the risk of menstrual TSS (the Oregon study, with its small number of cases, while not finding an association between menstrual TSS and tampon use in general, did find an association with a particular brand of tampon).^{5,6,15,16,57,70} Included among these studies are two performed before any information concerning this association had appeared in the medical literature or lay press.^{5,6} A study comparing tampon use among women with menstrual TSS in 1983 and 1984 with tampon usage patterns ascertained via a national survey found evidence of a continuing increased risk of menstrual TSS among tampon users.¹³ Furthermore, a multistate case-control study of menstrual TSS cases with onset in 1986–1987 documented that this association persisted at that time.¹⁸ No additional case-control studies have been conducted since that time.

Two early case-control studies demonstrated that the risk of menstrual TSS varied with tampon brand and/or style (i.e., absorbency), suggesting that risk was a function of tampon absorbency and/or chemical composition.^{15,16} The two more recent studies document clearly that risk of menstrual TSS is directly correlated with measured in vitro tampon absorbency,^{13,18} independent of chemical composition, but that chemical composition is also a factor.¹³ It is interesting to note that the correlation with tampon absorbency has persisted, despite the major alterations in chemical composition and marked decreases in the absorbencies of available tampons that have occurred since 1980. A reanalysis of data from earlier studies has suggested that the oxygen content of tampons is a better predictor of the risk of menstrual TSS than either chemical composition or absorbency.¹⁴ In vitro studies examining the effect of various surfactants on TSST-1 production have shown that they can have a dramatic effect on production of this toxin.⁷¹ These results suggest another tampon characteristic (i.e., type of surfactants present) that might influence the risk of menstrual TSS in users of various brands and styles.

The early case-control studies also examined the role of a number of other factors in determining the risk of developing TSS during menstruation. Four of the studies found that women with TSS were less likely to use oral contraceptives than were controls, although the differences in individual studies were not statistically significant.^{5,6,15,58}

†NS, not significant.

‡NA, data not available.

One study found that continuous use of tampons during the menstrual period was associated with an increased risk of TSS,⁶ while in another study a similar association, present on univariate analysis, did not remain significant in a multivariate analysis.¹⁵ Of four studies looking at the relationship between the history of a recent vaginal infection and the risk of TSS, only one found such an association. Factors found not to be related to the risk of developing menstrual TSS in one of more studies included marital status, income, parity, sexual activity, bathing, frequency of exercise, alcohol use, smoking, history of vaginal herpes infections, and frequency of changing tampons.

Postpartum TSS

Although numerous cases of TSS occurring during the postpartum interval have been reported, the lack of precise information concerning the incidence of TSS in various settings makes it difficult to be certain that the incidence in postpartum women is elevated. Those cases of postpartum TSS not related to infection of a cesarean section incision or an infection of the breast (i.e., mastitis and breast abscess) have occurred predominantly in association with the use of tampons to control the flow of lochia or the use of barrier contraception (i.e., diaphragms and contraceptive sponges).³⁰

Postoperative TSS

TSS has been associated with *S. aureus* surgical wound infections following a wide array of surgical procedures.⁶⁸ It has been suggested, however, that patients undergoing nasal surgery are at particularly high risk, presumably due to the frequency of *S. aureus* carriage in the nasopharynx and the difficulty of eradicating such carriage.²² The common use of “nasal tampons” and other packing material following nasal surgery also may play a role.

Other Nonmenstrual TSS

TSS can result from *S. aureus* infection at any body site. However, many nonmenstrual TSS cases are the result of cutaneous and subcutaneous *S. aureus* infections. Also, cases of TSS associated with *S. aureus* infection of the respiratory tract in the setting of influenza have received substantial attention.⁷² Risk factors for the development of such infections and/or associated TSS have not been studied. A relatively small proportion of nonmenstrual, nonpostpartum TSS cases are associated with vaginal *S. aureus* infections. One risk factor that has been identified in such cases is the use of contraceptive sponges.⁶² It remains uncertain whether or not diaphragm use is similarly associated with an increased risk of nonmenstrual TSS.

▶ MECHANISMS AND ROUTES OF TRANSMISSION

Like all *S. aureus* strains, those capable of causing TSS appear to be transmitted readily by person-to-person spread, both within the hospital and in the community. There is convincing evidence that a nurse transmitted a TSS-associated strain of *S. aureus* to hospitalized burn patients⁶⁷ and suggestive evidence that some cases of postoperative TSS are due to nosocomial spread of the causative organism by hospital personnel.^{68,69} In addition, vertical transmission from mother to newborn, with the development of TSS in both, has been reported.⁷³ Outside the hospital setting, transmission between husband and wife has been suggested by the almost simultaneous appearance of TSS in both, as has transmission between mother-daughter pairs (unpublished reports to the CDC). It is assumed, but not proven, that transmission in all these instances was by direct person-to-person spread. Nevertheless, it should be emphasized that in many TSS cases, particularly those associated with a focus of infection in the vagina, it may well be that disease is due to the introduction and/or multiplication of an endogenous *S. aureus* strain rather than to an exogenous source of infection.

▶ PATHOGENESIS AND IMMUNITY

TSS results from an infection with an appropriate strain of *S. aureus* in a susceptible host. Once a nidus of infection is established, onset of symptoms typically occurs 1–3 days later. The best evidence concerning incubation period comes from patients with postoperative TSS due to surgical wound infections. In these patients, the date when the infection became established is usually the day of surgery, and thus can be determined unequivocally. The median incubation period in such patients is two days.⁶⁸ When TSS is caused by *S. aureus* infection of the vagina during menstruation, onset of symptoms is typically on the third or fourth day of menstruation, although it can be earlier or later.

In most cases of TSS, the toxin TSST-1 is the bacterial product most likely to be responsible for many of the observed signs, symptoms, and abnormalities of laboratory values. There is, however, substantial evidence that one or more other staphylococcal products, particularly enterotoxin B, are capable of causing an indistinguishable illness.^{44,46} Furthermore, bacterial products other than TSST-1 that are made more commonly by *S. aureus* strains recovered from patients with TSS than by other strains have been described (see Sec. 4). For these reasons, it is likely that other staphylococcal products play a role in the pathogenesis of TSS. Furthermore, there is evidence that some of the multisystem derangements frequently observed in patients with TSS are due to the profound hypotension or shock that can occur and only indirectly to any staphylococcal products. For example, renal failure in TSS is probably secondary to hypotension-induced acute tubular necrosis, which in turn is the result of multiple factors, including: hypovolemia due to vomiting, diarrhea, increased insensible losses associated with a high fever and inability to ingest or retain fluids; and “thirdspacing” of fluids. Uptake of “endogenous” endotoxin from gram-negative intestinal flora also has been proposed as playing a role in the pathogenesis of TSS.⁷⁴

The biological properties of TSST-1 have been studied *in vitro* and *in vivo*, and attempts have been made to develop an animal model of TSS. *In vitro*, purified TSST-1 has been shown to stimulate the proliferation of T lymphocytes,⁷⁵ to inhibit immunoglobulin synthesis,⁷⁶ and to be a potent stimulator of interleukin-1 production by macrophages and monocytes.^{77,78} TSST-1 also has been shown to bind to and be internalized by epithelial cells,⁷⁹ suggesting that it can be absorbed from focal sites of infection. *In vivo*, TSST-1 has been shown to be pyrogenic,⁴⁰ to induce lymphopenia,⁸⁰ to decrease the clearance of endotoxin,⁸¹ and to increase susceptibility to endotoxin-induced shock.⁷⁴ It is now clear that many of the effects of TSST-1 are due to its potent *superantigen* properties, acting through the release of immune cytokines.⁸² While initially reported to be an enterotoxin (as evidenced by induction of vomiting in monkeys), preparations of TSST-1 not contaminated with other staphylococcal enterotoxins do not appear to induce vomiting.⁸³

Attempts to reproduce TSS in animals have included using mice, rabbits, goats, baboons, chimpanzees, and rhesus monkeys.^{55,84–93} In these studies, investigators either have attempted to infect the animals with TSS-associated *S. aureus* strains at one of a variety of sites (previously implanted subcutaneous chambers, vagina, uterus, and muscle) or have injected purified TSST-1 as a bolus or continuous infusion. The animal models that come closest to reproducing the syndrome observed in humans have been those using rabbits. Live TSS-associated *S. aureus* organisms inside a previously implanted subcutaneous chamber and continuous infusion of purified TSST-1 both result in fever, hyperemia of mucous membranes, hypocalcemia, elevated creatinine phosphokinase (CPK) and hepatic enzymes, renal failure, and death in a high proportion of rabbits.^{84,88} Also, the pathological changes observed postmortem in these animals are similar to those reported in patients dying of TSS.^{94,95}

These rabbit models have been used to study the host factors in susceptibility to TSS suggested as important by clinical and epidemiological data or by *in vitro* results. It has been found that the age, sex, hormonal status, and strain of rabbits used all have a substantial impact on susceptibility to “rabbit TSS.”^{85,86} Thus, older rabbits have been reported to be more susceptible than younger rabbits. Similarly,

male rabbits appear to be more susceptible than female rabbits, although castration abolishes this difference and estrogens protect male rabbits. Experiments concerning the contribution of endogenous endotoxin (i.e., endotoxin released by gut flora) to the pathogenesis of TSS have yielded conflicting results, although it appears that blocking the effect of endotoxin by giving polymyxin B does not consistently prevent rabbit TSS.⁸⁸ Preexisting anti-TSST-1 antibody, however, does appear to protect against TSS in the rabbit,⁹¹ and corticosteroids in high doses also decrease mortality.⁸⁸

Because of the observed association between menstrual TSS and tampon use, many investigators have looked at the effect of tampons and their constituents on the growth of *S. aureus* and the production of TSST-1 in vitro. At the same time, the effect of environmental conditions such as pH, PO₂, PCO₂, and cation concentration on the production of TSST-1 has been investigated. In general, studies have shown that tampons and their individual components inhibit the growth of *S. aureus* in vitro, regardless of the growth medium.^{96,97} Although some studies have suggested that *S. aureus* can use various tampon constituents as an energy source, these results have been challenged and their relevance to human disease questioned.^{98–100} Also controversial is the effect of tampons on the production of TSST-1 in vitro, with some studies showing that certain tampons and tampon constituents increase TSST-1 production and other studies showing no effect or inhibition of toxin production.^{97,99} It has been suggested that the effect of tampons on TSST-1 production (and possibly on the risk of menstrual TSS) is mediated by changes in the availability of magnesium, which is bound by certain tampon components.¹⁰¹ The various types of surfactants found on tampons also appear to influence the production of TSST-1, at least in vitro.

Growth conditions appear to be important in determining the amount of TSST-1 produced. Thus, an aerobic environment, neutral pH, and low levels of glucose, magnesium, and tryptophan all increase TSST-1 production, although some controversy has arisen about the effect of magnesium concentration on TSST-1 levels.^{101–105} It has been shown that in patients with TSS related to focal sites of *S. aureus* infection, growth conditions within the infected focus are well suited to TSST-1 production.¹⁰⁵ Also, while the vagina generally has been considered to be anaerobic, studies have shown that a substantial amount of oxygen is introduced when a tampon is inserted, leading to speculation that the amount of oxygen introduced with a tampon may be an important factor in explaining the increased risk of menstrual TSS among tampon users.¹⁰⁶ A role for proteases of either bacterial or human origin in the pathogenesis of TSS also has been suggested.¹⁰⁵ An earlier theory that the association between menstrual TSS and tampon use was mediated by the demonstrated induction of vaginal ulcerations by tampons¹⁰⁷ has received less attention ever since similar vaginal ulcerations were reported in at least one patient with menstrual TSS who did not use tampons.⁹⁴

► PATTERNS OF HOST RESPONSE

Clinical Features

An illness meeting all the criteria of the established TSS case definition is, by the very nature of the criteria, severe, and the majority of such patients are hospitalized for treatment. Some patients experience the relatively gradual onset of sore throat, fever, fatigue, headache, and myalgias over 24–48 hours, followed by vomiting and/or diarrhea, signs of hypotension, and the appearance of the characteristic diffuse “sunburn-like” macular skin rash. Other patients appear to have a much more dramatic onset over the course of several hours, with some reporting that they can remember the exact moment when they suddenly felt overwhelmingly ill.

Because an established set of strict criteria is used to define someone as having or not having TSS, all of the cases so defined are, not surprisingly, alike, regardless of the site of infection with *S. aureus*. There is, however, some variation. The temperature elevation in patients with TSS, while sometimes modest, can be extreme, with

temperatures in the range of 104–106°F being fairly common. The evidence of hypotension in an individual case can range from mild orthostatic dizziness to profound shock. The characteristic macular skin rash can be dramatic and obvious, with the patient appearing bright red throughout; it can be subtle and difficult to appreciate, particularly in dark-skinned individuals; or it can be localized. Similarly, the desquamation that occurs during convalescence (usually 5–15 days after the acute illness) can be of subtle flaking and peeling of skin on the face and/or trunk or can involve the loss of full-thickness sheets of skin, particularly on the fingers, hands, and feet. Depending on which systems are affected most prominently in an individual case, the multisystem involvement in TSS can produce rather different clinical pictures. In some patients, the involvement of the mucous membranes (e.g., sore throat, conjunctival and oropharyngeal injection) is severe and most prominent, while in other patients the gastrointestinal symptoms (vomiting and/or diarrhea) are predominant. Similarly, myalgias, thrombocytopenia, and involvement of the hepatic and renal systems can range from nil to severe. One study has suggested that the clinical spectrum of disease differs between menstrual and nonmenstrual TSS cases.⁴⁵

Patients who receive aggressive supportive therapy (e.g., fluids), appropriate antimicrobial agents, and drainage of any focal *S. aureus* infection usually respond rapidly and improve over the course of several days. However, patients in whom therapy is either delayed or in whom a focal *S. aureus* infection is not eradicated can have a stormy, life-threatening course. In cases meeting all the established criteria, the case-fatality ratio is 1–3% overall, although it increases with increasing age.¹⁹

The spectrum of illness of TSS has not been defined adequately due to the lack of a specific diagnostic laboratory test. It is evident that some illnesses not meeting all the criteria of the strict case definition, which was devised for use in epidemiological studies, represent milder forms of TSS. For example, few would question that an individual whose highest recorded temperature was 101.8°F, but who otherwise met all of the established criteria, had TSS. A number of authors have described patients of this kind,^{108,109} and some have attempted to fashion simplified and/or less rigorous case definitions for TSS.¹¹⁰ It is apparent that less rigorous case definitions are likely to be more sensitive but less specific in identifying TSS cases. Ultimately, however, it is not possible, in the absence of a specific diagnostic test, to determine where along a spectrum of increasingly milder and/or more atypical cases illnesses cease to be TSS and start to be something else. Thus, it is unclear whether a tampon-using menstruating woman with *S. aureus* in the vagina (or anyone else) who experiences headache, fatigue, and nausea could represent a very mild form of TSS. Such distinctions are made all the more difficult because of the relative frequency with which completely asymptomatic individuals are colonized with TSST-1-producing *S. aureus* in the nasopharynx, vagina, and probably other sites that are not normally sterile.

Diagnosis

As noted above, TSS can occur in individuals of any age, sex, and race. However, most recognized cases occur in a limited number of clinical settings. In women of reproductive age, TSS is most commonly seen during the menstrual period and the postpartum interval, although it can occur at other times as well, in association with focal *S. aureus* infections and in users of barrier contraception. TSS during pregnancy, however, is quite uncommon. Although patients undergoing nasal surgery may be at elevated risk, TSS related to a surgical wound infection is a possibility in any postoperative patient, particularly during the first 24–72 hours. In many such instances, there will be few or no local signs that the operative site is infected.⁶⁸ As noted earlier, the median interval between surgery and onset of TSS in such cases is two days, but the range is 12 hours to many weeks. TSS is an infrequent but serious consequence of focal *S. aureus* infections at every conceivable body site, although cutaneous and subcutaneous abscesses and other similar infections appear to predominate. In addition,

TABLE 18-4. DIFFERENTIAL DIAGNOSIS IN PATIENTS WITH SUSPECTED TSS

Kawasaki syndrome

Tubo-ovarian abscess
Staphylococcal scalded skin syndrome
Drug reactions/Stevens–Johnson syndrome

TSS has been reported to be a life-threatening complication of postinfluenza *S. aureus* infections of the respiratory tract.^{111,112}

The differential diagnosis for a patient suspected of having TSS depends, in part, on which features of the illness are most prominent. For example, patients in whom sore throat and fever predominate early are frequently suspected initially of having streptococcal or viral pharyngitis. In cases in which diarrhea and vomiting are more prominent, viral gastroenteritis is often considered. When the rash becomes apparent, scarlet fever, streptococcal TSS, and drug reactions are often suspected.

The differential diagnosis also can be influenced by the patient’s age and sex and the clinical setting in which the illness occurs. For example, cases in infants and very young children must be distinguished from Kawasaki syndrome and staphylococcal scalded skin syndrome. Similarly, in postpartum or postabortion women, other causes of fever and hypotension must be considered, such as endometritis and septic abortion. In individuals with appropriate exposure histories, leptospirosis, measles, and Rocky Mountain spotted fever should be included in the differential diagnosis. In summary, TSS can be confused fairly readily with a wide range of other conditions (Table 18-4).

► CONTROL AND PREVENTION

General Concepts

Menstrual TSS

Most strategies for decreasing the incidence of TSS have focused on menstrual TSS and its relationship to tampon use. In light of the demonstrated association between tampon use and risk of developing menstrual TSS, women were advised in 1980 that they could minimize their risk of developing menstrual TSS by not using tampons. In response, many women stopped using tampons, at least temporarily. The proportion of menstruating women who used tampons fell from approximately 70% in 1980 to less than 50% in 1981, but has rebounded to approximately 60–65% since that time.

In response to epidemiological and in vitro laboratory evidence concerning the possible roles of tampon absorbency and chemical composition in determining risk of menstrual TSS, most tampon manufacturers have dramatically altered both the absorbency and chemical composition of their products. After increasing markedly in the late 1970s, the measured in vitro absorbency of tampons has dropped sharply since 1979–1980, and one component, polyacrylate, has been eliminated from tampon formulations. In addition, one brand of tampons found to be associated with a high risk of menstrual TSS was withdrawn from the market altogether in 1980. All tampons sold in the United States in 2007 are made of cotton, rayon, or a blend of cotton and rayon.

All tampons now carry a label explaining the association between tampon use and menstrual TSS and describing the signs and symptoms of the illness. Tampon packages also carry a statement that women should use the lowest absorbency tampon consistent with their needs. Uniform absorbency labeling of tampons was required by the Food and Drug Administration beginning in 1989.

Although frequent changing of tampons has been recommended as a way of decreasing the risk of menstrual TSS, there is no evidence to suggest that changing tampons more often reduces risk. Evidence from one study suggests that alternating tampons and napkins during a menstrual cycle may decrease the risk of TSS.⁶

Postpartum TSS

Because women may be at increased risk of TSS during the postpartum period, they should avoid the use of tampons and barrier contraception during that interval.

Hospital-Acquired TSS

Other than those measures designed to minimize nosocomial infections in general (e.g., good hand-washing practices) and those recommended specifically for patients with other types of staphylococcal infections, there are no proven methods for decreasing the risk of TSS associated with infected surgical wounds and other nosocomial *S. aureus* infections.

Antibiotic and Chemotherapeutic Approaches to Prophylaxis

Appropriate antimicrobial therapy of an initial episode of menstrual TSS, combined with discontinuing tampon use, has been shown to reduce the risk of recurrent episodes during subsequent menstrual periods.⁵ The value of follow-up cultures and prophylactic antimicrobial agents in women with a history of menstrual TSS is unproven, although such measures may be justified in women who have had recurrent episodes of TSS. Because carriage of *S. aureus* at various body sites is so common and cases of TSS are relatively rare, there is no role for obtaining cultures from or giving chemoprophylaxis to individuals without a prior history of TSS.

Immunization

Although some consideration was given to attempting to develop a toxoid vaccine from TSST-1 soon after its discovery, no concrete steps in this direction have been taken. Given the high proportion of the population with naturally occurring anti-TSST-1 antibodies and the relative rarity of TSS, it would be prohibitively expensive and impractical to demonstrate that such a vaccine yielded clinical protection.

► UNRESOLVED PROBLEMS

Unresolved problems in our understanding of TSS relate primarily to its pathophysiology. While a clear link between the use of tampons and risk of menstrual TSS has been established, the specific characteristics of tampons responsible for this increased risk are unknown. The relative importance of absorbency, chemical composition, oxygen content, and perhaps other tampon characteristics, such as the surfactants used in their manufacture, in determining risk is uncertain. Similarly, while a direct correlation between measured tampon absorbency and risk of menstrual TSS has been demonstrated, it remains unclear whether or not users of the lowest absorbency tampons are at greater risk than nontampon users. At the same time, the role of tampon chemical composition in determining risk is ill-defined. As a result of all these uncertainties, it is unknown whether or not the “perfect tampon” (i.e., one that offers menstrual protection and has no associated increased risk of menstrual TSS) currently exists or can be developed.

Reye's Syndrome

Robert B. Wallace

What is now known as Reye's syndrome was first described in Australia in 1963,^{1,2} and shortly thereafter a series of similar cases was published in the United States.³ It is unclear whether cases occurred in prior eras. The syndrome as originally described was characterized by an acute encephalopathic clinical picture and fatty liver in children, with major neurological and metabolic manifestations often leading to death.⁴ Epidemiological, clinical, and metabolic studies have added considerable information on the nature of the condition, but it remains a syndrome that may be comprised of diverse causes and pathogenetic mechanisms.

Case Definition and Surveillance

Rates of occurrence of Reye's syndrome depend in part on the skill in clinical case recognition, the rigor of surveillance, and case definition.⁵ Clearly some definitions and criteria are much more encompassing than others, and will change the apparent occurrence rates of the syndrome. The epidemiological case definition used by the U.S. Centers for Disease Control⁵ includes:

1. Acute noninflammatory encephalopathy with:
 - a. Microvascular fatty metamorphosis of the liver confirmed by biopsy or autopsy, or,
 - b. A serum alanine aminotransferase (ALT or SGPT); a serum ammonia greater than three times normal
2. If cerebrospinal fluid is obtained, leukocyte count must be $\leq 8/\text{mm}^3$.
3. In addition, there should be no other more reasonable explanations for the neurological or hepatic abnormalities.

The illness generally occurs in two phases beginning with a clinical viral illness, with respiratory or gastroenterological manifestations, and within a few days progressing to overt encephalopathy. Case reports continue to appear in the worldwide literature, and have been reported in the neonatal period and in adults, although most occur in infants and children. The syndrome has been clinically staged according to the level of consciousness and corresponding physical signs.⁶

Other definitions have been more specific⁷ but none will be wholly satisfactory until a "gold standard" for the diagnosis appears, likely encompassing specific biomarkers. Recent evidence suggests, for example, that at least some cases originally labeled as being the syndrome were associated with known inborn errors of metabolism.⁷ Diagnosis rates may also vary according to the frequency of biopsy and autopsy, although the specificity of histopathological changes has been disputed. In fact, as more metabolic diseases are discovered that have a Reye's syndrome-like clinical picture, the clinical pattern of remaining cases may be changing over time.⁸ Continuous surveillance of Reye's syndrome began in 1976 in the United States, and the incidence of the syndrome has clearly decreased since. There were as many as 555 cases reported in a single year. However, in recent years the number of reported cases has been much smaller. Despite this, the surveillance effort remains active, and reporting is encouraged. With respect to reported occurrence in the United States, the author was unable to find a specific, dedicated surveillance report since the late 1990s.

There have also been differences in occurrence patterns among countries. For example, in Australia, occurrences may be nonseasonal

and children with Reye's syndrome have tended to be younger, generally less than five years of age. Cases in the United States occur predominantly in the fall and winter seasons, with a modal age distribution of 5–15 years. Further, the decline in the U.S. incidence rate for Reye's syndrome in the 1980s was initially more prominent in children under 10 years of age, although more recently all age groups have enjoyed some decrease. All of this suggests the possibility of age- and geography-related heterogeneity in the nature and causes of the syndrome.

Causes and Control of Reye's Syndrome

The causes of Reye's syndrome, including pathogenetic mechanisms, remain enigmatic,⁹ despite advances in understanding the pathogenesis of the condition.¹⁰ Hypotheses include genetic predisposition, possibly related to selected inborn errors of metabolism; exposure to environmental toxins such as various chemicals, pesticides, and mycotoxins; and use of medications such as salicylates and antiemetics. Also, at least in the United States, most cases are preceded by an acute viral infection, usually beginning 7–10 days prior to syndrome onset. Instances of infection with many categories of viruses have been documented, but the two most prominent are varicella and influenza B. Approximately, 5–30% of reported cases were varicella associated and explored the relation of case rates to the prevalent influenza strain.⁶ The synergistic effect of a second or dual viral infection in causing the syndrome has been postulated. Other viruses have been the subject of speculation but have not been rigorously evaluated.

The 1980s were characterized by the epidemiological assessment as to whether salicylates, particularly aspirin, have a causal role in the syndrome. After some anecdotal reports and case series, several case-control studies were performed in the United States. Although some of these were criticized on methodological grounds, in aggregate they suggested that the syndrome was at least in part related to the use of aspirin as treatment for the febrile illness preceding or during syndrome onset.¹⁰ No evidence was found implicating acetaminophen or other medications. In fact, the decline in Reye's syndrome incidence noted above has been related to public education and the subsequent decline in the use of aspirin for febrile conditions in children.¹¹ However, aspirin does not likely explain all cases of the syndrome, and other forces, yet unidentified, may be at work. In other countries such as Australia, aspirin was not related to the syndrome, particularly in children under 5 years of age,¹² and some of these cases are turning out to be other, defined metabolic disorders. Several other chemical agents and drugs have been suggested to be related to the syndrome, but conclusive evidence is generally lacking,¹³ and debate in the literature persists.¹⁴

► SUMMARY

Reye's syndrome appears to be an important and at least partially preventable entity, even if not fully characterized or etiologically explained. However, modern biology continues to suggest pathogenetic mechanisms. Continued surveillance is necessary to assess its public health impact, search for additional causes, and detect any important increases in incidence. Most authors suggest maintaining the recommendation to avoid aspirin use in children until more information is available.

Environmental Health

This page intentionally left blank

The Status of Environmental Health

Arthur L. Frank

Preventive medicine and public health advances continue to contribute to the well-being of persons, and central to modern changes are environmental issues that significantly shape the world. While great strides have been made over the past few decades, there are still areas of pressing concern and long-term danger.

While still not entirely clear in all respects, global climate change seems more and more real, with significant consequences if not modified. Recent policies in the United States have raised concerns about environmental degradation in such areas as water purity, clean air, the health of forests, and planning for future growth in population. It is becoming increasingly appreciated that sufficient clean water may not be as readily available in the future as in the past, with significant public impact. Superfund site cleanups have slowed dramatically. Endangered species seem more endangered.

On a global basis there have been pockets of progress. Individually the steps may seem limited, but over time they add up to significant protection of human health. Increasingly, countries are banning the use of asbestos, public transport—like the bus system in the capital of India—run on cleaner fuels, and cigarette smoking in public settings is decreasing through legislation. Far too much petroleum is still consumed, with a decreasing availability in sight and with insufficient reductions in use or development of alternative sources.

Occupational health problems continue to contribute to mankind's difficulties. Little has been done to reduce child labor around the world with increasing hazards for kids, given the nature of much of their work. The use of children in the sex trade or as soldiers is to be particularly condemned. Too many children work rather than go to school.

Some developed countries ban the use of certain dangerous chemicals, but not their production and export for use in societies where safety and health standards leave many at constant risk. The basic economics of work, with transnational movement of many jobs, contributes to the increasing gap between rich and poor, and to future lower standards of living in many places, without offsetting gains in less-developed countries.

As public health professionals, we must continue to fight for the well-being of all, and environmental issues can contribute to our collective betterment. This section of this famous book continues to address both traditional and cutting-edge issues. It has grown, as

public health has changed, from a small part of early editions into a significant part of the overall text. The topics covered essentially put a whole environmental and occupational text into the hands of readers, embedded in all the other wonderful material to be found in this venerable volume.

Over time there has been an increase in the number of journals devoted to occupational and environmental health issues. Given the often contentious and litigious nature of issues in this field, it has become ever more important that potential conflicts of interest be noted. Too often this does not happen. Regulations, especially in the United States, are now often effected by those who are to be regulated. This development, combined with the decreasing importance of labor unions with their declining membership, may leave many workers vulnerable to workplace hazards in the years ahead. With more and more jobs moving out of the United States there is a risk that workplaces in the future, compared to the recent past, will be globally less protected and safe.

Hindering the field of environment health as well is the continuing shortage of sufficient numbers of appropriately trained health professionals, including physicians, nurses, industrial hygienists, and others. Educational opportunities are shrinking, as is funding and support of such activities. Physicians, as a rule, still receive very little training in occupational medicine.

The basic methodology in terms of assessing workplace and environmental health hazards and their effects on people has not changed since the seminal work of Ramazzini more than 300 years ago. As is true for most medical assessments, obtaining a proper history is most important. The essential parts of such a history are to be found in Table 19-1 that provides a useful format for obtaining the necessary information in most, if not all, settings.

As one looks ahead to the future, there will continue to be problems at the heart of environmental and occupational health. Old issues will remain—child labor, agricultural work exposures, ergonomic problems, the use of tobacco—but there will be an added emphasis on newer issues such as genetic testing, use of mechanistic models to predict human disease, and the shift of certain diseases, like lung cancer, into societies poorly equipped to handle them. By making use of the materials in this section, it can be hoped that some lives will be made better.

TABLE 19-1. ENVIRONMENTAL AND OCCUPATIONAL EXPOSURE HISTORY

Current work: _____
 How long at this job? _____
 Description of work: _____

Any contact with dust, fumes, chemicals, radiation, noise, etc.?
 _____ Yes _____ No If yes, describe: _____

Describe any adverse effects noted: _____
 Are any fellow workers ill? _____ Yes _____ No
 If yes, describe: _____

Do you use any protective equipment at work?
 _____ Yes _____ No

Previous job history	<i>From</i>	<i>To</i>	<i>Exposures</i>
First regular job	_____	_____	_____
Next job	_____	_____	_____
Next job	_____	_____	_____
Vacation or temporary job	_____	_____	_____
Vacation or temporary job	_____	_____	_____

Military service or related exposures: _____

Have you lived near an industrial facility or has a family member worked in a setting where hazardous materials have been brought home? _____ Yes _____ No
 If yes, describe: _____
 Hobby history: _____
 Smoking history: _____
 Alcohol and drug use history: _____
 Comments: _____

Toxicology

Principles of Toxicology

Michael Gochfeld

Toxicology is the study of the harmful effects of chemicals, including drugs, on living organisms. Many books (see General References), and particularly *Toxicologic Profiles* published by the Agency for Toxic Substances and Disease Research, cover in detail the toxicology of individual substances. Freely available search engines allow access to innumerable Web pages with toxicological data, courses, and comments, the reliability of which requires careful assessment. This chapter focuses on generic and conceptual issues relating to properties of toxic substances in general, how they enter and move through the body, and the kinds of pathophysiological effects that they exert on various targets within the body that ultimately lead to the health effects. The rapid advances being made in molecular toxicology are beyond the scope of this chapter.

Historians¹ trace the modern history of toxicology back to Paracelsus (1493–1541), who recognized that a substance that was physiologically ineffective at very low dose might be toxic at high dose and therapeutic at intermediate dose. However, Gallo² identified human use of natural venoms in antiquity with a number described in the famed *Ebers Papyrus* (ca 1500 BC). In the Middle Ages, poisoning became a political tool and toxicological understanding therefore a necessity for both perpetrator and victim. In the past century, toxicology developed under the combined impetus of a burgeoning chemical industry, the quest for therapeutic agents, and concern over adulterated foods. In 1906, the United States enacted the Food and Drug Act, perhaps stimulated more by muckraking writings such as Upton Sinclair's *The Jungle*³ than by toxicologists.²

Although the general principles haven't changed since the previous edition (1998), toxicology is passing through a genetic revolution, with a heavy emphasis on understanding toxic mechanism at the presumably most basic level, the gene and its expression. Still in its infancy, and driven at first more by commercial ventures than scientific questions,^{4,5} toxicogenomics and proteomics offer great promise, but can be dealt with only slightly in this chapter. Likewise, the widespread importance of oncogenes, growth factors, cell cycling, cytokines, apoptosis as well as gene regulation, transcription factors, messenger cascades, have stimulated extensive research,⁶ but can be mentioned only briefly.

Toxic chemicals (*a*) enter and move through the environmental media (air, water, soil, food) at various concentrations until they come into contact with a target individual; (*b*) are taken up by inhalation, ingestion, through the skin, or by injection (exposure); (*c*) are absorbed into the bloodstream (uptake) reaching a certain concentration (blood level); (*d*) undergo complex toxicokinetics involving metabolism, conjugation, storage, and excretion as well as delivery to target organs (dose to target); and (*e*) affect some molecular, biochemical, cellular, or physiological structure or function to produce their adverse effect.

Internal distribution and the dose reaching a target organ, tissue, or cell are constantly modified by binding to carrier molecules, metabolic activation (or inactivation), storage in various tissues (e.g., polychlorinated biphenyls [PCBs] in fat, lead in bone), and by excretion.⁷ The relationships among these processes are demonstrated in Fig. 20-1. This chapter covers the classification of toxic chemicals, the manner in which exposure occurs and how it can be measured, the absorption and distribution of chemicals within the body, and finally the kinds of toxic effects that are produced. Emerging areas of toxicology are briefly considered.

► BRANCHES OF TOXICOLOGY

Toxicology is a broad discipline embracing such traditionally clinical areas as pathology, pharmacology, and clinical toxicology on the one hand, and molecular biology, biochemistry, and physiology on the other. Industrial toxicology, ecotoxicology, environmental toxicology, forensic, analytic, and regulatory toxicology are also prominent areas. Historically, toxicology was linked with pharmacology and focused on the toxic effects of pharmaceuticals. This remains a fundamental part of drug development and assessment. Industrial toxicology emerged to investigate the toxic effects of raw materials, intermediates, products, and wastes produced by commerce. Toxicology has subdisciplines linked to behavior, nutrition, biochemistry (including proteomics), and genetics (including toxicogenomics), which have opened new research horizons. Clinical toxicology focuses on the diagnosis and treatment of poisonings.^{8,9}

Toxicology is concerned with both lethal and sublethal effects. In the 1950s and 1960s lethal effects were the major emphasis, and many studies were aimed at identifying the lethal dose (LD)-50 for a chemical, the dose which killed 50% of the animals. Today, experimental toxicologists employ *in vivo* and increasingly *in vitro* techniques to study the effects of one or more chemicals or other stressors on biological functions, as well as survival. Efforts to limit animal research have stimulated the search for alternatives testing,¹⁰ although *in vitro* testing has limitations.¹¹ Two decades ago, molecular toxicology was a new frontier with an emphasis on the discovery of biomarkers.^{2,12} Increasingly, toxicologists focused on the cellular, biochemical, and molecular interactions and changes wrought by foreign chemicals, thereby elucidating their mechanisms of actions. In the past decade attention has shifted to genomic and proteomic investigations, focusing on the effects of chemicals on gene expression and protein synthesis. This research also identifies new kinds of biomarkers such as tumor-specific antigens.¹³ Phenomenological measurements of enzyme activity have been supplemented by studies of enzyme structure and gene-protein

Figure 20-1. A multicompartiment illustration showing movement of contaminants from environmental media, uptake through lungs, skin, and gut, distribution in blood to excretory, storage, or target organs. (Source: Courtesy EOHHSI.)

and protein-protein interactions. Receptor biology has emerged as a subdiscipline, stimulated in part by the interest in endocrine active xenobiotics, which may be active at picomolar (10^{-12}) concentrations.¹⁴ Many new and highly specialized journals—some mainly in electronic form—have appeared in the past decade. No attempt is made here to cover the rapidly evolving field of molecular toxicology.

Toxicological data are a major basis for environmental risk assessments, which in turn are increasingly used by regulatory agencies to assess chemical hazards, prioritize hazardous waste site cleanups, establish governmental policies, and set levels of allowable exposure. Such risk assessments produce quantitative or qualitative estimates of the magnitude of the risk of some adverse endpoint associated with a particular dose or exposure of a target population to a particular chemical, physical, or biological agent.

Ecotoxicology is a major subdiscipline, and data on exposure, distribution, and effects in ecosystems and organisms provides data used in ecological risk assessments (see Chap. 42). The publication of *Silent Spring*,¹⁵ by Rachel Carson in 1962, is often hailed as a landmark, not only for ecotoxicology, but for human environmental health concerns in general. Carson published on the overuse and misuse of pesticides despite intense pressure from the agrochemical and agriculture industries. She emphasized the inevitable escalation in toxicity of new pesticides as insects developed resistance to earlier generation insecticides.

Although not usually recognized as a subdiscipline, military toxicology has had a long history. The development of chemical warfare agents such as mustard gas¹⁶ was a driving force in the early twentieth century, and nerve gas research played a major role in the development of organophosphates, later used as pesticides. The development of antidotes and preventatives was likewise necessary. Although international treaties in the 1970s brought a halt to much of the chemical weapon development, the new millennium has brought increased emphasis on terrorism and preparedness for biological, chemical, and radiation hazards. This includes research into methods for early detection of release of hazardous agents,¹⁷ for monitoring humans for exposure or effects, and for the deployment of effective prevention, diagnosis, and treatment.¹⁸ Radiation toxicology lies largely in the domain of health physics, and is outside the scope of this chapter.

► EVOLUTIONARY BASIS OF TOXICOLOGY

Although the teaching of evolution in schools periodically comes under attack, the late Ernst Mayr emphasized that the basic principles

of organic evolution advanced by Darwin have withstood all challenges.¹⁹ Although the mechanisms by which evolutionary changes occur are still being elucidated,²⁰ through the acquisition of new data in field and laboratory, the basic phenomena of heredity, mutation and selection underlie the relatedness among all forms of life. These processes are augmented by random events, migration, interbreeding, and even horizontal transfer of genes across species boundaries.²¹ Evolution remains the basis of our understanding of toxicology,²² and the relationships between animal studies and human effects.²³ Evolutionary relatedness underlies the principles of extrapolating from animal studies to human exposures, and toxicologists take the underlying evolutionary principles for granted, while textbooks seldom specifically reference it. Since the 1960s when Fitch and Margoliash demonstrated the conservatism among amino acid sequences of some proteins and applied the concept of genetic distance among species,²⁴ toxicological research has advanced on many fronts. Humans share with ape ancestors approximately 99% of the genome. Yet within any given species, and probably more so in humans than any other, there are variations in gene sequences that alter protein structure in subtle ways, that in turn may effect nutritional requirements, physiological tolerances, mating prowess, or fecundity. Under different environmental regimes, one genotype may be favored over another, and over long periods of time, increasing trends toward wetness or aridity, may select for increased tolerance of the appropriate condition—directional selection. Genetic variation within a species allows for increased adaptiveness to changing environments or to environmental stressors.

► TYPES OF STRESSORS

The stressors that potentially harm the body can be broadly classified as physical (noise, temperature, radiation), biological (infectious, immunologic, allergenic), chemical, mechanical (ergonomic), and psychosocial. Toxicologists focus mainly on chemicals, both synthetic and those of natural biological origin, and on physical agents such as radiation. There are interactions among classes of stressors. Thus radiation, infection, or psychological stress may modify the effects of toxic chemicals,²⁵ and vice versa, and there is increasing attention to the effects of two or more chemicals administered together where synergistic, independent, or antagonistic effects may occur (see below).

The following definitions are important. *Toxicity* is the intrinsic ability of a substance to harm living things. A *xenobiotic* is any substance foreign to the body, including all synthetic chemicals as well as many natural substances. *Susceptibility* refers to the ability of a living thing to be harmed by an agent. It is influenced by genotype, by age and gender, and by environmental factors such as nutrition, prior exposure, and underlying state of health (for example, immune status). *Bioavailability* is the ability of a substance that enters the body to be liberated from its environmental matrix (air, water, soil, food), while absorptive capacity (of skin, lungs, or gastrointestinal [GI] tract) influences how much bioavailable material can enter the circulation. *Biotransformation*, or *intermediary metabolism*, is the biochemical change(s) a chemical undergoes once it reaches the cells of the body. This may lessen its toxicity (*detoxification*) or enhance it (*activation*) and may facilitate excretion. *Mechanism* refers to the way in which the toxic substance acts on a cellular or subcellular level to disrupt the living organism. *Threshold* is the lowest dose of a chemical that has a detectable effect.

► CLASSIFICATION OR TAXONOMY OF TOXIC AGENTS

One can organize knowledge in toxicology in terms of chemical agents or types of effect. Chemicals can be classified based on their structure, source, economic role, mechanism of action, or on their target organ. The lists below are not intended to be exhaustive.

Classification by Structure

Organic Chemicals

- Aromatics (e.g., phenols, benzene derivatives)
- Aliphatics (e.g., ethanes, ethenes)
- Polyaromatic hydrocarbons (PAHs)
- Chlorinated polyaromatics (e.g., dioxins, furans, PCBs)
- Chlorinated hydrocarbons (chlorinated alkanes and alkenes)
- Amines and nitriles
- Ethers, ketones, aldehydes, alcohols, organic acids

Inorganic Chemicals

- Acids and bases
- Anions and cations
- Heavy metals
- Metalloids (e.g., selenium, arsenic)
- Salts

Classification by Source

Many plants and animals secrete chemicals designed to keep them from being eaten.²⁶ The classic example is the Monarch butterfly, the larvae of which develop on milkweeds which contain alkaloids that the caterpillar incorporates in its own tissues. During metamorphosis the alkaloids are retained in the adult butterfly, and birds that eat a Monarch become sickened and quickly learn to avoid it and similarly colored yellow and black caterpillars or black and orange butterflies. Beetles may squirt hot cyanide compounds to deter predators. Plants that have been partially eaten by herbivores may load increased levels of distasteful alkaloid compounds in newly regenerated leaves. Similarly, many fungi secrete chemicals that inhibit growth of bacterial competitors. A wide variety of these naturally occurring bioactive substances or “toxins” have been adapted into some of our most familiar pharmaceuticals, for example, antibiotics.

Natural or Biological Compounds, “Toxins”

- Plant
- Bacterial
- Invertebrate
- Vertebrate

Synthetic Chemicals

- Industrial raw material, by-product, waste, or product
- Pharmaceutical agent

Environmental toxicology and risk assessment have focused mainly on synthetic chemicals, yet natural toxic compounds, called toxins or venoms, are widespread and include some of the most toxic agents known. Invertebrate toxins, mainly of marine origin, occasionally cause epidemic outbreaks of foodborne disease and have proven valuable research tools because of their highly specific modes of action. These include brevetoxin secreted by the dinoflagellates that cause red or brown tides along the southeastern United States coastline and many other warm ocean areas.²⁷ Many of these toxins have very complex structures, for example, the chain of 13 heterocyclic 5–7-membered rings that make up the backbone of ciguatoxin. These plant and animal toxins have evolved specifically to damage either predators or prey. A review of their toxicology is beyond the scope of this chapter.²⁶

Many pharmacologic agents are extracted directly from plants or microorganisms, or are patterned on natural compounds. Plants contain many insecticidal or deterrent compounds, and Bruce Ames has argued that there is no reason to be concerned about synthetic pesticide residues on food, since foods are loaded with natural pesticides at much higher concentrations.²⁸

Unfortunately this ignores the evolutionary history through which organisms would have adapted to chemicals naturally encountered in

the diet, while exposure to synthetic pesticides has occurred for only two or three human generations.

Classification by Use

Very often in clinical toxicology, the first thing one learns about a chemical exposure is the type of compound. Thus a would-be suicide patient may be brought in with “an overdose of sleeping pills,” or a worker may have been overcome while “using a solvent,” or a homeowner may report “some pesticide spray” making him/her ill. Examples of common use classes of materials that may have toxic effects include:

- Solvents
- Pharmaceutical agents
- Paints, dyes, coatings
- Detergents, cleansers
- Pesticides
- Acids, bases

Pharmaceuticals and Abused Substances. These are grouped together because of the tendency for very high concentrations of bioactive agents to be deliberately introduced into the body. In fact, many abused substances that were originally developed as pharmaceuticals (e.g., amphetamines, barbiturates, and narcotics) have profound toxic effects, quite apart from their addictive properties. By whatever route, and whether legal or illicit, these chemicals are used because of their high level of bioactivity. Even when the dosage used is in the therapeutic range, there may be undesired side effects, which are manifestations of toxicity. These may occur in most users (e.g., soporific effects of diphenhydramine) or rarely (anaphylaxis from penicillin). Certainly the most widespread toxic exposures involve the chronic inhalation of tobacco smoke by the smoker and those around them, and the chronic consumption of ethanol.

Classification by Mechanism of Action

Much exciting research in modern toxicology focuses on the mechanism by which a bioactive substance interacts with and alters its targets to produce its unwanted effects, for example:

- Enzyme inhibition
- Enzyme induction
- Formation of free radicals/active oxygen species
- Metabolic poisons
- Redox reactions: oxidants and antioxidants
- Macromolecular binding
- Interference with signal transduction (e.g., DNA, protein)
- Cell membrane disruption including lipid peroxidation
- Hormone activity (hormone synthesis, receptor regulation)
- Competitive binding of active sites or receptors
- Immune effects
- Irritants

Classification by Target Organ

Xenobiotics can act on any organ system in the body. The effects on these target organs are discussed in other chapters in this section. Standard textbooks of toxicology⁶ are organized by organ system, and several of the general readings deal with organ systems. The next chapter deals specifically with neurobehavioral toxicology.

Neurotoxin	Pulmonary toxin	Genotoxin (including mutagens)
Hematotoxin	Metabolic toxin	Immunotoxin
Nephrotoxin	Endocrine toxin	Carcinogen (including initiators and promoters)
Hepatotoxin	Dermatotoxin	
Cardiotoxin	Reproductive toxin	Teratogens

The liver is of particular importance in toxicology. Ingested substances absorbed into the blood stream go first to the liver via the portal vein on “first pass.” In the liver they may undergo metabolism, which may either detoxify or activate them. The liver may conjugate substances to facilitate their excretion in the urine or may secrete some substances into the bile. Liver cells are particularly vulnerable to toxins, and toxic hepatitis, manifest by abnormalities in liver function tests, may present as jaundice or as a fulminating fatal liver failure.

► CHEMICAL STRUCTURE AND TOXICOLOGY

Several chemical principles play important roles in toxicology. They influence how the chemical behaves in its environmental matrix, how it is absorbed into, metabolized by, distributed through, and excreted from the body, and how it exerts its toxic effect.

Chemical Species

There are different forms of many chemicals; a chemical variant of a metal is called a “species.” This may refer to organic versus inorganic state or to valence state; thus trivalent and hexavalent chromium are species of chromium,²⁹ and because CrIII is an essential nutrient while CrVI is a potent lung carcinogen,³⁰ the difficulty in reliably analyzing the concentrations of CrIII and CrVI in an environmental sample impedes our ability to protect potentially exposed people. Toxicologists have demonstrated that slight modifications in a chemical may drastically alter its effect.³¹ This is particularly true for the effects of certain metals, which, when in an organic complex, may have drastically different effects than their elemental or ionic form. For example, methylmercury and organotin are both more toxic than inorganic mercury or tin, but the reverse is true for arsenic, where naturally occurring organic species have lower toxicity than the inorganic arsenites and arsenates. These in turn can be methylated in the body to less toxic metabolites, a capacity that varies among individuals.³² The organic mercury and tin species have been incorporated in biocides such as fungicidal seed dressing and in marine paints to thwart the growth of barnacles. However, both methylmercury and alkyltin compounds are potent neurotoxins^{33,34} and have caused widespread ecotoxic effects in the marine environment.

Isomers and Congeners

Two chemical compounds that have the same chemical formula but differ in structure are called *isomers*. Thus butane, a four-carbon chain can appear as either normal (linear) butane or branched isobutane. *Congeners* have the same basic structure, but different numbers of atoms. For instance, dichlorophenol and trichlorophenol would be congeners while 2,4-dichlorophenol and 2,5-dichlorophenol would be isomers. The behavior in the body and the toxicity may vary greatly among isomers and congeners. Thus different chlorinated dibenzodioxins vary by orders of magnitude in their toxicity. Each compound can be assigned a toxicity potency (toxic equivalency factor or TEF) relative to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD),³⁵ and these TEFs are considered additive in causing cancer.³⁶

Structure-Activity Relationships

The converse of the variation in toxicity between isomers and congeners is that chemicals that are structurally similar may have similar types of toxic effects on the body, although the effects may be modulated in intensity by adjacent atoms. This forms the basis for much pharmaceutical research, the quest for agents that have a desired effect without undesired side effects. Understanding structure-activity relationships (SARs) is important in toxicology since one can often infer the effects of a chemical by knowing the effects of related compounds. Thus many short-chain chlorinated hydrocarbons have a common general anesthesia effect, even though their potency varies with their structure. Similarly, many metal ions are nephrotoxic to the proximal kidney tubule,³⁷ and many hallucinogenic compounds share a common active group. SARs have proven predictive of carcinogenicity identified

by long-term animal bioassays.³⁸ Quantitative-Structure-Activity Relationships (QSAR) play an important role, particularly in drug development³⁹ and in predicting toxicity.⁴⁰

► CHEMICALS IN THE ENVIRONMENT

Environmental toxicology is generally concerned with chemicals in the air, water, soil, and food we encounter in our home, community, and workplace environments. Our behavior greatly influences the microenvironments we frequent, the exposures we experience, and the ways that chemicals enter our body via ingestion, inhalation, percutaneous absorption, and even by injection. Table 20-1 indicates the factors that influence the uptake and toxicity of a material and the susceptibility of the host. Uptake varies by route of exposure and bioavailability. A given chemical may be readily absorbed from the lungs but may have negligible uptake through the skin or intestinal tract.

Chemicals in Air

Air pollution remains a major public health concern, and ozone is a ubiquitous irritant formed in the atmosphere. Probably the main substrates for excess ozone formation are oxides of nitrogen (the term for the family of NO_x) emitted in automobile exhaust. Another substance of concern is sulfur dioxide. Both ozone and sulfur dioxide are irritating to the respiratory system. Recent research has focused attention on particulates less than 2.5 μm in aerodynamic diameter (PM_{2.5} fraction), which are associated with increased mortality, particularly for people who have diabetes and ischemic heart disease.⁴¹ Attention has focused on sophisticated analysis of pulse rate,⁴² showing that particulate exposure decreases heart rate variability. Recent work also points to an association of PM_{2.5} directly with atherogenesis.⁴³

Although much of the research has been driven by outdoor air pollution, it is actually the indoor exposures which are often of greater magnitude and concern.⁴⁴ In the aftermath of the 1970s fuel crisis, newly constructed, “energy-efficient” office buildings tended to be relatively airtight, and fuel conservation programs greatly reduced the amount of fresh air (makeup air) added to air conditioning. This contributed to many reports of “sick-building syndrome.” Many homes have unsuspected air pollutants that are hazardous to health. Radon, a decay product from naturally occurring uranium in soil, occurs in gaseous form and emits alpha particles that cause lung cancer. Although alpha particles can penetrate only a very short distance (less than a millimeter), inhalation of the gas brings it in direct contact with lung tissue. Radon occurs in many parts of the United States and may reach relatively high concentrations in certain homes. A more common but less dreaded pollutant is nitrogen dioxide, which is formed

by combustion in a gas cooking range. Elevated levels of this irritant can be measured in a kitchen while cooking is in progress. Children living in homes with gas ranges may experience an excess of respiratory symptoms.⁴⁵ Recent attention has focused on molds which release both allergenic mycelia and spores as well as toxic secretions, which have been implicated in causing a variety of symptoms.⁴⁶

Many industrial processes emit vapors, smokes, or mists, which can be inhaled. Hence air is the major route of exposure for industrial workers. Most of the standards regarding industrial exposure refer to airborne concentrations above which inhalation could lead to adverse health effects.⁴⁷ See Chap. 46 on occupational exposures.

Chemicals in Water

Both surface and groundwater are used as community water sources. Many industrial and municipal wastes, both treated and untreated, are discharged directly to surface waters, and discharge permits allow certain quantities of toxic chemicals to be piped into streams, lakes, rivers, canals, and the ocean. Groundwater contamination occurs as contaminants leach downward through soil. Use of lead arsenate insecticide and organomercurial fungicide, once the mainstays of agricultural pest control, have been banned or curtailed, but these metals have gradually leached through the soil, eventually reaching groundwater, decades after they were applied. Solubility is the primary factor determining the behavior of chemicals in water. Many metal salts dissolve readily, while most of the larger organic molecules do not. Public drinking water sources are regulated with regard to several pollutants and must test for a suite of contaminants on a regular, usually quarterly basis. Private wells are not systematically tested. Although ingestion is the major pathway for water contaminants, volatile compounds in water escape during cooking and showering, offering a significant potential for inhalation exposure.

Chemicals in Soil

Soils have complex physical structures and compositions that vary greatly. The physical texture and water and organic content determine how chemicals will move through soil and influences their bioavailability. Some soils are naturally rich in toxic elements, such as the nickel-rich soils of New Caledonia or serpentine soils, to which unique groups of plant species have become adapted. However, human activities have resulted in soil contamination via fallout of air pollutants, discharge of liquid industrial or agricultural waste, or dumping of solid waste. Once a chemical is deposited on soil, it may remain in place or it may be washed away by water flowing over the surface (runoff) or by percolation down through the soil (leaching). Some chemicals may be readily leached from the upper layers of soil and carried down or away by water. Others may undergo biodegradation or photodegradation with the aid of microorganisms or sunlight. Some chemicals are persistent; for example, the chlorinated hydrocarbon pesticides and PCBs tend to remain unchanged in the soil for many years.

Soil particles that form fine dusts can become airborne and can be inhaled. Particles less than 5 μm in diameter are likely to reach the alveoli. Other particles may settle on food or water and be ingested. People may also ingest particles of soil that get on their fingers or under their nails or that are on the outer surface of vegetables. The ingestion of contaminated soil by toddlers is a major route of exposure and is often the major determining pathway in a risk assessment.

Chemicals in Food

Food may contain toxic chemicals from a variety of sources. Although regulations governing pesticide application (for example, the minimum number of days between spraying and harvest) are designed to protect workers and minimize residual pesticides in food, many vegetables still contain some pesticide residues. Some residues may be surface sprays that adhere to plant tissue, while others are systemic substances taken up through the roots and incorporated in the tissue. Hormones and antibiotics used in promoting animal growth can also be detected in certain foods as can food additives used to prolong shelf life or enhance flavor, texture, or color. Some of these

compounds have been demonstrated to have toxic effects in long-term low-level exposure experiments (see Chap. 33). In the process of cooking, particularly grilling, meats may contain carcinogenic heterocyclic amines.⁴⁸ Many plants contain chemicals that have physiological as well as nutritional function. Some have hormonal effects whereas others may be carcinogenic, or anticarcinogenic, such as isoflavones in soy beans,⁴⁹ or antioxidant phenolic constituents of green tea. The content of these plant chemicals may vary with the variety, geography, seasonality, soil composition, or even whether the plant has been attacked by insect pests.

Biological Amplification in the Food Chain. Among the phenomena that influence the movements of chemicals in the environment is the process of biological amplification. This phenomenon has been demonstrated in a variety of ecosystems and has implications for human exposure. Most examples of bioamplification concern lipophilic chemicals such as PAHs or organometals such as methylmercury. These substances may be present in water or soil at the parts per million level. When taken up by planktonic organisms, they tend to concentrate in the tissues of these organisms and only a small fraction of the uptake is excreted. At each step up the food chain (what ecologists call trophic levels), the organism retains more than it excretes and incorporates an ever-increasing amount of contaminant in its fat.

If the bioconcentration factor (BCF) were 10 for each level, then the plankton swimming in water with a 1 ppb concentration would accumulate 10 ppb, the fish larvae eating plankton would reach 100 ppb, small fish eating the larval fish 1000 ppb (1 ppm), and large fish eating the small fish 10 ppm. This example leaves the hapless human fish-eater consuming a huge dose of the amplified toxic material. A high lipid-water partition coefficient enhances bioamplification for organisms. However, some nonlipophilic materials may also undergo bioamplification if they concentrate in some other tissue (i.e., the thyroid) or bind to macromolecules.

► EXPOSURE TO TOXIC SUBSTANCES

Understanding human exposure is the unique feature of environmental medicine. Traditional approaches such as taking a history remain important, but more sophisticated approaches are required to understand exposure which takes place in the home, community, and workplace.

Exposure Assessment

Exposure assessment has emerged as a discipline that combines environmental sampling, chemical analysis, biomarkers, behavioral studies, and mathematical modeling to estimate the dose received by an individual.⁵⁰ It is necessary to investigate exposure formally as a system of coupled events.⁵¹ Exposure pathways involve contaminated air, water, soil, or food entering through the lungs, GI tract, or skin, each combination of which is a potential pathway as shown in Table 20-2 and Fig. 20-1. Each nonzero cell in Table 20-2 is a potential pathway, ranging from slight importance (+) to major importance (++++). The ingestion of soil by toddlers is often the determining pathway in residential and recreational risk assessment. Injection of drugs, metal shrapnel fragments, is a special case not usually dealt with in environmental toxicology.

When a human comes in contact with a contaminated medium, there is always the question about how much enters the body, is absorbed into the bloodstream, and reaches the target tissue. The bioavailability of a material in a particular matrix and the absorptive capability through the skin, intestinal mucosa, or alveoli can vary greatly and are difficult to measure directly. Likewise, the actual exposure of the target cells, tissues, or organs—the internal dose⁵⁰—is seldom known. Absorption varies with species, age, the vehicle or solvent, as well as the presence of carrier molecules. Children absorb some compounds such as lead more efficiently than do adults. Since they are also more likely to ingest soil and are more vulnerable to its

TABLE 20-2. EXPOSURE MATRIX*

Media/route	Inhalation	Ingestion	Percutaneous	Injection
Air	++++	++	0	0
Water	+++ (showering)	++++	++ (slurries/muds)	0
Soil/dust	+++	++++ (toddlers, diggers)	+	0
Food	0	++++	0	0
Other	+	+	0	++

*With permission from EOHHSI

effects, they are in triple jeopardy. Children who are undernourished are more likely to eat soil (pica) and are also more efficient at absorbing lead or cadmium, for example, from a diet deficient in iron or calcium. Children consume about 0.1 g of soil per day.⁵²

For a given contaminant, different pathways may be important for different compounds. For example, organic mercury is primarily taken up by ingesting contaminated seafood, while elemental mercury usually enters by inhalation.

Advances in instrumentation and analytic chemistry have supported great strides in direct measurement of environmental exposure. This is not without cost, because as our ability to analyze ever smaller quantities of an agent improves, our ability to deal environmentally and sociopolitically with such exposures has not kept pace. Analytic techniques that would formerly have yielded concentrations of “zero” or “nondetectable,” now provide results at parts per quadrillion (e.g., femtograms/gram). This has been referred to as the “vanishing zero.”⁵³

The discipline of industrial hygiene is particularly concerned with anticipating, estimating, and controlling exposure to workplace hazards.⁵⁴ For airborne hazards, industrial hygienists use a variety of pumps and collection media to capture pollutants in a known volume of air. These are then quantified in the laboratory and extrapolated to determine how much of the material a person is exposed to in an 8-hour period. Where particulates are involved, it is necessary to establish a size distribution to determine the portion that is of respirable size. Because exposures are not constant throughout the day, measurements must be made either at several times during the day or over several 8-hour work shifts. Exposures are expressed in terms of a time-weighted average (TWA) corrected to an 8-hour exposure.⁴⁷ Industrial hygiene has expanded to environmental hygiene, including evaluation of hazards in the home and community.

Bioavailability

An important aspect of exposure alluded to above is bioavailability.⁵⁵ How readily is a toxicant released from its environmental matrix? In the case of ethanol dissolved in water, there is virtually 100% uptake of the alcohol into the bloodstream. In the case of a metal bound to protein in our food, the uptake may depend on the efficiency of protein digestion. In the case of substances bound to soil, bioavailability may vary greatly. Bioavailability of 2,3,7,8-tetrachlorodibenzodioxin (“dioxin”) was low in soil from Newark, New Jersey, probably due to a high degree of organic compounds in the soil, while dioxin from the sandy soil at Times Beach, Missouri, had much higher bioavailability.⁵⁶

Bioavailability is also important for plants and consequently for humans that consume the plants. Certain pollutants in soil may be taken up by a plant and translocated to the leaves or fruits, which are subsequently harvested for human consumption. Depending upon the chemical species, concentration, pH, competing ions, etc, the plant may take up a large amount of the pollutant or none at all.

Absorption

Bioavailability and absorption combine to determine how much of a substance enters the bloodstream through ingestion, inhalation, or the skin. Bioavailability refers to properties of the matrix (e.g., how a

xenobiotic may be bound), while absorption refers to properties of the organ (how readily a xenobiotic passes through the alveolar membrane, intestinal epithelium, or the skin). Methylmercury, for example, has nearly complete absorption from the gut, while ingested elemental mercury will pass through the GI tract with virtually no absorption. Ingestion of elemental mercury poses a threat mainly when the intestinal tract is disrupted, for example, after surgery.⁵⁷

Lead absorption varies with age, children absorb about 50% of an ingested quantity compared to less than 10% for adults.⁵⁸ Absorption of lead and cadmium increases in women and children with low iron stores and other essential nutrients,^{58,59} and this effect is enhanced in pregnancy.⁶⁰

In Utero Exposure

Many chemicals exert an effect on the developing embryo and fetus. They may pass through the placenta and reach the fetus; in some cases achieving concentrations higher than the maternal circulation.⁶¹ Transplacental transport is not necessary, however, since a chemical may influence the fetus by altering blood flow.

▶ ACUTE AND CHRONIC EXPOSURE AND TOXICITY

The terms “acute” and “chronic” can refer either to the duration of exposure or to the resultant health effects. A single “acute” exposure to a toxic chemical may be sufficient to induce health effects that in turn may be either acute (followed by recovery), subacute, or chronic. Long-term or chronic exposure may be followed by no adverse health effects (if the dose is low), or by acute effects (which may occur when a sufficient dose is accumulated), or by chronic effects. In addition to having a long duration, chronic effects tend to be nonreversible.

More specifically with respect to toxicological studies on animals, acute toxicity can be defined as adverse effects usually occurring within 24 hours after a single dose. Subchronic effects usually occur after repeated dosing over up to 10% of the life span.⁶² Chronic exposure refers to dosing animals for more than 10% of their life span.⁶³ A particular dose may have a much greater effect when administered acutely than chronically, but in many cases repeated low doses cause effects not seen in acute toxicity.

ACUTE TOXICITY IS RATED AS FOLLOWS BASED ON THE PROBABLE LETHAL ORAL DOSE FOR HUMANS

Toxicity Class	Dose required/kg Body Weight	Approximate Amount Consumed
Practically nontoxic	> 15 g/kg	> 1 liter
Slightly toxic	5–15 g/kg	300–1000 cc
Moderately toxic	0.5–5 g/kg	30–300 cc
Very toxic	50–500 mg/kg	3–30 cc
Extremely toxic	5–50 mg/kg	0.3–3 cc
Supertoxic	< 5 mg/kg	< 0.3 cc

Acute LD-50s range from 10 g/kg for ethanol to .01 ug/kg for botulinum toxin.

Time-Dose Interactions

Physiologists grappled with this problem in the nineteenth century, finding that some combination of voltage and duration needed to be achieved to produce a response to a shock. At a lower voltage, longer duration was required. The lowest voltage (dose) at which a response could occur approaches an asymptote called the rheobase. Chemical dosing offers an analogy that is seldom quantified. A lay person knows that taking one tablet a day for 10 days is not the same as taking 10 tablets on a single day, although the total dose is the same. The time-dose relationship is complex and nonlinear. Moreover, different time-dose combinations can have very different qualitative as well as quantitative effects. A chronic or recurrent dosage may accumulate to exceed a certain threshold for a chronic effect, while an acute dose may be quickly eliminated without ever producing that effect. Conversely, a chronic daily dose may never reach an effect threshold. Hence a single daily dose of 1 oz of alcohol does not reach the threshold for producing impairment, and is reputed, in fact, to have beneficial effects.

► CHEMICALS IN THE BODY

What the body does to a xenobiotic, how it is distributed, altered, and eliminated, is referred to as toxicokinetics. What the chemical does to the body, how it interacts with target cells and intracellular targets, exerting its toxic effects, is referred to as toxicodynamics.

Toxicokinetics

Toxicokinetics is the totality of reactions that govern the uptake and distribution of a toxic substance and its metabolites throughout the body. It is based on the different rate constants that exist for metabolic processes in different tissues under different circumstances and on different partitioning coefficients, binding properties, etc. These reactions are competitive, such that the amount of material available for metabolism depends on the amount that has been sequestered in fat, bound to protein, or excreted in the urine.

The fate and effect of every substance that enters the body depend upon its absorption, transport, metabolism, storage, and excretion. Metabolism, for example, alters the binding properties and solubility of the original chemical and influences its toxicity and whether it will be stored or excreted.

Two factors that influence the entry of chemicals into cells include the perfusion rate of the organ and the diffusion rate of the substance across the membrane. Fick's law describes the passage of a xenobiotic across a membrane as proportional to the concentration gradient, the membrane surface area, and a compound-specific permeability coefficient. The latter in turn depends upon the condition of the membrane, the presence of receptors or transporters, and the lipid-aqueous partitioning of the compound. This is often measured as the solubility in octanol divided by the solubility in water. Excretion via urine, feces, exhaled air, or sweat is in turn determined by the relative solubility of the compound and its delivery to the kidney, liver, lungs, or skin. In general, compounds that are water soluble or conjugated are excreted via urine, while lipid-soluble compounds are secreted via the bile into the intestine.

Metabolic Activation versus Detoxification

In some cases such as lead, cyanide, and carbon monoxide, the xenobiotic itself is the active poison exerting its toxic effect directly on enzymes, cells, or macromolecules. In other cases (e.g., arsenate, hexane, carbon tetrachloride) reduction to arsenite or oxidation to 2,5-hexanedione or a CCl_3COO^* radical produces the ultimate toxicant. Some xenobiotics create reactive hydroxyl, peroxy, or alkoxy-free radicals.

An important feature of metabolism is its ability to both reduce and enhance toxicity. Although the liver is the major site for detoxification of xenobiotics, many toxics do not exert activity until they reach the liver and are metabolically activated, usually through an oxidative reaction. This forms more highly reactive intermediate

compounds that can interfere with other metabolic reactions or "attack" membranes, organelles, or macromolecules.

Phase I reactions involve oxidation (by dehydrogenases, flavin monooxygenases, cytochrome P450, and other systems), hydrolysis (for example by carboxylesterases, peptidases, paraoxonase), the formation and hydrolysis of epoxides, reduction (of azo and nitro groups, carbonyl, sulfides, and dehalogenation), and various other reactions. The P450 cytochrome-dependent enzyme system (see below) plays a major oxidative role. Phase II metabolism involves linking a substance to a glucuronide or adding acetyl or methyl radicals or conjugating it with amino acids or glutathione (GSH). Phase II reactions usually increase the hydrophilic nature of the substance, facilitating its excretion in urine.

The liver is the main organ of metabolism, but metabolic enzymes occur in most tissues. Within cells they are found mainly in the microsomal component of the endoplasmic reticulum, but also in the cytosol and other organelles. In addition, intestinal flora can play a significant role, for example bacteria in the colon can transform PAH into estrogenic metabolites,⁶⁴ although the significance of this is not yet known. Also there are active P450, glutathione-S-transferase (GST), and other metabolic enzymes in the nasal mucosa that modify inhaled xenobiotics.⁶⁵ Additional details are provided by Parkinson.⁶⁶

As an example, 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP) was produced accidentally during the synthesis of an illicit narcotic analog. MPTP is oxidized to the neurotoxic metabolite MPP^+ by monoamine oxidase B,⁶⁷ which in turn is transported by the dopamine transporter and concentrates in dopaminergic neurons where it inhibits cellular respiration, causing cell death. The inadvertent consumption of this by-product by substance abusers produced Parkinsonism in a large number of young people, and MPTP has now become a model drug for Parkinsonism research. Monoamine oxidase inhibitors block the toxicity of MPTP.

The common analgesic, acetaminophen, undergoes metabolism by P450 to a quinone, which interacts with liver proteins, causing centrilobular necrosis. It also undergoes activation through the prostaglandin H synthase (PHS) system in the kidney to produce a nephrotoxic free radical. The bladder epithelium is also relatively rich in PHS, which can metabolize certain aromatic amines into genotoxic metabolites which cause bladder cancer in humans and dogs. In rats, the predominant pathway is *N*-hydroxylation in the liver, such that the same amines cause liver tumors rather than bladder tumors.

Cytochrome P450

This system of iron-containing enzymes is very diverse performing oxidation, hydroxylation, epoxidation, and dealkylation reactions on a great variety of substrates.⁶⁸ An entire subdiscipline has developed around understanding the species, tissue, substrate, and reaction specificity (or lack thereof) of the many P450s found in various organisms. The P450s were also called the liver microsomal oxidase system since the highest concentration is found in the microsomes (endoplasmic reticulum) of hepatocytes, but P450s are found in virtually all tissues. They are heme-containing proteins, which have peak absorption at 450 nm when complexed with carbon monoxide. P450 oxidation reactions can result in hydroxylation, the formation of epoxides from carbon-carbon double bonds, the cleavage of esters, dehalogenation, and other reactions.⁶⁹

P450 monooxygenase enzymes that catalyze a variety of reactions, are divided into families 1, 2, 3, and 4. Members of different families have lower than 40% amino acid sequence identity. Within these families are subfamilies: 1A, 1B, 2A, 2B, 2C, 3A, etc, within each subfamily the proteins have 40–55% homology. Proteins with greater homology have the same number, for example 1A1, 1A2, 2A6, 2B6, 2C8, 2C9, 2C19, 3A4, etc. There are at least 15 of these different enzymes in the liver. Many new isoforms of P450 are being discovered.

The P450 enzyme that metabolizes caffeine is referred to as P450 1A2 and is often abbreviated CYP1A2 (while the gene that produces it is written in lowercase italics *cyp1A2*). Other examples of specific P450 reactions are the hydroxylation of testosterone at position 6 by CYP3A4, and of coumarin at position 7 by CYP2A6. A particular

substrate may be metabolized by more than one P450, while conversely each P450 catalyzes more than one reaction. Thus CYP3A4 can hydroxylate testosterone at several positions and also dehydrogenate it to 6-dehydrotestosterone.⁶⁶ Xenobiotics may have multiple metabolic pathways, thus CYP2D6 oxidizes the aromatic ring of propranolol and CYP2C19 metabolizes the side chain, directing propranolol into two different pathways. Conversely the conversion of acetaminophen to its quinone metabolite can be accomplished by three different P450s. Many of the discrete P450s have been detected in studies of drug metabolism, and their natural substrates have not always been identified. Many of the P450s are inducible rather than constitutive enzymes. That is, the amount of P450 activity remains low until a suitable substrate is present which activates the gene that governs the expression of a particular P450.

Current interest in P-450 focuses on heritable deficiencies or polymorphisms that influence individual susceptibility to xenobiotics.^{70,71} A mutation in the gene for CYP2D6 interferes with metabolism of the drug debrisoquine, and about 5–10% of Caucasians but less than 1% of Japanese are “poor metabolizers.” Conversely 20% of Japanese are poor metabolizers of the anticonvulsant *S*-mephenytoin due to deficiency of CYP2C19. Since these P450s are not substrate specific, these deficient individuals may be intolerant of certain other xenobiotics, whether environmental or pharmacologic.

Tissue Specificity. CYP1A2 is expressed in liver cells but not in other tissues, while CYP1A1 is low in liver (of most mammals, but not guinea pigs or rhesus monkeys), but high in other tissues. Since the two catalyze different reactions, a single substrate may follow different metabolic pathways in different tissues. This is a rapidly evolving area of research with important applications on pharmacology and toxicology.⁷²

Induction. It has long been known that certain xenobiotics induce the formation of metabolic enzymes.⁷³ CYP1A2 is induced by a variety of PAHs and indoles. CYP3A4 is induced by barbiturates, while CYP2D6, which metabolizes many different drugs, is constitutive rather than inducible. CYP2D6-deficient individuals are hyperresponsive to certain drugs. However, they are likewise protected from certain environmentally caused cancers such as lung, bladder, and liver cancer, because of their failure to activate certain procarcinogens. Whether this is a direct effect of CYP2D6 deficiency remains to be determined. There is a tenfold variation in the liver content of CYP3A4.^{74,75,76} This may add credence to the use of a 10× uncertainty factor in risk assessment to protect the most susceptible individual.

Flavin-Containing Monooxygenases

Flavin-containing monooxygenases are another family of microsomal enzymes that require NADPH and oxygen to catalyze the metabolism of various xenobiotics that contain nitrogen (e.g., amines), sulfur (e.g., thiols), and phosphorus (e.g., organophosphates). There are several forms of these oxygenases, which have different distributions in various organs and species. Thus mouse and human liver have a high concentration of FMO3 and low concentration of FMO1 and the reverse is true in the rat, but both are present in high concentrations in the kidneys of all three species. Hepatocytes in female mice have higher expression of FMO1 and FMO3 than do male mice.⁷⁷

Phase II Reactions

These include several important conjugation reactions, some of which accelerate the elimination of xenobiotics.

Glucuronidation. A series of enzymes called uridine diphosphate glucuronosyltransferases, found in various tissues of mammals other than felines, catalyze the conjugation of xenobiotics with glucuronides, which are usually water soluble, allowing excretion in the urine (low molecular weight forms) or in the bile.

Glutathione (GSH) Conjugation. Many xenobiotics are electrophilic and will react with GSH. The conjugation is accelerated by cytosolic glutathione-S-transferase (GST) enzymes. GSH conjugates

can be excreted in the bile or can be transformed to water-soluble metabolites in the kidney and excreted in the urine. Polymorphisms at the GST loci result in variable efficiencies of the conjugation reaction. Depletion of GST-P1 in the lungs has been associated with increased susceptibility to lung disease and the effects of smoking, and enhanced apoptosis of lung fibroblasts.⁷⁸ Despite early suggestions, a meta-analysis of 20 studies did not find that GSTM1 deficiency was a risk factor for colon cancer.⁷⁹ Divalent cations readily bind with sulfhydryl groups, including GSH, and indeed, treatment with mercury increases the activity of several enzymes involved in the synthesis of GSH and the reduction of glutathione disulfide (GSSG).⁸⁰ Conversely acetaminophen depletes GSH levels in liver; both the depletion and the subsequent hepatotoxicity are inhibited by diallyl sulfone, a metabolite of garlic,⁸¹ which inhibits CYP2E1 which activates acetaminophen.

Other Reactions. Sulfation results in the formation of a water-soluble ester due to the transfer of the SO₃ moiety. Methylation and amino acid conjugation are minor pathways. *N*-Acetylation is a major pathway for aromatic amines or hydrazines. It is catalyzed by *N*-acetyltransferases (NAT). These are cytosolic enzymes found in most mammals, except canines. There are at least three forms of NAT, and a deficiency in either activity or structure of NAT2 results in slow acetylation of certain drugs (for example, the antituberculosis drug, isoniazid). This deficiency occurs in about 70% of the Middle East population, in 50% of Europeans, and in 20% of Asians. Sulfur transferases have been found to have a wide role; for example, the enzyme 3-mercaptopyruvate sulfurtransferase is capable of detoxifying cyanide by transferring a sulfur, forming the less toxic thiocyanate.

Sequestration of Xenobiotics. The amount of a substance available to affect a target organ or excrete depends on how much has been stored or bound. Sequestration of an agent in an organ need not be permanent. Stored substances may be slowly or quickly released from such relatively inactive depots as bone or fat. Lipophilic substances such as chlorinated hydrocarbons and organometals are generally found in fatty tissues or in lipid components of cells and membranes. They may be released in large concentrations from fat during starvation or illness. Metal ions such as strontium and lead compete with calcium for deposition in bone, and bone therefore provides a long-term storage depot for these ions. For example, lead accumulates in bone and may be suddenly released during the remodeling of bone that occurs in menopause⁸² and organochlorines may be mobilized from fat during periods of rapid weight loss.

Metallothioneins are low-molecular weight proteins rich in sulfhydryl groups, which are involved in the regulation of zinc and other cations. Some metals such as cadmium can induce the formation of metallothioneins in the liver, and these proteins in turn bind the metal and influence its transport to other organs.

Routes of Excretion

Xenobiotics and their metabolites are excreted mainly through the urine and feces, but also through the lungs, sweat, milk, and through the sloughing of skin and hair. Renal clearance is greatest for substances that are water soluble or that are conjugated into hydrophilic complexes. Fecal excretion usually occurs for substances that are lipophilic or can be conjugated into lipophilic complexes. Enterohepatic cycles may exist to interfere with excretion. A substance that is lipophilic can be secreted into the intestine, from which it is immediately reabsorbed, redistributed to the liver, conjugated with bile, and returned to the gut. Humans exposed to organic mercury, excrete it mainly in feces, while inorganic mercury exposure is reflected mainly by urinary excretion. For organics, molecular weight influences the excretory pathways. Higher chlorinated PCBs are excreted mainly in feces while mono- and dichloro PCBs are excreted mainly in urine.

Volatile compounds are excreted through the lungs. At any moment, the concentration of volatiles in expired air depends on how much has just been inspired (but not absorbed), as well as how much

is released to the lungs from the bloodstream. Measurement of volatiles in expired air is potentially useful for monitoring VOC exposure.

Short-chain chlorinated hydrocarbons are highly volatile, and whether consumed in water or inhaled, they are excreted via the lungs. Once they reach the liver, they are oxidatively metabolized into polar metabolites, which are water soluble and are not excreted in the air.

Biological Half-Lives. The concept of a radiologic half-life, whereby the radioactive decay of a compound can be predicted, is mirrored by the biological half-life, the time it takes for half of a dose of a xenobiotic to be eliminated. However, as elimination may follow a two- or three-phase decay curve, the half-life is only an approximation, and estimates of half-lives vary among studies and among individuals as well. The individual variation in half-life of cadmium in the kidney has been estimated to range from a few years to a century.⁸³

► DEFENSES

Over many generations, organisms develop adaptations to environmental stressors including toxic chemicals. Fish and crustacea that live in contaminated water or sediments must have adaptations for tolerance, not required of conspecifics living in pristine conditions. Killifish, for example, living in contaminated bays such as New Bedford Harbor, Massachusetts, have experienced strong artificial selection for tolerance, and have quickly (about 50 years) evolved genetic resistance to the toxic effects of PCBs and PAHs.⁸⁴ The basis of tolerance may be genetic, requiring selection of the more tolerant organisms over generations, or physiological (for example, by enzyme induction or organ hypertrophy). Transfer experiments have verified that organisms moved from clean to contaminated environments lack the tolerance acquired either genetically or physiologically.⁸⁵

Defenses begin at the behavioral level. Organisms can avoid contaminated environments. Contaminated foods can be tasted and rejected. In primate family groups, one individual may taste a fruit and wait for hours before encouraging other members to partake. Noxious chemicals may cause the individual to vomit or feel abdominal pain, which would be a warning to avoid such items now and in the future and would be communicated to other group members. At the physiological level, chemicals may cause enzyme induction which hastens their own breakdown, thereby protecting against subsequent dose. Some sulfur-rich molecules such as GSH scavenge many xenobiotics, binding them and preventing their uptake by target tissues. Defenses also operate on the cellular level in the form of lysosomes.

► TOXICOLOGICAL EFFECTS AND PHARMACODYNAMICS

Endpoints or Responses

A toxicological effect may be manifest at the molecular, cellular, tissue, organ, individual, or population level. Some effects such as death, acute respiratory illness, skin rashes, and toxic hepatitis may be readily apparent, while others may be subtle, requiring sophisticated testing for identification. Endpoints depend on the toxic properties of a chemical and what the researcher chooses to study. A chemical may be highly specific, such as the effect of benzene on the bone marrow causing leukemia, or nonspecific. Endpoints may be sought in any organ system or any tissue type. They need not be clinically significant.

Recently, attention has focused on subcellular and molecular targets of poisons and on biomarkers. Toxicology is concerned with all of these forms and levels of injury.

Dose-Response Curve

Although many toxicological studies simply report the presence or absence of a particular effect, the hallmark of toxicology is the

Figure 20-2. The classic sigmoid dose-response curve showing a threshold and asymptote of maximal response.

dose-response curve. This is predicated on the fact that a high dose of a substance usually has a greater effect on any endpoint than does a low dose. The dose-response curve (Fig. 20-2) plots the dose along the X-axis and the endpoint response along the Y-axis. The typical dose-response curve has the sigmoid shape illustrated. It is a cumulative percent response curve showing the severity of response of an individual given increasing dose (individual curve), or the number of individuals responding (population curve).

It is customary to measure dose in terms of the amount of the agent divided by the body weight of the organism, for example, milligrams of chemical per kilogram of body weight. In some cases, for example, acute toxic effects or sensitization of the skin, eye, or respiratory tree, the toxicant is not distributed throughout the body, and the dose per body weight is therefore not a good predictor of effect. In such cases different units must be used, such as concentration in a volume of air or on an area of skin.

In interpreting dose-response data from animal studies, it is necessary to know the species, strain, age, and sex of the test animals, the conditions of exposure, as well as the dose. Endpoints include death, presence of lesion (e.g., tumor), number of lesions, and anatomic, physiological, biochemical, molecular, or behavioral changes. Thus if one were concerned with neurotoxic, nephrotoxic, and lethal characteristics of a particular chemical, one would draw three dose-response curves, graphing the severity of each effect against dose. Fig. 20-3 shows nested dose-response curves for the number of people manifesting each different endpoint (increasing in threshold and severity from left to right) with different levels of organomercury exposure. Thus, difficulty in speech occurred at a much lower dose than coma and death.

The common features of most dose-response curves are shown in Fig. 20-2. Initially, there is a flat subthreshold portion where an increase in dose produces no detectable effect. The threshold is the lowest dose that produces an observable effect. Beyond that point, the curve tends to rise steeply and often enters a linear phase where the increase in response is proportional to the increase in dose. Eventually a maximal response is reached, and the curve flattens out. Various endpoints have been used to reflect toxicity. Traditionally toxicologists were interested in the LD-50, the dose which killed half of the exposed animals. The Y-axis was therefore the number of animals dying at each dose. Various chemicals could be ranked in terms of their LD-50. This proved to be a very narrow indication of toxicity, and many other endpoints have proven more useful, but one can still speak of the response dose, or RD-50, or the effective dose, or ED-50. Since typical toxicological studies used only a few doses, it was unlikely that the actual LD-50 dose would be used. The same data can be plotted using a probit scale for the Y-axis, resulting in a straight line, which allows the LD-50 (or RD-50) to be identified from the graph.

Figure 20-3. Nested dose-response curves for different clinical manifestations of organomercury poisoning based on the epidemic in Iraq (1971), showing the progression in thresholds from the relatively minor but early sign of paresthesias to lethality, estimated at the time exposure ceased. Solid squares = paresthesias, open squares = ataxia, solid triangles = dysarthria, open circles = deafness, solid circles = death. (Source: Takizawa Y. *Epidemiology of mercury poisoning*. In: Nriagu J, ed. *The Biogeochemistry of Mercury in the Environment*. Amsterdam: Elsevier; 1979.)

Hormesis. Many substances that are essential elements or nutrients at low doses, for example, iron and chromium, become toxic at high doses. Whether certain other nonessential, xenobiotics, or radiation, also have a beneficial dose range (*hormesis*) is controversial. Hormesis has been promoted as a general phenomenon.⁸⁶ However, confusion arises between unitary phenomenon where a particular agent produces a specific response that follows a U-shaped curve rather than a sigmoid curve, and other situations where there are compound responses such as growth, immune responsiveness, and longevity.⁸⁷ Confusion also arises between the terms beneficial and harmful on the one hand versus high and low on the other. Thus a beta-blocking agent may produce a monotonic beta-blockade in the autonomic nervous system, but this may be viewed as beneficial (therapeutic range) or harmful (toxic range). Hormesis, if it occurs, may have regulatory implications, but is not helpful in understanding toxicology.

Composite curves

Where a substance produces more than one kind of response separate curves should be drawn for each, such as the organomercury curves (Fig. 20-3). If one of the responses is beneficial, a downward curve can be drawn, while the traditional upward curve illustrates the toxic response (Fig. 20-4). This can allow detection of a safe or therapeutic region, above which the undesirable or toxic effects are reached. For example, eating fish provides great nutritional benefits, but above a certain level of consumption the benefits are outweighed by the toxic constituents (mercury and PCBs).⁸⁸ This would not be considered an example of hormesis since the endpoints are very different.

Thresholds. Thresholds (Fig. 20-2) are a familiar concept to physiologists and biochemists. A particular response may not occur at a very low dose or intensity of stimulus. Thresholds probably exist for most toxicological exposures. Thus we can live normal lives even though we are exposed to myriad chemicals, albeit at low (sub-threshold) levels. Experience with radiation, however, indicated that even at very low doses there was a measurable response. There did not seem to be a definable threshold, or the threshold was very close to zero. This led to our understanding of a no-threshold approach to carcinogens.⁸⁹ This is one of the most controversial issues in toxicology, with critics claiming that there must be a level of radiation below which no harm occurs, or even where there is benefit. The National Research Council's Committee on Biological Effects of Ionizing Radiation (BEIR-7 Committee) has (June 2005) reaffirmed that the linear-non-threshold model is still the best approach to cancer risk assessment for low doses of radiation (BEIR).⁹⁰

The concept of a threshold is also a source of severe controversy in the case of chemical carcinogens,⁹¹ where, theoretically at least, a single molecule may be the critical molecule that induces a cancer transformation in a cell. Some scientists believe that there must be a threshold for cancer as there is for other toxicological reactions. Others argue, on theoretical grounds, that since no threshold (below which no cancer risk exists) has been demonstrated, there probably is not a threshold. In the light of the ongoing controversy, some governmental regulatory agencies have concluded that, until we are more certain, it is prudent to act as if there were no threshold for carcinogens. Thus the application of a no-threshold approach to chemical carcinogens can be viewed as a policy decision rather than a scientific decision.⁹²

Latency

Latency is the time between a stimulus and a response or, in toxicology, the time between an exposure and an effect. In some cases (for example, acute exposure to hydrogen sulfide), the effect is felt in seconds, and the latency is therefore measured in seconds. In the case of

Composite benefit-risk by dose curve

Figure 20-4. Composite benefit and risk by dose curve, summing the dose-response curves for harm (H1, H2) and benefit (B) to arrive at net benefit-harm composites (N1, N2). Up-arrows under X-axis indicate thresholds. (Source: *The Environmental and Occupational Health and Sciences Institute*.)

asbestos-induced mesothelioma, a cancer of the lining of the chest or abdomen, the latency is on the order of 40 years, that is, the cancer may not develop until 40 years after the first exposure occurred.⁹³

If the latency is very short, as with acute effects, it is usually easy to establish a cause-effect relationship. When the latency is much longer, the cause may be long-forgotten before the outcome is realized. Accordingly, only sophisticated epidemiologic studies can identify cause-effect relationships with long latencies. In some cases there is a dose-response relationship for latency, that is, at higher doses latency is reduced.

Reversibility

Since most individuals recover from most toxic exposures, it is clear that many toxic effects are reversible. Inhibition of a biochemical pathway may be reversed if a competing agent is introduced to bind up the xenobiotic. If a cell is killed, it does not come back to life, but in almost all organs, regeneration of new cells occurs to take over the role of the damaged cells. In the case of genetic damage to the nucleic acid molecules, sophisticated biochemical reactions called “DNA repair” mechanisms are brought into play and eliminate, in various ways, the damaged DNA. Cells with irreparable DNA damage may be eliminated by apoptosis. Our DNA repair mechanism(s) become less efficient as we age, and this is one of the factors associated with the increased incidence of cancer in older people.

► SUSCEPTIBILITY

Although it is well known that individual humans vary in their susceptibility to different stressors, and although some of the factors modifying susceptibility are well known, there is a great need for research on susceptibility. In experimental animal species, strain, gender, and age influence susceptibility. Indeed, some rodent strains are bred for enhanced susceptibility to certain diseases. If a population of organisms were exposed to a fixed dose of a chemical, one could graph the responses with a histogram—how many individuals had no, low, medium, or high response. If response is quantitative, a smoothed histogram could be drawn. This might take the form of a normal, log-normal (Fig. 20-3), or some other distribution. If only one gender were susceptible, the curve would be skewed. Or if only very young and very old individuals were susceptible, the curve would be bimodal.

Other sections of this chapter describe the role of genetic polymorphisms which alter metabolism rates for xenobiotics and consequently risk of disease. These polymorphisms can be used as susceptibility biomarkers, for example, particular variants of CYP1A1, CYP1B1, GSTM1, NAT2, and CYP2E1.⁹⁴

Susceptibility is thus a complex phenomenon. Emphasis on single nucleotide polymorphisms is one of the simpler areas, and epidemiology has been fruitful in identifying subgroups with increased or decreased susceptibility due to abnormalities of phase I or phase II enzymes. Mutation of the gene *cyp2D6* alters drug metabolism, and a case-control study showed about a 70% increased risk of acute myelogenous and lymphoblastic leukemias among poor metabolizers at the CYP2C19 and 2D6 loci, the increased risk for the latter occurring only after age 40.⁹⁵ CYP1A1 abnormalities have been associated with increased lung cancer risk in some studies,⁹⁶ but not others.⁹⁵ Studies of phase II enzymes may be more rewarding. Variation in NAT2 activity reveals that slow acetylators have increased bladder cancer rates, while fast acetylators have increased colon cancer. Many enzymes are involved in hormone metabolism and variations in activity may contribute to variation in cancer rates in hormone-sensitive tissues, particularly breast. The importance of epigenetic effects is now becoming evident.

► MECHANISMS OF TOXICITY

Understanding how a chemical causes its adverse effect is important in directing research or influencing risk assessments. New advances

in biology including understanding of gene regulation, transcription factors, polymorphisms, receptors, cytokines, oncogenes, cell cycling, intracellular membranes, vesicles and transport, DNA repair, apoptosis, and epigenetic effects have greatly expanded the horizons of mechanistic toxicology since 2001.

Metabolic Poisons

These include substances that disrupt metabolic pathways, for example, cyanide compounds, which inhibit cellular respiration. Binding to an enzyme and altering its tertiary structure and its active site is a common mechanism. Some substances act within cells to alter the structure or function of internal membranes, such as endoplasmic reticulum, or organelles, such as mitochondria. Many chemicals act on mitochondria, interfering with their energetic function and resulting in swelling and loss of detail on electron micrographs and necrosis of cells.

Macromolecular Binding

Chemicals may bind to various macromolecules such as proteins, hemoglobin, or nucleic acids. These adducts may interfere with function or may be silent. Some are reversible, being repaired within hours, while others persist and may presage future cancer. The presence of DNA adducts may reflect genotoxic or carcinogenic properties, although their utility as biomarkers of cancer susceptibility has not been determined.

Cellular Poisons

Cellular poisons are substances that damage cells or cell membranes, causing necrosis or lysis or apoptosis. Membranes are functional as well as structural entities, and chemicals that interfere with membrane transport systems may have major consequences. Some xenobiotics are transported into cells by transporters that normally transport endogenous compounds. Toxic agents may react with either the protein or lipid component of the membrane nonspecifically or by binding to specific receptors. Many naturally occurring toxins cause lysis of cells (necrosis), for example, the hemolysins in certain plants and snake venoms. Some heavy metals act directly on the cell membrane, interfering with the sulfhydryl binding responsible for membrane integrity and altering membrane fluidity.⁹⁷

Apoptosis versus Necrosis

Apoptosis, often called “programmed cell death” is a necessary part of the life history of a cell, but is also a mechanism of toxicity. Gene activation leads to proteins that prepare the cell for apoptosis, which ends with phagocytosis of cell fragments, without concomitant inflammation.⁹⁸ This is an essential feature during development, allowing the remodeling of tissues. Apoptosis selectively eliminates cells with damaged DNA and also counters the clonal expansion of neoplastic cells. Inhibition of apoptosis, for example, by estrogens, allows mutations to accumulate and tumor proliferation to occur. Hormone-dependent tumors expand when the hormone inhibits apoptosis, while an antiestrogenic drug, such as tamoxifen, allows apoptosis to occur. Conversely, the tumor-promotor phenobarbital inhibits apoptosis.⁹⁹ The inhibition of apoptosis thus enhances the proliferative phase of carcinogenesis.¹⁰⁰ New cancer treatments focus on harnessing apoptosis to destroy tumor cells.¹⁰¹

Apoptosis kills cells by disrupting the cytoskeleton, affecting the nucleus and mitochondria. It occurs in all forms of life, and in all types of cells. Caspases, a group of proteases, are activated by an apoptotic signal and begin the process of destroying the cell, in a complex cascade of enzyme-enzyme interactions. Nuclear and cytoplasmic membranes condense and break into membrane-bound bodies, while in necrosis the effect can be on the cell’s energy cycles or on the cell membrane, causing cells to swell and lyse.¹⁰²

Enzyme Induction

Because of the specificity of enzymes, the body cannot at all times maintain a full supply of all the enzymes that may be needed for every

situation. Accordingly only some enzymes are constitutive (present in full supply), while many are inducible (produced in response to the presence of substrate). In normal development and cell cycling, the induction of appropriate enzymes is carefully regulated, whereas induction by xenobiotics is usually disruptive. Many substances induce the expression of the enzymes that will act on them, and within 12 or 24 hours the amount of enzyme protein present within a cell may increase by several orders of magnitude. Some enzyme systems are highly specific and act only on a single substrate, others are non-specific and catalyze classes of reactions on a wide range of substrates. The substrates vary in their potency at inducing enzymes. Enzyme induction plays an important role in metabolizing xenobiotics, either enhancing their toxicity or reducing it. However, sometimes the most important consequence of the enzyme induction is the greatly accelerated metabolism of endogenous bioactive compounds. For example, the pesticide DDT induced enzymes that broke down estrogen, and the resulting hormone deficiency disrupted reproduction of many animal species.

Receptors and Ligands

Advances in biochemistry include identifying the role of receptors and ligands and their regulation as an important part of many toxic interactions. Although some toxic interactions take place in solution, toxicologists have increasingly recognized that toxic effects usually involve binding of the toxicant to some active receptor site on an enzyme or membrane or to some intracellular ligand. The xenobiotic itself becomes the ligand for its receptor. A familiar example is the binding of neuroinhibitory substances to the receptors on the postsynaptic membrane or the myoneural junction. The xenobiotic-receptor interaction involves affinity, efficacy, potency, and reversibility. Receptors are important components of normal cellular function and account for the remarkable specificity of many cell processes. It is now realized that many hormone effects are mediated by hormone-specific receptors in particular target tissues, for example, the estrogen receptor. Some toxic effects occur because a xenobiotic is capable of binding to a hormone receptor or a neuroreceptor and interfering with the normal action of the endogenous chemical. Binding may be activating or inactivating.

The compound 2,3,7,8-TCDD, often known simply as dioxin, has proven a valuable tool for toxicological research.¹⁰³ Its effects are in part mediated by binding to the Ah (aryl hydrocarbon) receptor which encodes a transcription factor allowing TCDD and coplanar PCBs and PAHs to affect gene expression.¹⁰⁴

Related substances that bind to the Ah receptor have effects similar to TCDD, but with vastly different dose-response curves related to their binding affinity. By binding to estrogen-like receptors that might normally be activated by estrogens, dioxin may inhibit the proliferation of breast cancers. This is based on animal research. However, a study of the dioxin-exposed communities around the Givaudan chemical plant in Seveso, Italy, which exploded, releasing a cloud of dioxin, showed a deficit of breast cancer, although other cancers were elevated.¹⁰⁵

A normal feature of receptor models is that they are reversible, allowing the same biological function to be rapidly repeated. Toxic effects involving receptors often are much less reversible (for instance, the binding of carbon monoxide to hemoglobin or the inhibition of cholinesterase by organophosphate pesticides). This leads among other things to competitive inhibition between the xenobiotic and the endogenous compound.

Immunotoxins

Immunotoxins act by suppressing or activating the immune system and through autoimmunity and hypersensitivity. Immunosuppression predisposes to infectious complications and virus-induced cancers. Some alter the formation of immunoglobulins, while others affect the lymphocytes. Some agents interfere with the production or function or lifespan of the B and T lymphocytes. B cells control antibody-mediated or humoral immunity. T cells mature in the thymus and are the main factor in cell-mediated immunity. T cells are classified on

the basis of surface antigens, and it is now commonplace to quantify a variety of T-cell subpopulations and determine which functions have been inhibited.

Substances known to interfere with the immune system include polyhalogenated aromatic compounds (e.g., 2,3,7,8-TCDD), metals (e.g. lead and cadmium), pesticides, and even air pollutants (e.g., NO₂, SO₂, tobacco smoke). Mercury, for example, causes autoimmune changes and glomerulonephritis in the brown Norway rat strain but none in the Lewis strain. This appears related to a depletion of the RT6⁺ subpopulation of T lymphocytes in the former but not in the latter.¹⁰⁶ Xenobiotics may cause T cells, NK cells, and particularly macrophages to release cytokines which initiate inflammatory responses. The release of tumor necrosis factor alpha from various cells can stimulate epithelial cells to produce chemotactic signals that recruit leukocytes. Oxidants can activate transcription factors (for example NF-kappaB), which influence inflammatory mediators.¹⁰⁷

Sensitizers. Sensitizers are substances that act through the immune system to induce an increased immune response. These can be complete allergens or haptens. The main target organs are the skin itself and the respiratory system. Nickel and poison ivy (*Rhus*) contact dermatitis are common examples of such skin sensitization. Occupational asthmas reflect sensitization of the lung and airways to aerosols. The tests used to evaluate immunotoxicity include quantification of IgE, IgM, IgG, counts of B cells, T cells and their subsets, T helper and suppressor cells and their activity, natural killer cells and their activity, and cytokine levels, for example, interleukin-2 production.

Genotoxicity

Radiation and various chemicals are capable of damaging DNA, the genetic material, or interfering with the processes involved in chromosomal replication and cell division. Damage occurring in the germ cells may be heritable, while those occurring in somatic cells are not.

Mutagenesis. Some substances interact with genetic material, causing either point mutations, chromosomal damage, or interference with meiosis, mitosis, or cell division. A variety of tests can measure these effects including chromosomal aberrations, aneuploidy, sister chromatid exchange, translocation assays, micronucleus formation, glyophorin A assay, and T-cell receptor genes. New genetic techniques allow sequencing of genes and detection of changes at specific codons.

Mutation Spectrum. Genetic analysis can reveal a pattern of GC or AT base pair substitutions, deletions, or duplications at a single gene locus in individuals with a particular exposure. The relative frequency of the different mutations—the spectrum—may differ depending on the nature of the exposure. For example, somatic mutations at the X-linked hypoxanthine phosphoribosyltransferase (*hprt*) gene are mainly deletions (49%) or base pair substitutions (44%). Although GC substitutions are commoner in nonsmokers, there was a slight increase in AT substitutions in smokers.¹⁰⁸ However, after radiotherapy there was a substantial increase in rearrangements and deletions, which persisted for at least several years.¹⁰⁹

Ras Oncogenes. Genotoxic chemicals may cause mutation in proteins called proto-oncogenes producing the mutant oncogene that encodes for a modification of the natural protein product. Some changes such as that in the *ras* proto-oncogene increase cell susceptibility to cancer. The 21-kDa protein (*p21*) binds with a receptor on the inner cell membrane and mediates responses to growth factors. Mutation at codon 13 “locks” the protein into the active form such that it no longer responds to other cell signals. With signal transduction impaired, this permanent activation is associated with malignant transformation and proliferation.¹¹⁰

Tumor Suppressor Genes (*p53*). Certain proteins inhibit cell division cycles. If the genes that encode these control proteins mutate,

the resulting gene product may lack the inhibitory effect, allowing unbridled cell proliferation. One of these, the *p53* gene, encodes a 53-kDa protein, which among other functions inhibits cell growth, slowing the process of neoplastic transformation. Once thought to be a tumor antigen, elucidation of its suppressor role required two decades of study.¹¹¹ Transgenic mice that lack *p53* develop cancer at an early age.¹¹² Humans heterozygous for normal *p53* suffer the Li-Fraumeni syndrome with increased risks for cancer at a young age. Contrary to radiation, chemical carcinogens do not attack DNA randomly; rather there are hot spots vulnerable to adduct formation. There is an association between a change in the 249th codon of the *p53* product in people exposed to aflatoxin B₁ and in people with hepatocellular carcinoma, suggesting that the toxin may cause cancer by this highly specific mutation.¹¹³ Similarly benzo[a]pyrene, a lung carcinogen, consistently forms adducts with guanine at the 157th, 248th, and 273rd codon of *p53*.¹¹⁴

Reproductive Effects

The processes of gametogenesis, fertilization, implantation, embryogenesis, organogenesis, and birth are complex and subject to many errors. Major errors incompatible with life generally result in abortion, which can be viewed as a quality control procedure. Adverse reproductive consequences include failure to form gametes (e.g., azoospermia) and formation of abnormal gametes. Once gametes are formed, several factors may intervene to prevent fertilization, embryogenesis, or implantation. There is concern that many synthetic chemicals, particularly those that bind to hormone receptors, may interfere with one or more of these steps. A notable case is dibromochloropropane (DBCP), a nematocide, which induced oligospermia or azoospermia in the men who manufactured and packaged DBCP. Those with azospermia never recovered normal spermatogenesis after cessation of exposure. Lead also interferes with spermatogenesis. A long list of chemicals has been implicated in toxicity to the male reproductive system (including interfering with spermatogenesis, semen quality and sperm motility, erection, and libido). The list of chemicals affecting female reproduction includes cancer chemotherapeutic agents, other pharmaceuticals, metals, insecticides, and various industrial chemicals.¹¹⁵ Cord blood is routinely collected in many centers, and can be used to measure levels of toxicants or other biomarkers in the neonate.¹¹⁶

Teratogenesis

From conception through birth and maturation, the organism undergoes a bewildering series of carefully timed events that require the formation and replacement of tissues. Some substances interfere with the complex processes of morphogenesis. Depending on the stage of embryogenesis and fetogenesis, they may affect different organ systems, leading to embryonic death, major structural birth defects, slowed maturation, or even postnatal effects such as learning difficulties.¹¹⁷ Thus, there is a sequence of critical windows in development, during which a xenobiotic may produce a specific defect. In general, exposure prior to implantation is likely to be lethal. Exposure during organogenesis begets birth defects or embryo lethality. Later in fetal life, one sees intrauterine growth retardation or fetal death or functional changes that interfere with birth or postnatal development. Approximately 3% of live births have detectable congenital abnormalities, and additional congenital defects may become apparent later in life. Some of the defects are genetic or chromosomal in origin, but some are due to chemical exposures (including drugs taken by the mother).

The recently recognized field of behavioral teratology involves study of some of these effects, such as the impact of lead exposure on psychomotor development and learning. The fetal alcohol syndrome reflects the specific toxicity of ethanol ingested by the mother on the development and behavior of the newborn.

Endocrine Disruptors

This rubric applies to a wide range of substances and a wide range of effects and is an area of major controversy highlighted by Theo Colburn's book, *Our Stolen Future*.¹¹⁸ The ability of DDT to influence

estrogen metabolism through enzyme induction has been established since the early 1960s, but recent research has shown a wide range of effects in various animal species from compounds that resemble hormones or that interact with hormone receptors to enhance or inhibit normal endocrinologic function particularly related to development, maturation, and reproduction.¹¹⁹

Many of these compounds occur naturally in vegetables and have been called "phytoestrogens." These include a group of isoflavonoid and lignin polycyclic compounds. At the same time that concern is voiced regarding interference with reproduction and development, their beneficial features are being exploited. One isoflavonoid, coumestrol, antagonizes estrogen during embryonic development, leading to reproductive abnormalities in behavior and hormone function. Others, such as genistein, protect against certain hormone-dependent breast cancers by competing with estrogens, or against other cancers by inhibiting proliferation, differentiation, or the vascular supply.¹²⁰ However, public concern has focused more attention on industrial chemicals with endocrine activity, particularly on Bisphenol A and nonylphenol, exposure to which is widespread in developed countries.¹²¹ A group of structurally diverse xenobiotics that activate a peroxisome proliferator receptor in the liver, may alter steroid metabolism.¹²² PAHs with steroidal-like structures have weak estrogenic and antiestrogenic action.

Research is proceeding on many fronts¹²³ including using the bioengineered yeast estrogen screen, in which the human estrogen receptor and estrogen response elements are expressed to screen for the action of various xenobiotics. The potency of these compounds is influenced by environmental persistence and bioamplification, bioavailability, and binding affinities.¹²⁴ Most attention focuses on estrogenicity, either enhancement (in relation to estradiol) or inhibition. Binding to the estrogen receptor can be activating or blocking. Moreover, other parts of the endocrine system such as the thyroid and hypothalamic-pituitary-adrenal axis are also vulnerable to interference.

Oxidative Stress and Free Radicals

In addition to its critical role in supporting cellular respiration and oxidation-reduction reactions throughout the body, oxygen plays a more sinister role in toxicity. Normally there is a balance between oxidative and antioxidant reactions. However, oxidative reactions have long been known to play important roles in inflammation, aging, carcinogenesis, and toxicity.¹²⁵ Much of this is mediated by the formation of superoxide radicals.

Toxicologists speak of reactive oxygen species, some of which are free radicals. These are designated in formulas with a star or asterisk. Oxygen can receive an electron and form a superoxide anion radical, which can in turn react with hydrogen to form hydrogen peroxide, which reacts with free electrons and hydrogen ion to form water and a highly reactive hydroxide radical. In the course of these reactions, the highly reactive free radicals, particularly the hydroxy radical, are available to attack macromolecules, initiating a variety of toxic effects. The superoxide anion radical is formed in many oxidation reactions, where oxygen acts as an electron receptor. Thus chromium increases the formation of superoxide anion and nitric oxide in cells and enhances DNA single-strand breaks.¹²⁶ Glucose-6-phosphate dehydrogenase (G6PDH) is essential in cells facing oxidative stress, which in turn increases the amount of G6PD in exposed cells.

The fungicide maneb damages dopaminergic neurons through oxidative stress, an effect enhanced by GSH depletion.¹²⁷ Transgenic mice that overexpressed superoxide dismutase or GSH peroxidase were relatively resistant to the antioxidant effect of maneb combined with paraquat.¹²⁸

In response to the potential harm that these reactive oxygen species may cause, the body has evolved antioxidant defenses, including water-soluble vitamin C and lipid-soluble vitamins E and A. Superoxide dismutase, a metalloprotein, and GSH-dependent peroxidases, in association with GSH reductase, serve to scavenge free radicals. One of the consequences of free radical formation is reaction with lipids, including those in cell and organelle membranes, to form lipid peroxides, which in turn lead to cell damage and dysfunction.

Lipid Peroxidation

Some cytotoxicity of chlorinated hydrocarbons such as carbon tetrachloride are mediated by peroxidation of membrane lipids, which can be caused by a variety of reactive oxygen species.¹²⁹ An active area of research involves identifying naturally occurring and synthetic compounds that interfere with lipid peroxidation.¹³⁰ For example, peroxide radicals can attack fatty acids in the cell membrane producing a lipid peroxy radical, which self-converts through a series of reactions into lipid aldehydes, which result in both membrane disruption and the generation of new free radicals.

Nitric Oxide

A major recent development has been recognition of the complex roles that nitric oxide (NO) plays in the cell as an intracellular messenger. This occurs in the nervous system, lung, and liver, where synthesis is altered by xenobiotics.¹³¹ NO also has antithrombotic properties and is a potent vasodilator. L-Arginine is converted to nitric oxide by a calcium-dependent, NADPH-dependent cytosolic enzyme, nitric oxide synthase (NOS).¹³² This formation is coupled to activation of glutamate receptors.¹³³ Excess NO production increases intracellular free radicals enhancing neuronal degradation.¹³⁴ A common polymorphism (Glu to Asp at the 298th codon) impairs these activities.¹³⁵

► CARCINOGENESIS: INITIATION AND PROMOTION

Cancer is not a single disease, but includes a great many diseases that share a common property of uncontrolled cell proliferation. Normally cell proliferation proceeds in controlled fashion ensuring an adequate number of new cells for any given physiological task. Carcinogens dysregulate this process. It is customary to divide carcinogenesis into stages: *initiation*, *promotion*, *proliferation*, and clinically apparent *disease*. Initiation is the process by which the genetic material of the cell is altered, predisposing it to cancer.¹³⁶ Such genetic abnormalities are often repaired, or initiated cells may be destroyed as part of the body's defense against cancer. However, we are exposed to initiating events throughout our lives. Initiated cells may survive but remain dormant, perhaps controlled by the immune system. In the presence of *promoters*, initiated or mutated cells have a selective growth and division advantage over normal cells. Promotion is the process by which initiated cells are stimulated or allowed to become cancerous,¹³⁷ and proliferation is the stage of clonal expansion. At each of these stages, defenses may reverse or retard the process of carcinogenesis and tumor growth.¹³⁸

Effects on Signal Transduction

Cell cycles are regulated by molecules that serve as signals to activate certain receptors that transduce signal (change the form of the signal) to influence genes. Signal transduction pathways typically alter gene expression or modify gene products, either enhancing or inhibiting their function. Many endogenous signal chemicals (such as hormones) as well as xenobiotics can alter gene expression by activating transcription factors, which in turn promote the transcription of certain genes.

► MIXTURES AND INTERACTIONS

Even today most toxicological study and virtually all toxicological regulation is based on a single compound tested and regulated one at a time. However, for several decades it has been appreciated that chemical exposure is rarely to a single compound, and that exposures occur either as mixtures of chemicals or against a backdrop of health status, lifestyle, pharmaceuticals which influence susceptibility. Many studies of two chemicals at a time are performed, but few triadic studies have been attempted. Mixture research can either be synthetic, testing two or more chemicals together, or analytic, testing a mixture and then trying to determine which components cause an

effect. Because of the need to test multiple doses, mixtures research could employ Latin square design common in other disciplines.

Interactions

When two chemicals are administered together or when an individual is exposed to a mixture of chemicals, there may be various interactions identified as follows: (a) *independence* or *additivity*: each substance produces its own effect appropriate for its dose; (b) *synergism*: the combined effect is greater than either substance would produce alone or additively, that is, it is supra-additive but rarely actually multiplicative; and (c) *antagonism*: the combined effect is less than one would have expected from one or both chemicals administered alone. A classic example of a truly multiplicative interaction is the case of asbestos and smoking.¹³⁹ Asbestos exposure increases the risk of lung cancer fivefold, while smoking increases the risk of lung cancer about tenfold over the nonsmoker's risk. The asbestos worker who smokes has a risk about 50 times greater than the person with neither exposure. Synergism may occur when substance A enhances the effect of B, promotes its activation, or interferes with its degradation and excretion. Antagonism occurs when A interferes with the uptake of B, competes with it for metabolic enzymes or substrates, or enhances its degradation or excretion.

Although truly synergistic interactions are rare, supra-additive interactions are probably common. In combination, the fungicide maneb and the herbicide paraquat, two chemicals likely to be used in farming, cause altered motor activity and coordination, a "Parkinsonian disease phenotype" in mice at doses below which either could cause such damage alone,¹⁴⁰ and this effect as well as reduction of dopaminergic neurons on the nigrostriatal pathway, is enhanced in elderly (18-month old) mice.¹⁴¹

There is a synergistic interaction between aflatoxin B1 (itself a potent hepatocarcinogen) and hepatitis B. Hepatitis patients exposed to aflatoxin are at greatly increased risk compared with normal subjects.¹⁴² Many xenobiotics, such as the PCBs and dioxins, induce enzymes (for example the P450s), which in turn alters the metabolism of endogenous chemicals and drugs.¹⁴³ The oxidation of toluene, for example, is greatly increased by prior exposure to PCBs. Co-contamination with mercury and PCBs occurs in various species of wildlife, and synergism between them has been proposed as a cause of developmental defects.¹⁴⁴

Likewise, phthalates and PCBs cause a supra-additive reduction of human sperm motility.¹⁴⁵ Expanded toxicological investigation of mixtures is essential to advance our understanding of hazards, exposures, and risk.¹⁴⁶ In addition to chemical mixtures, other modifying factors such as stress, can influence how an organism responds to a xenobiotic. In a classic and rare triadic (three-chemical study), White and Carlson¹⁴⁷ showed that caffeine potentiated combined effect of trichlorethylene and epinephrine in causing cardiac arrhythmias in rabbits. The combination of lead and restraint (stress) on pregnant rats had a greater effect on corticosterone levels in offspring than either treatment alone.¹⁴⁸

Age Interactions

Not surprisingly, chemicals can have different effects at different stages of the life cycle, from critical windows in prenatal development to enhanced vulnerability during reproductive life or old age. Genotoxic compounds affect older individuals preferentially because the DNA-repair function involving base-excision and adduct removal gradually declines with age. In rodents (*Peromyscus*) many enzymes involved in metabolism undergo systematic life-cycle changes.¹⁴⁹ Parkinsonism is a disease of the elderly, and traditionally age is considered the only definite risk factor. Evidence for a chemical-age interaction has been shown in mice where the fungicide maneb has a greater effect in 18 month old animals than in young adults.¹⁴¹ Older animals did not experience an increase in tyrosine hydroxylase activity to compensate for the absolute depletion in amount of the enzyme.

Interactions in the Environment

Interactions among chemicals in the environment are also prominent, but are beyond the scope of this chapter. For example, in air sunlight causes the photochemical oxidation of sulfur and nitrogen oxides (SO_x and NO_x) to produce ozone. Ozone itself interacts with volatile organics to produce acids and aldehydes.¹⁵⁰

► CLINICAL EVALUATION OF TOXICITY

Clinical toxicology usually refers to the emergency diagnosis and treatment of episodes of acute poisoning. Yet clinicians play an important role in the understanding of chronic poisonings as well. This requires an appropriate “index of suspicion,” accurate identification of possible hazards, and an estimation of the magnitude and circumstances of exposure, as well as delineation of toxic effects. The clinician obtains a detailed medical, social, environmental, and occupational history (see Chap. 19), performs a physical examination, and uses a variety of clinical and laboratory tests, including the assessment of biomarkers of exposure and effect. When a patient presents with a symptom complex or disease and a history of exposure to one or more substances, there is a twofold challenge. The first is to determine whether the chemical(s) can or do cause the disease. This is termed *general causation*, and often employs the Bradford-Hill postulates.¹⁵¹ The second, *specific causation* is whether exposure was sufficient to cause a particular person’s disease.

Evaluation of pulmonary damage may be apparent on chest x-rays, pulmonary function tests, or by alterations in the cells obtained by bronchoalveolar lavage. Or pulmonary cells obtained by bronchoalveolar lavage (or possibly by sputum induction) may be used in a lymphocyte proliferation test to identify specific sensitivities, for example, to beryllium.¹⁵² Damage to liver can often be detected by disturbances in the pattern of various enzymes that serve as markers of liver cell damage. Similarly, severe kidney damage may be reflected in the excretion of large proteins such as albumin, while low molecular weight proteins may be biomarkers of earlier damage.¹⁵³ The emerging discipline of proteomics seeks patterns of biomarkers sensitive enough to detect early damage, and specific enough to identify the cause.¹⁵⁴

► BIOMARKERS

The past decade has seen a tremendous emphasis on *biomarkers* in understanding toxic effects on humans^{155,156} and other organisms.¹⁵⁷ In the broadest sense, anything that can be measured (for example, blood pressure and historical information) could be included under the rubric of “biomarker,” for there is no clear distinction between these clinical measures and those identified through molecular biology, biochemistry, or analytic chemistry. The highest level of biomarker is direct measure of the chemical or a specific metabolite in human tissues.¹⁵⁸ However, for many chemicals, particularly low-molecular-weight organics, rapid metabolism or excretion renders this not feasible. Table 20-3 provides examples of biomarkers.

It has been convenient to divide biomarkers into three categories: markers of susceptibility, markers of exposure, and markers of effect. However, the distinction is blurred in practice, for example, when a xenobiotic (such as benzo[a]pyrene) forms an adduct with DNA that can be considered an effect, a marker for exposure, or (if it increases the risk of cancer), a marker of susceptibility (future likelihood of developing cancer). Biomarkers of exposure indicate how much of a substance has contacted or been absorbed into the body. Biomarkers of susceptibility are used to identify individuals with unusually high (or low) susceptibility to a particular stressor or xenobiotic. Biomarkers of effect are directly related to the toxic endpoint of interest. For example, cholinesterase depression by organophosphate pesticides is an effect biomarker, the means by which OPs cause disease, but are poor exposure markers since the levels among people do not correlate closely with exposure. Familiar biomarkers

TABLE 20-3. EXAMPLES OF BIOMARKERS

■ Biomarkers of Exposure

Specific chemical agent in blood, urine, hair, nails, exhaled air, feces
Specific metabolite in blood, urine, exhaled air
Specific effect marker can be exposure biomarker

■ Biomarkers of Effect

Male reproduction

Semen quality and sperm count and motility
Mullerian-inhibiting factor
Chromosomal aberrations
DNA adducts in sperm

Female reproduction

Chorionic gonadotropin assay
Urinary hormone assays

Pulmonary

Pulmonary function testing
Airway reactivity (challenge tests)
Pulmonary cytology
Clara cell protein 16

Immunology

Immunoglobulin levels
Lymphocyte counts (types, subtypes)
Lymphocyte function assays
T-cell-dependent antibody assays
Lymphocyte proliferation tests
Cytokine/chemokine activity
Receptor expression assays
Macrophage/leukocyte respiratory burst response

Lead poisoning

Blood lead
Zinc or erythrocyte protoporphyrin
Delta-amino levulinic acid in urine
Delta-amino levulinic acid dehydratase activity
Bone lead by X-ray fluorescence

■ Biomarkers of Susceptibility

Age, sex

Single nucleotide polymorphisms in proteins

Phase I metabolic enzymes
Phase II transferases
p53 tumor suppressor gene sequence

Metabolic enzyme activity

DNA repair assays

include blood lead (a biomarker of exposure) and zinc protoporphyrin (a biomarker of effect from lead exposure). The study of biomarkers in various human populations has been labeled *molecular epidemiology*.¹⁵⁵ Single nucleotide polymorphisms (SNPs) in CYP2D6, for example, result in fast or slow metabolism of certain substrates, rendering individuals more or less susceptible to toxicity, depending upon whether the xenobiotic metabolized by CYP2D6 is active in its native or metabolized form. The metabolism of PAHs by CYP1A1 is also subject to genetic variation, enhancing the susceptibility to lung cancer from the benzo[a]pyrene in tobacco smoke. Similarly, SNPs in phase II enzymes such as *N*-acetyltransferase may enhance susceptibility to bladder cancer in those exposed to aromatic amines, while reducing susceptibility to certain lung carcinogens.

Clara cells are nonciliated cells of the bronchi which secrete a 16-kD anti-inflammatory protein (CC16), which has been proposed as a marker of increased epithelial permeability. CC16 levels in blood were increased in healthy volunteers exposed to ozone,¹⁵⁹ but were decreased in workers exposed to NO_x.¹⁶⁰

There is a great variety of potential biomarkers, and new analytic methods continually enhance the ability to measure lower and lower levels of a marker, while advances in molecular biology add to the variety of potential markers.¹⁵⁶ Biomarkers of exposure are usually the

xenobiotic itself or a specific metabolite. Biomarkers of susceptibility are often genetic, but measurement of iron-binding saturation may indicate susceptibility to cadmium absorption, for example.¹⁶¹ Biomarkers of effects may be physiological, cellular, biochemical, or molecular. Actual application of molecular markers is growing rapidly.

Biomarkers complement environmental measurements in tracking the movement of a xenobiotic from its source, through the environment, to and into the body, and thence to metabolic, storage, ecretion, and/or target organs. Biomarker utility depends on sensitivity, specificity, and predictive value.

Biomarkers for Lead

Using lead as an example, the commonest approach to assessing exposure is simply to measure the lead content of a sample of whole blood. In the United States this is expressed as $\mu\text{g}/\text{dL}$ while in other countries it is reported as $\mu\text{mol}/\text{L}$. The amount of lead circulating in the blood at any time represents the recent intake as well as any mobilization from the storage organs, particularly bone. One target for lead is hemoglobin synthesis. Lead blocks several of the enzymes in the heme pathway, particularly delta-aminolevulinic acid dehydratase (ALA-D), resulting in the buildup and excretion of ALA in the urine. Ferrochelatase is also inhibited, resulting in increased protoporphyrin, capable of binding zinc instead of iron. Free erythrocyte protoporphyrin (FEP) and zinc protoporphyrin (ZPP) levels increase at high blood lead levels. Urinary ALA, once used as the biomarker of choice for lead poisoning, was considered too sensitive for monitoring occupational exposures. FEP or ZPP became widely used, particularly in evaluating childhood lead poisoning, but are not sufficiently sensitive now for evaluating changes when blood lead is below $10 \mu\text{g}/\text{dL}$. Urinary ALA and FEP were biomarkers of exposure and also biomarkers of effect since they were in the direct pathway by which lead produces anemia.

Interest in the chronic and cumulative exposure to lead, poorly reflected by current blood leads, has led to studies of bone lead, since bone is the major repository of lead in the body and accumulates lead in lieu of calcium. In vivo X-ray fluorescence has proven effective in some studies as a measure of lifetime exposure. This technique revealed that men as well as women mobilize lead from bone as they age.¹⁶²

Hair is not used for assessing lead, however, the concentration of mercury in hair is a good indicator of methylmercury intake, but does not reflect inorganic mercury exposure, while blood mercury reflects inorganic or elemental exposure and correlates with dental amalgams.¹⁶³

The National Research Council's Board on Environmental Studies and Toxicology has a Committee on Biologic Markers, which has published monographs on markers in pulmonary toxicology,¹⁶⁴ reproductive toxicology,¹⁶⁵ and immunotoxicology.¹⁶⁶ The potential application of biomarkers are boundless. They can be used to estimate exposure, internal dose, and dose to target cells. They can be the endpoint in dose-response assessments. They can be used to distinguish exposed from unexposed populations for epidemiologic studies. The study of biomarkers is largely in the domain of analytical chemistry. Enhanced specimen processing and analytic methodology have led to the vanishing zero, as chemical analytic instruments can now measure in the picomolar (10^{-12}) and even femtomolar (10^{-15}) range while new fluorescent technique advertise biological detection at the attomolar (10^{-18}) and even zeptomolar (10^{-21}) level, the latter approaching Avogadro's number for the number of molecules in a mole of a substance (6.22×10^{23}). Genomics now plays a major role in the quest for biomarkers.

Adducts

Adducts are formed when a chemical or its metabolite binds with macromolecules, particularly nucleic acids, but also proteins such as hemoglobin. Smokers, for example, have higher levels of benzo[a]pyrene adducts to DNA than do nonsmokers.¹⁶⁷ Some adducts are repaired within hours, while others persist. A variety of techniques have been used to assess adduct formation, including the 32P postlabeling (Randerath) technique based on differential mobility of DNA bases involved in adduct formation. This method has yet

to prove useful in screening other populations. DNA-protein cross-linking is promoted by a variety of genotoxic chemicals including hexavalent chromium.¹⁶⁸ Two benzene metabolites, hydroxyquinone and muconaldehyde, induce DNA-protein cross links supra-additively.¹⁶⁹

Radiation Damage and Chromosomes

The main body of information on the genetic effects of ionizing radiation derives from the 60-year follow-up of atom bomb victims of Hiroshima and Nagasaki conducted cooperatively by the United States and Japan through the Radiation Effects Research Foundation. The chromosomal damage in 2300 survivors shows a clear dose-response relationship that parallels the incidence of leukemia in the same population.¹⁷⁰ Radiation toxicology is summarized by Harley.¹⁷¹

► CAUSALITY: ENVIRONMENTAL CHEMICAL EXPOSURE AND HEALTH EFFECTS

In the laboratory, establishing causality between a chemical exposure and a health effect depends upon sound experimental design with careful attention to alternative hypotheses. It may or may not involve careful definition of the mechanism by which the effect is achieved. In the community, determination of cause and effect is much more difficult. Under these "natural" conditions, the hazardous substance is not always identified or may be present in mixtures, and the dose and the conditions and time frame of exposure are seldom known. It may be difficult to ascertain who is exposed as well as to what. Often there is a bewildering array of symptoms and signs suspected or attributed to the putative cause. Simply defining relevant health effects may be a costly and frustrating venture, while linking them to specific exposures may be impossible.¹⁷²

Scientists and clinicians may not appreciate that the courts impose entirely different standards for establishing causation. Moreover, standards of causation differ under different bodies of law. Thus, in some jurisdictions one may have to establish a "reasonable probability," in other cases it must be "more likely than not," or "without this event the outcome probably would not have occurred." In some circumstances one must establish an attributable risk, how much of the outcome can be related to the particular exposure. In other cases, the causation is "presumptive" unless proven otherwise. For example, the U.S. Congress required the Veterans Administration to give veterans the benefit of the doubt in cases involving herbicide exposure, and certain diseases in exposed veterans are now presumed to be related to herbicide exposure and qualify for compensation.

Case study: Vietnam Veterans Exposed to Herbicides

Among the herbicides used in Vietnam to deny cover and destroy crops, Agent Orange (a 1:1 mixture of two common herbicides) became a great concern. Synthesis of one component, 2,4,5-trichlorophenoxyacetic acid, resulted in a small amount of an unwanted condensation product, 2,3,7,8-tetrachloro-dibenzodioxin (TCDD), generally considered the most toxic synthetic compound. Extensive studies of veterans and other populations exposed to herbicides have resulted in different levels of confidence regarding causation. Table 20-4 gives an example of causal associations for various medical conditions and herbicide exposure in Vietnam (from the Institute of Medicine).¹⁷³

Establishing causation is one of the most challenging tasks in environmental toxicology. The Hill postulates mentioned above provide guidance. When toxicological studies give conflicting results, the weight of evidence approach is used. Careful review of the body of epidemiologic and toxicological evidence cannot always provide definitive answers, even for commonly studied chemicals to which many people are exposed. And only a small percentage of chemicals have been adequately studied. Elucidation of the causes of Gulf War Syndrome¹⁷⁴ and World Trade Center cough, provide additional examples.¹⁷⁵

TABLE 20-4. FOUR LEVELS OF ATTRIBUTABILITY FOR DISEASES IN VIETNAM VETERANS¹⁷³

■ Sufficient Evidence of Causation
Chronic lymphocytic leukemia
Soft-tissue sarcoma
Non-Hodgkin's lymphoma
Hodgkin's disease
Chloracne
■ Limited or Suggestive Evidence of an Association
Respiratory cancer
Prostate cancer
Multiple myeloma
Early-onset peripheral neuropathy
Porphyria cutanea tarda
Type II diabetes mellitus
Spina bifida in offspring
■ Inadequate or Insufficient Evidence
Hepatobiliary cancer
Oral, nasal, pharyngeal cancer
Many other cancers
Reproductive effects and birth defects
Many other conditions
■ Limited or Suggestive Evidence of no Association
Gastrointestinal tumors
Brain tumors

► TOXICITY TESTING

Toxicologists employ a wide variety of systems and paradigms to test chemicals in order to predict their effects on human health or the environment. Studies range from modeling, in vitro studies in cell components and cell cultures, animal experiments, and human epidemiology. The factors that affect toxicity in humans (Table 20-1) must be considered in designing the experiments. One must choose the appropriate animal model or in vitro test system. If using animals, the genetic strain, gender, and age of the animal must be selected. The dosage schedule, single or multiple, and acute, subchronic, chronic, as well as appropriate dose levels must be chosen. The route of administration should be relevant to natural conditions of exposure. The experiment should last long enough to fully encompass any effects that have a long latency. And appropriate controls must be selected. In addition to these design features, there are standards for good laboratory practices which indicate how animals must be cared for and how data must be recorded. This provides for appropriate quality assurance methodology. Increasingly, a variety of in vitro test systems are replacing many studies traditionally done in animals.

Bioassays of the National Toxicology Program

The National Toxicology Program (NTP), operated by the National Institute for Environmental Health Sciences, sponsors long-term rodent studies to detect the carcinogenic or other toxic properties of chemicals.¹⁷⁶ Chemicals are selected depending on the data needs of governmental agencies and in response to public concerns. The standard protocol is two species (rat, mouse), both sexes, and a minimum of 50 individuals for each category, with oral dosing over a 2-year "life span." These 2-year bioassays can provide information on metabolism and genetic, reproductive, and developmental toxicity as well as on toxic effects on various organ systems. The NTP bioassays serve an important role in screening new chemicals for carcinogenic activity and classifying them with respect to human carcinogenicity. However, the main application has been the use of the tumor incidence data in risk assessment. Only a small fraction of chemicals in commerce have been tested in these assays which are expensive and timeconsuming, and alternative techniques are sought to provide reliable answers more economically.¹⁰

Transgenic and Knockout Mice

For decades, toxicologists have taken advantage of rodent strains inbred for specific metabolic or susceptibility characteristics that rendered a particular strain suitable for a particular test. Genetic engineering has produced mice with highly specific defects that might not have arisen by chance, thereby offering a new array of "tools" for toxicological research. Thus, a mouse can be designed to be deficient in a particular protein or overexpress it, and traits can be combined in the same animal such as the severe combined immunodeficiency (SCID) mouse.

Human Exposure Studies

Human experimentation always presents ethical challenges and must be balanced against the value of the information gained. It should be confined to questions that cannot be answered by other methods, and must be designed to avoid serious harm to subjects. It is conducted under rigorous scrutiny by institutional review boards and must contain safeguards to avoid harm to patients. Many studies have been done using ingested or injected routes. Improved technology controlling air flow, particle generation, and vapor delivery has allowed the use of carefully controlled inhalation studies as well.¹⁷⁴ Unfortunately, one alternative to carefully controlled chamber studies are the inadvertent, uncontrolled, industrial exposures that have taken place in many settings without benefit of IRB review.

► ANIMAL WELFARE AND ANIMAL RIGHTS

Toxicologists have become increasingly attentive to the animal welfare/animal rights movements. Proponents of animal rights argue that animals have intrinsic rights that, in the extreme, should protect them from any and all use in experimental research. Whether "animal rights" are guaranteed by either human or divine "law," is beyond the scope of this chapter. However, animal welfare is clearly an important issue for toxicologists. The Animal Welfare Act (AWA) is administered by the Animal and Plant Health Inspection Service of the U.S. Department of Agriculture. Currently it applies only to mammals, exclusive of mice and rats. The discovery and standardization of alternatives to animals in research and testing systems is an active research area, and several journals are devoted to this topic. The challenge is to develop test systems, for example, cell cultures, that mimic the whole animal, but a major limitation is the rapid dedifferentiation of cultured cells with loss of the critical phenotype, that limits extrapolation.

Experimental animals should be spared unnecessary stress, discomfort, or pain. The AWA requires that alternatives to painful procedures be considered. Increasingly, researchers have sought alternative models that do not require whole animals. At the same time, animal research has been redesigned to use fewer animals and to minimize pain and discomfort. The National Science Foundation and National Institutes of Health have recognized the importance of animal welfare not only from a humane perspective but because stressed animals cannot provide an unbiased response in experimental situations. Accordingly, researchers using animals must take into account animal care guidelines, which stipulate the conditions under which animals must be kept and the availability of veterinary care. Research protocols must be reviewed by institutional animal care committees as well as by human subjects review boards. Animal facilities must be inspected and accredited, usually by the Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC).

With the recognition that stress is an important modifying factor in toxicology,²⁵ toxicologists must be more attentive to the stresses imposed on animals (even mice and rats) by handling and procedures, but also animal care and crowding.

The concern over animal welfare reaches its peak when primates are used. Primates are expensive to acquire and maintain, and most studies of primates can afford only a few animals who often live under unnatural and extremely stressful conditions. In addition, since

extrapolation from primates to humans is not always more appropriate than extrapolation from other animal models, most toxicology research does not involve primates, and the trend has been to close rather than expand primate research facilities.

► REGULATING TOXIC EXPOSURES

Protecting people and ecosystems from hazardous chemicals requires the interplay of governmental and nongovernmental bodies. There is a complex governmental regulatory framework for toxic chemicals in the environment. Each agency has distinct jurisdiction, and unfortunately there is not always consistency among agencies. Among these agencies and programs are the following:

Food and Drug Administration

This agency is responsible for protecting the integrity of food, drugs, and cosmetics (see Chap. 47) and ensuring that harmful levels of xenobiotics, additives, and adulterants are not present. It sets allowable daily intakes (ADIs) for various chemicals. A major change in the Food Quality Protection Act of 1996 was to increase its coverage of chemicals while setting aside the Delaney Amendment, which forbids any animal carcinogen as an additive or pesticide which left a measurable residue in food.

Occupational Safety and Health Administration

Established in 1970 by the Occupational Safety and Health Act, this branch of the U.S. Department of Labor is required to set standards that will protect workers from adverse health consequences (see Chap. 46). The Occupational Safety and Health Administration (OSHA) establishes permissible exposure limits (PELs), to which a worker could be exposed 40 hours a week for a 40-year working lifetime, and short-term exposure limits (STELs), the latter being ceiling values that cannot be exceeded for more than 15 minutes. Unfortunately most of its PELs are seriously outdated, based on 1968 data.

Environmental Protection Agency

The Environmental Protection Agency (EPA) has far-flung responsibility for protecting the environment. EPA sets and enforces regulations regarding amount of tolerable pollution and levels of contamination in soil, air, and water. It implements the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), originally passed in 1947, and the Toxic Substances Control Act (TSCA), originally passed in 1976, as well as Clean Air and Clean Water Acts, and many others. One of the latter acts established the National Toxicology Program and requires EPA to evaluate data on any new chemicals proposed for manufacture and importation.

Department of Transportation

The Transportation Act governs the labeling and handling of hazardous chemicals shipped in interstate commerce. It requires classification and testing of chemicals to determine the type and extent of hazard they might pose in the event of a spill.

► PRODUCT SUBSTITUTION

Both environmental and industrial toxicology have focused on the development of substitutes for widely used, but unacceptably toxic, chemicals that for various reasons are no longer acceptable. The chlorofluorocarbons (CFCs), used as refrigerants and propellants, have global atmospheric effects catalyzing the destruction of atmospheric ozone, which resulted in an international agreement to phase out their use. The development of compounds that share CFCs desirable properties and are also nontoxic and environmentally friendly is a major area of research. Likewise, the widely used dry-cleaning fluid

tetrachloroethylene is a possible human carcinogen. This has prompted a quest for alternative dry-cleaning substances, including the use of liquid carbon dioxide.¹⁷⁸

Chlorine. Another controversy concerns the movement to ban all chlorine-containing products. Many of the chlorinated solvents are classified as known or probable human carcinogens. Exposure to chlorination products in drinking water has been linked to low birth weight and small head circumference,¹⁷⁹ and to intestinal cancer,¹⁸⁰ although the potency is low and causality is in question.

Organomanganese in Gasoline. The removal of organic lead from gasoline was a major success in applied toxicology. However, its proposed replacement, methylcyclopentadienyl manganese tricarbonyl (MMT) may greatly increase exposure to manganese, itself a potent neurotoxin that causes a parkinsonian-like syndrome. MMT has been used in Canada since 1977, and urban pigeons have higher levels of manganese than do rural ones, consistent with traffic-related contamination.¹⁸¹ Widespread use of this compound in gasoline seems bound to repeat the lead-in-gasoline tragedy of the mid-twentieth century. In 1997, Canada terminated the use of MMT. EPA's attempt to prevent incorporation of MMT in gasoline was overthrown by Ethyl Corporation's court challenge. To date, however, MMT has not found its way into U.S. automotive fuel.

► PRECAUTIONARY APPROACH

Although society has always recognized the importance of precaution, it is not always embodied in regulatory practice. The Toxic Substances Control Act uses a precautionary approach, requiring pre-market testing of new chemicals. The precautionary approach developed extensively in the 1990s with regard to new technologies, and its generalization is that the existence of uncertainties, or the lack of definitive information, should not delay the regulatory or other control of new technologies or substances, where there is a reasonable presumption of serious or irreparable harm. Those who introduce new substances or processes bear the obligation of demonstrating their safety. This view competes with the alternative that a substance or technology is innocent until proven guilty, which at its most conservative requires demonstrating effects in humans. Advocates of precaution argue that human epidemiologic studies require large amounts of funding and that the most definitive prospective studies take long time periods, and that certainty requires multiple studies. Since epidemiologic methods are inherently conservative (low alpha and high beta, favoring type II errors over type I errors), a precautionary approach should always be considered.¹⁸²

► FUTURE DIRECTIONS

Imaging

New imaging techniques such as Positron Emission Tomography (PET), functional magnetic resonance imaging (fMRI), and MRI microscopy, offer great promise in toxicological research in vivo. These techniques have rapidly assumed prominence in clinical medicine, toxicology is beginning to exploit them.

Toxicogenomics

The promise of these new technologies is just being realized. The ability to produce *gene-chips* has opened new horizons for research. Gene expression arrays provide semiquantitative responses to xenobiotics, and data clustering techniques allow identification of which genes are up-regulated and down-regulated in response to a particular challenge. Due to the large number of responses (thousands of dependent variables read simultaneously), informatics is developing in tandem, building on principles of numerical taxonomy and multivariate clustering techniques established a generation ago by Sokal and Sneath.¹⁸³

The rapidly growing genomics literature illustrates two major trends in research: a descriptive pattern approach and a mechanistic approach. The former relies heavily on cluster analysis to elucidate patterns of gene response or protein increase or decrease in response to treatment. The latter tests hypotheses regarding particular gene-gene and gene-protein responses.¹⁸⁴ In view of the rapid developments in chip technology, identification and annotation of gene sequences on chips, it has become challenging to relate current findings to those published only a few years ago.¹⁸⁵

Nanotechnology

New technologies introduce new materials. While the future of nanotechnology is bright and imaginative, the hazards posed by solid phase structures small enough to be absorbed through membranes require study. Nanoparticles in the 1 to 100 nanometers (0.1 μm) size range occur naturally, and some have been in production for a long time (e.g., carbon black). Combustion, such as diesel exhaust produces a range of particle sizes, some in the ultrafine range (less than 100 nm aerodynamic diameter, and these have disproportionately higher inflammatory effects than an equal mass of fine particles.¹⁸⁶ Small nanoparticles can enter cells and be transported along axons. The smaller the particle, the greater its surface to volume or mass

ratio, and the greater potential for bioactivity. Extensive planning is required for meaningful nanotoxicology research.¹⁸⁷

Toxic Environments

Environmental health has traditionally examined environmental media in terms of pollutant concentrations in air, water, soil, and food. Research has shown the importance of interactions among chemicals and between chemicals and other factors such as stress. The social and home environment can be toxic as well¹⁸⁸ influencing both exposure and response to contaminants such as lead and cocaine. Moreover, urban and suburban environments impose their own stresses, which are attracting attention to the “built environment”¹⁸⁹ and the issue of environmental justice, an important part of environmental toxicology should be a major part of the national exploration of health disparities¹⁹⁰

► OLD DIRECTIONS

Among the many traditional areas of toxicology that require increased attention, two stand out in my mind: (1) mixtures and interactions and (2) time-dose interactions. As the new frontiers with dazzling technologies attract attention and funding, these traditional areas may have trouble competing for decreasing scientific grant funds.

Neurobehavioral Toxicity

Nancy Fiedler • Joanna Burger • Michael Gochfeld

The nervous system is a prominent target for many poisons that can cause morphological or functional damage.¹ Classical neurotoxic effects include the depression of central nervous function by anesthetic-like solvents, the weakness from anticholinesterase pesticides, the tremor of chronic mercurialism, or the peripheral neuropathy of lead poisoning. Recent attention has focused on dementia attributed to chronic solvent exposure and on neurodevelopmental disruption and cognitive impairment caused by prenatal exposure to ethanol, mercury, lead, and polychlorinated biphenyl (PCBs). Whereas evaluation of nervous system function was formerly the domain of the neurologist and electrophysiologist, neurobehavioral testing offers another dimension of evaluation that is important for several reasons. First, neurobehavioral tests are sensitive to subtle behavioral changes that may occur at doses lower than those required to cause anatomical or physiological changes or even symptoms or signs that can be observed by the clinician.²⁻⁵ Second, because neurobehavioral toxins can affect the higher levels of function and functional integration essential for complex cognitive processes, neurobehavioral (including psychometric) tests offer standardized methods to evaluate these critical and somewhat unique aspects of human behavior.

Although acute effects are often dramatic, the discipline has become increasingly concerned with chronic effects such as impaired learning, memory, vigilance, and depressed psychomotor performance. Persistent behavioral effects can occur as a consequence of acute poisoning or from prolonged exposure to low levels of chemicals.⁶ Neurobehavioral evaluations of exposed individuals or groups provide an opportunity to objectively evaluate the many nonspecific symptoms such as weakness, dizziness, irritability, listlessness, anorexia, depression, disorientation, incoordination, difficulty in concentrating, or personality changes, which are sometimes attributed to environmental exposures.

Ultimately toxicity occurs through the interaction of a chemical and a molecular target,⁷ yet in neurobehavioral toxicology we often treat the nervous system as a “black box.” Lotti¹ notes the frustrating

search for morphological correlates or markers of functional toxicity. In some instances, the molecular approach has been rewarding, although many mechanisms remain elusive. For example, neuropathy target esterase (NTE) was identified as the target for the organophosphate-induced delayed polyneuropathy (OPIDP).⁸ Although this mechanism was proposed in 1975, the physiological function of NTE remains obscure, and although the reaction of organophosphates (OPs) with NTE is understood, details of the subsequent cascade leading to the polyneuropathy is not known.⁹ Moreover, the known function of NTE (which allows measurement of its activity) is not related to the likelihood of developing the polyneuropathy. This neuropathy is characterized by distal axonal degeneration in both the central and peripheral nervous systems. OP pesticides are apparently less potent than tri-ortho-cresyl phosphate in causing OPIDP.⁹

Similarly, lead alters the sensitivity of the *N*-methyl-D-aspartate (NMDA) receptor complex. Several areas of the brain are rich in NMDA receptors, and the density of receptors varies with time during development. Antagonists of NMDA receptors impair learning in several study designs.¹⁰⁻¹² For example, in birds, NMDA antagonists block the learning of song.¹³ The ramifications of this change on imprinting, learning, and memory, which are influenced by the NMDA receptor in certain parts of the brain, are an active area of neurobehavioral research.^{14,15} Lead also blocks voltage-dependent calcium channels that mediate neurotransmitter release.¹⁶ While researchers continue the search for mechanisms to explain toxicity at the molecular level, behavioral methods to detect and quantify changes in function from acute and chronic exposure have developed in parallel. For example, in 1973 the National Institute for Occupational Safety and Health (NIOSH) convened a Behavioral Toxicology Workshop for Early Detection of Occupational Hazards³ which reviewed research findings on many substances in various organisms and considered the tools that could be applied for evaluation of behavioral toxicity.² During the past 30 years, the field has grown rapidly with a variety of experimental paradigms and clinical

approaches for detecting behavioral manifestations of neurotoxicity.^{17,18} There have been extensive reviews of experimental and clinical findings (see General References).

In this chapter, we review the target components of the nervous system, examples of neurotoxicants, the kinds of behavioral abnormalities seen, and some of the neurobehavioral tests currently used for evaluating such abnormalities.

► TARGET COMPONENTS OF THE NERVOUS SYSTEM

Hypothalamic-Pituitary-Adrenal Axis (HPA)

The hypothalamus is a major physiological control area of the brain and hypothalamic signals to the pituitary cause the release of various hormones which control other endocrine organs including the adrenal. Maternal exposure to lead, for example, permanently alters the HPA responsiveness in offspring.¹⁹ Prenatal exposure to morphine inhibits the HPA and alters the hypothalamic metabolism of serotonin, inducing chronic sympathoadrenal hyperactivity; when exposed to ether by inhalation, morphine-treated rats failed to increase tyrosine hydroxylase or epinephrine.²⁰

Autonomic Nervous System

Toxins structurally similar to neurotransmitters may enhance (agonist) or inhibit (antagonist) the normal function of either the parasympathetic or sympathetic systems. Many widely used drugs have primary or side effects on the autonomic system, and organophosphates interfere with parasympathetic function. Recent findings suggest that exposure to lead may permanently increase corticosterone levels in rats and alter responsiveness to stressors among the adult offspring of animals exposed during gestation and through lactation.¹⁹ Thus, lead and perhaps other neurotoxicants may exert their effects directly on the autonomic nervous system but may also exacerbate the effects of other external stressors.

Peripheral Nervous System

Peripheral neuropathies may occur when a xenobiotic kills nerve cells, destroys the axon, or causes myelinopathies. Even subtle damage to the myelin can be detected by nerve conduction velocity studies. Axonopathies involve a dying back of the axon itself (for example, that caused by *n*-hexane).²⁰ These defects can be detected by electrophysiologists or neuropathologists. Peripheral neuropathies may affect either sensory nerves, motor nerves, or both; usually sensory nerve fibers are most susceptible.²¹ The *n*-hexane axonopathy is a classical case of a specific metabolite (the 2,5-hexanedione), which causes cross-linking of neurofilaments, manifested by axonal swelling and dissolution.²² Carbon disulfide causes a similar cross-linking axonopathy, while the acrylamide neuropathy involves adducts of microtubule-associated proteins, impairing synaptic vesicle transport.²² The hexane axonopathy is a sensitive finding, occurring at relatively low doses; however, at high dose in acute CNS degeneration of the vestibular and cerebellar regions, it becomes the dominant lesion.²³ Arsenic causes subclinical sensory neuropathy detectable by the vibration threshold measurement (see below).²⁴

Central Nervous System

The central nervous system (CNS) is the primary domain of neurobehavioral toxicology. Neurotoxic effects in the brain are often complex, with elusive pathologic changes that affect associations among neuronal pathways. Improved histochemical approaches allow pathologists to detect changes in dendritic patterns and interconnections, for example, between two nuclei in the brain as well as the localized destruction of specific types of nerve cells. Many neurobehavioral effects are due to agonistic or antagonistic actions on neurotransmission in the CNS.

Brain development is an intricately timed and coordinated process involving multiple cell signaling molecules and pathways

that influence cell differentiation, neuronal migration, positioning, and synaptogenesis. Reelin, a signaling molecule is required for neuronal positioning and the ultimate layering of the neocortex. Mice that are heterozygote deficient develop with an ataxic, "reeling," gait. Ethanol interfered with reeling action, resulting in the failure of migrating neurons to stop at the appropriate position.²⁵

Research on how the brain achieves the so-called higher functions (learning, memory, creativity, cognition, etc.) gradually expands our understanding. Ablation studies (opportunistic or deliberate) and computer analogy are examples of approaches to understanding brain function. In addition, with the advent of single-photon emission computed tomography (SPECT), functional MRI, and positron emission tomography (PET), functional imaging has revealed the brain structures involved in the performance of various cognitive functions.²⁶ Some preliminary studies suggest that PET scanning could begin to clarify how brain function may be affected by solvent encephalopathy even when static CT and MR images have shown no structural abnormalities. For example, PET scanning has been used to document encephalopathy due to solvent exposure.²⁷

In addition to clarifying structural-functional relationships, it is necessary to clarify how substances pass through the blood-brain barrier (BBB) at different times in the life cycle, and what happens to them once they enter the brain. Methylmercury (MeHg), for example, readily passes the blood-brain barrier and to some extent is demethylated in the brain, but much remains to be learned about these processes and how their toxic effects are mediated.

Basal Ganglia

The recognition that Parkinson's disease (PD) did not have a familial basis has prompted research on possible environmental causes. Agricultural chemicals have been implicated, and rodents exposed to the herbicide paraquat, provides an animal model. The combination of paraquat + maneb augmented the PD effect, with reduction in locomotor activity, particularly in older mice, reflecting a reduction in dopaminergic neurons.²⁸

► SELECTED NEUROBEHAVIORAL TOXINS

This section provides a brief overview of neurobehavioral toxicants. (For more detail, see General References.) Many commonly occurring chemicals are neurotoxic. Table 20-5 indicates the variability in effects produced by some common neurotoxicants. Data from the National Health and Nutrition Examination Survey (NHANES III) comparing children's cognitive abilities to serum cotinine (a nicotine marker), reported a decrement in reading scores and block design (both verbal and spatial measures).²⁹ Carbon monoxide at relatively low levels (equivalent to carboxy hemoglobin [COHb] < 10%) impairs vigilance, tracking, and ability to drive.^{30,31}

Virtually all solvents, whether aliphatic or aromatic, chlorinated or not, have acute depressant effects on the nervous system, many of them sharing common anesthetic properties. It is also apparent that there are important chronic effects from solvent exposure both in animals and workers, particularly based on research in Scandinavia.³²⁻³⁴ Nerve conduction remains altered for many years following cessation of solvent exposure, while memory and learning, mood, impulse control, and motivation are impaired.³⁵ Long-term exposure causes a toxic encephalopathy with memory and motor deficits. However, testing and diagnostic criteria are not standardized.³⁶ Smokers who have the GSTM1-null genotype appear to be at a greater risk of solvent-induced chronic encephalopathy than smokers with normal GSTM1.³⁷ Rats chronically (30 h/week for 6 months) exposed to 1500 ppm toluene show permanent 16% depletion of neurons in the inferior regions of the hippocampus.³⁸ Styrene effects have been studied in several occupational groups^{39,40} with both specific changes (impaired reaction time and color vision) and more general mood alterations.⁴¹

Carbon disulfide effects are manifest in almost all components of the central and peripheral nervous systems (particularly distal part

TABLE 20-5. EXAMPLE OF BEHAVIORAL IMPAIRMENTS ASSOCIATED WITH VARIOUS TOXIC SUBSTANCES

of long axons) in humans through neurofilament cross-linking.^{42,43} Evidence of peripheral neuropathy (paresthesia, numbness), cranial neuropathy, dementia (confusion), parkinsonism, acute psychoses, irritability, and memory loss have been attributed to this compound.⁴⁴

Many metals, for example, lead, mercury, manganese, and arsenic, are also neurotoxic, but these tend to have discrete nervous system effects (Table 20-6). The species of metal influences its impact. Thus organic tin compounds cause weakness and paralysis as well as central disturbances, partly through a dopamine effect.⁴⁵ Organic arsenic affects the optic nerve and retina, while inorganic arsenic produces polyneuritis and weakness. Tremors, and in severe cases ataxia, occur with either inorganic or organic mercury poisoning; however, organic mercury also produces visual field changes,⁴ while inorganic mercury produces personality disturbances characterized as *erethism*. This syndrome involves irritability, labile temper, pathologic shyness (avoiding close friends), depression, loss of sleep, fatigue, and blushing. In some cases there is a dose-response curve between the occurrence of symptoms and the concentration of mercury in urine. Dental amalgams are associated with increased urine mercury, but the extent to which such elevations are conducive to neurological or psychological symptoms is unclear. On the other hand, MeHg disrupts both the developing and the mature CNS, interfering with visual, auditory, and somatosensory function.⁴⁶ Exposed rats developed specific antibodies to neurotypic and gliotypic proteins and had reduced glial fibrillary acid protein in their cortex. Pathologic changes include neuronal degeneration and demyelination and an increase in astroglia with accumulation of MeHg.⁴⁷

Lead poisoning has been extensively studied in children and adults.^{48,49} Lead is universally deleterious to the developing nervous

system. Ultrastructural studies show altered axonal development and dendritic deployment with fewer neural connections, leading among other things to impaired cognition and concentration.⁵⁰ This is associated with deficiency in expression of a specific nerve growth-associated protein (GAP-43). Perinatal and postnatal exposure to lead resulted in depressed mRNA levels for GAP-43 in rats.⁵¹ Importantly, lead effects (impulsive behavior, poor concentration, poor working memory) persisted at least to age 11, particularly in children who had not been breast-fed. Whether breast-feeding conveys protective nutrients or has primarily social benefits remains to be elucidated. Impulsivity is one of the changes lead induces in rodents.⁵²

In several studies, prenatal exposure to certain PCB isomers has been implicated in causing impaired neurobehavioral and cognitive development in babies and young children. Despite controversy, the evidence appears to be consistent using several populations and evaluation techniques^{53,54} (see Behavioral Teratology below). The new millennium has seen attention focus on polybrominated diphenyl ethers, persistent chemicals, developed as fire retardants, which can cause hyperactivity in rats.⁵⁵

A more esoteric compound is MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), a synthetic substance produced accidentally in the attempted synthesis of meperidine analogs by substance abusers. A metabolite of MPTP damages the dopaminergic cells of the substantia nigra, leading to irreversible parkinsonian symptoms.⁵⁶ This important discovery provided a model for studying parkinsonism.¹ In addition, many psychoactive chemicals both licit and illicit, including ethanol and hallucinogens, have their primary effects on neurobehavioral performance.

► BIOCHEMICAL MECHANISMS

The “black box,” or phenomenological, approach to neurobehavioral toxicology is yielding to mechanistic studies. Advances in molecular and cell biology and biochemistry are elucidating many aspects of brain function that will facilitate making predictions and designing of new tests. An important benefit is to enhance interpretation of behavioral toxicology studies. Advances in molecular biology will suggest new populations to study and will provide new biomarkers to validate exposures.

Neurotransmitters

Neurobehavioral toxicology is intimately dependent on advances in understanding neurotransmitter function, which go beyond the role of transducing nerve impulses. The behavioral abnormalities attributed to low-level lead exposure may involve, in part, alterations in dopaminergic transmission,⁵⁷⁻⁵⁹ while learning deficits from lead are related to glutamic transmitters.⁶⁰ Also, lead may have a more global effect on the release of several neurotransmitters by altering calcium homeostasis.⁶¹ Maternal exposure to lead increased dopamine and serotonin in the brain of offspring, but decreased glutamate levels in the cortex.⁶²

TABLE 20-6. AVAILABILITY OF NORMATIVE DATA (VALIDATED ON LARGE NORMAL AND NONNORMAL POPULATIONS) FOR VARIOUS NEUROBEHAVIORAL TESTS

<i>Test</i>	<i>Function</i>
Visual reaction time	Psychomotor
Auditory reaction time	Psychomotor
Santa Ana	Psychomotor
Grooved pegboard	Psychomotor
WAIS subtests

Block design	Cognitive nonverbal
California Verbal Learning Test	Verbal memory
Benton Retention Test	Visual spatial memory
Embedded figures	Perception profile of mood states
SCL-90	Mood affect

Nitric oxide, an intracellular messenger, is formed from L-arginine by the enzyme nitric oxide synthase (NOS), found in many tissues including brain, where it is constitutive rather than inducible. It modulates the secretion of hormones such as adrenocorticotropic hormone (ACTH) and is in turn regulated by estrogen, which enhances the expression of mRNA for NOS in parts of the brain (e.g., ventromedial nucleus of the hypothalamus) rich in estrogen receptors.⁶³ This may be one of several mechanisms by which endocrine-disrupting chemicals modulate behavior.

5-Hydroxytryptamine (serotonin) research covers very broad areas central to neurobehavioral toxicology. Various receptor systems such as opioid receptor antagonists and agonists are under investigation for their control of serotonin synthesis and release.⁶⁴ Xenobiotics, particularly pharmaceuticals such as MAO inhibitors, can produce a serotonin syndrome from elevated serotonin levels.

Neuropeptides

An exciting area of neurobiology is the study of neuropeptides such as substance P, neurokinin A, thyrotropin-releasing hormone, and neuropeptide Y. Their functions, distribution, and control of synthesis and breakdown are an active area of research, particularly with regard to substance abuse. For example, neuropeptide Y, a vasoconstrictor peptide found in sympathetic nerve terminals and the adrenal medulla as well as in the plasma,⁶⁵ modulates the release of glutamate, GABA, norepinephrine, dopamine, somatostatin, serotonin, nitric oxide, growth hormone (GH), and corticotropin-releasing factor (CRF). It has a neuroprotective role against excitotoxic agents.⁶⁶

Receptor Biology

Technical advances in probing for up- or down-regulation specific receptors on various cell populations, and for measuring ligand interactions, has greatly expanded understanding of toxicology. Estrogen receptor studies illustrate how hormones can regulate neurotransmitters in the brain.⁶⁷ Upregulation of the NMDA receptor in the rat forebrain by ketamine appears to be the mechanism leading to apoptosis.⁶⁸

Thyrotropin-Releasing Hormone

Certain cells of the hypothalamus contain thyroid hormone receptors that, when activated, regulate gene expression of various proteins that mediate the hormone effect on the nervous system development.⁶⁹ These may play a role in behavioral teratology. Certain PCBs (for example 2,3',4,4,5 penta-PCB, but not 3,3',4,4,5 penta-PCB) are structural mimics of triiodothyronine and stimulate neural differentiation in cell culture.⁷⁰

Nerve Growth Factors

In 1986, Montacalcini and Cohen received the Nobel Prize for discovering growth factors that influence the differentiation of nerve cells. The mechanism by which growth factors are regulated and how they in turn "control" cell differentiation and ultimately behavior are being investigated using transgenic animals that lack particular receptors. This is becoming an important tool in neurotoxicology and will provide new models for studying behavior.⁷¹

► ANIMAL MODELS IN NEUROBEHAVIORAL TOXICITY

Animal research contributes significantly to our understanding of neurotoxicity and neurobehavioral changes. No animal model adequately mimics the complex neurobehavioral performance of humans, particularly in the intellectual domain. However, many important advances in understanding brain function have been derived from studies mainly on rodent and avian models. Rodent studies allow large sample sizes to be employed, while avian studies take advantage of the fact that, like humans, birds rely primarily on visual and acoustic rather than olfactory or tactile communication. The fact that a chemical produces

the same effect on learning, for example, in a wide variety of animal species is important validation of its role in humans. Eye-limb coordination, cerebellar function, and even learning are common to all vertebrates, and even cognition may be identified in many so-called "lower" organisms.⁷² In recognition of the important contribution of animal behavior studies to shaping our understanding of human behavior,⁷³ three pioneers of animal behavior research, Konrad Lorenz, Niko Tinbergen, and Karl von Frisch were awarded the Nobel Prize in biology and medicine in 1973.

Animal experimentation also provides the opportunity to assess exposures and effects that cannot be studied in humans. Developing species-appropriate test batteries is an exciting challenge for behavioral toxicologists.^{74–76} Animal studies have focused on discrimination of stimuli, learning deficits, disturbance of locomotion or balance, decreased performance of previously learned tasks, memory deficits, altered activity patterns, and changes in normal behavior patterns related to reproduction or maintenance. A wide variety of paradigms have been employed to understand the effects of stresses on the nervous system, and many of these can be applied to humans. In addition, some research has examined how the neurobehavioral effects of a toxic chemical or physical stressors can be exhibited in offspring of the exposed individual.

Learning and Memory Tasks

Experimental intervention allows specific probes of behavior and performance. Early testing employed Y mazes and other learned visual discrimination tasks. Experiments with rats and mice examined how toxins affect the speed of learning a maze after a reward or punishment was offered in one or the other arms.^{77,78} Learning impairment offers a valuable paradigm. Animals are treated with drugs or other chemicals before or after a learning situation or conditioning stimulus to see whether subsequent performance is enhanced or impaired. Injection of glucose enhances, and injection of insulin impairs, learning of foot-shock avoidance tasks.⁷⁹

Passive avoidance training allows investigation of substances that affect a calcium-calmodulin-dependent protein kinase in the same forebrain nuclei. Kinase activity increases within 10 minutes after training. Antagonistic drugs cause amnesia.⁸⁰

Imprinting

Many young animals form an attachment to a parent or other individual whom they see, hear, or smell shortly after birth. This "imprinting" behavior is pronounced in a variety of birds, and the ability of various chemicals to impair the imprinting behavior has been studied. Imprinting depends on NMDA receptors in the forebrain, where antagonistic drugs reduce imprinting behavior.⁸¹ NMDA antagonists block olfactory imprinting in rats.⁸²

Parental Recognition

An important function of imprinting is the ability to recognize parents and relatives to gain food or protection and avoid aggression from strangers. Since this behavior has direct survival value, it can be used to test the relevance of effects of neurotoxic chemicals. Lead-exposed herring gull chicks have poor discrimination and longer latency for choosing between a parental surrogate and a stranger⁸³ and these effects differ depending on the age of exposure, indicating the presence of a critical developmental window for this effect.

Conditioning Studies

In studies involving conditioning of psychomotor performance, animals are trained to perform tasks in response to certain stimuli. They are then exposed to a substance, and the disruption of performance is quantified.^{84,85} With time, the behavioral tests have become more sophisticated and now include such paradigms as nonspatial and spatial delayed matching to a sample, serial position sequences, and multiple fixed-interval reinforcement tests in animals trained with operant conditioning.^{74,85–87} These studies examined learned behavior and relied on the production of the desired behavior, followed by measurement of

its sensitivity to environmental stimuli.⁷⁴ Alterations in visual performance can be useful endpoints in conditioned animals.⁸⁸ The great advantage of these methods is that they can detect subtle differences in behavior of animals that otherwise appear normal; however, they do require experience in the operant conditioning techniques.

Fixed Interval Schedule-Controlled Paradigm (FISC)

Conditioning studies can employ reinforcement to the animal that responds a particular number of times (variable or fixed ratio) or after an interval. In the fixed interval paradigm, the animal is reinforced for giving an appropriate response after a stimulus has been on for a particular time. Once the conditioning is established and stable, the exposure can be applied to determine whether the learned response is impaired or abolished. For example, the fixed interval behavioral response was modified by novelty in lead-treated but not control animals.¹⁹

Discrimination Conditioning

Animals can be conditioned to respond differentially to a variety of stimuli, and the effects of various substances on this ability offer a sensitive test of discrimination. This conditioning has been expanded to more relevant neurotransmitters, and animals can be trained to discriminate these from saline.¹⁴

Intracerebral Injection

In combination with stereotactic techniques and histochemical studies of the brain, the localized injection of agonist and antagonistic chemicals into specific regions of the brain is contributing to the understanding of localization of behavioral functions, and conversely, as functions are localized, it becomes feasible to test many new substances for specific agonist or antagonist activity. For example, serotonin inhibits the pre-mating lordosis behavior of female rodents by acting on 5-hydroxytryptamine 1A receptors, but it enhances the same behavior at 2A/2C receptors. The relative activity of these receptor classes varies during the estrous cycle.⁸⁹

Open Field Exploratory Behavior

Animals have a natural tendency to explore novel environments. This involves a combination of locomotory and perceptual events, and toxicants may inhibit one or both or may lead to agitation and more rapid behavior. A comparison study of behavioral and neurochemical traits in 15 inbred mouse strains revealed that the former had higher heritability than the latter.⁹⁰ In addition to moving around an enclosure, rodents rear up periodically. Dopamine plays a prominent role in modulating locomotor activity. Activity cages divided into grids with light sensors can detect movement (frequency of breaking beams in both horizontal coordinates), as well as frequency of rearing, and can distinguish animals engaged in perimeter exploration from activity confined to the central grid squares. Mice treated with paraquat showed decreased horizontal but not vertical activity.⁹¹

► NATURALISTIC STUDIES

Naturalistic observations of behavior conducted in the laboratory and in the field employ behaviors that occur naturally in the organisms (for example, locomotion, balance, or predator defense).^{75,92} In many of these studies, the toxic agent such as lead interferes with learning or learning retention and the subsequent performance of learned tasks.

Under natural conditions, animals have somewhat predictable or stereotyped ways of behaving that can be quantified. Such behaviors may be directly relevant to their survival and successful reproduction. Toxicants that affect such behavior can have far-reaching effects on fitness. Some behaviors examined include pecking accuracy and pecking rate of pigeons,⁹³ activity rates in mice,^{94,95} nest site defense in falcons,⁹⁶ monkey behavior,⁹⁷ dove courtship sequences,⁹⁸ begging behavior,

and food manipulation in terns,⁷⁵ and web-weaving in spiders.⁹⁹ In most of these studies, the effect was clearly demonstrable by directly observing individuals.

The advantage of the naturalistic behaviors is that the behaviors are important for fitness and have been shaped and perhaps optimized by evolution. Thus predator avoidance is a natural part of an animal's behavioral repertoire, while pushing a button may not be. Conversely, operant conditioning paradigms afford tighter control of experimental situations. Yet natural behaviors such as locomotion,⁷⁶ exploration, righting ability, depth perception, thermoregulation, aggression, avoidance,⁷⁵ learning, and parental recognition are all amenable to laboratory and field experimentation where variables can be controlled.^{75,100} Experiments with herring gulls injected with lead in the wild indicated that the effects that were observed were similar and as severe as results in the laboratory. Recovery, however, was quicker and parental behavior partially ameliorated behavioral deficits to allow the chicks' partial recovery of cognitive function.⁹²

While most neurotoxicology studies on animals examine the direct effect of exposure, some multigeneration studies have yielded important results,^{101,102} showing that the offspring and even grandchildren of treated animals may manifest behavioral deficits. Exposure of one or both parents can affect behavior in offspring. If both parents are exposed, the impact is greater than if either one is exposed alone.¹⁰¹

It seems reasonable to conclude that animal behavioral models will continue to be useful for understanding many aspects of behavioral toxicology, for developing useful questions and approaches for clinical application, and for validating generalizations developed in humans. Conversely, for some of the higher functions, humans will remain the primary test subjects and improved epidemiologic studies employing both old and new psychometric approaches will be fruitful. These must avoid type II errors as rigorously as type I errors are avoided.¹⁰³ Such studies must be opportunistic, recognizing exposures that have already occurred, while the animal models will allow the use of controlled exposures and testing of new paradigms. Neurobehavioral studies in animals also afford the opportunity to design comprehensive studies of mixtures.¹⁰⁴

Sensory Systems

Vision

The visual system is both a target for neurotoxic agents and a crucial function for testing. Intact visual systems are required for accurate performance on many tests used to assess higher order cognitive function. Neurotoxicants may affect visual functions directly and thus confound interpretation of performance on tests of cognitive function unless visual function is assessed separately.¹⁰⁵ Visual evoked potentials use electroencephalographic techniques to measure brain wave responses to light. Neurobehaviorists test such functions as visual acuity, alteration of visual fields, color vision, contrast sensitivity, and critical flicker fusion. For example, Mergler and colleagues¹⁰⁶ reported loss of color vision and contrast sensitivity among workers exposed chronically to organic solvent mixtures.^{107,108} Neuro-optic pathways are vulnerable to the effects of styrene, which impair color discrimination. A recent meta-analysis of styrene's effects on color vision supports increased errors in performing a color discrimination task with an estimated increase of the color confusion index of 2.23% after 20 ppm exposure over eight work years.¹⁰⁹ Color vision loss associated with solvents is typically characterized as a blue/yellow deficit. Such a deficit is associated with reduced function of the blue cones or their associated ganglion cells.^{110,111} Because color vision loss also occurs with age, Benignus et al.¹⁰⁹ equated the loss associated with 20 ppm styrene exposure over 8 working years as comparable to 1.7 additional years of age. Campagna and colleagues¹¹² found that color vision loss is dose-dependent and can be significantly detected above 4 ppm. Other investigations also support loss of color vision with toluene¹¹³ and mixtures of solvents (e.g., xylene, methyl ethyl ketone, acetone).¹¹⁴

The Critical Flicker Fusion task tests CNS discriminatory ability, by the point at which lights flickering at an increasingly rapid rate

appear to fuse into a constant source. Lead-exposed workers showed impairment.¹¹⁵ Contrast sensitivity reflects the ability to detect subtle differences in lighter and darker areas of a stimulus (i.e., luminance). Detecting differences in contrast allows detection of words on a page and is the basis for perception of stimuli used to assess higher order cognitive functions particularly for computer-based testing. Several studies of workers chronically exposed to neurotoxicants reveal reduction in contrast sensitivity¹¹⁶ particularly for mid-spatial frequencies.¹¹⁷ However, contrast sensitivity is also affected by visual acuity and other diseases such as diabetes. These different approaches thus evaluate the receptive capability of the eye itself and ultimately the ability of the brain to process and respond to information transmitted from the eye.

Hearing

Hearing evaluation is a necessary precursor to neurobehavioral testing since many tests rely on hearing for accurate performance. As with the eye, some tests evaluate the external receptor, while others determine the response of the brain to sound. Certain neurotoxic chemicals, for instance the antibiotics streptomycin and kanamycin, damage the auditory nerve pathway. More subtle changes in our ability to detect loudness, pitch, and timbre are the domain of the psychoacoustician and in special cases can be evaluated as part of a neurobehavioral assessment.

The working environment of those who are routinely exposed to neurotoxicants often includes exposure to noise, which may result in damage to the sensory cells of the inner ear. Also, neurotoxicants may directly interfere with hearing through effects on the central or peripheral nervous system. Morata et al.¹¹⁸ suggested that noise and organic solvents such as carbon disulfide, toluene, and trichloroethylene may interact to produce hearing loss and perceptual impairments. Morioka et al.,¹¹⁹ reported that the upper limit of hearing was reduced among workers exposed to styrene.

Olfaction

Unlike virtually all other mammals, humans rely relatively little on olfaction to find their food or detect danger. Nonetheless, olfaction has been shown to influence human appetite and sexual development,¹²⁰ and we are capable of distinguishing the odor of our mates from those of other individuals. Disruption in the olfactory sense either due to loss of olfaction (hyposmia or anosmia) or hypersensitivity to odors has been associated with exposure to neurotoxicants. The University of Pennsylvania Smell Identification Test (UPSIT) is a standardized multiple choice scratch and sniff test, assessing the ability to correctly identify odors.¹²¹ Decrements in the sense of smell were documented with the UPSIT for paint-manufacturing workers¹²² exposed to solvents. The authors hypothesized that these deficits are related to peripheral effects on olfactory neurons causing dysfunction. Olfactory threshold tests determine the lowest concentrations at which an odorant can be reliably detected. Exposure to metals, for example cadmium, also reduces olfactory acuity as demonstrated by increased olfactory thresholds (decreases sensitivity).¹²³

While neurotoxicant occupational exposures can result in loss of olfactory acuity by acting directly on the olfactory neurons, individuals exposed to chemical odors accidentally either at work or in communities sometimes report a heightened sensitivity to odors.¹²⁴ This sensitivity may arise as a result of a conditioned response in which symptoms of irritation, precipitated initially by a chemical exposure, are later associated with the odors that accompany much lower exposure concentrations of the original and similar chemicals.¹²⁵ Although a heightened sensitivity to odors is reported, this hypersensitivity has yet to be validated using standardized olfactory threshold testing.^{121,126}

Taste

Although the food industry conducts extensive subjective research on tastes, there is little objective literature on the impact of chemicals on taste sensitivity. Many chemicals have specific "tastes," while others seem to induce abnormal tastes such as the metallic taste that

characterizes lead poisoning (but is not a lead taste) and the garlic-like taste that occurs with selenium but is not a selenium taste. There is a close linkage between olfaction and taste, albeit different peripheral receptors and diminished olfactory sensitivity or discrimination will interfere with taste. Taste actually lends itself to objective study more readily than olfaction, since one can control and determine the concentration of a substance in solution more easily than in air.

Touch and Vibratory Sensation

Physical examination of light touch and pain sensation and of temperature and two-point discrimination can be elaborate and time-consuming, but in the hands of an experienced neurologist can detect subtle nervous system malfunction. However, evaluation of touch is actually quite complex. In addition to skin receptors, there are receptors in underlying tissues and muscle. The sensory perceptual examination of the Halstead-Reitan Neuropsychological Battery is used to assess accuracy of finger tip touch and the ability to perceive numbers and shape from tactile sensations.¹²⁷ Finger and toe vibratory threshold, assessed with a device that allows amplitude and frequency of vibration to be manipulated ("Vibrometer"),¹²⁸⁻¹³⁰ has been sensitive to subtle changes in threshold among workers exposed to solvents¹³¹ and pesticides.¹³² Vibration threshold may also be altered among workers who use vibrating hand-held tools.¹³³ Although the pressure applied by the patient may confound measurement, a physical device can be used to control pressure applied by the individual. Specific protocols for evaluating vibration thresholds are available in a manual published by the Agency for Toxic Substances and Disease Registry (ATSDR), describing a recommended neurobehavioral test batteries for environmental health field studies.¹³⁴

Temperature

Ability to discriminate slight changes in temperature is also affected by chemical exposure. Devices that provide objective control of temperature, combined with a forced-choice paradigm, allow the clinician or researcher to evaluate this modality.¹²⁹

Position Sense and Vestibular Function

The dorsal columns of the spinal cord carry information on position to the brain, where the labyrinth and vestibular apparatus detect the positions of the eyes, head, and body, and the sensorimotor system compensates by adjusting muscle tone to maintain posture. Its function depends on the saccular and utricular macules that sense linear acceleration of the head and the semicircular canals, which sense angular acceleration. Visual and proprioceptive impulses also feed this system. Disruption of either the sensory components or the central vestibular function can cause dizziness and vertigo. Tests for sway,¹³⁵ straight-line walking, and the Romberg's tests are traditional ways of measuring the performance of these tasks. In addition to testing position sense, these tests are dependent on intact motor and vestibular functions. A force platform system is recommended by NIOSH as a more precise system to measure subtle changes in postural sway under conditions that separate the effects of vision, proprioception, and vestibular function on postural sway.^{136,137} Postural equilibrium, controlled by the vestibular system, was shown to be affected by 0.015% blood alcohol concentration.¹³⁸ Other acute exposures to neurotoxicants such as acetone and methyl ethyl ketone have not shown increases in postural sway.¹³⁹ However, acute measures of exposure to chlorpyrifos, an organophosphate pesticide, were associated with greater postural sway in more challenging conditions to include eyes closed and soft-surface conditions.¹⁴⁰ Similarly, acute indicators of exposure to lead have been shown to have subclinical but significant effects on postural sway in children and adults.¹⁴¹⁻¹⁴³

Motor Function

Motor deficits may be due to muscle disease, disorders of the motor cortex or pathways, changes in the reflex pathways controlling tone, or central disorders (cerebellum, basal ganglia), which interfere with both volition, fine tuning, and coordination of motor function. The

dopaminergic system is a major regulator of tone and voluntary movements and is affected by a variety of xenobiotics.

A physical examination can detect changes in muscle mass (particularly asymmetry) and physical weakness. Behavioral tests focus on the motor system as a manifestation of central function, for example, reaction time (see below), rapid alternating movements, and fine muscle control. Many compounds that produce acute intoxication (i.e., alcohol) affect sensory-motor function, producing alterations of gait and posture. Some neurotoxicants affect motor nerves, leading to reduced strength, coordination, and fine muscle control. Finger Tapping and Grooved Pegboard¹⁴⁴ are tests with normative standards that are frequently employed to assess loss of fine motor coordination and speed due to neurotoxicants.¹⁴⁵ Loss of ability to perform previously learned motor sequences, apraxias, may be an indication of neurotoxicity, and some of the animal paradigms appear directly analogous to this deficit.

Basal Ganglia

The basal ganglia and cerebellum constitute the extrapyramidal motor system, often a target of toxic chemicals. The functional relationships of the basal ganglia to the striatum and cerebral cortex are described in standard texts. Damage to these ganglia or the corticostriatal-pallidal-thalamic-cortical loop is associated with a variety of disorders including ataxias, tremors, akinesia or dyskinesia, athetosis, dystonia, and myoclonus. This system is characterized by the variety of neurotransmitters (e.g., γ -aminobutyric acid [GABA], dopamine) associated with particular functional components. Toxic damage by MPTP to the substantia nigra, for example, is known to produce parkinsonism.¹⁴⁶ Selected neurobehavioral tests of fine motor function may detect early damage to this system.

Cerebellar Function

The cerebellum refines motor function and contributes to balance, posture and tone, repetitive movement, coordination, and spatial location. Gross cerebellar dysfunction is manifest as staggering gait, swaying or stumbling, ataxias involving movements of specific limbs in which the timing of contraction of antagonistic muscle groups is disrupted, and loss of controlled rapid alternating movements, dysdiadochokinesia. MeHg targets the cerebellum, producing ataxia at relatively low doses (Fig. 20-3).

Cognitive Evaluation

Complete neurobehavioral examination is an interdisciplinary endeavor requiring the participation of the physician, neurologist, psychologist, and electrophysiologist. A complete examination will include an interview, a physical examination, and one or more sensory and neurobehavioral tests, supplemented where necessary by electrophysiology.

Interview. The interview provides the examiner with an important opportunity to observe the mood, affect, and behavior of the individual. This can be supplemented by a structured psychiatric interview such as the Diagnostic Interview Survey¹⁴⁷ or the Structured Clinical Interview for the Diagnostic and Statistical Manual¹⁴⁸ and mental status examination.¹⁴⁹ The interview allows one to explore the contribution of "organic" and "psychologic" pathology and to detect anxiety, depression, changes in intellectual function, and other performance.

Personality, Mood, and Affect. A number of epidemiologic studies indicate that personality changes are among the earliest indicators of neurobehavioral toxicity. Erethism, attributable to inorganic mercury (see above), is probably the classic example of this. Mood changes associated with solvents^{150,151} and classroom hyperactivity behavior attributed to lead¹⁵² are additional examples where mood and personality in general may be altered, without necessarily showing specific focal changes. While a number of instruments document these complaints and compare an individual patient's symptoms to a normative group, the cause of these symptoms cannot be ascertained.

That is, such symptoms may be secondary to other cognitive deficits or may be a primary effect of exposure to neurotoxicants. This is further illustrated by the Orebro Q-16, a questionnaire shown to be sensitive to but not specific for neurotoxicity symptoms due to solvent exposure.¹⁵³ Standardized symptom checklists such as the Symptom Checklist-90,¹⁵⁴ the Beck Depression Inventory,¹⁵⁵ and the State-Trait Anxiety Scale¹⁵⁶ are screening tools for psychiatric symptoms that offer comparison of the patient's symptom reports to those of other patient and nonpatient normative groups. The Minnesota Multiphasic Personality Inventory-2 (MMPI-2)¹⁵⁷ is a more extensive questionnaire used to assess psychopathology. Although the MMPI-2 requires more time to administer (at least 1 hour), the advantages of this instrument are scales to assess the validity of the patient's responses (e.g., denial or exaggeration of symptoms) as well as subtle and obvious items associated with clinical scales of psychopathology.

Neurobehavioral Testing

In the presence of uncertainty, a major rationale for neurobehavioral testing is the prevailing assumption that subtle behavioral changes in cognitive function may be the most sensitive indicator of exposure to toxics.¹⁵⁸ Just as liver function tests can measure cell damage, conjugation, or metabolic ability, so neurobehavioral tests have distinct target functions as outlined below.

Moreover, there is the increasing recognition that levels of exposure formerly thought safe or unlikely to produce health effects are now known to have far-reaching consequences on important behavioral functions. Most evident among these is the impact of low-level lead exposure on hyperactivity and intellectual development in children.¹⁵⁹ Weiss¹⁶⁰ argues effectively that even small decrements in intellectual function may shift the population distribution such that more individuals will fall below the normal range of function (i.e., IQ < 70). An extensive literature documents the sensitivity of neurobehavioral tests to acute and chronic neurotoxicant exposures such as lead, organic solvents, and pesticides.^{145,161,162} However, this literature is by no means uniform and is significantly affected by adequate documentation of exposure to neurotoxicants among the individuals tested.

Psychometric Tests in Neurobehavioral Evaluation

Although an interview and a mental status examination can detect many gross changes, psychometric tests are useful to extend the sensitivity of the examination by detecting and quantifying subclinical effects. Psychometric tests for which there is a long history of validation and a database of normative data can be particularly useful in evaluating an individual. Many new tests, lacking such normative data, may be difficult to interpret on an individual basis, but may be useful in large-scale screenings or epidemiologic studies.

The following is a discussion of the core functions recommended for assessment of a patient exposed to neurotoxicants. There are many tests in the literature. Those cited as illustrative of various functions are those that have normative data to allow interpretation of an individual's performance. Unlike statistical group comparisons in a research context, individual assessment of dysfunction is dependent upon comparison to baseline or pre-exposure test results for the individual or to normative standards for a group of individuals of similar age, gender, education, and ethnicity. It is important to be alert to cultural and language biases in evaluating test results. For example, if an individual's performance on a test of a particular function is markedly lower (e.g., one to two standard deviations) than his estimated pre-exposure ability, the clinician may suspect deficits due to exposure.

In addition to demographics, neurobehavioral performance is also effort dependent. That is, an individual's performance will be affected by her/his motivation to perform well or conversely to perform poorly. Secondary gain related to worker's compensation or other litigation may influence the individual even at a subconscious level. Therefore, part of a thorough examination should include an assessment of motivation. This can be performed directly with the use of tests that use a "forced choice" method to detect negative response

bias, defined as below chance performance (e.g., Test of Memory Malingering)¹⁶³ or through analysis of discrepancies within neurobehavioral tests such as poorer performance on simple relative to more complex operations (e.g., recognition memory is less than recall).^{164,165} Slick et al.¹⁶⁶ reviews the methods for detection of malingered performance and offers criteria to diagnose definite, probable, and possible malingered neurocognitive dysfunction. In addition to test criteria mentioned above, the clinical interview is an important source of data for determining motivation. For example, if self-reported symptoms, observed behavior during the interview, or background information is discrepant from neurobehavioral test performance, then malingering may be suspected.

Overall Intellectual Ability

Tests of cognitive verbal ability are generally more familiar to the patient and include such tests as vocabulary, comprehension, and reading (e.g., revised Wechsler Adult Intelligence Scale (WAIS-R)¹⁶⁷ National Adult Reading Test).¹⁶⁸ These tests are regarded as most resistant to the effects of neurotoxicants since they reflect abilities that are well-rehearsed and long-standing.¹⁶⁹ If an individual's verbal abilities have declined significantly, this usually reflects serious or chronic damage. Such deficits can occur with significant head injury or stroke, but generally not with exposure to neurotoxicants unless the latter has occurred over a number of years at significant levels¹⁶² producing a well-defined dementia such as "painter's syndrome"¹⁷⁰ or chronic toxic encephalopathy. Thus, the patient's performance on a vocabulary test is frequently used as an estimate of pre-exposure function if pre-exposure testing is unavailable. While this is a standard in the literature, a recent investigation directly comparing actual pre-exposure and current vocabulary scores revealed that exposures to neurotoxicants may have a more significant impact on tests of highly practiced skills (e.g., vocabulary) than previously assumed.¹⁷¹ Tests of cognitive nonverbal functions are generally more complex and reflect ability not related to verbal skills such as the Raven's Progressive Matrices.¹⁷² These tests are useful in situations where estimates of ability, unbiased by verbal skills, are needed.

Psychomotor Functions

Psychomotor function requires integration of sensory perceptual processes, such as vision or hearing, with motor responses. For example, simple reaction time or the latency (milliseconds) of a button press in response to a visual or auditory cue provides the simplest method for assessing psychomotor function. The time between presentation of the stimuli is varied and may affect performance. At a more complex level, a patient may be asked to place pegs into holes as quickly as possible,¹⁷³ a task requiring more motor skill than reaction time. Tests of psychomotor function such as Digit Symbol¹⁶⁷ have consistently been among the most sensitive indicators of deficits due to neurotoxicants.¹⁶⁹ The patient records symbols with their corresponding number according to a key while being timed. While memory substantially aids performance, it is not necessary since the key is always present.

Attention/Concentration

A precursor to performance on neurobehavioral tasks is the ability to scan the environment, orient to the appropriate stimulus, and sustain attention to a task, with more complex tasks requiring relatively greater levels of sustained attention. Neurotoxicants can disrupt this ability as demonstrated with such tests as Digit Span of the WAIS-R in which the individual is asked to repeat an increasing string of digits (digits forward) or to reverse the digits (digits backward) immediately following their verbal presentation.¹⁷² Trials A and B, in which the individual connects numbers or numbers and letters in sequence, tests psychomotor skills, visual attentiveness, and the ability to think flexibly under time pressure.

Tests of vigilance require sustained attention over relatively longer periods of time such as for continuous performance tests in which the individual responds to a specific target presented among

similar nontarget stimuli. Vigilance tasks are sensitive to low-level effects of alcohol^{174,175} and to the interaction of neurotoxicants, fatigue, and variation in the interstimulus interval.

Memory and Learning

Tests of memory/learning assess a patient's short-term memory by presenting stimuli (e.g., words, digits, pictures) visually or auditorially and asking the patient either to recall or recognize these stimuli immediately or after a delay (e.g., 30 minutes). The California Verbal Learning Test involves the presentation of a list of words that the patient is asked to recall.¹⁷⁶ For other memory tests, pictures of abstract drawings or actual objects are presented to the subject, who must then reproduce these drawings from memory (e.g., Benton Retention Test).¹⁷⁷ Short-term memory loss is one of the most frequent clinical complaints of patients exposed to neurotoxicants,¹³⁵ and it has been substantiated in studies of neurobehavioral deficits due to solvents, lead, mercury, and pesticides.¹⁷² If a patient's performance on a short-term memory task is well below his or her general ability as assessed by a vocabulary test, then complaints of memory problems may be substantiated.

Temporal Properties of Performance

One of the most subtle measures of acute neurobehavioral deficits is a slowing in function.^{178,179} While peripheral neuropathies are characterized by slowing of nerve impulse conduction, it is the slowing of central functions that are evaluated in neurobehavioral testing. Whether this can be thought of as an "increased resistance" in the CNS, or the need for adaptation wherein alternative pathways are sought for particular functions, is a subject for future research. It is not known whether cells die, interconnections shrink or wither, or biochemical communication is inhibited, but probably all of these mechanisms apply.

Test Batteries in Behavioral Neurotoxicology

A number of investigators and clinicians have developed test batteries for use in human behavioral neurotoxicology.^{159,180,181} A review by Anger¹⁸² provides a guide to their features and limitations. In general, these batteries include tests representative of several basic functions. For example, the World Health Organization recommended a core battery of tests (Neurobehavioral Core Test Battery) to assess the following functions: psychomotor, cognitive nonverbal, cognitive verbal, memory/learning, perceptual speed, and mood.¹⁷⁰ Tests are categorized as representative of a particular function, but often involve more than one function for adequate performance (e.g., reaction time and visuospatial perception affect psychomotor function).¹²⁷ The Adult Environmental Neurobehavioral Test Battery (AENTB) is another screening battery recommended for evaluation of environmental exposures that are presumed to be lower than those occurring at the workplace.¹⁸³

In the late 1970s, researchers recognized the potential of computers to challenge the nervous system in a repeatable, objective fashion and to score performance in real time. Epidemiologic studies have been significantly enhanced by the use of computerized neurobehavioral test batteries such as the widely applied Neurobehavioral Evaluation System¹⁸⁴ and the Behavioral Assessment and Research System (BARS).¹⁸⁵ The advantages of the computer are (a) consistency of application, (b) reduced need for highly trained testors, and (c) automatic recording of data in real time. Disadvantages have been (a) capital costs for purchasing several computers, (b) many target populations not being computer literate, (c) lack of motivation and stimulation provided by a live examiner and loss of opportunity to observe performance, and (d) lack of normative data for interpretation of individual performance. The Cambridge Automated Neuropsychological Test Automated Battery (CANTAB)¹⁸⁶ is a computerized battery of nonverbal tests of attention, memory, and executive function that are largely language independent and culture free. CANTAB is comparable to tests used in the animal literature and has been used extensively with patients who have brain injury or

neurodegenerative diseases, children, and in tests of therapeutic agents. CANTAB may prove to be of particular interest for the extrapolation of neurobehavioral findings in animals, where higher exposure concentrations are possible, to analogous performance in humans. The disadvantage of computer batteries is the lack of feedback and social interaction through which an examiner can maintain a subject's motivation.

► BEHAVIORAL TERATOLOGY

The developing nervous system undergoes dramatic growth and expansion of function, not only prior to birth, but throughout the first decade of life. Normal brain formation requires the orchestration of various signals and processes to achieve cell differentiation, migration, positioning, process-formation, and synapse formation, at the right time. Anatomical changes such as increasing myelination occur during the first years of life, and associations are formed that make possible complex motor patterns, fine-tuning of coordination, concept formation, pattern recognition, and more highly learned tasks such as speech and communication. For some tasks, such as learning language, there appear to be "critical periods" during which learning proceeds more rapidly and effectively. Young children find it easier to learn new languages than adults, but this "window" does not have sharp edges. Animals or humans that are isolated from speakers during a critical period may find it difficult or impossible to learn speech at a later time. There may be critical periods for development of other functions as well.¹⁸⁷ As organisms mature, their locomotory ability, learning, and knowledge should increase appropriately for their age. There is increasing evidence that even low-level chemical exposure may have profound impact on the orderly acquisition of nervous system function. The magnitude of such changes is not fully appreciated, and the field of behavioral teratology is in a rapid growth phase.

Neural Cell Adhesion Molecules

These cell surface proteins play crucial roles in the migration and connection of cellular elements of the developing nervous system. Xenobiotics can cause dysmorphogenesis and serious neurological impairment. The expression of NCAMs is timed, resulting in the increase and decrease of signals at different times in development. Their expression is implicated also in learning and memory and immune responses. In rats MeHg altered the temporal expression NCAM and polysialylation of NCAM on day 30, but not on day 15 or 60.¹⁸⁸ In lead-injected baby gulls, synaptosomal polysialylated NCAM expression was found on day 34, and *N*-cadherin was reduced on day 34 and day 44, but by day 55 there were no differences in *N*-cadherin expression, or polysialylated NCAM expression.¹⁸⁹ These parallel results identify one potential mechanism for the developmental neurotoxicity of these metals.

Lead and Child Development

Probably the best documented behavioral teratology is associated with lead. At blood lead levels formerly thought innocuous (i.e., below 25 µg/dL), children still show depressed intellectual development,¹⁹⁰ and more subtle effects may occur at levels below 15 µg/dL. Elementary school children with higher body burdens of lead were rated by their teachers as being more easily distracted, less persistent, less independent and organized, more hyperactive and impulsive, more easily frustrated, and showing poorer overall functioning, compared with children in the lower lead groups. Needleman et al.'s study shows remarkable dose-response relationships between dentine-lead levels and poor school ratings. Children with higher lead did more poorly on verbal and digit span components of IQ tests.¹⁹⁰

As late as the 1970s, the average blood lead in urban American was approximately 15 µg/dL (0.6 µmol/L). The removal of lead from gasoline has resulted in a decline of blood leads in less than a generation to a national average of around 2 µg/dL. This has unmasked the low-level toxicity, which reveals that impairment of cognitive development by

lead is continuous, even below 10 µg/dL, with no evidence of a threshold yet identified.¹⁹¹

Although the main impact of lead is related to the peak of exposure in the 18–30 month range, subsequent exposure at least to age 7 is also associated with IQ decrement.¹⁹²

Methylmercury

All forms of mercury are toxic, and MeHg is one of the most toxic forms. The classic case of Minamata disease involved over 2000 people in fishing families who became ill in the 1950s from eating fish from Minamata Bay (Kyushu Island, Japan), which had been contaminated by industrial effluent. The syndrome and epidemic are graphically illustrated.¹⁹³ Victims developed a range of symptoms, and many babies were born with congenital Minamata disease: blindness, profound mental and physical retardation. Another large outbreak of organomercury poisoning occurred in Iraq in people who ate seed grain treated with an organo mercurial fungicide. Similar outbreaks occurred in Guatemala and also affected a family in New Mexico (see Fig. 20-3 for symptoms in the Iraq epidemic). In North America and Europe, the growing source of concern is mercury released from power plants that is transported in the atmosphere and falls out some distance from its source. Inorganic mercury in the falls out is converted to MeHg by anaerobic bacteria in the sediments of lakes and rivers. MeHg is readily bioavailable and undergoes bioamplification up the food chain, resulting in high levels (> 100 ppb) in the tissues of many kinds of fish that people consume. Adults who consume fish daily experience elevated blood mercury levels and may become symptomatic, while mothers who consume fish frequently transfer MeHg to the fetus where it reaches a higher concentration than in the mother.¹⁹⁴ At high levels, this impacts neurobehavioral development. Several long-term studies of populations that consume large amounts of fish and whales have yielded somewhat different results. The Faroe Island study¹⁹⁵ showed an impact, particularly on the Boston Naming Test and on auditory evoked potential, related to the child's cord blood mercury. A Seychelle Island study has not documented effects attributable to prenatal mercury exposure.¹⁹⁶ Other studies in New Zealand and the Amazon support some relationships of MeHg to neurodevelopmental effects.¹⁹⁷ In addition to effects of cognitive function, prenatal exposure to MeHg may influence locomotor activity mediated by dopamine.¹⁹⁸

Polychlorinated Biphenyls

It has long been known that PCBs interfere with locomotion and learning in rodents¹⁹⁹ and with learning and cognition in monkeys.²⁰⁰ Interference with cellular metabolism, neurotransmitters, and thyroid hormone also have been proposed.^{201,202} Several epidemiologic studies have assessed neurobehavioral deficits in populations exposed to PCBs and related compounds.²⁰³ There is evidence of developmental neurotoxicity including low IQ, from the Japanese Yusho incident, involving prenatal exposure to PCBs and furans.²⁰⁴ Several years later, a similar event, the Yu-Cheng incident in Taiwan, resulted in heavy PCB exposure (exceeding 1 g in some cases) as well as dibenzofurans. Children born to exposed mothers had multiple defects at birth and showed developmental delays and lowered performance on neurological examination and standard tests of cognition. The fact that these abnormalities did not correlate well with measures of post-birth maternal exposure²⁰⁵ illustrates the importance of measuring fetal exposure in determining neurodevelopmental defects. Linkage to a persistent chemical is evidenced by the poor performance of children born to exposed mothers more than 6 years after the exposure.²⁰⁶

Jacobson and colleagues studied babies born to women who ate PCB-contaminated fish from the Great Lakes. Some of these women had elevated serum and milk PCB levels, and their babies showed slowed neurobehavioral development,²⁰⁷ which has persisted for several years. Some of the abnormalities are predicted by cord serum PCB levels.²⁰⁸ Rogan and Gladen studied 931 children of mothers who did not, as a group, have unusually high PCB exposure. Children with higher prenatal PCB exposure at birth were more likely to be

hypotonic and hyporeflexic and showed poorer psychomotor performance on the Bayley Scales. These changes were not related to post-natal PCB exposure²⁰⁹ and did not persist after age 5.²¹⁰

The Oswego Newborn and Infant Development project examined the behavioral effects in human newborns, infants, and children of mothers who had consumed fish from Lake Ontario.²¹¹ Fish from this lake are contaminated with a wide range of toxic chemicals, including PCBs, dioxin, dieldrin, lindane, chlordane, cadmium, mercury, and mirex. Newborns were classified into high, medium, and low maternal exposure groups and were tested on the Neonatal Behavioral Assessment Scale in their first and second day after birth. The groups did not differ demographically, but after many confounders were eliminated, the high-exposure babies showed a greater number of abnormal reflexes and less mature autonomic responses than babies in the other groups. This confirms Jacobson et al.'s original findings.^{207,212} This study also found a dose-response relationship between fish consumption and decreased habituation to mildly aversive stimuli and is similar to results found in laboratory rats fed Lake Ontario salmon.²¹³

► CONFOUNDERS OF BEHAVIORAL PERFORMANCE

Neurobehavioral evaluation requires the concentration and cooperation of the subject, yet these behaviors too may be diminished in chemical-exposed individuals. Interpretation of test results in the individual must take into account a variety of confounders that are only briefly mentioned here. Many of the confounders have a *global* effect, that is, they interfere with all aspects of performance rather than with particular subtests. Subjects who have a high level of anxiety may find it difficult to concentrate on complex tasks, particularly on tests of vigilance. Lack of familiarity with the test context or with the expectations, particularly if the testing is not conducted in one's first language, will certainly interfere with performance. Subjects who believe they are being evaluated for poisoning may be hesitant about participating in so many "psychologic" tests that may suggest that the examiners don't believe their complaints are "real." Subjects may also have personal reasons for performing suboptimally. However, most subjects do attempt to do their best. Computerized batteries proved baffling to subjects who were not familiar with the use of computers, although this confounder is gradually diminishing as computer use expands in all sectors of society.

Age and Gender

Age is a universal confounder in neurobehavior. Depending on the modality, performance improves during childhood, peaks in the teens and twenties, and then declines. Many neurobehavioral functions decline steadily with age.^{14,213} In addition to well-known effects on short-term memory, aging produces alterations in cognitive function as well, although this varies greatly among individuals, from frank dementia as in Alzheimer's disease to very subtle changes. Many well-established tests have age-adjusted scoring. Reaction time increases and performance on psychomotor tasks decreases with age. In rats, age may also indirectly impair performance by enhancing the negative effects of stress.²¹⁴ The dopaminergic neurons also degenerate with age, resulting in some cases of late-onset parkinsonism. Oxidation of dopamine produces reactive oxygen species, which may enhance the degeneration of these neurons. Glutathione blocks the dopamine-induced apoptosis.

On an average, males and females differ in a variety of nervous system functions related to language, fine motor skill, and spatial perceptions. These differences are far from deterministic, and most tests do not have sex-adjusted scoring. Some differences related to early brain development were influenced by sex hormones in utero, while others reflect gender-specific learned skills.

Physical Condition

Lack of sleep, drowsiness, a recent full meal, or recent use of drugs, alcohol, or tobacco may also have global effects on performance. Examiners should elicit subjective evaluations of wakefulness and

should carefully observe the subject. A pretest questionnaire should determine the time at which alcohol, cigarettes, or specific medications were used. Unrelated illnesses may affect performance. Diabetes or other metabolic states may interfere with alertness. Dementias due to other causes such as head injuries will complicate interpretation of test results.

Learning and Experience

Learning poses an additional confounding problem in interpreting neurobehavioral tests, particularly when tests are to be repeated in a prospective study. The time interval between testing, the individual subject's learning ability, and the test's complexity will alter the learning curve or practice effect of repeat testing. This phenomenon needs to be quantified to interpret accurately changes in test performance over time. One method to deal with practice effects is to provide practice sessions for all tests to reduce the impact of a learning curve. Familiarity with computers enhances performance on the computerized batteries. Educational level may confound some tests.

Language and Culture

Perhaps the most important problems are the inherent intellectual and cultural biases of many of the tests. Designed for white, English-speaking, educated, middle-class patients, the tests may require major modifications before being applied to less educated and/or non-English speaking cohorts, much less to worker populations from distant cultures. Straight word-for-word translations are not necessarily adequate for overcoming cultural biases. Studying cultural impacts on performance should be viewed as a challenge for the coming decade.

► STRESS

Stress is a very general term for any agent or condition that alters the status quo. Organisms adapt to stress in many ways. Cold stress, for example, stimulates thermoregulatory responses. Strain represents the bodies' pathophysiological response when adaptive mechanisms are exceeded or fatigued. Although the measurement of catecholamines is used as a metric of stress, not all physiological, psychological, or behavioral effects are mediated by catecholamines. Adding stress to an exposure model enhances or unmasks subject responses.²¹⁵ The combination of lead plus restraint (stress) of pregnant females results in increased catecholamine excretion in offspring.²¹⁶

► FUTURE DIRECTIONS

Building on the foundation of clinical psychology and neurobiology, behavioral toxicologists have assembled a variety of test approaches that yield important information about nervous system response to toxic chemicals. In many cases, the mechanisms are uncertain and the pathologic lesion unrecognized. The molecular, biochemical, and microanatomic changes are being revealed. New ways of probing receptors and new breeds of transgenic or "knockout" animals that lack a particular gene offer the opportunity to identify specific mechanisms.

A neurotoxicant may act on a discrete target such as the basal ganglia or may disrupt associations between different parts of the brain, interfering with intellectual functions such as cognition and memory. These all provide an active domain for research in a variety of disciplines using a variety of models. New test equipment requires validation on a variety of populations and interpretation depends on improving exposure assessment as well. As the field of neurobehavioral testing matures and tests become validated on increasing numbers of "normal" individuals, one may achieve greater certainty in evaluating subtle abnormalities.

Neuronal peptides and nervous system development were two research needs identified in 1980 and still central today. The interaction of xenobiotics with cytokines, genes, gene products, cell differentiation, apoptosis, cell assembly, and neuronal connections

during development is basic to improving the understanding of neurobehavioral development and behavioral teratology.

As with general toxicology (Chap. 20, Principles of Toxicology), the effects of mixtures and the interactions of chemicals with stress, are important but challenging research areas. Nutritional state can modify both response to neurotoxicants and performance on tests. The relation of omega-3 fatty acids to dementia and cognitive function is controversial since cases had higher levels of PUFAs than controls.²¹⁷ One possible explanation for different results of MeHg exposure and neurobehavior outcome comparing the Faroes and Seychelles studies is the greater diversity of fresh fruits and vegetables available in the tropical Seychelles compared to the temperate Faroes.

Most mixture research is dyadic (two agents at a time), but even using controls and several doses, and deciding whether the pre-treat or coadminister, can result in many combinations for each of which several animals must be employed. Gene chip technology allows the same approach to be applied to identifying gene expression effects, which are up-regulated and which are down-regulated.

Neuroimaging studies, particularly PET scans and functional MRI, are exciting horizons that neurotoxicologists are just beginning to explore. The development of small-animal imaging systems should advance this field rapidly. Studies that can localize the distribution of xenobiotics or their metabolites in specific brain regions are desirable.

The blood-brain barrier itself needs much more examination. This is actually a system involving the blood-brain interface and the blood-cerebrovascular fluid interface. The characteristics of metal transport across or sequestration in the barrier have implications for toxicity. Barriers change with age and can be disrupted by chemicals.²¹⁸

Stress and experience require structural modifications in the healthy brain (plasticity), and plasticity and neuronal replacement are important research topics. Toxicants can interfere with the plasticity of the brain, resulting in long-term impairment of learning. This may be a much more sensitive, yet hard to measure, endpoint than structural or behavioral measures.²¹⁹

Environmental and Ecological Risk Assessment

Michael Gochfeld • Joanna Burger

Risk assessment is a formalized process for characterizing and estimating the magnitude of harm resulting from some condition—usually exposure to one or more hazardous substances in the environment. This chapter addresses what risk assessment is, what it is used for, and how it is done. “Environmental risk assessment” usually refers to human health risks, while “ecological risk assessment” refers to damage to natural or artificial ecosystems, wildlife species, and endangered species. There are some common properties and important differences.^{1,2} Environmental risk assessment interfaces with environmental toxicology and exposure assessment, while ecological risk interfaces with ecotoxicology. Risk assessments are used in a wide variety of context, for example, to establish no effect concentrations³ which can inform cleanup levels,⁴ sediment quality standards,⁵ or comparison of alternative remediation strategies. Ecological risk is also applied to the probability of extinction of species or populations (population viability analysis) due to chance⁶ or pollution,⁷ and to the likelihood that exotic species will become invasive.⁸ Increasingly, governments and the public have realized that it is critical to protect the health and well-being of ecological systems, both for their own value as well as for the ecological services that they provide for humans including safe drinking water, clean air, fertile land for agriculture, unpolluted waters for fisheries, erosion control and stabilization of coastal environments, and places for recreation and other aesthetic pursuits so important to people.⁹ Ecological risk has been linked with the growing interest in restoring damaged habitats.¹⁰ Moreover, changes in ecosystem health can have direct effects on human health by changing human exposure to disease organisms.¹¹ Risk assessment for genetically modified crops bridges human health and ecological concerns.¹² Harmonization of ecological and human health risk assessment has been done on a few occasions (see below).^{13,14}

Risk assessments are intended to provide objective information to inform public policy decisions.¹⁵ Their utility for individual risk is variable. Risk assessments are used in other walks of life from bridge construction to finance to medical errors,¹⁶ and more recently to terrorism.¹⁷ Risk assessment is primarily a scientific endeavor, while risk management refers to those actions taken by society to ameliorate risks. Risk management takes into account human values and fiscal concerns and determines what risk assessments need to be done and how they are to be used, but the methods and outcomes of risk assessment should not be biased by these concerns.¹⁸ Risk management may involve policy decisions that set particular standards for contaminants in air, water, soil, or food, or they may reflect particular decisions on whether and how much to remediate a hazardous waste site.

There is ongoing controversy as to whether risk assessment can remain value-free or whether that is an illusion. In 1983, the modern environmental risk assessment approach was codified by the National

Research Council’s “red book” on *Risk Assessment in the Federal Government*,¹⁸ which laid out a four-step approach: hazard identification, dose-response assessment, exposure assessment, and risk characterization. It emphasized that risk assessment was value free and suggested the existence of a firewall between risk assessment and risk management.¹⁸ Over the ensuing decade it became apparent that divorcing risk assessment from risk management was seldom possible, and the Presidential/Congressional Commission on Risk Assessment and Risk Management (PCCRARM) completely reversed the separation approach by declaring that risk assessment was an integral component of risk management and that values influenced what risks were assessed, how they were assessed, and how the results were used (Fig. 21-1).^{19,20} Even more radically, PCCRARM placed stakeholders in the center of the entire process, suggesting that they become involved in setting the context for risk assessment, participating in decisions about what questions should be answered and the methodologies employed, and contributing to the interpretation and subsequent risk management decisions. Stakeholders included all persons and agencies with an interest, broadly interpreted, in the outcome. PCCRARM also defined risk management broadly as “the process of identifying, evaluating, selecting, and implementing actions to reduce risk to human health and to ecosystems. The goal of risk management is scientifically sound, cost-effective, integrated actions that reduce or prevent risks while taking into account social, cultural, ethical, political, and legal considerations.” No more comprehensive definition has been proposed.

Protecting human health does not necessarily protect ecosystems and their component communities and organisms from harm.²¹ Humans may be less or more susceptible to certain chemicals than either wild or experimental animals. Also, the process of remediating contaminated soil may seriously disrupt fragile ecosystems, while conversely, the establishment of new wetland ecosystems is being used for wastewater treatment to prevent environmental contamination.²²

Risk assessment involves *target populations*, either real or hypothetical, and the question of how much increased risk will occur if a group of people or a natural ecosystem is exposed to a certain amount of a hazardous substance or condition over a certain period of time. Major descriptions of the risk assessment process^{18,19} and its role in policy¹ have been published (see General References), and various refinements are added to take into account the great uncertainties attached to risk estimation.

Although risk assessment can provide probabilities with great apparent precision, they are accompanied by such broad uncertainties that utility is often compromised. Since risk assessment is imperfect, or often gives results that are unpopular, there have been many attempts to refine it. Most of these have focused on reducing the worst

Figure 21-1. Risk management framework from the *Presidential/Congressional Commission on Risk Assessment and Risk Management* report. The framework encourages managing risks in a broader context, involving stakeholders who are concerned or affected by the risk management process, and using an iterative approach rather than a preordained outcome.

case assumptions, replacing conservative default values with “realistic” values, which in some cases may make things seem less risky. Only a few of these innovations can be dealt with here.

The U.S. National Academy of Science’s National Research Council has several committees investigating various aspects of risk assessment to enhance its scientific quality and its effectiveness in informing public policy on the environment and health. Several important volumes have been published including the Committee on Risk Assessment Methodology’s volume on *Issues in Risk Assessment*²³ and the Committee on Risk Characterization’s *Understanding Risk*,¹ the latter focusing specifically on the transfer of risk information to policy.

► APPLICATIONS OF RISK ASSESSMENT

There is a rapidly growing literature on specific applications of risk assessment.^{24,25} The social implications of the risk assessment process have been discussed by many authors including Lowrance,²⁶ Imperato and Mitchell,²⁷ and Jasanoff.²⁸ Particularly since 2001, in the aftermath of 9/11, risk assessment has been applied to terroristic events and the consequences of biological, chemical, or radiological attacks. Risk assessment was developed primarily by regulatory agencies to provide a rationale for setting enforceable standards for toxic chemicals in air, water, food, soils, consumer products, and wastes, including cleanup of hazardous waste sites, and determining “how clean is clean.” It is now used to set priorities, to compare risks, to identify research needs, and to generate information for cost-benefit analysis. Determining priorities for action is the first step in policy making. Comparative risk assessment is part of prioritization, but it has also become mandated by the 1990 amendments to the Clean Air Act, which direct the EPA

to allow a regulated industry to “trade” among various risks as an alternative to reducing the risks of one chemical.

Veterinary Applications

The policy implications of veterinary risk assessment can be as far reaching as for human health, and this extends to wildlife zoonoses as well.²⁹ One part of the growing world trade movement is the Agreement on the Application of Sanitary and Phytosanitary Measures to reduce importation of plant and animal pests and diseases. In this context, risk assessment is required mainly for risks to human consumers of the plants and animals,³⁰ but it has also been applied to animal health. It is not clear how risk assessment was used in dealing with avian flu in Asia and by whom and how the decision to kill millions of domestic fowl was made. However, although foot and mouth disease resulted in Britain slaughtering thousands of cattle, formal risk assessment was applied to noninfected potential candidates, allowing a more restrictive cull.³¹ Risk assessment has been applied to several other major livestock diseases, including bovine spongiform encephalopathy,³² parasite movements,³³ West Nile virus,³⁴ and mosquito-borne bluetongue disease of livestock.³⁵ It has been used to assess a gill disease in salmon farming³⁶ and the likelihood of rabies entering Britain with pets.³⁷ It is also applied to the environmental contamination by veterinary chemicals excreted by livestock and pets,³⁸ which can be studied using the ecological risk paradigm of mesocosms.³⁹

Terrorism and Preparedness

Since 2001, the United States has focused heavily on all aspects of terrorism and preparedness for both natural, nonnatural (industrial, transportation), and deliberate (terrorism) disasters,⁴⁰ and risk assessment has been used in several ways including estimating the likelihood and magnitude of terrorist events, the design and vulnerability of infrastructure,⁴¹ food supply,⁴² drinking water,⁴³ consequences of infectious disease outbreak, and industrial chemical hazards.⁴⁴ Since absolute protection (detection, interdiction) are presumably not possible and even subabsolute protection is prohibitively expensive, risk assessments offer the opportunity of identifying priorities for investing limited resources in prevention or consequence reduction, for example, in protecting critical infrastructure.⁴¹

National security and preparedness policy, including detainment versus human rights, vaccination versus individual liberty, and redundancy versus cost-containment, can benefit from risk management/risk assessment appraisal.⁴⁵ More specific applications include the risk of sheltering in place versus fleeing,⁴⁶ and information and data system integrity.⁴⁷

Military Applications

The French mathematician, Poisson, was a progenitor of risk assessment, who developed the distribution that bears his name, for estimating rare events. This was first applied to the probability of Prussian army soldier injuries from being kicked by horses. Broader considerations of risk in military strategy and tactics are not considered here. Risk assessment has been applied to excess injury rates among occupying forces⁴⁸ and former international peacekeepers,⁴⁹ to risks from forced anthrax vaccination,⁵⁰ to psychiatric hospitalization,⁵¹ as well as how to monitor troops for exposure to chemicals.⁵² Despite a long history of mysterious syndromes associated with troops in battle, the failure to predict the physical and/or psychological risks and consequences of exposures to Agent Orange, oil well fires, prophylactic drugs, and other exposures, are reflected in the problems reported by veterans of the Vietnam and Gulf Wars.⁵³

Future Land Use of Contaminated Sites

Economic and demographic factors constantly change land-use priorities dictating the reuse and redevelopment of former industrial and agricultural sites, many of which are highly contaminated. Risk assessment needs to be closely linked with future land-use decisions. In the aftermath of the Cold War, The Department of Energy’s widespread

legacy of radioactive and chemical waste on its nuclear weapons complex represents the largest reuse challenge. Cleanup decisions and goals are linked to future land use, requiring assessment of (1) ecological versus human health, (2) worker versus public health, (3) among competing contaminated areas, in order to prioritize remediation and use limited remediation dollars cost-effectively.⁵⁴ Stakeholders who would potentially use or be affected by remediation and land use, are concerned about environmental health risks, even more than property value risks.⁵⁵ Groundwater contamination may limit redevelopment more than soil contamination.⁵⁶ An iterative balancing of future land-use options with their associated risk scenarios and implications is still in its infancy.⁵⁴

Energy and Transportation

The increasing recognition of a crisis in energy, reliance on fossil fuel impacted by international markets, offers a fertile area for risk assessment and risk-risk balancing. Nuclear energy suffered setbacks in the United States, and no new nuclear plants have been built in a generation, yet limited, costly, and polluting fossil fuel, may increase the attractiveness of nuclear energy in the future—particularly after past disasters are forgotten. Despite intense efforts at risk communication, the nuclear industry seems no closer to gaining public acceptance in the United States than a generation ago, sharing many of the features of genetically modified organisms.⁵⁷ Balancing the hazards of handling, transporting, and storing nuclear waste against the various social, economic, and health consequences of other fuels is important. Both nuclear accidents and nuclear wastes are problematic, and the future of Yucca Mountain as a permanent waste repository, has engendered repeated risk investigations involving radiation, engineering, and geology.⁵⁸ A Monte Carlo analysis allowed estimate of peak-of-the-mean exposure for a 10,000-year compliance period,⁵⁹ but there is also the requirement of a million-year security for the repository, and such assurance seems unachievable. Likewise, increased use of compressed natural gas instead of gasoline or diesel for public buses imposes an increased risk of explosion and increased fatality rate from those rare events.⁶¹

► BALANCING RISKS AND COSTS

There are several ways of applying environmental risk assessment in making policy decisions. One can estimate risks associated with a variety of hazards (for example, different hazardous waste sites) and use them to prioritize remediation, starting first with those sites that pose the greatest risk to the greatest number. One can compare an estimated risk with a level of so-called *acceptable risk* (see below) and decide whether or not to take an action. One can treat the reduction of risk as a benefit and perform a cost-benefit analysis for any proposed solution, recognizing that benefit in terms of lives, health, or environmental quality is not easily compared with monetary costs. In another mode, one can contrast the risks from two or more alternative decisions (e.g., to clean up or not to clean up or to ban or not to ban) and may choose the path with the lowest risk. This is called risk-risk balancing.

Remediation workers at hazardous waste sites do face risks beyond those related to the chemical, biological, or radiological hazards themselves, and worker risk is sometimes used to balance the risk reduction of costly cleanups. Such risk balancing usually fails to acknowledge that the same workers would face risks at other jobs if a particular remediation project is abandoned.⁶²

Risk assessment is or can be used in applications for siting permits for hazardous facilities such as nuclear plants, liquified natural gas depots, municipal solid waste incinerators, and hazardous waste sites.⁶³ Because of the wide confidence limits around many risk estimates (*uncertainty*) and the controversies over how to do risk assessments, many management applications of risk analyses may be premature. Nonetheless, risk analysis has played an important role in many governmental decisions, such as management of dioxin-contaminated soil⁶⁴ and the setting of safe drinking water standards.⁶⁵

The dangers of allowing risk management to intrude on risk assessment are highlighted by the Office of Management and Budget's (OMB) attack on the Occupational Safety and Health Administration's risk-based cadmium standard. Not only did OMB display "a fundamental lack of understanding" about risk assessment, but it used a flawed approach to try to second-guess the risk assessment.⁶⁶

Balancing Benefits and Risks of Fish Consumption

There is an extensive literature on the benefits of eating fish both for children and adults. The benefits accrue from the low fat, nutritional protein, from the omega-3 fatty acids (PUFAs), and probably from the avoidance of less healthy food choices. Various agencies have estimated the distribution of food consumption in different populations, and have used average consumption (downwardly biased by noneaters and seldom-eaters), in determining the safety of eating fish. The contaminants in fish are mainly methylmercury and PCBs, and there are two populations who incur these risks: those few adults who eat a lot of fish and a vulnerable subgroup including pregnant women and young children who may be at risk even from moderate consumption. Among the high-end fish eaters are nutritionally conscious people who abjure red meat, recreational anglers, and subsistence fishers. The EPA uses 19 kg/year as the average fish consumption for the general population (including those who eat no fish) and 55 kg/year as the subsistence consumption level. However, many fishermen interviewed along the Savannah River in South Carolina reported exceeding 55 kg/year, some even exceeding 100 kg of fish in a year.⁶⁷ A patient who reported eating an average of about 18 meals of fish per week estimated her annual consumption at over 250 kg/year, with a preference for Swordfish and Tuna, enough to make her symptomatic from mercury.⁶⁸ Pregnant women, on the other hand, are advised to avoid certain fish entirely and to eat less than 12 oz (340 g) per week of other fish. At that rate, consuming fish averaging 0.2 ppm mercury (wet weight), a 60 kg female would exceed the EPA reference dose of 0.1 ug/kg/day.

Most published studies have been of contaminants in recreationally caught fish, while most people obtain their fish from commercial sources. Dioxins and PCBs accumulate in fish and are higher in farm-raised Atlantic salmon from Europe than in the same salmon farmed in South America or than wild-caught Pacific Salmon; even average-frequency consumers would elevate dioxin intake into the health risk range.⁶⁹ Hence it is necessary to provide good guidance on fish that are low in contaminants.⁷⁰ Further research on both the dose-response curves for benefits and the harm curves from MeHg and organochlorines will produce a composite benefit-risk by dose curve that can make risk communication more accurate and more meaningful.⁷¹ Moreover, the FDA advisory includes the reassurance: "There is no harm in eating more than 12 ounces of fish in 1 week as long as you don't do it on a regular basis." and "Just make sure you average 12 ounces of fish a week." Both of these statements are unsupported and misleading. Fish remain a healthful and important source of nutrition, but wise choices of which and how much to consume are essential.

Environmental Equity

Although it has long been known that the most hazardous workplace or community exposures are not uniformly distributed, and that persons in lower socioeconomic groups are most likely to encounter such hazards in their work or home, only since 1990 when Bullard's book *Dumping in Dixie*⁷² appeared, has attention focused on "environmental justice" or "equity." This inequity is not universal, for depending on the economic history of a community or country, industrialization can mean prosperity as well as hazard.⁷³

► ACCEPTABLE RISK

One common goal of environmental risk assessment is to identify whether a particular exposure scenario or environmental level of an agent is "acceptable" or whether a target population can continue to

be exposed to a current level without unacceptably high consequences. This requires society to identify levels of harm that it considers “acceptable” and to recognize that what may seem acceptable to a risk manager or regulator may not seem “acceptable” to a target population. What constitutes unacceptably high risk to one person (e.g., sky diving) may be a provocative challenge to another. The risk estimate can be used to establish an appropriate regulatory approach or policy that will protect the public from greater exposure.⁷⁴

The process of establishing “acceptable risk” is a human values and social decision, not a scientific one. For cancer, it has become traditional to state that an exposure to a hazard is acceptable if it does not cause an elevation in the lifetime death rate of cancer greater than one in a million exposed people. If we accept for sake of argument that approximately 20% of people die of cancer, a 1 in a million or 10^{-6} elevation of risk means that instead of 200,000 out of a million people dying of cancer, the level will be 200,001. Clearly, this immeasurably small elevation of risk cannot be identified by any current or projected epidemiologic methods. Nor is it easy to communicate such an infinitesimally small increment. By contrast, regulations regarding occupational exposures or natural hazards (i.e., radon) tolerate a much higher risk (on the order of 10^{-4}), but this too is immeasurably small, particularly compared to the risks faced by asbestos workers, more than 30% of whom eventually died of an asbestos-related cancer⁷⁵ or by chromate workers for whom a lifetime lung cancer risk may exceed 1 in 10.⁷⁶ Most epidemiologists are content if they can identify a 50% increase in risk, whereas 1 in 10,000 translates into 0.01% increased risk. Nonetheless, these “acceptable” levels play an important role in risk management. Recognizing that the 1 in a million risk may be more theoretical than practical, one increasingly sees agencies using a 1 in 100,000 or even 1 in 10,000 risk for nonoccupational exposures.

Before one determines whether a risk is acceptable or not, it is necessary to define an endpoint. Table 21-1 provides a spectrum of endpoints ranging from those like early death from cancer to emotional disturbances. There is a tendency to treat the first entries as the most consequential, and indeed risk assessment has been preoccupied with cancer. Yet some people are disabled by their emotional reactions to hazardous exposures. Society must determine how safe it wants to be⁷⁷ and how much it is prepared to sacrifice for that level of security.

Unfortunately, the persons who most often decide whether or not to invest in environmental safety are usually not those most at risk. Although the Environmental Protection Agency (EPA) sets a risk level 10^{-6} excess cancer deaths as the cutoff between acceptable and unacceptable, some persons argue that this is an unrealistically small level since most of the risks that most people willingly face (e.g., driving an automobile) are much higher. Indeed, the cancer risk of living in a home with 4 pCi of radon per cubic meter has been estimated on the

order of between 1 in 100 and 1 in 1000 excess cancers, but even in the radon belt, many people choose not to test their homes or remediate the elevated level.⁷⁸ Courts have become involved in the risk debate, at least insofar as it involves interpreting biomedical evidence.⁷⁹

Once a risk estimate has been calculated, it becomes a major challenge to communicate the risk to responsible officials, the media, and potentially at-risk individuals, for the manner in which individuals perceive risk often bears little resemblance to the actual magnitude of their risk.⁸⁰

As Low as Reasonably Achievable (ALARA)

When risk cannot reasonably be reduced to what is deemed an acceptable level, regulation employs the ALARA (As Low as Reasonably Achievable) or in the United Kingdom ALARP (As Low as Reasonably Practical) approach, while control of emissions may require the BACT (Best Available Control Technology). These have the advantage of being performance rather than specification standards.

► ENVIRONMENTAL RISK ASSESSMENT PARADIGM FOR CARCINOGENS

The basic four-step approach to environmental risk assessment for carcinogens as outlined below was codified by the National Research Council in 1983.¹⁸ In the late 1970s, there was heavy emphasis on improving dose-response information; by the early 1980s the research emphasis had shifted to improving understanding of the appropriate mathematical models for low-dose extrapolation. By the late 1980s, it was realized that the exposure assessment phase required much research attention. In the 1990s, attention focused on understanding the mechanisms by which agents produce disease and modifying the generic risk assessment process accordingly.⁸¹ In the late 1990s, susceptibility emerged as a major concern for risk assessors. By 2000, emphasis had again shifted to understanding the magnitude and impact of uncertainty, how it should be analyzed and communicated.⁸² And risk has come full circle with increasing discussion of improving the hazard assessment and selecting appropriate mathematical models for low-dose extrapolation⁸³ and for estimating uncertainty.⁸⁴

Establishing the guidelines for carcinogen risk assessment has been a painstaking process as indicated in the following table. The EPA Guidance finally released in March 2005 began wending its way through the federal bureaucracy in 1976.

Hazard Identification

The first step is to define the hazard and establish the endpoint that will be used in the risk assessment (Table 21-2). This means identifying a toxic substance or mixture and naming one or more endpoints (e.g., lung cancer, neurotoxicity) which are of concern. For a hazardous waste site, it begins with a list of the chemicals (usually from the list of 129 priority pollutants) that have been identified in the soil. One or a few chemicals are then selected based on their quantity, mobility, coherence with health reports, or actual exposure measurements.

Dose-Response Assessment

This usually involves extensive review of the toxicological and/or epidemiologic literature to ascertain whether dose-response curves can be constructed for the endpoints of concern or whether specific thresholds have been determined. Unfortunately, for many compounds the only dose-response data are from old studies that used dosing levels appropriate for determining an LD-50, but not appropriate for low-dose extrapolation. Almost inevitably, one must rely on extrapolation to a lower dose.

Exposure Assessment

Estimating exposure to the target population is essential.⁸⁶ This requires measurements or models of contaminants from sources,

TABLE 21-1. SPECTRUM OF ADVERSE CONSEQUENCES CONSIDERED BY RISK ASSESSORS IN APPROXIMATELY DECLINING ORDER OF SEVERITY

Shortening of life (mortality)
Cancer versus other causes
Illness or injury leading to disability
Acute versus chronic
Permanent versus temporary disability
Serious versus minor disability
Illness or injury with temporary disability followed by recovery
Chronic versus acute
Serious versus minor disability
Physical discomfort without disability
Psychological disorder with behavioral consequences
Posttraumatic stress disorder
Anxiety reaction
Stress reaction
Chronic frustration and anger
Emotional discomfort

TABLE 21-2. CHRONOLOGY OF LANDMARKS IN CARCINOGEN RISK ASSESSMENT (EPA 2005)⁸⁵

1976—EPA issued “Interim Procedures and Guidelines for Health Risk Assessments of Suspected Carcinogens”
1983—National Research Council “Risk Assessment in the Federal Government”
1986—Publication of the first Guidelines for Carcinogen Risk Assessment
1996—EPA published for public comment the Proposed Guidelines for Carcinogen Risk Assessment. The proposed guidelines underwent Science Advisory Board (SAB) review in 1997
1999—EPA’s Advisory board and Children’s Health Protection Advisory Committee (CHPAC) reviewed the Draft Final Revised Guidelines
2001—In November EPA published in the Federal Register a Notice of Intent to finalize the cancer guidelines and extended the opportunity to provide comment
2003—In March EPA released draft Final Cancer Guidelines and draft Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens for public comment
2004—In March EPA received SAB comments (PDF, 40p) on the Supplemental Guidance
2004/5—In response (PDF, 7p) to an SAB recommendation, EPA extended the analysis supporting the Supplemental Guidance
2005—In March EPA published final Cancer Guidelines and Supplemental Guidance

through environmental media (including fate and transport), contact with the receptor, bioavailability and absorption, and finally an estimate of dose to a target organ or tissue or cell. Exposure assessment must take into account the measured or estimated concentration of a substance (air, water, food, soil) and all applicable routes of exposure (inhalation, ingestion, skin absorption) (see Table 20-2). This requires knowing how individuals behave: where they spend their time, what they eat, how much they drink, and many other variables which can be incorporated into increasingly sophisticated models.⁸⁷ In many cases, the actual site-specific or case-specific data are unavailable, and default values are used. Preferably, direct observations or questionnaires can be used to obtain case-specific exposure estimates. For example, our studies of risks from consuming fish contaminated by metals or radionuclides required site-specific estimates of how much fish fishermen actually consume.⁶⁷ Increasing attention focuses on estimating probability distributions for all aspects of exposure including behavior influencing hours at home, minutes of showering and water use,⁸⁸ and food consumption.⁸⁹ Exposure assessment must incorporate estimates of bioavailability and increasingly relies on physiologically based pharmacokinetic models to provide estimates of the internal dose, the dose actually delivered to the target organ.⁹⁰

Obtaining empirical distributions relevant to exposures (drinking water, air volumes, market baskets, etc.) for different populations and age groups is costly but important.

Risk Characterization

This involves a quantitative estimate of the exposure level at which a particular level of excess risk exists. In the case of cancer, one constructs a dose-response curve based on animal studies of cancer and performs a low-dose extrapolation to estimate the dose that would produce a particular excess of cancer (for example, a 10^{-6} increase, resulting in one additional case per million exposed people). The toxicological data used may involve the presence of tumors, the number of tumors per animal, or the time-to-tumor from initial dosing. A variety of biological models of carcinogenesis have been advocated, each leading to selection of different mathematical extrapolations. The one-hit model assumes a linear relationship between dose and outcome,

starting at the smallest dose above zero (i.e., no threshold), with the slope of the line determined from the available studies. It assumes no threshold and is basically drawn from our understanding of radiation and cancer. Multistage models take into account our understanding of chemical carcinogenesis as a process involving initiation and promotion.⁹¹ Crump⁹² proposed a linearized multistage model, now widely used. This is contrasted with the linear no-threshold (LNT) model,⁹³ the Armitage-Doll multistage model, and more recently the Moolgavkar-Vernon-Knudsen model, which emphasizes mutational events⁹⁴ involved in initiation rather than in promotion. The LNT model derived from radiation carcinogenesis has been considered controversial, particularly when applied to chemical carcinogenesis. Recently (June 2005), the U.S. National Academy of Sciences Committee on the Biological Effects of Ionizing Radiation, has issued its BEIR VII report,⁹⁵ reaffirming that the LNT model is the correct model to use for radiation and cancer. Since most toxicological studies and occupational epidemiology cohorts have been dosed or exposed to levels far above those encountered by the general public, it is necessary to extrapolate from these high doses to presumed effects at low doses, using one of the above models. The Carcinogen Assessment Group of the EPA has prepared cancer potency estimates referred to as slope factors (also labeled $q1^*$ values) for a number of common carcinogens using the linearized multistage model which is currently considered the most generally applicable extrapolation approach for chemical carcinogens.⁸¹ These estimate the number of excess cancers associated with a unit increase in dose. These and other valuable data are available in EPA’s IRIS database (<http://www.epa.gov/iriswebp/iris/index.html>).

Other models such as dose-distribution models give higher estimates of dose and are considered less protective of the public health, although future research may validate their use for some substances. It is likely that where several models give similar estimates of risk for a substance and one model gives a very divergent estimate of risk, one can safely rely on the evidence of the concordant estimates.

► CARCINOGEN CLASSIFICATIONS

The International Agency for Research in Cancer has a five-tier system for classifying chemicals on the basis of human cancer, and the EPA system is analogous (Table 21-3).

- Group 1. Known human carcinogen: adequate evidence in humans
- Group 2A. Probable human carcinogen: limited evidence in humans but sufficient evidence in animals
- Group 2B. Possible human carcinogen: limited evidence in humans and less than sufficient in animals
- Group 3. Not classifiable: this category is used most commonly for agents, mixtures, and exposure circumstances for which the evidence of carcinogenicity is inadequate in humans and inadequate or limited in experimental animals.
- Group 4. Probably not carcinogenic in humans. Evidence suggests not a carcinogen in either humans or animals.

The EPA uses the similar categories but they are labeled A, B1, B2, C, D, E (Table 21-3).

Interspecies Extrapolations

One of the controversial aspects of risk management is the utility of risk assessments based on animal toxicology without supporting human epidemiology. The evolutionary relatedness among animals, their common derivation, and the high degree of homology among protein structures provides the basis for the principle of animal extrapolation to humans. It is important to realize, however, that such basic phenomena as the presence of enzymes and consequent metabolism vary not only among species, but among strains of a species,

TABLE 21-3. COMPARISON OF THE IARC AND EPA CARCINOGEN CLASSIFICATIONS

Classification	Evidence in Humans	Evidence in Animals	IARC Group	EPA Group
Known human carcinogen	Adequate epidemiologic evidence in humans		1	A
Probable human carcinogen	Limited evidence	Sufficient	2A	B1
Possible human carcinogen	Inadequate Limited	Sufficient Limited or less than sufficient	2B	B2 C
Not classifiable	Inadequate evidence	Inadequate or limited	3	D
Probably not a human carcinogen	Substantial negative evidence	Substantial negative evidence in at least two species	4	E

between sexes, and over the course of the lifespan.⁹⁶ The response of experimental animals (or of human subjects) may vary with many factors. In some cases the fact that a toxic substance produces the same effect (e.g., bladder cancer or leukemia) in several species of animals makes one confident that interspecies extrapolation is valid. For a carcinogen that produces cancer in many species, but in each case involving a different organ system, extrapolation is more uncertain. Finally, a substance may be a carcinogen in one species, but not in another. Almost all known human carcinogens are also known animal carcinogens, and it is prudent to assume that animal carcinogens, particularly those that cause cancer in both sexes and more than one species, are probable human carcinogens as well.

Where data are available to estimate cancer potency for a single chemical from both animal studies and human epidemiologic studies, there is a high correlation⁹⁷ validating the use of animal toxicological data. The basic problem is that one does not know *a priori* whether the human is more or less susceptible to the agent than the experimental animal used in a study. Incorporating a safety factor of 10 assumes that humans are no more than 10-times more sensitive. However, humans are just as likely to be less sensitive than more sensitive, and in many cases the sensitivity is not known. Thus in the case of 2, 3, 7, 8-TCDD (dioxin), guinea pigs are about 1000 times more sensitive than rats while it is not clear whether humans are closer to guinea pigs or to rats.

Interpreting the Model

To minimize animal pain and stress, the quest of alternatives to animal models valid for risk assessment is a priority of the National Toxicology Program. Before selecting a model, one establishes a level of acceptable risk. This enables one to ask, what dose of chemical would increase the cancer risk by one case in a million. The mathematical model allows one to extrapolate downward until one reaches that very low dose associated with one in a million excess risk.

If one uses the LNT model, this dose will be much lower than if one uses the probit model. Environmentalists seeking to prevent any unnecessary exposure to carcinogens will tend to favor the model giving the lowest allowable dose, while an industrialist responsible for controlling exposures in and around his or her factory will feel more comfortable if the less conservative probit model is used, thus relaxing his or her burden somewhat. Unfortunately, much of the debate over which model to use has focused on the political and economic consequences of the choice rather than on the scientific basis. This is perhaps inevitable since there has been only slow progress toward determining the biological basis for model selection for specific chemicals. Understanding the mechanisms by which toxic substances produce their effects at the molecular and cellular level can help clarify the risk approach.

In addition to estimating a critical dose, one can calculate the 95% confidence limits around an estimate. To ensure protectiveness of public health, one reports the upper 95% confidence limit as the

“upper bound” of the risk estimate. In addition, one can establish a science-policy decision of using a no-threshold model in cancer risk assessment.⁹³ In other countries, a no-threshold model is used for genotoxic carcinogens, but not necessarily for other carcinogens such as promoters.⁹⁸

Thus the compromise solution is the linearized multistage model.⁹² This takes into account the two-stage process of carcinogenesis, recognizing that a single hit may not be sufficient to cause a cancer. The dose estimated by the linearized multistage model is intermediate between the doses generated by the other two models. The EPA has also selected a “one-in-a-million excess risk,” often indicated as a 10^{-6} excess risk, as the point at which it will make decisions to regulate exposures.

Modeling Endpoints Other than Cancer

There are attempts to harmonize risk assessment for noncancer and cancer endpoints.⁹⁹ Although the method described under Risk Assessment for Noncancer Endpoints is still prevalent, there are attempts to bring dose-response extrapolation to bear on other endpoints. A model for developmental toxicology incorporates many parameters to estimate cell kinetic rates, and the population of cells with normal and abnormal kinetics, from which developmental abnormalities can be inferred.¹⁰⁰

► RISK ASSESSMENT FOR NONCANCER ENDPOINTS

Risk analyses for noncancer endpoints use a variety of approaches usually based on the highest dose known to produce no effect (no observed adverse effect level [NOAEL]) or if only the control dose had no effect, the lowest dose known to produce an adverse effect (lowest observed adverse effect level [LOAEL]) can be used.¹⁰¹ Ideally, one would use data from epidemiologic studies including the most sensitive human subpopulations, where there has been a lifetime of adequate exposure by appropriate routes as well as a lifetime of follow-up (to ensure that events with long latency are not missed). In such a study, the exposure would be documented for all subjects for all years, and any outcome would be correctly diagnosed and recorded. These conditions are never met. One must rely either on incomplete epidemiologic studies or on animal studies. Since most published animal studies were not designed for risk assessment, one must be cautious in interpreting them, and new studies with more appropriate design would be helpful. Studies with very short-term exposure or with short-term follow-up are usually not incorporated in risk assessments.

Several terms need to be understood.

Benchmark Dose. An alternative to relying on a NOAEL, the benchmark dose is the lower confidence limit on a dose which produces an effect in some percent of test animals (usually set at 1, 5, or 10%). It is derived from modeling. It is usually less conservative (less protective), and is linked to an assumption that a certain percent of

illness (up to 10% of the population) is tolerable. Estimates of benchmark doses need to account for exposure uncertainty.¹⁰²

Conservative. When applied to models or standards, more conservative equates to more protective. This has no relation to and is often opposite to the political meaning of conservative.

NOEL and NOAEL. In toxicological studies, these are the no observable effect level and no observed adverse effect level, respectively. The NOAEL is the dose at which there was no biological or statistically significant adverse effect. Often there may be measurable effects that are not known to have adverse consequences (hence the term NOEL). It is sensitive to the doses chosen for the study.

LOAEL. Lowest observed adverse effect level. In some studies, even the lowest dose induced a significant adverse effect. Rather than throw out such studies, use these data, but treat the LOAEL differently from a NOAEL, incorporating a 10X uncertainty factor. Since most toxicological data used in risk assessment were not collected with risk assessment in mind, one is often confronted with LOAELs rather than NOAELs.

Reference Dose (RfD), or Acceptable Daily Intake (ADI). The RfD is established by the Environmental Protection Agency based on risk assessments for noncancer and nongenetic endpoints.^{37,103} This is a daily dose expressed usually in $\mu\text{g}/\text{kg}/\text{day}$ that one could be exposed to every day (usually for a 50-year lifetime) without experiencing any adverse effect.

Safety Factor (SF), or Uncertainty Factor (UF). A margin of safety (often arbitrary) introduced into the regulatory process to account for uncertainties in the biomedical database. Since they do not necessarily ensure *safety*, most authors prefer to label them uncertainty factors. Various UFs are used to calculate an RfD from an NOAEL or LOAEL. The most common default values for these are:

- To use animal data to protect humans,^{38,104} UF 10
- To protect the most sensitive human individuals, UF 10
- To calculate a chronic or lifetime RfD from a study using only a subacute or acute exposure, UF 10
- If the RfD is based on an LOAEL rather than an NOAEL, UF 10

Although the choice of these values of 10 may be arbitrary, subsequent data analyses have tended to support their utility.¹⁰⁵ However, if all four conditions hold, then the combined UF equals 10,000, resulting in an RfD that is four orders of magnitude lower than the LOAEL. Some authors believe that this is overly and unreasonably protective and have countered with lower default values or none at all. In some cases, substance-specific research may point to a different safety factor.

Making the Calculations

In using these levels, one selects the highest NOAEL or the lowest LOAEL for a nontrivial endpoint reported in the literature as the starting point for calculations. One also makes certain assumptions about exposure. The standard human target is the 70-kg adult male. However, if susceptible subpopulations include children, females, or ethnic groups, a more appropriate body mass should be chosen. Exposure is assumed to occur over a 50- or 70-year life span, but in many cases involving childhood exposure, a different critical period is selected. The acceptable daily intake, or reference dose, is calculated by dividing the NOAEL by a denominator comprising all applicable uncertainty factors multiplied together.¹⁰⁵

Physiologically Based, Pharmacokinetic Models (PBPK)

The above methodology has been criticized as being overconservative, introducing too many arbitrary UFs. Since the value of “10” is a default value, critics seek more “realistic” estimates.⁹⁹ The use of benchmark doses divided by uncertainty factors derived from geometric standard deviations has been proposed as less overconservative.¹⁰⁶ The use of pharmacokinetic models may offer a way of avoiding reliance on the default values.¹⁰⁷ For example, using the concentration of tetrachloroethylene in the air in a shower, a PBPK can predict the concentration delivered to the brain after both inhalation and dermal exposure.

Instead of relying on an RfD (daily intake), one can calculate a reference target tissue level (RTTL).¹⁰⁸ Research is underway on using PBPK approaches to convert external measurements (concentrations in air) to dose to target.⁹⁰ The utility and believability of PBPK will be enhanced through independent evaluation of the assumptions, the input distributions, and parameters used.^{109,110}

Receptor Kinetics and Gene Expression

Recent advances in molecular and cell biology point to the role of receptor-mediated gene expression in cells as part of toxicological responses. Xenobiotics may bind to (or inhibit) receptors intended for naturally occurring mechanisms. Increasing knowledge of these mechanisms and modeling will improve understanding of the shape of the dose-response curve.¹¹¹ Xenobiotics can influence gene expression, upregulating or downregulating messengers or receptors, and can act on cell cycles, messenger cascades, DNA repair and each mechanism has different implications for risk assessment. The utility of toxicogenomics in risk assessment will likely focus on understanding susceptibility and toxic mechanisms.¹¹²

► RADIATION RISK ASSESSMENT

Radiation risks must be interpreted against a background of omnipresent radiation level from cosmic, terrestrial, and internal sources. Typical radiation exposure ranges from about 100 mrem to 500 mrem/year, depending largely on altitude, and standards are based on levels over this background, even though there is a substantial cancer burden attributable to background, and the recent reaffirmation that radiation cancer-risk follows a linear no-threshold model (BEIR VII, 2005).⁹⁵ Although radiation can be measured with precision, its impact is often difficult to assess. For example, the attributable risk of thyroid cancer to Chernobyl fallout could not be estimated until the background thyroid rate was known, and this estimate remains elusive.¹¹³

► BIOLOGICAL AGENT RISK ASSESSMENT

Although risk assessment has developed mainly in the realm of chemicals and toxicology, biologic agents lend themselves to risk assessment. Arthropod-borne disease represents life cycles in host animals, insect vectors, and human patients. There are probabilities associated with each life-cycle transition—for example, the probability that an infected mosquito will bite a person, the probability of a high virus titer in its saliva, the probability of an infectious dose being delivered. Similarly, the efficacy of various barriers in blocking exposure, for example, behavior and insect repellents, or the effectiveness of UV light and respiratory protection against tuberculosis transmission can be analyzed. Risk assessment has long been an integral part of food safety and drinking water quality, and is used in evaluating agricultural practices.¹¹⁴

► INFORMATION USED IN RISK CHARACTERIZATION

Epidemiology and experimental toxicology provide information for risk assessment. Epidemiological studies concern the appropriate species, humans, but they are often limited by uncertainties as to exposure and lack of power to detect small increases in risk. It is difficult to detect with statistical confidence an increase in risk (incidence of disease or death) unless it exceeds by more than 100% that which occurs in a reference or control group, and the use of methods such as meta-analysis to increase power is often necessary. Meta-analysis, though controversial, is proving a valuable tool in interpreting epidemiologic studies and makes use of the fundamental scientific process of building confidence from replicating studies. Moreover, epidemiologic studies often lack power, and insisting on a .05 level of significance introduces a strong bias against finding associations between exposure and outcome. These conservative features

argue for the precautionary principle.¹¹⁵ Goldstein and Carruth¹¹⁶ point to the emerging role of the precautionary approach in World Trade Organization policies, where risk assessment is already entrenched, and question the assertion that precaution is the antithesis of risk. Rather precaution is part of a spectrum to be invoked when uncertainty is high and adverse consequences large.¹¹⁷

Toxicological studies have the advantage usually in terms of accuracy of exposure and dose measurements, but in many cases there are uncertainties on converting animal doses to human exposures, and sometimes it is hard to define the relevance of an observed effect for predicting human disease or disability.

Dose-Duration and Risk

Typically risk assessment focuses on lifetime exposure and lifetime risk, and in many cases assumes that exposure occurs at a more or less constant daily level over a period of years or even a 50- or 70-year lifetime. Radiation risk assessments are more likely to apportion risk over time, recognizing that childhood exposure has different impacts from adult exposure, but even the radiation dose-distribution is used qualitatively. The relationship between duration and dose is complicated, and largely unstudied. A person with a bottle of 30 tablets who takes one each day would have a different experience than if all 30 tablets were consumed at one sitting. Peak doses may exceed thresholds which are never reached by small daily doses, even over a long time period. On the other hand, repeated doses may produce other diseases which do not occur in those that survive an acute dose. More data on dose-duration is a major research need. At the same time, age is a major variable influencing susceptibility and response,¹¹⁸ and particularly during development and childhood there are critical windows during which exposure may exert an effect that does not occur earlier or later in life.

The Maximally Tolerated Dose

Critics of risk assessment point to the reliance on worst-case approaches such as the maximally tolerated dose (MTD) used in laboratory studies as leading inevitably to overestimates of risk. The MTD is the highest dose “that does not alter the animals’ longevity or well-being” from unrelated effects.²³ The National Research Council’s Committee on Risk Assessment Methodology (CRAM) concluded that the MTD is useful mainly for qualitatively identifying carcinogens and was not intended to be the only data used for quantitatively estimating risk.²³

Extreme Value Theorem

Risk assessments are regularly used to estimate low-probability/high-consequence events. Extreme value is a branch of statistics focusing on extreme deviations from the median of probability distributions. Although used mainly actuarially, it is useful for evaluating highly unusual events such as 100-year floods. The Netherlands has built its dikes just tall enough to retain a 10,000-year flood event, or to be breached only once in 100,000 years,¹¹⁹ recognizing that such events could occur next year. Extreme value approaches could be applied to estimate risks to the most highly sensitive (supersensitive) individuals, who may be much more than 10 times as susceptible as the median of the population.

Uncertainty

Uncertainty permeates the risk assessment process. Even when the mechanism by which an agent produces disease is well understood, uncertainty is introduced in the dose-response data from animal studies, the exposure assessment, and the risk estimation process. These uncertainties may be multiplicative, leading to orders of magnitude differences in estimate depending on the assumptions one uses. It is important to distinguish between uncertainty introduced by inadequate data or choice of methodology from the inherent variability among individuals.¹²⁰ Thus in a population for which an average exposure assessment can be estimated, some will behave in a way that minimizes, while others maximize, their potential exposures. Similarly individuals vary in their susceptibility to different hazards. A

variety of approaches is being suggested to reduce the uncertainty in risk assessments. Monte Carlo (randomization) simulations have been used to produce a distribution of estimates.^{121,122} However, formal uncertainty analysis is probably less important than efforts to reduce the uncertainties through toxicological and epidemiologic research enhanced by the increasing availability of biomarkers and through careful site-specific studies of exposure.

Susceptibility

The past decade has seen burgeoning interest in individual variability in susceptibility to hazardous agents (see Chap. 18-A). This variability can be genetic or acquired. Age, gender, and race influence susceptibility.^{123,124} Acquired variability may reflect overall health status, concurrent exposures, diet, and lifestyle. Major research breakthroughs are being made in understanding the contribution of genetic variability, particularly in the P-450 enzyme system on susceptibility. Most of this research focuses on the consequences of single-nucleotide polymorphisms, although the largest source of variance in susceptibility is due to polygenic interactions, pleiotropism, and epigenetic factors.

Individual versus Collective Risk

The process of risk assessment is concerned with collective risks facing a target population rather than an individual. Policy makers, likewise, are concerned with protecting groups from unacceptable exposures and risks. However, many decisions regarding risks are made at the individual level. And even when a group is exposed, its members try to interpret and respond to the risk as individuals. It seems reasonable to assume that, once a risk has been estimated for a group, any individual within that group will face the average risk. However, within a population the risk is distributed unevenly, depending on variation in exposure and susceptibility, such that any individual may have a risk much lower or higher than the estimate.

Limitations of Risk Assessment

Some of the limitations of risk assessment are inherent in the underlying toxicological and epidemiologic databases, the lack of adequate exposure data, or incomplete outcome ascertainment. Specific issues alluded to above include: (a) For the most part risk has been and will continue to be based on published animal research. However, until recently, toxicological research on animals was not designed with quantitative risk assessment in mind, hence the choice of doses and number of animals used may have been appropriate for descriptive purposes, but not for the low-dose extrapolations used in risk assessment. (b) Many of the endpoints of concern in humans have not been adequately studied in animal models. (c) The uncertainties inherent in extrapolating from animals to humans have engendered controversy. (d) Human epidemiologic studies of adequate power are usually too sparse to contribute to risk assessment, hence the continued necessity of relying on animal models. (e) Human exposure data are often inadequate. (f) In cancer-risk assessments, there are dramatic differences depending on which mathematical model is used. (g) Risk estimates based on collective exposure are not easily translated into individual risk. (h) The temporal aspects of dose, peak exposures, and duration are generally ignored in chemical risk assessment and only superficially considered in radiation risk assessment. (i) There is the continuing debate over what constitutes an acceptable risk level, which often overrides biomedical estimates of risk.

Although these concerns interfere with performance and application of risk assessments, the process has become increasingly robust, so that it does serve useful functions in ordering priorities, in comparing the risks of different solutions, and in providing some data for establishment of policy.

► RISK PERCEPTION

Some individuals engage in extremely risky behavior on a regular basis as part of their job and may receive hazardous duty pay in recognition

TABLE 21-4. RISK PERCEPTION DICHOTOMIES

<i>Acceptable, or Reduces Apparent Riskiness</i>	<i>Unacceptable, or Increases Apparent Riskiness</i>
Assumed voluntarily or self-imposed	Borne involuntarily or imposed by others
Adverse effect immediate	Outcome delayed
Alternatives not available, a necessity	Alternatives available, a luxury
Risk certain	Risk uncertain
Occupational exposure	Community exposure
Familiar hazard	Feared or “dread” hazard
Consequences reversible	Consequences irreversible
Some benefit gained from assuming risk	No apparent benefit to persons at risk
Hazard associated with perceived good	Someone else profits at “my expense”

of this risk. Others engage in risks for recreational purposes or thrill. At the opposite pole of such risk-taking behavior are risk-averse individuals. One might predict that a risk-taking individual, such as a skydiver or a mercenary soldier, would willingly undertake other risks such as smoking, driving without a seat belt, tolerating radon in their homes, or living next to a hazardous waste dump, while risk-averse individuals take public transportation to a 9-to-5 job, wear a hard hat while walking near tall buildings, frequently check their homes for radon, have their car undergo frequent safety inspections, and shun all activities or exposures that enhance their risk of becoming ill or injured.

However, risk perception is not that simple, influenced by many factors other than knowledge of risks.¹²⁵ Some individuals who willingly take great risks fear having their drinking water contaminated even at immeasurably low levels. A person may complain that they are sensitive to mold, yet continue to smoke. The fact that, in general, individuals tend to overestimate negligible risks and underestimate severe ones is a source of frustration to risk analysts and policy makers alike, and this has engendered the rapidly growing field of “risk perception research.”¹²⁶ Perceived risks to natural resources such as forest biodiversity are shaped more by underlying value systems than by specific knowledge of impacts.¹²⁷

Unfortunately, many efforts to understand *risk perception* and improve *risk communication* are aimed at marketing a particular viewpoint—that is, trying to convince people to accept a particular level of risk that is politically or economically expedient. Although not usually recognized, the field has its roots in the study of “marketing,” which emerged in the 1950s and 1960s to understand factors motivating human purchasing decisions. Although the risk perception literature rarely references its parent discipline, many common principles can be recognized. Nonetheless, important advances and generalizations have been developed.¹²⁸

Lowrance²⁶ is credited with popularizing the understanding of risk perception and what constitutes acceptable risk. He described the series of “dichotomies,” originally proposed by Fischhoff, which influence human perception of risk. Some of these are shown in Table 21-4.

The goal of risk perception research is to understand how individuals appreciate risks, how they make their risk-taking and risk-avoiding decisions, and how to bring their understanding of specific risks into congruence with the actual levels of risk. This will reduce the anxiety levels where risk is overestimated and may influence behavior, preventing significant exposure where risk is underestimated. All too often, risk managers have the goal of reducing anxiety and encouraging people to accept exposures, particularly those that would be costly to mitigate. However, examples of the need to enhance awareness and response to underestimated exposures include convincing people to have their homes tested for radon and to have exposure mitigated if the radon level is high and educating people regarding the hazards of smoking tobacco.

Although people in different parts of the world and at different socioeconomic levels face different kinds of risks and make risk decisions driven by different factors, there are some universal features to risk perception. For example, Hinman et al.¹²⁹ showed a remarkable concordance between United States and Japanese respondents regarding the things they dread (with nuclear accidents, radiation waste, and nuclear

war at the high end for both countries); however, there was less concordance between countries in the knowledge about the 30 hazards tested.

Comparisons of lay public versus “experts” consistently reveal that the former views technology as more risky than the latter, apparently independent of the technology and risks.¹³⁰ Among scientists, those in the life sciences and those in academia tend to perceive greater risks from nuclear waste than do physical scientists or those in industry or government.¹³¹ The latter are also more willing to impose risks on others. Not surprisingly, employees of a nuclear plant perceived a lower risk of accidents than did the general public.¹³²

Demographic factors influence perception in complex ways. In some studies more educated people who may have a better understanding of science and technology are more accepting of technological hazards,¹³³ but the fact that people of lower socioeconomic status and education fear such developments relates in part to their perception that they personally are at greater risk.¹³⁴ Perceived risks for any hazard correlates with one’s perception of personal risk from that hazard, but is tempered by any benefits from that hazard.^{135,136}

► RISK COMMUNICATION

Like risk perception, there is a growing field of research surrounding the methods that can be used to impart risk information to the public as well as to individuals. Risk assessment and risk management are highly charged fields where politics and emotion mix freely with science, and ultimately whom you trust determines your views of risk.¹³⁷ The landmark book *Improving Dialogue with Communities: A Risk Communication Manual for Government* identified the challenges that government officials face when bringing news (particularly unpleasant news) about a local environmental hazard to communities.¹³⁸ Public utilities and corporations have also invested in improving their communication with their neighboring communities, both to comply with Superfund Amendment Reauthorization Act (SARA) title 3 and with community right-to-know laws in some states and to create channels of communication in case of an accident. Although this was true when written in 1996, many communities have apparently lost interest in SARA title 3 and the Local Area Planning Committees established under SARA have become inactive. Moreover, SARA was predicated on public access to information about hazards in the community, while the rising industrial secrecy engendered by homeland security fundamentally undermines the access of the public to hazard information.

Models of Risk Communication

In many circumstances, risk communication has been a one-way path between the “expert” and the “public” following a *source-receiver model* in which the recipient is passive and is expected to respond to the message in a predicted manner. Very frequently the anticipated response does not materialize. Two-way communication (sometimes called a *convergence model*),¹³⁹ is necessary so that the receiver can inform the sender what parts of the problem are important, thereby shaping the message they receive. In communicating with non-English speakers, the primary focus is usually on correct translation, but we

found that direct classroom interaction was more effective than relying on a well-translated illustrated pamphlet in communicating about fish consumption to pregnant Latinas.¹⁴⁰

Risk Comparisons

Risk assessors, not realizing that individuals must put risk into very personal contexts, often lament that the public reacts irrationally to risks. Risk comparison is an approach to communicating risk by contrasting unfamiliar risks with familiar ones. Common reference points include the risk of driving so many miles in a car, the radiation risk of a transcontinental air flight, and the lung cancer risk from smoking a pack of cigarettes per day. The implication is that a risk lower than these should be acceptable. Yet individuals may rationally accept the necessary (and predictable) risk of transcontinental flight, while shunning the perceived (and uncertain) risk of having a communication tower constructed in their community. The perception is colored by the personal gain and utility of the former and the lack of vested interest in the latter. Aesthetic considerations also color perceptions of risk. A nonsmoker may take the one-pack-a-day comparison as evidence of high and unacceptable risk. The concept of risk comparison thus often makes more sense to the communicator than to the communicatee. The dichotomies shown in Table 21-4 help us understand this apparent paradox.

Temporal Characterization of Risk

As an alternative to risk comparison, very low lifetime risks can be transformed into a time frame that may help some people grasp their significance. Thus a one in 100,000 lifetime risk in a town of 2000 people translates into one death in 3500 years (50×70 year lifetimes).¹⁴¹

Media Coverage of Risk

One often gains the impression that newspaper and television coverage exaggerates the hazards of everyday life, with stories that bear little relationship to the actual magnitude of public health hazard.¹⁴² Nonetheless the media are an important source of hazard and risk information for many people, and the media therefore could play a crucial role in providing a balanced perspective on risk. Although many toxicologists shun journalists for fear of being misquoted, there is a substantial basis for believing that environmental news coverage can be improved if a dialogue between toxicologists, risk assessors, and reporters can be developed.¹⁴³

Stakeholders and Citizens' Advisory Boards (CABs)

Various agencies, including large corporations and the Department of Energy, form advisory boards representing various types of stakeholders. These can voice concerns to which the company can respond proactively. CABs can focus attention on the risks that they view as significant and can identify acceptable alternatives or programs. At some factories they actually participate in fence-line monitoring programs. Their actual contribution to policy outcomes, however, is variable.¹⁴⁴

Improving the involvement and usefulness of communities, particularly minority communities, in agency decisions, as well as a need to evaluate risk communication methodologies have been identified as high priorities for risk communication research.¹⁴⁵

► ECOLOGICAL RISK ASSESSMENT

Ecological Risk Assessment has emerged as the discipline to evaluate the risk of stressors to ecological systems (including their component organisms), and it has borrowed heavily from the human risk assessment four-step paradigm:^{13,23} hazard identification, dose-response, exposure assessment, and risk characterization.^{146,147} The use of Ecological Risk Assessment is now common, as is evidenced by the over 100 guidance documents published in the last decade.¹⁴⁸ While initial risk assessors searched for commonalities in risk methodologies, recent guidance has stressed the importance of site-specific information.

Evaluating risk to ecological systems is far more complex than is human health risk assessment because of the complexities of ecosystems. Ecosystems include both the abiotic (soil, air, water) and biotic components, and the latter includes a wide range of species with different life spans (from minutes to hundreds of years), different life history strategies (some have few offspring, others lay millions of eggs), different life stages (e.g., egg, larvae, adult), and vastly different susceptibilities to stressors. It is for this reason that ecological risk assessment must be conducted with a particular objective in mind, with a particular range of species of concern. Moreover, where human health risk assessments lead to a probability of adverse harm, there is no comparable metric for ecological risk assessments.

The hazard identification phase of ecological risk assessment therefore requires input from public policy makers, risk managers and regulators, and the general public.^{1,149} All of these stakeholders must work in an iterative framework to provide the background, scope, and objectives for an ecological risk assessment. Most of the federal agencies involved in ecological risk assessment have acknowledged the importance of this initial phase and of including stakeholders. The inclusion of a range of managers, regulators, and interested and affected parties in the design and implementation of risk assessments has improved their usefulness.¹⁵⁰⁻¹⁵² Moreover, because of the complexities within ecosystems, the endpoints or measures of risk must be carefully defined and selected. This is not a trivial aspect, and a range of endpoints is often used. In human risk assessments one has to worry about only one species; in ecological assessments the structure and function of the system as well as the survival of component species are of concern.

Selecting the target endpoint is challenging. Is it a particular ecosystem function such as productivity, or the amount of energy or matter channeled through the system, or is it a size of a component population? One critical difference between human and ecological risk assessment is that, whereas the health and well-being of each individual human is important, for ecological systems (except for endangered species) it is the population viability that is of concern.

There is still a lack of dose-response and exposure data for plants and animals in most ecosystems. Most estimates of exposures come from measuring the levels of chemicals in various tissues. There are few monitors available for wild animals, and the cost would be prohibitive for obtaining either large sample sizes or data on many different species. Replicating ecosystems on a scale suitable for research has required aquarium-level (microcosm) and pond-level (mesocosm) models,^{64,153} the latter still restricted to a few research stations. Technological advances in the development of tools, such as chemical-specific hazard quotients for risk characterization,¹⁴⁸ species sensitivity distribution methods,¹⁵⁴ and GIS¹⁵⁵ have provided more quantification to the process.

A recent phase in ecological risk assessment is to focus on a large area scale, a so-called *landscape* approach.^{65,156,157} The problems that ecological systems face often can be examined only on a regional basis where the health and well-being of meta-populations can be assessed. In addition, researchers are trying to estimate the resiliency of ecosystems or the time required for them to recover from a disturbance or contamination.^{66,158} As with human health risk assessment, it is often challenging to determine whether a risk assessment has achieved its purpose since long-term studies are required to determine whether predictions have been borne out.

Most ecological risk assessments deal with only one chemical or a class of chemicals, such as the antifouling algacide irgarol¹⁵⁹ or metals,¹⁶⁰ yet organisms in nature are exposed to several stressors or chemicals of concern. Further, exposure usually occurs for several organisms at a time.¹⁶¹ Consideration of a wider range of chemicals, and a wide range of organisms has led to attempts to protect most organisms, most of the time. In some cases, screening risk assessments and probabilistic risk models are used.¹⁶²

Although human and ecological risk assessment often proceed independently for a given site, the selection of indicators that can be used to assess both human and ecological health has the greatest utility.^{163,164} This has led to development of methods to integrate a

framework for human health and the environment.¹⁴⁷ This allows for the integrated assessment of all exposed species, rather than concentrating on only humans, and is more apt to lead to sustained effort and future biomonitoring.

► NATURAL RESOURCE DAMAGE ASSESSMENT

Natural Resource Damage Assessment is a legal and regulatory strategy to monetize damage to natural resources, mainly from contamination. Penalties assessed can be used, and are often required to offset the specific damage by remediating contamination, rehabilitating damaged habitats, reintroducing organisms, or by offsets such as purchasing alternative habitat. The information required for NRDA is often the same as that used in a risk assessment,¹⁶⁵ although it is only damage, not risk, that can be penalized. Nonetheless, ecological risk assessment could play a major role in achieving sound NRDA decisions.

► CONSERVATION MEDICINE

Although the role of animals as hosts and vectors of human disease is a century old, conservation medicine employs a comprehensive approach to evaluating risks, prevention and control at the intersection of human, animal, and ecosystem health,¹⁶⁶ combining principles of epidemiology and epizootiology. Several examples are considered below; others include Hantavirus and avian influenza. Among animal epidemics, chytridiomycosis has gained prominence for causing or contributing to the worldwide population crashes among many species of frogs.¹⁶⁷

West Nile Virus

Many human viral diseases exist in wild animal reservoirs. The risk assessment process for West Nile Virus (WNV) must take into account the impact not only on humans, but on its avian hosts. Widespread declines of bird populations have been predicted, although the main victims thus far are members of the Corvidae family, crows and jays.¹⁶⁸ These species are especially vulnerable to WNV. Risk assessment should influence pest control policies (repellents, sprays, environmental controls), and which mosquito species to target.¹⁶⁹ Bird populations may be more vulnerable to widespread, ill-advised insecticide spraying than to the virus itself, while the efficacy of most spray programs has not been documented.

Organochlorines and Avian Reproduction

Organochlorines (OCs) are persistent chemicals in the environment and in animals and bioaccumulate in the food chain. OCs, particularly DDT, induce metabolic enzymes which normally metabolize steroids, including estrogen. This was the first endocrine disruptor identified. Birds that ate large fish or other birds, accumulated high levels in their tissues, and suffered reproductive failure, particularly noticeable in laying eggs with very thin shells (due to rapid transit through the oviduct) and increased embryo lethality. The most noticeable victims were Bald Eagles, Ospreys, Peregrine Falcons, and Brown Pelicans. The banning and restriction of OC use led to a decline in residues and improved reproduction;¹⁷⁰ however, continued persistence in local food chains still threatens these species in some areas.¹⁷¹ Other examples of secondary poisoning are numerous, and risk assessment for agrochemicals must include assessment of impact on nontarget organisms.

Diclofenac and Vulture Declines

Vultures are large birds that scavenge animal remains. They play important roles in community sanitation as well as in the “burial” rituals of certain religious communities in India. These large soaring birds have been conspicuous parts of the Asian skyline, but beginning in the mid-1990s, a precipitous decline in vulture populations, total disappearance in some places, was noted. Where once several dozen birds would be in view, none occurred. Investigations of infectious

and chemical agents, led to the discovery that an anti-inflammatory drug used in cattle was highly nephrotoxic to the vultures that eventually ate these cattle.¹⁷² Risk assessments for veterinary pharmaceuticals generally take into account human consumers, and the vultures demonstrate that there are additional receptors.

► RISK ASSESSMENT AND JUNK SCIENCE

The applications of risk assessment to policy making are widespread and contentious. Some stakeholders oppose risk assessment on ethical grounds, some because of lack of understanding, and some because of vested interests in outcomes. Critics of regulation have popularized the term “junk science” in an attempt to discredit the basis of many risk assessments. Although the criticisms may be targeted at the values and acceptable risk levels, rather than the data and analyses, the “junk science” rubric is intended to discredit the results and overemphasize the uncertainties, thereby dissuading policy makers from using risk results.¹⁷³ The tobacco industry, for example, misrepresented the scientific method in its oft-repeated claim “there is no proof that smoking causes cancer.” The accumulation of scientific studies to the contrary support the alternative statement “there is no doubt that smoking causes cancer.” Therefore, junk science works both ways. Those who misrepresent the nature of the scientific method to the courts, the media, and even the peer review process are engaged in junking science. Misunderstanding and misuse of hormesis is a long-standing and growing example of junk science.¹⁷⁴ Policy makers also have to be alert for shills, for example, scientists who reported findings developed for them by the tobacco industry.¹⁷⁵

► VENUES FOR RISK-RELATED RESEARCH

The University and the Corporation are the traditional bastions of research. Risk-related research has also been performed extensively within the regulatory agencies such as the Food and Drug Administration and the Environmental Protection Agency. Increasingly, however, risk-related research is being performed by nongovernmental agencies and by environmental consulting firms and much of this research enters the peer-reviewed literature. As university researchers find themselves increasingly constrained by limits imposed by institutional review boards, certain kinds of research may be relegated to nonacademic centers, where protection of human subjects may not receive the same priority. Since the essence of science is falsifiability and reproducibility, research that cannot be replicated because of ethical concerns or policies, for example the immersion of “volunteers” in a bath of hexavalent chromium, a known human carcinogen,¹⁷⁶ would be difficult to replicate, and is therefore of questionable value and should not be used for risk management. The issue is of what kinds of research data can be accepted as science transcends modern risk assessment.

► HARMONIZATION

The desirability and limitations of harmonizing methods for human and ecological risk assessment have been mentioned above. Harmonizing scientific, political, and judicial interpretations of risk information should be considered as well. Courts in different jurisdictions have interpreted risk differently, ranging from ignoring it, to requiring demonstration of a twofold excess relative risk in epidemiologic studies, although most individuals would consider even a 10% increase in a serious risk as unacceptable. Harmonizing radiological and chemical risk assessment is challenging, and for radiation the protection of organisms thus far depends on protection of humans despite evidence of ecosystem sensitivity to the contrary.¹⁷⁷ Finally, international harmonization, at least among North America, Europe, and Japan would be a valuable exercise. Currently, the precautionary approach is

viewed more favorably in Europe than in the United States, although the difference in impact may be slight. And even within Europe, countries differ in how they approach acceptable risk.¹¹⁹

► FUTURE PRIORITIES

Risk assessment continues to evolve on many fronts from the basic four-part paradigm to bioterrorism,¹⁷⁸ and new mathematical approaches are linked to expanding data sets. Although risk assessment is criticized as being both over- and underconservative,¹⁷⁹ involvement of stakeholders at all stages coupled with enhanced methods, should converge on greater acceptability. New metrics such as quality-adjusted life years¹⁸⁰ may enhance both the estimation and communication of risk. As with toxicology in general, risk assessment for mixtures is an essential development. Accounting for the duration-dose trade-off is beginning to attract more attention,¹⁸¹ both for research and application to standard-setting policy. The spatial analysis and depiction of risks is a rapidly growing field.^{182,183} Brownfields' redevelopment is one of the few urban health initiatives to retain high political visibility in the United States,¹⁸⁴ and enhanced use of risk approaches will facilitate wise and economic use of contaminated lands. Risk assessment has its detractors as well as exploiters.

Biomarkers

Michael D. McClean • Thomas F. Webster

Biological markers, or biomarkers, are indicators of events occurring in a biological system. While exposure refers to contact between a substance and the surface of the human body via inhalation, ingestion, or dermal contact, biomarkers provide information about the activity of a substance once it is absorbed. Whether the agent of interest is the original substance to which the individual was exposed or a metabolite, biological monitoring can provide useful information about exposure, early health effects, and susceptibility. Figure 22-1 presents a conceptual model for exposure-related disease.

Biological monitoring is typically conducted by analyzing biological materials such as blood, urine, hair, breath, milk, and saliva, whereas other options such as lung tissue, liver tissue, adipose tissue, and bone are considerably more invasive and rarely available. The usefulness of different materials strongly depends on the compound of interest.

► BIOMARKERS OF EXPOSURE

Biomarkers provide exposure measurements that are potentially more biologically relevant than personal exposure measurements. Personal exposure represents the total amount of a substance that is available for absorption, but only a portion of the total passes across the skin, gastrointestinal tract, and/or respiratory tract. *Internal dose* is the amount of a substance that has been absorbed and is, therefore, available to undergo metabolism, transport, storage, or elimination. Similarly, only a portion of the internal dose is eventually transported to the critical target site. *Biologically effective dose* represents the amount of a substance or metabolite that reaches the site of toxic action and could, therefore, result in an adverse effect.

One of the key advantages associated with using biomarkers to assess exposure is that measurements of internal dose and biologically effective dose integrate personal exposures over multiple exposure routes (inhalation, ingestion, and dermal contact). Additionally, exposures often vary widely over time such that repeated personal measurements (e.g., air samples) would be necessary to characterize average long-term exposure; however, a single biological measurement can often provide information about average long-term exposure, while also incorporating individual-specific differences in metabolism or other biological processes that may also affect dose.

A common example of a biomarker of internal dose is the measurement of alcohol in either exhaled breath or blood to determine the amount of alcohol an individual has consumed. Ethanol affects the central nervous system such that most individuals begin to show measurable signs of mental impairment at approximately 0.05% blood alcohol concentration, and motor function continues to deteriorate with increasing concentrations. Additionally, ethanol is volatile and transfers from blood to the alveolar air sacs such that ethanol is also detectable in exhaled breath in proportion to the concentration in blood. Accordingly, the measurement of ethanol in exhaled breath provides a useful and easily obtained measure of internal dose.

A common example of a biomarker of biologically effective dose is the analysis of DNA adducts (*addition products*) in peripheral blood samples. When certain substances such as polycyclic aromatic hydrocarbons (PAHs) are absorbed, hepatic metabolism leads to the formation of highly reactive epoxides. One specific example is the transformation of benzo[a]pyrene, classified as a probable human carcinogen, to benzo[a]pyrene-diol-epoxide which can then covalently bind to guanine in DNA. Following reaction with genetic material, DNA adducts can increase the risk of mutation and may thereby initiate the carcinogenic process. DNA adducts are typically measured in peripheral white blood cells as a surrogate measure for adduct burden in other (inaccessible) target tissues. DNA adducts are typically considered a biomarker of exposure since a metabolite of the substance to which exposure occurred is measured at the site of toxic action (i.e., DNA); however, animal studies have shown that carcinogenic potency correlates well with adduct burden such that DNA adducts are often used as a surrogate for cancer risk, and, therefore, more as a biomarker of effect.

Exposure assessment plays a critical role in environmental and occupational epidemiology. Traditional methods for assessing exposure, such as questionnaires and measurements of environmental media (air, water, food, etc.), are prone to error, particularly for retrospective studies. Random error in assessing exposure will, on average, reduce a study's ability to link exposure to disease and tend to bias results toward the null. Biomarkers, if properly utilized, can improve exposure assessment. Examples include studies of the relationships between aflatoxin and liver cancer, phthalates and reproductive effects, neurotoxicity and exposure to lead, methyl mercury and PCBs.¹⁻⁵

Biomarkers of exposure are not a panacea however. The best measure of exposure depends on both the compound and outcome of interest.⁶ Concentrations in serum or other readily available biological materials may not always provide good measures of levels in target tissues that are difficult or impossible to sample, for example, bone or brain. In addition, the timing of exposure is of key importance for both developmental effects, where in utero exposure is often of prime importance, and cancer, where relevant exposures may have taken place decades before diagnosis. Failure to take such considerations into account can cause otherwise careful biomarker studies to provide biased results.

Biomarkers of exposure have many uses besides etiologic research. Comparing internal doses with exposure estimates based on measurements in environmental media and questionnaires can help to identify important routes of exposure. Recent examples include studies of asphalt,⁷ phthalates,⁸ and polybrominated diphenyl ethers (PBDEs).⁹ When properly validated, biomarkers can be helpful in assessing risk of disease, for example, blood lead, serum cholesterol. Periodic cross-sectional studies of the population (*biomonitoring*) can supply information on exposure trends, telling us whether environmental policies are effective or providing warnings of potential

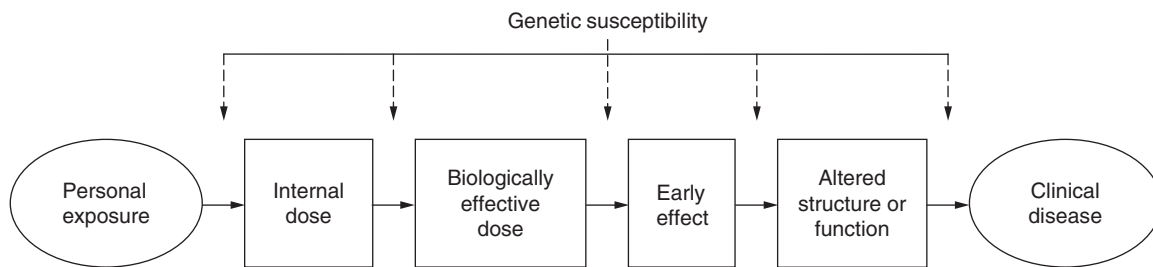

Figure 22-1. Conceptual model for exposure-related disease.

problems. For instance, the dramatic decline in blood lead concentrations over the last several decades is a notable achievement, while the continued presence of elevated levels in certain segments of the population shows where effort is still urgently needed. Using banked breast milk samples, PBDEs (brominated fire retardants commonly used in consumer products) were found to have increased exponentially in people over the last several decades.¹⁰ This discovery catalyzed both new research and a phaseout of certain uses. Comparing levels of compounds across different segments of the population—for example, age, sex, race/ethnicity, occupation, geography—can provide information about equity and exposure to potentially vulnerable populations. Despite its limitations, the U.S. National Health and Nutrition Examinations Survey (NHANES) is a notable example of biomonitoring.¹¹

► BIOMARKERS OF EFFECT

Biomarkers of exposure have had the most success in environmental and occupational epidemiology, but there is also considerable interest in other types of biomarkers. Reduced acetylcholinesterase activity is a classic biomarker of effect resulting from exposure to organophosphate pesticides. While DNA adducts are often considered markers of biologically effective dose, mutations in particular genes, a possible result of DNA adducts, can provide markers of early effects in the process leading to cancer. For example, a specific mutation in *p53*, an important tumor suppressor gene, has been found in liver cancer patients from areas with high aflatoxin exposure.¹ Sperm counts have been extensively used as markers in studies of male reproductive toxicants. Measurement of anogenital distance is a recent innovation in this field.¹² Imaging technology, particularly functional MRI scans of the brain, hold promise for neurotoxicology.¹³
