Cyanide (as free cyanide)	0.2	0.2	Nerve system or thyroid dysfunction	Discharge from steel/metal factories; discharge from plastic and fertilizer factories
Fluoride	4.0	4.0	Bone disease; in children may lead to mottled dentition	Water additive which promotes strong teeth; erosion of natural deposits; discharge from fertilizer and aluminum factories
Lead	zero	TT ^b ; action level=0.015	Infants and children: delays in physical or mental development including deficits in attention span and learning abilities Adults: kidney damage; high blood pressure	Corrosion of household plumbing systems; erosion of natural deposits
Mercury (inorganic)	0.002	0.002	Kidney damage	Erosion of natural deposits; discharge from refineries and factories; runoff from landfills and croplands
Nitrate (measured as nitrogen)	10	10	Infants below the age of 6 months drinking water containing nitrate in excess of the MCL could become seriously ill and, if untreated, exposure may lead to death. Symptoms include shortness of breath and blue-baby syndrome.	Runoff from fertilizer use; leaching from septic tanks, sewage; erosion of natural deposits
Nitrite (measured as nitrogen)	1	1	Infants below the age of 6 months who drink water containing nitrite in excess of the MCL could become seriously ill and, if untreated, exposure may lead to death. Symptoms include shortness of breath and blue-baby syndrome.	Runoff from fertilizer use; leaching from septic tanks, sewage; erosion of natural deposits
Selenium	0.05	0.05	Hair or fingernail loss; numbness in fingers or toes; circulatory disorders	Discharge from petroleum refineries; erosion of natural deposits; discharge from mines
Thallium	0.0005	0.002	Hair loss; blood; kidney, intestine, or liver disorders	Leaching from ore-processing sites; discharge from electronics, glass, and drug factories
■ Organic Chemicals				
Acrylamide	zero	TT ^b	Nervous system or blood disorders; increased risk of cancer	Added to water during sewage/wastewater treatment
Alachlor	zero	0.002	Eye, liver, kidney, or spleen disorders; anemia; increased risk of cancer	Runoff from herbicide used on row crops
Atrazine	0.003	0.003	Cardiovascular system or reproductive disorders	Runoff from herbicide used on row crops
Benzene	zero	0.005	Anemia; decrease in blood platelets; increased risk of cancer	Discharge from factories; leaching from gas storage tanks and landfills
Benzo(a)pyrene (PAHs)	zero	0.0002	Reproductive difficulties; increased risk of cancer	Leaching from linings of water storage tanks and distribution lines
Carbofuran	0.04	0.04	Disorders of blood, nervous, or reproductive system	Leaching of soil fumigant used on rice and alfalfa
Carbon tetrachloride	zero	0.005	Liver dysfunction; increased risk of cancer	Discharge from chemical plants and other industrial activities

Chlordane	zero	0.002	Liver or nervous system disorders; increased risk of cancer	Residue of banned termiticide
Chlorobenzene	0.1	0.1	Liver or kidney dysfunction	Discharge from chemical and agricultural chemical factories
2,4-D	0.07	0.07	Kidney, liver, or adrenal gland disorders	Runoff from herbicide used on row crops
Dalapon	0.2	0.2	Minor kidney changes	Runoff from herbicide used on rights of way
1,2-Dibromo-3-chloropropane (DBCP)	zero	0.0002	Reproductive difficulties; increased risk of cancer	Runoff/leaching from soil fumigant used on soybeans, cotton, pineapples, and orchards
<i>o</i> -Dichlorobenzene	0.6	0.6	Liver, kidney, or circulatory system disorders	Discharge from industrial chemical factories
<i>p</i> -Dichlorobenzene	0.075	0.075	Anemia; liver, kidney, or spleen damage; changes in blood function	Discharge from industrial chemical factories
1,2-Dichloroethane	zero	0.005	Increased risk of cancer	Discharge from industrial chemical factories
1,1-Dichloroethylene	0.007	0.007	Liver dysfunction	Discharge from industrial chemical factories
<i>cis</i> -1,2-Dichloroethylene	0.07	0.07	Liver dysfunction	Discharge from industrial chemical factories
<i>trans</i> -1,2-Dichloroethylene	0.1	0.1	Liver dysfunction	Discharge from industrial chemical factories
Dichloromethane	zero	0.005	Liver dysfunction; increased risk of cancer	Discharge from drug and chemical factories
1,2-Dichloropropane	zero	0.005	Increased risk of cancer	Discharge from industrial chemical factories
Di(2-ethylhexyl) adipate	0.4	0.4	Weight loss, liver dysfunction, or possible reproductive difficulties	Discharge from chemical factories
Di(2-ethylhexyl) phthalate	zero	0.006	Reproductive difficulties; liver dysfunction; increased risk of cancer	Discharge from rubber and chemical factories
Dinoseb	0.007	0.007	Reproductive difficulties	Runoff from herbicide used on soybeans and vegetables
Dioxin (2,3,7,8-TCDD)	zero	0.0000003	Reproductive difficulties; increased risk of cancer	Emissions from waste incineration and other combustion; discharge from chemical factories
Diquat	0.02	0.02	Cataract formation	Runoff from herbicide use
Endothall	0.1	0.1	Stomach and intestinal disorders	Runoff from herbicide use
Endrin	0.002	0.002	Liver dysfunction	Residue of banned insecticide
Epichlorohydrin	zero	TT ⁱ	Increased cancer risk, and over a long period of time, gastrointestinal disorders	Discharge from industrial chemical factories; an impurity of some water treatment chemicals
Ethylbenzene	0.7	0.7	Liver or kidney disorders	Discharge from petroleum refineries
Ethylene dibromide	zero	0.00005	Disorders of liver, stomach, reproductive system, or kidneys; increased risk of cancer	Discharge from petroleum refineries
Glyphosate	0.7	0.7	Kidney dysfunction; reproductive difficulties	Runoff from herbicide use
Heptachlor	zero	0.0004	Liver damage; increased risk of cancer	Residue of banned termiticide
Heptachlor epoxide	zero	0.0002	Liver damage; increased risk of cancer	Breakdown of heptachlor
Hexachlorobenzene	zero	0.001	Liver or kidney disorders; reproductive difficulties; increased risk of cancer	Discharge from metal refineries and agricultural chemical factories
Hexachlorocyclopentadiene	0.05	0.05	Kidney or stomach dysfunction	Discharge from chemical factories
Lindane	0.0002	0.0002	Liver or kidney disorders	Runoff/leaching from insecticide used on cattle, lumber, gardens
Methoxychlor	0.04	0.04	Reproductive difficulties	Runoff/leaching from insecticide used on fruits, vegetables, alfalfa, livestock
Oxamyl (Vydate)	0.2	0.2	Slight nervous system effects	Runoff/leaching from insecticide used on apples, potatoes, and tomatoes
Polychlorinated biphenyls (PCBs)	zero	0.0005	Skin changes; thymus gland disorders; immune system deficiencies; reproductive or nervous system difficulties; increased risk of cancer	Runoff from landfills; discharge of waste chemicals

(Continued)

TABLE 48-5. NATIONAL PRIMARY DRINKING WATER REGULATIONS AND MAXIMUM CONTAMINANT LEVELS (MCLs)^a (Continued)

Contaminant	MCLG ^b (mg/L) ^c	MCL or TT ^b (mg/L) ^c	Potential Health Effects from Ingestion of Water	Sources of Contaminant in Drinking Water
Pentachlorophenol	zero	0.001	Liver or kidney disorders; increased cancer risk	Discharge from wood-preserving factories
Picloram	0.5	0.5	Liver dysfunction	Herbicide runoff
Simazine	0.004	0.004	Blood disorders	Herbicide runoff
Styrene	0.1	0.1	Liver, kidney, or circulatory system disorders	Discharge from rubber and plastic factories; leaching from landfills
Tetrachloroethylene	zero	0.005	Liver dysfunction; increased risk of cancer	Discharge from factories and dry cleaners
Toluene	1	1	Nervous system, kidney, or liver disorders	Discharge from petroleum factories
Toxaphene	zero	0.003	Kidney, liver, or thyroid disorders; increased risk of cancer	Runoff/leaching from insecticide used on cotton and cattle
2,4,5-TP (Silvex)	0.05	0.05	Liver disorders	Residue of banned herbicide
1,2,4-Trichlorobenzene	0.07	0.07	Changes in adrenal glands	Discharge from textile finishing factories
1,1,1-Trichloroethane	0.2	0.2	Liver, nervous system, or circulatory disorders	Discharge from metal degreasing sites and other factories
1,1,2-Trichloroethane	0.003	0.005	Liver, kidney, or immune system dysfunction	Discharge from industrial chemical factories
Trichloroethylene	zero	0.005	Liver disorders; increased risk of cancer	Discharge from metal degreasing sites and other factories
Vinyl chloride	zero	0.002	Increased risk of cancer	Leaching from PVC pipes; discharge from plastic factories
Xylenes (total)	10	10	Nervous system damage	Discharge from petroleum factories; discharge from chemical factories
■ Radionuclides				
Alpha particles	none ^d — zero	15 picocuries per Liter (pCi/L)	Increased risk of cancer	Erosion of natural deposits of certain minerals that are radioactive and may emit a form of radiation known as alpha radiation
Beta particles and photon emitters	none ^d — zero	4 millirems per year	Increased risk of cancer	Decay of natural and man-made deposits of certain minerals that are radioactive and may emit forms of radiation known as photons and beta radiation
Radium 226 and Radium 228 (combined)	none ^d — zero	5 pCi/L	Increased risk of cancer	Erosion of natural deposits
Uranium	zero	30 ug/L as of 12/08/03	Increased risk of cancer, kidney toxicity	Erosion of natural deposits

Notes

^bDefinitions:

Maximum Contaminant Level (MCL)—The highest level of a contaminant that is allowed in drinking water. MCLs are set as close to MCLGs as feasible using the best available treatment technology and taking cost into consideration. MCLs are enforceable standards.

Maximum Contaminant Level Goal (MCLG)—The level of a contaminant in drinking water below which there is no known or expected risk to health. MCLGs allow for a margin of safety and are nonenforceable public health goals.

Maximum Residual Disinfectant Level (MRDL)—The highest level of a disinfectant allowed in drinking water. There is convincing evidence that addition of a disinfectant is necessary for control of microbial contaminants.

Maximum Residual Disinfectant Level Goal (MRDLG)—The level of a drinking water disinfectant below which there is no known or expected risk to health. MRDLGs do not reflect the benefits of the use of disinfectants to control microbial contaminants.

Treatment Technique—A required process intended to reduce the level of a contaminant in drinking water.

^cUnits are in milligrams per liter (mg/L) unless otherwise noted. Milligrams per liter are equivalent to parts per million.

^dEPA's surface water treatment rules require systems using surface water or groundwater under the direct influence of surface water to (a) disinfect their water, and (b) filter their water or meet criteria for avoiding filtration so that the following contaminants are controlled at the following levels:

- *Cryptosporidium*: (as of 1/1/02 for systems serving >10,000 and 1/14/05 for systems serving <10,000) 99% removal
- *Giardia lamblia*: 99.9% removal/inactivation
- Viruses: 99.99% removal/inactivation
- *Legionella*: No limit, but EPA believes that if Giardia and viruses are removed/inactivated, Legionella will also be controlled
- Turbidity: At no time can turbidity (cloudiness of water) go above 5 nephelometric turbidity units (NTU); systems that filter must ensure that the turbidity go no higher than 1 NTU (0.5 NTU for conventional or direct filtration) in at least 95% of the daily samples in any month. As of January 1, 2002, turbidity may never exceed 1 NTU, and must not exceed 0.3 NTU in 95% of daily samples in any month.
- HPC: No more than 500 bacterial colonies per milliliter.
- Long Term 1 Enhanced Surface Water Treatment (Effective Date: January 14, 2005); Surface water systems or (GWUDI) systems serving fewer than 10,000 people must comply with the applicable Long Term 1 Enhanced Surface Water Treatment Rule provisions (e.g., turbidity standards, individual filter monitoring, *Cryptosporidium* removal requirements, updated watershed control requirements for unfiltered systems).
- Filter Backwash Recycling: The Filter Backwash Recycling Rule requires systems that recycle to return specific recycle flows through all processes of the system's existing conventional or direct filtration system or at an alternate location approved by the state.

⁶More than 5.0% samples total coliform-positive in a month. (For water systems that collect fewer than 40 routine samples per month, no more than one sample can be total coliform-positive per month.) Every sample that has total coliform must be analyzed for either fecal coliforms or *E. coli* if two consecutive TC-positive samples, and one is also positive for *E. coli* fecal coliforms, system has an acute MCL violation.

⁷Fecal coliform and *E. coli* are bacteria whose presence indicates that the water may be contaminated with human or animal wastes. Disease-causing microbes (pathogens) in these wastes can cause diarrhea, cramps, nausea, headaches, or other symptoms. These pathogens may pose a special health risk for infants, young children, and people with severely compromised immune systems.

⁸Although there is no collective MCLG for this contaminant group, there are individual MCLGs for some of the individual contaminants:

- Trihalomethanes: bromodichloromethane (zero); bromoform (zero); dibromochloromethane (0.06 mg/L). Chloroform is regulated with this group but has no MCLG.
- Haloacetic acids: dichloroacetic acid (zero); trichloroacetic acid (0.3 mg/L). Monochloroacetic acid, bromoacetic acid, and dibromoacetic acid are regulated with this group but have no MCLGs.

⁹MCLGs were not established before the 1986 Amendments to the Safe Drinking Water Act. Therefore, there is no MCLG for this contaminant.

¹Lead and copper are regulated by a treatment technique that requires systems to control the corrosiveness of their water. If more than 10% of tap water samples exceed the action level, water systems must take additional steps.

For copper, the action level is 1.3 mg/L, and for lead is 0.015 mg/L.

²Each water system must certify, in writing, to the state (using third-party or manufacturer's certification), that when acrylamide and epichlorohydrin are used in drinking water systems, the combination (or product) of dose and monomer level does not exceed the levels specified, as follows:

- Acrylamide = 0.05% dosed at 1 mg/L (or equivalent)
- Epichlorohydrin = 0.01% dosed at 20 mg/L (or equivalent)

TABLE 48-6. NATIONAL SECONDARY DRINKING WATER REGULATIONS AND SECONDARY MAXIMUM CONTAMINANT LEVELS (SMCLs)*

Contaminant	Secondary MCL	Noticeable Effects above the Secondary MCL
Aluminum	0.05–0.2 mg/L [†]	Colored water
Chloride	250 mg/L	Salty taste
Color	15 color units	Visible tint
Copper	1.0 mg/L	Metallic taste; blue-green staining
Corrosivity	Noncorrosive	Metallic taste; corroded pipes and fixture staining
Fluoride	2.0 mg/L	Tooth discoloration
Foaming agents	0.5 mg/L	Frothy, cloudy; bitter taste; strong odor
Iron	0.3 mg/L	Rusty color; sediment; metallic taste; reddish or orange staining
Manganese	0.05 mg/L	Black to brown color; black staining; bitter metallic taste
Odor	3 TON (threshold odor number)	“Rotten-egg,” musty or chemical smell
pH	6.5–8.5	<i>low pH</i> : bitter metallic taste; corrosion <i>high pH</i> : slippery feel; soda taste; deposit formation
Silver	0.1 mg/L	Skin discoloration; graying of the white portion of eye
Sulfate	250 mg/L	Salty taste
Total Dissolved Solids (TDS)	500 mg/L	Hardness; deposits; colored water; staining; salty taste
Zinc	5 mg/L	Metallic taste

[†]mg/L is milligrams of substance per liter of water

Development of US Drinking Water Regulations

Regulations addressing the protection of drinking water and the public's health continue to be added in earnest to the original Safe Drinking Water Act of 1974 as illustrated in Table 48-4. In 1996, an important amendment to the SDWA required the EPA to develop a process for setting drinking water standards in the United States that includes determination of whether setting a standard is appropriate for a particular water contaminant, and if so, what that drinking water standard should entail. As part of the 1996 amendment to the SDWA, drinking water standard-setting procedures now incorporate inclusion of peer-reviewed science and support data to allow for an intensive technological evaluation of the contaminant under consideration. This standard-setting process includes evaluation of many factors such as (a) the occurrence of the contaminant in the environment; (b) the probability of human exposure and risks of adverse health effects in the general population and sensitive subpopulations; (c) the availability of analytical methods of detection; (d) the technical feasibility of the regulation; and (e) the impact of regulation on water systems, the economy, and public health.¹³

In order to set new drinking water standards not already regulated by the SDWA, the EPA must first make determinations about which water contaminants to regulate. This regulatory determination is a formal decision on whether to issue a national primary drinking water regulation for a specific water contaminant. The decision “to regulate” a water contaminant is based upon (a) the projected adverse health effects from the contaminant and the public health risk; (b) the extent of occurrence of the contaminant in drinking water and the likelihood that the water contaminant occurs in public water systems at levels of concern; and (c) a determination as to whether regulation of the contaminant would present a “meaningful opportunity” for reducing risks to human health.¹³ Water contaminants that meet these criteria for possible regulatory consideration were included in the *National Drinking Water Contaminant Candidate List (CCL)* that was originally published March 2, 1998. The CCL catalogs contaminants that (a) are not already regulated under SDWA; (b) may have adverse human health effects; (c) are known to or anticipated to occur in public water systems; and (d) may require regulations under the SDWA.

The Safe Drinking Water Act requires that the EPA periodically publish a National Drinking Water Contaminant Candidate List or CCL. The first CCL published in March of 1998 contained 60 water contaminants, and the second CCL was published in February of 2005 after the agency decided to continue research on the list of contaminants on the first CCL. The Drinking Water Contaminant Candidate List published in 2005 (the second CCL) includes the Microbial Contaminant Candidates and the Chemical Contaminant Candidates presented in Table 48-7. The second CCL includes 51 water contaminants of the original 60 unregulated contaminants from the first CCL published in 1998 including nine microbiological contaminants and 42 chemical contaminants or contaminant groups. In July 2003, the EPA announced its final determination for a subset of nine water contaminants from the first CCL and concluded that sufficient data and information was available to make the determination not to regulate *Acanthamoeba*, aldrin, dieldrin, hexachlorobutadiene, manganese, metribuzin, naphthalene, sodium, and sulfate. Therefore, these nine water contaminants were not included in the updated 2005 Contaminant Candidate List.¹³ A second cycle of preliminary regulatory determinations from the second CCL is underway and final regulatory determinations will be announced in August of 2006. It is important to note that future drinking water contaminant regulations are not limited to making regulatory determinations for only those contaminants on the CCLs. If information becomes available indicating that a specific water contaminant presents a public health risk, a decision to regulate a previously unregulated contaminant may occur in the interest of public health.¹³

Determination of New Drinking Water Standards

In order to propose and finalize a *new drinking water standard* or National Primary Drinking Water Regulation for a drinking water contaminant candidate on the CCL, the EPA follows a regulatory process that includes (a) conducting studies to develop analytical methods for detecting a new water contaminant; (b) determining whether the contaminant occurs in drinking water; (c) evaluating the treatment technologies necessary to remove the specific contaminant

TABLE 48-7. DRINKING WATER CONTAMINANT CANDIDATE LIST—FEBRUARY, 2005 (SECOND CCL)***■ Microbial Contaminant Candidates**

Adenoviruses
Aeromonas hydrophila
Caliciviruses
Coxsackieviruses
Cyanobacteria (blue-green algae), other freshwater algae, and their toxins
Echoviruses
Helicobacter pylori
Microsporidia (Enterocytozoon and Septata)
Mycobacterium avium intracellulare (MAC)

■ Chemical Contaminant Candidates

1,1,2,2-tetrachloroethane	DDE
1,2,4-trimethylbenzene	Diazinon
1,1-dichloroethane	Disulfoton
1,1-dichloropropene	Diuron
1,2-diphenylhydrazine	EPTC (s-ethyl-dipropylthiocarbamate)
1,3-dichloropropane	Fonofos
1,3-dichloropropene	p-Isopropyltoluene (p-cymene)
2,4,6-trichlorophenol	Linuron
2,2-dichloropropane	Methyl bromide
2,4-dichlorophenol	Methyl-t-butyl ether (MTBE)
2,4-dinitrophenol	Metolachlor
2,4-dinitrotoluene	Molinate
2,6-dinitrotoluene	Nitrobenzene
2-methyl-Phenol (o-cresol)	Organotins
Acetochlor	Perchlorate
Alachlor ESA and other acetanilide pesticide degradation products	Prometon
Aluminum	RDX
Boron	Terbacil
Bromobenzene	Terbufos
DCPA mono-acid degradate	Triazines and degradation products of triazines
DCPA di-acid degradate	Vanadium

*Provided courtesy of the Environmental Protection Agency and accessible at <http://www.epa.gov/safewater/mcl.html>.

from drinking water; and (d) investigating the potential health effects resulting from exposure to the specific water contaminant. This regulatory process allows the federal agency to determine if a new drinking water regulation or primary standard needs to be developed for a water contaminant on the CCL, whether a drinking water guidance or health advisory should be released, or if no action is necessary at all for the water contaminant under regulatory consideration.¹³

Drinking water contaminant candidates on the 2005 CCL presented in Table 48-7 have been divided into priorities for future regulation based upon their occurrence in drinking water, as determined by the National Contaminant Occurrence Database, and their potential human health effects. Beginning in August 1999, a National Contaminant Occurrence Database (NCO) was developed that stores data on regulated and unregulated microbial, chemical, radiological, and physical contaminants as well as other types of contaminants that are likely to be present in finished, raw, and source waters of public water systems in the United States and its territories. In addition, the SDWA mandated that the National Academy of Sciences (National Research Council) conduct studies on the potential health effects associated with contaminants found in drinking water. A series of nine reports has been published under the title *Drinking Water and Health* with the first edition published in 1977.¹⁴ The original report is comprised of a 939-page compendium of the myriad health effects associated

with exposure to microbial, radiological, particulate, inorganic, and organic chemical contaminants present in drinking water including risk assessments for development of human cancer resulting from exposure to chemical contaminants in drinking water. The subsequent publications through 1989 have compiled data on (a) the risks associated with chlorination and disinfection by-products in drinking water; (b) the toxicological profiles of drinking water contaminants; (c) the epidemiological trends, risk assessments, and pharmacokinetics of several drinking water contaminants; and (d) suggested no-adverse-response levels (SNARLs) for acute and chronic exposures to selected chemical contaminants in drinking water.

As part of the process of proposing and finalizing a National Primary Drinking Water Regulation or primary drinking water standard for a specific water contaminant on the Drinking Water Contaminant Candidate List or CCL, the EPA reviews available health-effects studies and drinking water occurrence data. The EPA then sets a *Maximum Contaminant Level Goal (MCLG)* for the water contaminant under regulatory consideration which is defined as the maximum level of a contaminant in drinking water at which no known or anticipated adverse health effects occur and which allows for an adequate margin of safety.¹³ MCLGs are nonenforceable public health goals, and since MCLGs consider only public health risk and not the limits of detection and water treatment technology, they may be set at a level that many water utility systems cannot meet in the United States. It is very important to note that MCLGs consider the health-effects risk from water-borne exposure to contaminants by *sensitive subpopulations including infants, children, geriatric populations, and those with compromised immune systems*. The MCLG for each type of water contaminant is determined as follows:

- **Noncarcinogenic Chemical Contaminants:** For chemical compounds that may lead to adverse noncancerous health effects, the MCLG is based on the reference dose (RFD), which is an estimate of the amount of a chemical that a human may be exposed to on a daily basis that is not anticipated to cause adverse health effects over a lifetime. As part of this RFD calculation, sensitive subpopulations are included and the level of uncertainty may span an order of magnitude. The RFD is multiplied by a typical adult body weight (70 kg) and divided by daily water consumption (estimated at 2 liters) to provide a Drinking Water Equivalent Level (DWEL). The DWEL is multiplied by a percentage of the total daily exposure to the chemical compound contributed by exposure to drinking water (often 20%), and this calculation provides the final determination of the MCLG for the noncarcinogen chemical under consideration.¹³
- **Carcinogenic Chemical Contaminants:** If there is credible evidence that a chemical compound may cause cancer and there is no dose below which the chemical agent is considered safe, the MCLG for the chemical compound is set at zero by the EPA. If the chemical compound is carcinogenic but a safe dose can be determined, the MCLG is set at a level above zero that is considered to be safe.¹³
- **Microbial Contaminants:** For water-borne microbial contaminants that may present public health hazards, the MCLG is set at zero since in many cases ingesting one protozoa, virus, or bacterium may cause adverse health effects, particularly in sensitive populations most at risk for morbidity and mortality from water-borne exposure. The EPA continues to conduct health effects studies to determine whether there is a safe level above zero for specific water-borne microbial contaminants. To date, this “safe level above zero” has not been established.¹³

Once an MCLG is determined for a specific water-borne contaminant, the EPA may establish an enforceable primary drinking water standard, which in most cases is set as a *MCL*, defined as the maximum permissible level of a contaminant in water which is delivered

to any user of a public water system.¹³ The MCL is established as close to the MCLG as feasible as directed by the Safe Drinking Water Act, which delineates the following conditions: (a) the level that may be achieved with the use of the best available technology (BAT), treatment techniques, and other means which EPA finds are acceptable after examination for efficiency under field conditions and not solely under laboratory conditions, and (b) the level that may be achieved taking the cost of treatment into consideration. If there is no reliable method that is economically and technically feasible to measure a water contaminant at particularly low concentrations, a *treatment technique (TT)* is established rather than an MCL. A treatment technique is defined as an enforceable procedure or level of technological performance which public water systems must follow to ensure control of a specific water contaminant. Two current examples of treatment technique rules include the Surface Water Treatment Rule that addresses disinfection and filtration and the Lead and Copper Rule that optimizes corrosion control.¹³

After establishing either an MCL or TT for a specific water-borne contaminant, the EPA must complete an economic cost-benefit analysis to determine whether the benefits of any proposed primary drinking water standard under consideration justify the cost of treatment based upon affordable technology for large public water systems. Considering this economic evaluation, the EPA may adjust the MCL for a particular class or group of public water systems to a level that “maximizes health risk reduction benefits at a cost that is justified by the benefits.”¹³ Each state in the United States has been authorized to grant *variances* for new drinking water standards to small water systems serving up to 3300 people, if the system cannot afford to comply with a new drinking water regulation and the small system installs EPA-approved variance technology. States can also grant variances to public water systems serving 3301–10,000 residents but only with EPA approval. However, the SDWA does not allow small water systems to be granted variances for microbial contaminants in drinking water.

It is imperative that small public water systems receive special consideration from the EPA since more than 90% of all public water systems in the United States are categorized as small and these small systems face the greatest challenges in providing potable water at affordable rates for their U.S. residents. Therefore, the 1996 Amendments to the SDWA provided states with affordable options that are appropriate for small public water systems so that they may comply with primary drinking water standards. As part of this special consideration, the EPA must identify treatment technologies that achieve primary drinking water standard compliance and that are affordable for public water systems serving fewer than 10,000 people when setting new primary drinking water standards. These special considerations may include packaged or modular systems and point-of-entry/point-of-use treatment devices under the control of the small public water system as part of a state variance. When such alternative technologies cannot be developed and implemented, the EPA must identify affordable technologies that maximize water contaminant reduction and protect the public’s health.¹³

In addition, under certain circumstances, *exemptions* from drinking water standards may be granted to allow additional time to develop alternative compliance options or establish financial support. However, after the exemption period expires, the public drinking water system must be in compliance with the primary drinking water standard. Most importantly, the terms of any state variance or exemption to a primary drinking water standard must guarantee no unreasonable risk to the public health. Primary drinking water standards go into effect 3 years after they are finalized by the EPA. If capital improvements are required by the public water system in order to comply with the new drinking water standard, the EPA’s administrator or the local state may allow this 3-year implementation period to be extended up to 2 additional years.¹³

Every 5 years, the EPA repeats the cycle of revising the Drinking Water Contaminant Candidate List or CCL by making regulatory determinations for five water contaminants and identifying up to 30 contaminants for unregulated monitoring. Every 6 years, the EPA

also reevaluates existing primary drinking water regulations to determine if modifications are necessary as well.¹³ The U.S. regulatory process and primary drinking water standard-setting process aims to ensure the safety and quality of water for all U.S. residents and can be expected to be in continuous state of change for the foreseeable future.

► TYPES OF WATER CONTAMINATION

Although the United States has one of the safest water supplies in the world, those responsible for the continued safety of our nation’s water are faced with constant and newly emerging environmental challenges to water quality. Multiple reservoirs of infection, modes of transmission, and sources of contamination from microbial, chemical, and radiologic water-borne agents present continuous challenges to protecting the public from water-related disease resulting from exposure to contaminated waters.¹ The Centers for Disease Control and Prevention, in addition to other organizations responsible for water quality and safety in the United States, has focused their efforts on four critical areas of water contamination that are of public health significance and warrant water protection measures.¹

- **Drinking Water Contamination:** Water-related disease associated with exposure to drinking water may result from microbial, chemical, or radiologic contamination of drinking water supplies. Microbial contamination of drinking water frequently results from animal or human sewage contamination of source water that has not been adequately treated by available disinfection or filtration procedures. In addition, other challenges to water safety from microbial contamination include infectious pathogens such as *Cryptosporidium parvum* that are resistant to routine water treatment technologies. Chemical contamination of drinking water may result from multiple sources ranging from agricultural run-off to leakage from underground storage tanks to industrial discharges and chemical spills. Chemical contamination of drinking water may be generated from naturally occurring phenomenon (i.e., arsenic, lead, and copper erosion of natural deposits) or from human activities (i.e., nitrate contamination from fertilizer use or discharge of chemical solvents from industrial processes). Radiologic contamination of drinking water may also present a public health problem arising from naturally occurring or man-made contamination from various industrial and power-generating processes.¹
- **Recreational Water Pollution:** According to a report from the Environmental Protection Agency, as many as 40% of U.S. beaches, rivers, estuaries, and lakes may be polluted with microbial or chemical contaminants.¹⁵ Exposure to contaminated water has resulted in recreational water outbreaks as a result of exposure to water-borne contaminants in such venues as swimming and wading pools, lakes and ponds, rivers and canals, decorative fountains, hot tubs, and springs over the past several decades. Recreational water exposure to infectious pathogens such as *E. coli* O157:H7, *Cryptosporidium parvum*, and *Naegleria fowleri* have the potential to cause serious morbidity and mortality particularly in susceptible populations such as children.¹
- **“Special Uses” Water Contamination:** Water used for special purposes other than drinking and recreational activities may also become contaminated and pose a public health threat and act as a potential source of contamination. The use of water is essential to medicine, agriculture, aquaculture, and commercial food and bottled water production in the United States. Unfortunately, water-borne pathogens may thrive on biofilms in dental and medical devices (such as catheters and dialysis machines) and grow on piping in air-conditioning systems and cooling towers (e.g., *Legionella pneumophila*). Agricultural wastewater may become contaminated with both microbial

and chemical contaminants including infectious zoonotic pathogens, pesticides and herbicides, and nitrates from fertilizer use. In addition, animal hormones and pharmaceuticals used in agriculture may retain their biological activity when ingested by humans exposed to agricultural wastewater. Ingestion of fish and seafood found in waters contaminated with high concentrations of enteric bacteria, parasites, and viruses, marine toxins, and chemical contaminants such as mercury may also cause adverse health effects particularly in susceptible populations such as pregnant women and developing fetuses.¹

- **Intentional Water Contamination:** Another area of public health concern and focus of water protection countermeasures in the United States is the possibility of intentional acts of water terrorism.^{1,16} This possible water contamination scenario could potentially involve a community-wide water-borne disease outbreak or a cluster of water-related cases from chemical or radiologic toxicity in the general population or in sensitive subgroups most at risk for disease and death. Therefore, the possibility of water contamination from a covert or overt terrorist event remains a public health threat in the United States that could result in water-related disease resulting from biological, chemical, or radiological agents.^{1,16}

Microbial Contaminants in Water

Acute microbial infection was the primary cause of death in one in five Americans in the early 1900s with a significant percentage of this morbidity and mortality resulting from unchecked exposure to water-borne cholera and typhoid.^{17,18} During the past century, protection efforts by water utilities and public health agencies have played a major role in preventing microbial pollution of potable water supplies in the United States.¹ By the early 1980s in America, most water utility practitioners and public health specialists were relatively comfortable controlling microbial contamination with existing water quality monitoring standards and conventional treatment methodologies.^{18–20} However, the decade of the 1990s has been characterized as “the decade of the microbe” with the emergence and reemergence of infectious pathogens as a serious challenge to both food and water safety.^{19,21,22}

This “new” microbial era presents many formidable tasks to those responsible for water safety as well as the medical community that may be unaware or unfamiliar with the growing list of potential water-borne pathogens to consider when evaluating patients, particularly vulnerable populations most susceptible to water-borne disease.²³ One very difficult aspect of protecting potable water and preventing water-related disease resulting from microbial contaminant exposure is the fact that water-borne pathogen disease trends are constantly changing and evolving as public health threats. The list of emerging and reemerging infectious diseases resulting from exposure to water-borne pathogens has grown exponentially during the past decade.^{24,25} The potential threat of bioterrorist assault on water reserves adds other water-borne pathogens to this growing list.^{18,26,27} Currently, the water-borne microbial agents of public health and clinical significance in the United States may be divided into three categories: (a) *bacterial pathogens*, (b) *protozoan parasites*, and (c) *enteric viruses*.¹ The primary infectious pathogens that have either been identified as transmissible through contaminated water or have been increasingly suspected of water-borne transmission based upon growing epidemiologic evidence are presented in Table 48-8.^{1,20,24,28,29,30}

Chemical Contaminants in Water

Historically in the United States, the primary concern of those responsible for providing safe drinking water has been protection from microbial contamination, and when microbial contamination of drinking water occurs, there is no question that public health is threatened.^{1,31} Preventing microbial contamination of drinking water supplies is still a primary focus for those local, state, and federal authorities responsible for supplying potable water to U.S. residents. However, during the past two decades, the chemical contamination of drinking water and chemical pollution of watersheds and water reserves has become a growing problem for public health specialists and water utility practitioners. In addition, the presence of chemical contaminants in drinking water has become a widely recognized concern of the public.³² Chemical terrorism with specific attacks on our national infrastructure, including drinking water resources, presents another possible public health threat.¹⁶

TABLE 48-8. SELECTED WATER-BORNE PATHOGENS OF PUBLIC HEALTH SIGNIFICANCE^{a†}

<i>Bacterial Pathogens</i>	<i>Protozoan Parasites</i>	<i>Enteric Viruses</i>
Campylobacter sp.	Entamoeba histolytica	Hepatitis A and E
Pathogenic Escherichia coli	Giardia lamblia	Norwalk and Norwalk-like
Diarrheagenic Escherichia coli	Cryptosporidium parvum	Rotavirus
Salmonella sp.	Acanthamoeba sp.	Adenoviruses
Shigella sp.	Naegleria fowleri	
Vibrio cholerae	Balantidium coli	
Yersinia enterocolitica	Microsporidia sp.	
Legionella sp.	Cyclospora cayetanensis	
Mycobacterium avium	Toxoplasma gondii	
Leptospira sp.		
Helicobacter pylori		

^aThe selected pathogens included in this table have either been identified as transmissible through contaminated water or have been increasingly suspected of water-borne transmission based upon growing epidemiologic evidence. [†]Modified from *Recognizing Waterborne Disease and the Health Effects of Water Pollution: Physician On-line Reference Guide* accessible at ww.WaterHealthConnection.org. (Last JM. *Public Health and Human Ecology*. Stamford, CT: Appleton and Lange; 1998.)

Primary drinking water standards with maximum contaminant level goals (MCLGs) and maximum contaminant levels (MCLs) have been established in the United States for 80 *chemical and radiologic agents* as of 2005 as detailed in Table 48-5 and include regulatory standards for inorganic and organic contaminants, disinfectants and disinfection by-products, and radionuclides. The potential health effects from ingestion of these drinking water contaminants as determined by the Environmental Protection Agency and the primary sources of these contaminants in U.S. drinking waters is also presented in Table 48-5 for review.

Unfortunately from an ecological point of view, water and water sediments are the final repositories or “sinks” for thousands of pounds of industrial and agricultural chemicals in the United States that are used by our modern society. An estimated 70,000 chemicals are in commercial use in the United States with approximately 700 new chemical agents synthesized each year.^{1,33} Each chemical agent may represent a “potential contaminant or parents of daughter contaminants born of reactions of these compounds with other compounds in the aquatic environment.”^{1,34} Of the 70,000 industrial and agricultural chemical agents in use in the United States, approximately 500 compounds have been evaluated for carcinogenic potential with the vast majority never being subjected to thorough toxicity testing for human health effects.^{1,33} Regulatory agencies and water quality specialists are often faced with determining the significance and fate of these chemical compounds in the aquatic environment only after these compounds have been developed and are in use.^{1,34} Water utility practitioners are often tasked with removing these chemical agents from water resources while hundreds more new chemical compounds are being synthesized each year.

For example, more than 1000 specific synthetic organic chemicals (SOCs) at the nanogram to microgram per liter concentration have been identified in drinking water supplies in the United States. These compounds result from industrial and municipal discharges, urban road runoff, and reaction of chlorine in water treatment with natural organics. Most of the synthetic organic chemicals identified in drinking water have not been evaluated for potential human health effects, and the National Research Council indicates that only about 10% of the organic chemicals in water have even been identified.¹⁴ If potential human health effects have been established for specific chemical contaminants, these health effect profiles have generally been based on animal studies conducted on individual chemical contaminants. Therefore, there is uncertainty as to the actual risk posed to humans who may be ingesting very low concentrations of combinations of chemical contaminants over an extended period of time during their lifetime. Such rare types of epidemiological investigation assessing the synergistic effects of multiple chemical agent exposure in drinking water have been far from definitive and require ongoing and continuous reassessment of the risk.

MCLs are generally not available for thousands of chemical agents that might be in the public water supply since the scientific studies needed to determine their health effects are simply not available. Also, the analytic burden for assessing the presence and the concentration of all water-borne chemicals would be inordinately great since assessing the presence and concentration of these chemical compounds requires experienced analysis and sophisticated instrumentation. Most large water supply laboratories are equipped with atomic absorption spectrophotometers that will identify heavy metals in water; however, gas chromatograph-mass spectrometers are required for determination of synthetic organics in water but are many times more costly and far fewer laboratories are equipped for these types of determinations. What can be stated with certainty is that the situation with regard to acceptable levels of chemical contaminants in drinking water is constantly changing and will undergo continuous reassessment.

Radiologic Contaminants in Water

Radiologic contamination of public water supplies may be naturally occurring or result from man-made activity. The radiologic agents of importance that are regulated in drinking water are presented in

Table 48-5 and include alpha particles, beta particles and photon emitters, Radium 226 and Radium 228, and Uranium.¹³ Radium 226 is among the more important of the naturally occurring radionuclides and is found in groundwater as a result of geological conditions such as erosion of natural deposits. On the other hand, man-made radiologic contamination of water generally affects surface waters as a result of fallout from weapons testing and releases from nuclear power plants and users of radioactive materials.³⁵

The establishment of limits for radioactivity in water suffers from the same uncertainties as those inherent in establishment of limits for many chemical contaminants of water; that is, the assumptions that there is no threshold below which any dose is considered to be harmless and that the human health effects are proportional to the dose. In addition, when establishing limits, the cost of achieving certain levels of radioactivity in a water supply must be weighed against the expected risks and benefits in reduced radiation exposures to the resident population served by the water supply.¹³ Naturally occurring radium contamination in drinking water is often of greater concern than man-made radioactive contamination, particularly since naturally occurring radiologic contamination disproportionately affects small water supplies that draw from groundwaters. For example, radium concentrations as high as 50 pC/L have been reported and some 500 community water supply systems in the United States deliver water that exceeds this standard. If other sources of water cannot be found, the radium can be removed by ion exchange, although this increases the concentration of sodium and may be of concern to that portion of the population requiring low-sodium diets. Radon, a daughter product of radium, is a naturally occurring radionuclide in groundwater, and surveys indicate that approximately 70% of groundwater supplies in the United States have detectable radon. Accordingly, while radon is not likely to pose a problem for larger community supplies, it may be a problem for individual or very small supplies.

▶ WATER-BORNE DISEASE TRENDS AND SURVEILLANCE

One of the most critical outcomes of appropriate water quality management and conscientious source water protection is the prevention of water-borne diseases and the effects of water pollution on the health of the U.S. population. Monitoring water-borne disease trends resulting from exposure to biological, chemical, or radiologic contaminants in both drinking water and recreational waters provides valuable surveillance data that (a) reveals deficiencies in water quality management, (b) exposes penetration of the “multiple barrier” protection approach to ensuring safe drinking water, and (c) provides credible information for improving water quality regulations at the local, state, and federal levels.

Previously in the United States, during the period of 1920 to 1970, monitoring data regarding water-borne disease outbreaks (WBDOs) was collected by various researchers and different federal agencies.³⁶ However, since 1971, the Centers for Disease Control and Prevention (CDC), in coordination with the Environmental Protection Agency and the Council of State and Territorial Epidemiologists, has maintained a collaborative nationwide surveillance system that tracks the occurrences and causes of WBDOs associated with U.S. drinking water.³⁷ In 1978, characterization and tabulation of water-borne disease outbreaks associated with recreational water exposure was added to this national surveillance system.³⁸ The U.S. water-borne disease surveillance system incorporates surveillance data from each state, territory, and locality regarding water-borne disease outbreaks resulting from both microbial and chemical contaminant exposure associated with drinking water, recreational water, and other types of water exposures.^{37,38} This important historical surveillance database is used by federal agencies including the CDC and EPA to (a) identify the types of water systems, the underlying deficiencies of water systems, and the etiologic agents associated with outbreaks from drinking water; (b) identify the etiologic agents, types of aquatic venues, water-treatment systems, and the deficiencies associated with recreational water-borne disease outbreaks; (c) to evaluate and

reassess the adequacy of treatment technologies and prevention strategies for providing safe drinking water and recreational waters; and (d) establish national research priorities based upon water-related outbreak trends that may provide the basis for improved water-quality regulations in the future.^{37,38} These drinking water and recreational water surveillance activities are also utilized to (a) characterize the epidemiology of WBDOs, (b) identify changing trends in the etiologic agents that cause WBDOs in the United States, (c) determine why the outbreaks occurred in a specific water venue or community, and (d) prevent water-borne disease transmission. The results of these surveillance activities are currently reported in the *MMWR Surveillance Summaries* published by the CDC with one summary dedicated to drinking water-associated outbreaks and a second summary dedicated to recreational water-associated outbreaks.^{37,38}

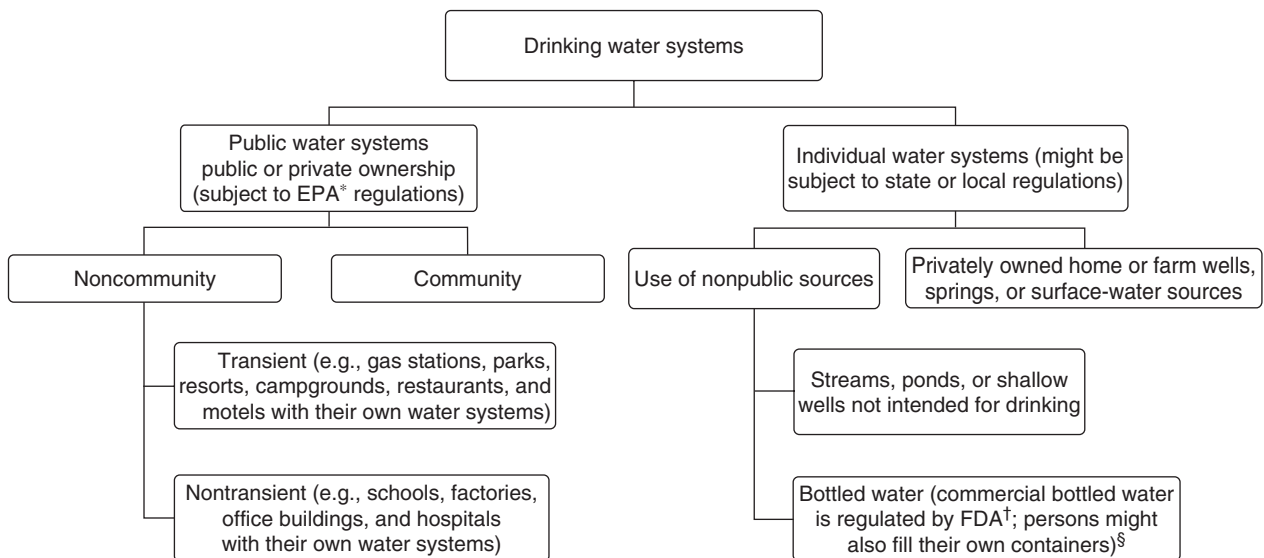

It is important to note that the surveillance data reported in these surveillance summaries represent only a portion of the burden of human disease associated with drinking water and recreational water exposure since endemic water-borne disease risks are not included and reliable estimates for the number of unrecognized WBDOs are not available, potentially leading to underreporting of outbreaks and cases of water-related disease.^{37,38} In addition, other confounders may lead to underreporting of water-borne disease cases and outbreaks, including but not limited to: (a) not all water-related outbreaks are detected, investigated, and subsequently reported to CDC or EPA; (b) inadequate diagnosis and underreporting of cases of water-borne disease by medical practitioners often confound water-borne disease surveillance programs and chemical exposure registries; (c) the sensitivity of this surveillance system has not been assessed; (d) water-borne outbreaks occurring in national parks, tribal lands, and military bases may not always be reported to state or local authorities; (e) availability of laboratory testing, requirements for reporting diseases, and the financial resources available to local health departments for surveillance and investigation of probable outbreaks may restrict reporting; and (f) this surveillance system is passive and the accuracy of the data depends solely on the conscientious reporting of the agencies involved (i.e., state, local, and territorial health departments).^{1,37,38} For these reasons, the true incidence and prevalence of water-borne disease outbreaks in the United States resulting from microbial, chemical, or radiological contamination of drinking and recreational water is probably greater

than is reflected in these U.S. national surveillance systems.^{1,37,38} Even with these restrictions, it is extremely valuable to review the state of water-borne disease associated with exposure to drinking water and recreational waters contaminated with microbial, chemical, or radiologic agents as a “window” to the effectiveness of water quality management in the United States. A brief review of the most recent water-borne disease outbreak surveillance data reported by the CDC and EPA for drinking water and recreational water is summarized below.

Water-Borne Disease Trends Associated with Drinking Water

The most recent *MMWR Surveillance Summary* detailing water-borne disease outbreaks associated with drinking water was published in 2004 and summarizes data collected from the reporting period of 2001–2002.³⁷ In order to understand the surveillance data included in this surveillance summary of outbreaks associated with drinking water, the following definitions are important to note and understand. According to the CDC and EPA, two criteria must be met in order for an event to be defined as a drinking water-associated disease outbreak. First, more than two individuals must have experienced similar symptoms after exposure to the contaminated drinking water; that is, an outbreak is not an individual case of a specific water-borne disease. However, this first criterion is waived for a single case of laboratory-confirmed primary amebic meningoencephalitis (PAM) or for a single case of water-borne chemical poisoning if associated water-quality data indicates contamination by the chemical compound in question.³⁷ The second criterion developed by the CDC and EPA states that epidemiologic evidence must implicate drinking water as the probable source of the water-related illness or disease. It is important to note the following: (a) reported outbreaks caused by contaminated water or ice at a point of use such as contaminated water faucets or serving containers are not classified as drinking water-associated outbreaks, and (b) WBDOs associated with cruise ships are not reported in the CDC/EPA surveillance summaries.³⁷

Water-borne disease outbreaks are reported by the CDC and EPA according to *different types* of drinking water systems; this classification scheme is summarized in Fig. 48-2. Public water systems are classified as either *community* or *noncommunity* systems and are

* Environmental protection agency.

† Food and drug administration.

§ In certain instances, bottled water is used in lieu of a community supply or by noncommunity systems.

Figure 48-2. Classification of water systems used for reporting water-borne disease outbreaks by the CDC and EPA. (Courtesy of the Centers for Disease Control and Prevention. Adapted from Blackburn B, Craun GF, Yoder JS, et al. *Surveillance for waterborne-disease outbreaks associated with drinking water—United States, 2001–2002*. In *Surveillance Summaries*, October 22, 2004. MMWR. 2004;53(No. SS-8):23–45.)

regulated under SDWA. Of the approximately 161,000 public water systems in the United States, 33% are community systems and 67% are noncommunity systems that include 88,000 transient systems and 20,000 nontransient systems (refer to Fig. 48-2 for details).^{37,39} Despite representing the minority of water systems in number, community water systems serve 273 million U.S. residents or more than 93% of the U.S. population.³⁹ In addition, although 91% of public water systems are supplied by groundwater, more Americans (66.2%) have their drinking water supplied by public systems served by surface water. Finally, approximately 17 million U.S. residents, or only 6.0%, rely upon private, individual water systems.³⁹ Drinking water-associated outbreaks involving water not intended for drinking, such as lakes, springs, and creeks used by campers, are also classified as individual systems as are sources such as bottled water.³⁷ Each drinking water system evaluated for a water-borne disease outbreak is also classified by the underlying deficiency that caused the water-borne outbreak and includes (a) untreated surface water; (b) untreated groundwater; (c) treatment deficiencies such as temporary interruption of disinfection, chronically inadequate disinfection, or inadequate or no filtration; (d) distribution system deficiencies such as cross-connection contamination, contamination of water mains during construction or repair, or contamination of a water storage facility; and (e) unknown or miscellaneous deficiency including contaminated bottled water or a water source not intended for drinking such as irrigation water.³⁷

Water-borne disease outbreaks associated with drinking water categorized by year and etiologic agent are presented in Fig. 48-3 spanning the reporting period of 1971–2002.³⁷ The number of water-borne disease outbreaks associated with drinking water by year and type of water system affected is presented in Fig. 48-4 for the period of 1971–2002.³⁷ Both figures illustrate a significant improvement in the number of reported water-borne disease outbreaks associated with drinking water in the United States since early reporting in 1971. Drinking water-associated outbreaks classified by etiologic agent, type of water system, water source, and underlying system deficiency from the most recent reporting periods of 2001–2002 are presented in Fig. 48-5. During this most recent reporting period, a total of 31 outbreaks

associated with drinking water were reported in 19 states causing illness in an estimated 1020 persons resulting in 51 hospitalizations and seven deaths.³⁷ Of these 31 water-borne disease outbreaks, 61.3% resulted from a known infectious water-borne pathogen, 16.1% were attributed to water-borne chemical poisoning, and 22.6% resulted from an unknown etiology (Fig. 48-5).³⁷ In the water-borne disease outbreaks of known infectious etiology, 19.4% were caused by *Legionella* species, 16.1% were caused by water-borne viruses, 16.1% arose from water-borne parasites, and 9.7% resulted from water-borne exposure by bacteria other than *Legionella* species.³⁷

During the 2001–2002 reporting period for drinking water-associated water-borne disease surveillance, six drinking water-associated disease outbreaks were attributed to *Legionella* sp. that caused illness in 80 exposed individuals and resulted in 41 hospitalizations and four deaths.³⁷ During this same reporting period, five outbreaks affecting 727 persons were attributed to water-borne viral infections that were all determined to be of norovirus etiology. Illnesses from these five water-borne viral outbreaks resulted in two hospitalizations and one death.³⁷ In addition, five drinking water-associated water-borne disease outbreaks affecting 30 individuals were attributed to parasitic infection with three *Giardia intestinalis* outbreaks, one *Cryptosporidium* sp. outbreak, and one *Naegleria fowleri* outbreak resulting in five hospitalizations and two deaths with both deaths caused by water-borne *Naegleria fowleri* infection. Three outbreaks affecting 27 individuals were attributed to bacterial infections other than *Legionella* species and included one *Escherichia coli* O157: H7 outbreak, one *Campylobacter jejuni* outbreak, and an outbreak involving coinfection with two different bacteria, *Campylobacter jejuni* and *Yersinia enterocolitica*. Water-borne illness resulting from these three water-borne bacterial outbreaks resulted in three hospitalizations and no deaths.³⁷ Seven drinking water-associated water-borne disease outbreaks affecting 117 persons were reported that involved acute gastrointestinal illness (AGI) of unknown etiology that resulted in no hospitalizations or deaths and lead to no confirmation of the suspected etiologic agent.³⁷ Five outbreaks affecting 39 individuals were attributed to chemical contamination of drinking water with two outbreaks resulting from

* Beginning in 2001, Legionnaires disease was added to the surveillance system, and *Legionella* species were classified separately.

† Acute gastrointestinal illness of unknown etiology.

Figure 48-3. Number of water-borne disease outbreaks associated with drinking water by year and etiologic agent in the United States, 1971–2002. (Courtesy of the Centers for Disease Control and Prevention. Adapted from Blackburn B, Craun GF, Yoder JS, et al. Surveillance for waterborne-disease outbreaks associated with drinking water—United States, 2001–2002. In *Surveillance Summaries*, October 22, 2004. MMWR. 2004;53(No. SS-8):23–45.)

* Excludes outbreaks of Legionnaires disease.

Note:

Individual = Private or individual water systems (9% of U.S. population or 24 million users)

Community = Systems that serve >25 users year round (91% of U.S. population or 243 million users)

Noncommunity = Systems that serve <25 users and transient water systems such as restaurants, highway rest areas, parks (millions of users yearly)

Figure 48-4. Number of water-borne disease outbreaks* associated with drinking water by year and type of water system in the United States, 1971–2002. (Courtesy of the Centers for Disease Control and Prevention. Adapted from Blackburn B, Craun GF, Yoder JS, et al. Surveillance for waterborne-disease outbreaks associated with drinking water—United States, 2001–2002. In *Surveillance Summaries*, October 22, 2004. MMWR. 2004;53(No. SS-8):23–45.)

* Other than *Legionella* species.

† Excludes outbreaks attributed to *Legionella* species.

§ No outbreaks were attributed to untreated surface water.

Figure 48-5. Drinking water–associated outbreaks by etiologic agent, water system, water source, and water system deficiency in the United States, 2001–2002. (Courtesy of the Centers for Disease Control and Prevention. Adapted from Blackburn B, Craun GF, Yoder JS, et al. Surveillance for waterborne-disease outbreaks associated with drinking water—United States, 2001–2002. In *Surveillance Summaries*, October 22, 2004. MMWR. 2004;53(No. SS-8):23–45.)

excessive levels of copper and a third from elevated levels of copper and other metals. One water-borne chemical outbreak was caused by ethylene glycol contamination of a water supply of a school and another by ethyl benzene, toluene, and xylene contamination of bottled water. However, illnesses from these five water-borne chemical outbreaks associated with drinking water resulted in no hospitalizations or deaths.³⁷ Although there has been improvement in the reduction of water-borne disease outbreaks associated with contaminated drinking water, the medical and public health consequences of these type of outbreaks may lead to significant morbidity and mortality for those most susceptible to water-related disease as detailed above.¹

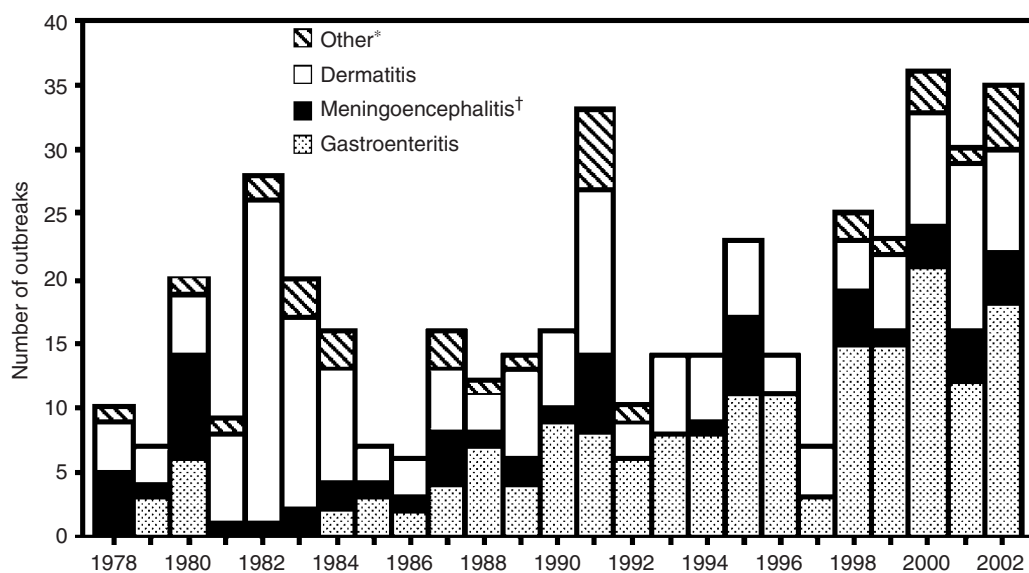

Water-Borne Disease Trends Associated with Recreational Waters

Unlike drinking water regulation, state and local governments in the United States establish and enforce regulations to protect recreational waters from both naturally occurring and man-made contaminants.³⁸ Since standards for operating, disinfecting, and filtering such water venues as public swimming and wading pools are regulated by state and local health departments, regulations vary throughout the United States. In 1986, the EPA published guidelines for microbiologic water quality that applied to recreational freshwater such as lakes and rivers as well as marine water; however, states throughout the United States have latitude regarding their recreational water regulations and health advisory guidelines regarding warning signs to alert potential recreational water bathers about contaminated freshwater quality.^{38,40} Unfortunately, contaminated freshwater venues used for recreational activities may require weeks or even months to improve or return to acceptable levels of safety. In either treated or freshwater venues, prompt identification of potential sources of water contamination and appropriate remedial action is necessary to protect the safety of recreational waters.

The most recent *MMWR Surveillance Summary* detailing water-borne disease outbreaks associated with recreational waters

was published in 2004 and summarizes data collected from the reporting period of 2001–2002.³⁸ In order to understand the surveillance data included in this surveillance summary of outbreaks associated with recreational waters, the following definitions are important to note and understand. According to the CDC and EPA, two criteria must be met in order for an event to be defined as a recreational water–associated disease outbreak. First, more than two individuals must have experienced similar symptoms after exposure to water or air encountered in a recreational water venue. However, this first criterion is waived for a single case of laboratory-confirmed primary amebic meningoencephalitis (PAM), a single case of wound infection, or a single cases of chemical poisoning if associated water-quality data indicates contamination by the chemical compound in question.³⁸ The second criterion developed by the CDC and EPA for reporting states that epidemiologic evidence must implicate recreational water or the recreational water setting as the probable source of the water-related disease or illness.³⁸ Under these definitions, recreational settings or venues include swimming pools, wading pools, whirlpools, hot tubs, spas, waterparks, interactive fountains, and freshwater and marine surface waters. When recreational water outbreaks are analyzed, these outbreaks are separated by *type of venue*: (a) *untreated* venues include fresh and marine waters, and (b) *treated* venues include the remaining settings such as swimming pools, wading pools, whirlpools, hot tubs, spas, waterparks, interactive fountains, etc.³⁸

Water-borne disease outbreaks associated with recreational water categorized by year and type of illness are presented in Fig. 48-6 spanning the reporting period of 1978–2002.³⁸ The number of water-borne disease outbreaks leading to gastroenteritis-associated with recreational water by year and water type (treated versus untreated freshwater) is presented in Fig. 48-7 for the period of 1978–2002.³⁸ Both figures illustrate a significant increase in the number of reported water-borne disease outbreaks associated with recreational water in the United States since early reporting in 1978, particularly in treated recreational water venues. Recreational water-associated outbreaks leading to gastroenteritis classified by etiologic agent and type of exposure (treated versus untreated freshwater) from the reporting period of 1993–2002 is presented in Fig. 48-8.

* Includes keratitis, conjunctivitis, otitis, bronchitis, meningitis, hepatitis, leptospirosis, pontiac fever, and acute respiratory illness.

† Also includes data from report of ameba infections (Source: Visvesvara GS, Stehr-Green JK. Epidemiology of free-living ameba infections. *J Protozool.* 1990;37:25S–33S).

Figure 48-8. Water-borne disease outbreaks of gastroenteritis associated with recreational water exposure by etiologic agent and type of exposure in the United States, 1993–2002. (Source: Courtesy of the Centers for Disease Control and Prevention.³⁶)

During the 2001–2002 reporting period, a total of 65 outbreaks associated with recreational water exposure were reported in 23 states leading to water-borne illness in 2536 individuals that resulted in 61 hospitalizations and eight deaths.³⁸ Of these 65 reported recreational water outbreaks, the following illness pattern emerged: (a) 46.2% resulted in outbreaks of *gastrointestinal disease*; (b) 32.3% resulted in recreational water outbreaks of *dermatitis*; (c) 12.3% resulted in water-borne outbreaks of *meningoencephalitis*; and (d) 9.2% resulted in outbreaks of *acute respiratory illness* including one outbreak of unknown etiology, one outbreak of Pontiac fever, and four outbreaks caused by chemical contaminants for water-borne exposure.³⁸ Of the 65 recreational water outbreaks reported in 2001–2002, 32.3% were associated with untreated freshwater and 67.7% resulted from exposure to treated water such as chlorinated water. Of the 30 outbreaks of water-borne gastroenteritis resulting from recreational water activities, 40.0% were associated with freshwater or surface marine water exposure and 60% were associated with exposure to treated water venues.³⁸

Of the reported water-borne disease outbreaks associated with recreational water exposure that resulted in *gastroenteritis-related recreational outbreaks*, 40.0% were caused by parasites, 20.0% resulted from water-borne bacteria, 16.7% resulted from exposure to water-borne viruses, and the remaining 23.3% of recreational water outbreaks were of unknown etiology (refer to Fig. 48-8 for details). *Cryptosporidium* species remained the most common cause of recreational water outbreaks associated with treated water exposure, and toxigenic *E. coli* serotypes and norovirus were the most commonly identified sources of outbreaks associated with untreated freshwater exposure. The etiologic agents that were suspected or identified in *nongastroenteritis-related recreational outbreaks* during this reporting period included *Pseudomonas aeruginosa*, *Naegleria fowleri*, *Legionella* species, *Bacillus* species, *Staphylococcus* species, avian schistosomes, and chlorine-based pool chemicals and products.³⁸ During this reporting period, eight cases of laboratory-confirmed primary amebic meningoencephalitis (PAM) were attributed to *Naegleria fowleri* infection from recreational water exposure resulting in a 100% mortality rate with eight deaths resulting from summertime contact with contaminated lake or river water.³⁸ During 2001–2002, a total of 21 outbreaks of dermatitis were identified resulting from recreational water exposure to swimming in freshwater lakes and rivers and exposure to public and private pool and spa use.³⁸ Although there has been improvement in the reduction of water-borne disease outbreaks associated with contaminated drinking water, the trend for morbidity and, at times, mortality associated with exposure to contaminated recreational waters both in treated venues and untreated freshwater and surface marine waters is disturbing. The resulting medical and public health consequences of these types of recreational water-associated outbreaks may lead to significant morbidity and mortality for those most susceptible to water-related diseases as detailed below.¹

Susceptible Populations and Water-Related Disease

When assessing the impact of water-borne disease on the general population, it is important to recognize the fact that certain individuals may be at greater risk for the morbidity and mortality that may result from exposure to microbial, chemical, or radiologic contaminants in both drinking and recreational water.^{1,41} The U.S. national drinking water standards address this important issue and intend “to protect the

general public as well as those groups of individuals who may be more sensitive than the general population to the harmful effects of contaminants in drinking water.”⁴² Susceptible or vulnerable subpopulations may experience medical sequelae at lower levels of exposure to specific contaminants in water than the general population.¹ The variability of host susceptibility presents several significant challenges to managing and preventing water-related disease in vulnerable or sensitive populations most at risk for water-related disease including but not limited to:

- The segment of the population identified as at increased risk from lower levels of exposure to water-borne microbial, chemical, or radiologic contaminants currently represents 20% of the U.S. population. This percentage is expected to increase as the average American life span increases and immunocompromised individuals survive longer.^{1,41}
- There are many biological factors that influence susceptibility to specific water-borne contaminants. Susceptible or high-risk populations may develop severe and fatal systemic disease from the same water-borne exposure that may present as an asymptomatic or mild illness in the general population.^{1,43} For example, the case fatality ratio for pregnant women from an infection of hepatitis E during a water-borne disease outbreak is 10 times greater than that for the general population.^{1,41}
- An individual’s susceptibility to water-borne contaminants does not remain constant or fixed over time.^{1,44} During an individual’s lifetime, their susceptibility changes with age from a highly susceptible developing fetus to a low-risk status as a healthy adult to increased susceptibility as an elderly patient with chronic disease.¹
- Even members of the general population not specifically designated as high risk or vulnerable subgroups may at various times in their life become more susceptible to water-borne contaminant exposure.¹ Intermittent illnesses or accidental trauma may shift the susceptibility status of a healthy low-risk individual to one of a susceptible patient requiring special consideration and protection from the adverse health effects of water contaminant exposure.^{1,44}
- Specific individuals may experience water-related disease due to a greater level of exposure to water-borne contaminants than the general population. This enhanced level of exposure may be due to biological factors such as higher ratios of skin surface to body mass in children resulting in a proportionally greater body burden of water contaminants than in adults.^{1,45}

Selected susceptible subpopulations who may be at greater risk for developing water-related disease from exposure to water-borne biological, chemical, and radiologic contaminants than the general population are presented in Fig. 48-9 for review.^{1,18,30,41,42,46} It is important to define and characterize which members of the U.S. population may be considered susceptible or sensitive subpopulations in order to determine whether their specific risk profile for developing water-related disease warrants special health precautions. Individuals in these sensitive subgroups warrant special attention and risk reduction education in order to prevent the adverse health outcomes that may result from their increased risk of developing water-related diseases. Since the primary targets for water quality management and water

Figure 48-9. Susceptible subpopulations at greatest risk for water-related disease from exposure to water-borne biological, chemical, and radiologic contaminants. Patients undergoing immunosuppressive therapy including organ transplant recipients
Patients treated with chemotherapeutic agents including cancer patients
Patients with preexisting clinical disorders or chronic diseases resulting in impairment of the renal, hepatic, or immunologic system

safety regulations in the United States may not completely eliminate the risk of developing water-related disease from biological, chemical, and radiologic contaminants in water, the following *special health precautions and risk reduction behaviors* are warranted for susceptible populations most at risk: (a) updated health advisories for health-care providers detailing prevention guidelines for specific “at risk” groups (Fig. 48-9) when water contamination events occur or when there is concern that water exposure may lead to disease; (b) concise patient information addressing risk characterization and risk reduction activities to reduce overall risk of exposure to water-borne contaminants; (c) risk communication information addressing the specific risk of disease from water-borne contaminant exposure and “avoidance behavior” guidelines for “at risk” groups; and (d) recommendation for alternative sources of drinking water for high-risk patients when appropriate.¹ Implementation of these risk-reduction activities may lead to improved health outcomes for the susceptible populations at increased risk for suffering from the morbidity and mortality that may result from exposure to water contamination.¹

► TREATMENT OF WATER AND WASTEWATER

Treatment of waters to make them suitable for subsequent use by humans requires physical, chemical, and biological processes.³ Some portion of this purification process may take place in nature, but when natural cleansing cannot ensure a suitable level of water quality, engineered processes in water treatment plants are frequently necessary.⁴⁰⁻⁴⁷ Sophisticated engineering processes are increasingly required to address the contamination that impairs the quality of water from increasing human-made pressures. In addition, resistance to nature’s purification process may also be overwhelmed by population growth and expansion in the face of fixed natural resources including limited water resources. The processing steps or unit processes used for purifying drinking water are briefly described below, while those used for treating wastewater are described in the Wastewater Collection and Disposal section of this chapter.

Distillation. The processes of evaporation and condensation maintain the hydrologic cycle (Fig. 48-1). Engineered distillation is used for desalination and for other applications where special water quality may be needed in a community. The distillation process produces the purest water of any of the processes listed below with only volatile organics persisting after treatment.

Gas Exchange. In the gas exchange process, oxygen is added to water, and dissolved gases such as carbon dioxide and hydrogen sulfide are removed. This process of reducing unpleasant taste and odor may also assist in the oxidation of iron and manganese, rendering these compounds more easily removable. Aeration is also an important natural process restoring water quality in polluted rivers and other bodies of water and is also used in water purification and wastewater treatment processes.

Coagulation. During the coagulation process, colloidal and suspended particles are brought together to form large “flocs” that settle more easily during the purification process. This process occurs naturally in lakes and other bodies of water but it is an important process in water purification and is supplemented by the addition of coagulants such as aluminum sulfate or synthetic polymers. The resultant “floc” layer is subsequently removed by sedimentation, filtration, or both.

Flocculation. In nature, water contaminant mixing is induced by the velocity of flow in rivers or by wind, thermal, or density-induced currents in lakes and reservoirs: the resultant aggregation process causes interparticle contact. This process of flocculation is engineered in water treatment plants and in coordination with the process of coagulation aids in the formation of large floc particles that are more easily removed from treated water.

Sedimentation. Under the action of gravity, many water-borne particulates including bacteria settle to the bottom of a body of water. However, since the settling velocities of these small particles are low, turbulence or swift currents interfere with sedimentation so that the process is effective only in slow-moving bodies of water such as lakes. In engineered water purification facilities, special tanks that minimize extraneous currents are used encouraging settling of the smallest and most dense particles. The engineered process of coagulation assists in the sedimentation process.

Filtration. During the filtration process, water passes through a granular media and fine particulates are removed by adhesion to the granular media and by sedimentation in the pore spaces of the media. Removal of particles by filtration is not accomplished by straining as the particles removed are generally much smaller than the spaces between the grains of the medium. In some instances, biological growth on the filter may assist with removal of water-borne particles and with biochemical degradation of the adsorbed organic matter. In nature, the process of filtration occurs as water percolates through the soil.

Adsorption. While some adsorption takes place during the process of filtration, often special media designed to adsorb water contaminants are also employed during water purification processes. Activated carbon, both in granular form as filters and in powdered form as an additive to water, is used to adsorb unpleasant taste and odors and a wide variety of organic chemical contaminants in water.

Ion Exchange. In the ion exchange process of water purification, resins from both natural and synthetic sources are used to remove specific ion contaminants. The most common products are zeolites that are used for removing calcium and magnesium that are water hardness-producing ions and replacing them with sodium.

Disinfection. A wide variety of disinfection procedures are employed during the water purification process for destroying pathogenic microorganisms that may cause water-borne disease. Sterilization of water during large-scale water purification procedures is not intended or a necessary target goal for water treatment. The most common disinfection procedure for water purification is chlorination.

Other water treatment processes are available for specific treatment applications, such as treatment to help prevent corrosion and to manage the solids or sludge that accumulate during the water treatment process. The handling and disposal of waste sludge is a difficult problem, particularly at wastewater treatment plants where the sludge is often noxious and can constitute a health hazard itself. Other water treatment processes may be required in specific locations where a community water system may be needed to remove substances such as ammonia, phosphorus, radioactivity, or water contaminants specific to the community’s geological location or industrial activities. In general, one or more of the unit processes mentioned above will be employed in a specific community water treatment system depending upon the level and types of water contaminants present in source water.

Where the target for water treatment is potable water, the selection of the treatment process is dependent on the quality of the water source. For example, groundwaters may require only aeration and disinfection, while heavily polluted surface waters may require all the unit processes described above. Community wastewaters that may include the presence of industrial wastewater discharges also select treatment processes that result in an effluent that protects the receiving water and the “downstream” uses of the released water for the neighboring community. If the effluent is to be discharged into an ocean, fewer processes are likely to be required than if the effluent is intended for discharge into a small, fragile stream or for reuse for nonpotable purposes later.

► ENGINEERED WATER PURIFICATION PROCESSES

The conventional sequence of engineered processes for the purification of surface water for potable purposes includes flocculation and

Figure 48-10. Typical structural profile of a water treatment facility in the United States. (Adapted from Fair GM, Geyer JC, Okun DA. Elements of Water Supply and Wastewater Disposal. New York: John Wiley & Sons; 1971.)

coagulation, sedimentation, filtration, and disinfection. This type of engineered water purification treatment is intended to remove color, turbidity, microorganisms, colloidal particles, and some dissolved substances. Some of these processes may be omitted where the waters are drawn from a protected source and are free of unwanted color and turbidity. However, this type of conventional treatment is not applicable to dissolved synthetic organic chemicals and is only moderately effective in the removal of heavy metals and radioactivity. If these water contaminants are present in a community water source, additional processes such as adsorption on granular-activated carbon may be required. The following sections describe, and Fig. 48-10 illustrates, the principal unit processes required in most water purification plants in the United States.

Coagulation. The coagulation processes often include chemical addition, rapid mixing, and flocculation. The process removes finely divided suspended material, colloidal material, microorganisms, and to some extent dissolved substances of larger molecular size by producing flocs sufficiently sized to be removed by sedimentation, filtration, or both. The raw source water that is being processed may be highly colored or free of color or with high or low turbidity. The water-borne particles responsible for color and turbidity are not discernible by the naked eye, but after coagulation, the individual floc particles are easily observed ranging from 1 to 2 mm in diameter. The principal coagulants used for water purification are alum, aluminum sulfate available in solid or liquid form, and ferric salts such as ferric sulfate. These aluminum and iron salts in solution form trivalent aluminum and ferric ions that react with alkalinity, which may be naturally present or may be added to the process with lime or soda ash. The addition of these coagulants reduces the pH of the treated water since optimum coagulation is a function of the pH level.

The aluminum hydroxide is essentially insoluble and forms a loosely bound gelatinous structure. The process is one in which the trivalent ions interact with the contaminant materials in the water to reduce the forces of repulsion among them allowing larger and larger aggregates to form with accretion. As natural colloids are largely negatively charged, the positive ions are effective in neutralizing and allowing this coagulation process to proceed. When large amounts of coagulants are required for treatment, a reduction in pH may result and the treated water may become somewhat more corrosive. The use of natural or synthetic polymers for treatment may reduce coagulant requirements by tenfold. The proper amount of coagulant and polymer and the optimum pH for a community treatment facility are determined by jar tests or by pilot plant studies in the design phase of a new facility. Jar tests are then run routinely at the treatment facility as a guide to the adjustment of the chemical concentrations needed in response to changing temperature and the variable quality of the raw source water.

Chemical feeding equipment selection is based upon the required chemical, the required precision of feeding, and the variety

of concentrations necessitated by changing water quality that may be gradual or with a changing flow that may be sudden and frequent. After the necessary chemicals are added to the treated water, it is customary to utilize rapid mixing equipment to make certain that the treatment chemicals are distributed uniformly in the water. Turbine or propeller mixers are commonly used, but if the treated water is to eventually be pumped, the chemical treatment may be added on the suction side of the pump, using the pump as the mixer. Hydraulic mixing may also be used, and the water pipes themselves can be used if there are sufficient bends to ensure the necessary turbulence, or stators may be inserted in a pipe. The time required for rapid mixing of the chemical treatment is only seconds in length.

The coagulation process is aided by flocculation produced in special tanks, where mechanical paddles or diffused air stirs in water gently, promoting the conjunction of suspended particles and the resulting large flocs then settle easily. The parameter of concern in the design of such tanks is the velocity gradient or the velocity variation across an element of water. In practice, the velocities in flocculation tanks vary from about 1 m/s at the entrance to the tanks, decreasing to about 0.2 m/s near the outlet, with a retention time of 30 minutes. Specific requirements vary with different raw waters and variations in temperature, so that the flocculator is designed to accommodate the worst situation, which generally occurs in winter.

Sedimentation. The effluent from the flocculation tanks with large but variable-sized flocs is subsequently led into sedimentation tanks, where the flocs are encouraged to settle. The detention time, again depending on the level of quality in the water to be treated, varies from 2–6 hours. The required water-treatment facility capacity is divided into two or more units to permit one unit to be out of service without requiring shutdown of the plant. Commonly, these tanks are rectangular in design and approximately 4–5 meters in depth. When the rate of accumulation of floc at the bottom of these tanks is expected to be too significant to be easily removed manually, mechanical sludge collectors may be installed. When the sludge can be stored at the bottom of the tank for several months without creating problems in the treatment process and subsequently removed manually, mechanical sludge collectors can be dispensed, saving the cost of equipment and maintenance.

Another useful treatment configuration, particularly where facility space is at a premium, is the upward flow or sludge blanket clarifier, a process in which the treated water after flocculation moves up through a floc blanket that is suspended in the tank by the upward velocity. The water impurities are removed in the blanket and the resultant effluent is clear. These upward flow units were initially developed for softening water, but their cost saving economics have encouraged their use in conventional water treatment as well. A compact arrangement for an upflow unit in combination with the flocculator is in concentric tanks with the flocculator in the center and sedimentation on the outside.

However, unless first-class supervision of water treatment operation can be ensured, the conventional horizontal-flow sedimentation tank is preferred for water treatment as it is far less subject to disturbance.

An improvement in the efficiency of water treatment sedimentation tanks can be obtained by increasing the area on which the floc can settle. Initially, this process was completed by installing intermediate bottoms in horizontal-flow tanks. A more effective approach has been the installation of a series of sloping plates or tubes installed in the top of the sedimentation tank through which the floc-bearing waters must flow before reaching the effluent weirs. The flocs settle on the plates or in the tubes and then fall to the bottom of the tank. Such modification settlers can be installed in existing tanks to improve their water treatment performance.

Management of Sludge. The material that falls to the bottom of water treatment tanks as sludge is now identified as a *residual* to encourage its recovery as a by-product of the treatment process. At one time water treatment sludge was returned to the community water treatment river from which the community's source water was drawn. But today, this residual is considered a pollutant and must be reclaimed or disposed of properly. Discharge of this residual into the community sewer treatment system for final handling and disposal at the wastewater treatment plant is an expeditious solution. Otherwise, transport by truck to a landfill or other acceptable place for disposal may be required. In such instances, dewatering of the sludge is appropriate to reduce weight of the product and cost of transportation. For this purpose, sand drying beds, vacuum filtration, filter presses, or centrifuges, all processes similar to those used for handling sludge in wastewater-treatment plants, may be used after water treatment.

Filtration. Floc particles that escape the sedimentation tank during water treatment are removed by filtration. The conventional filter in a water treatment process is approximately 1 meter in depth and comprised of sand grains varying in size from 0.5 to 1.0 mm. This granular material rests on a bed of graded gravel or on a specially designed underdrain system made of porous plates or false bottoms of various types with small orifices to ensure uniform backwashing of treated water. As water passes down through the filter beds, the floc settles in the interstices or is adsorbed onto the surface of the sand grains. When the amount of floc accumulated in the filter is sufficiently large enough to impede the flow of water, the filter is backwashed using filtered water sometimes accompanied by air. A filter run may last 48 hours, and the filter-washing process lasts 10 minutes in duration. Approximately 3–5% of the filtered water is required for backwashing, and the contaminated backwash water can be retained and returned to the water treatment plant influent. The cleansing of the filter is accomplished by expanding the sand bed with water introduced into the bottom of the filter. On completion of this wash process, the sand settles back into place with the finest particles at the top and the coarsest at the bottom. This configuration of particles limits the effectiveness of the filter, as the top layer tends to remove most of the floc particles and the remainder of the depth of the filter remains unused. One approach currently accepted to alleviate this situation is the use of dual media or even multimedia filters, where granular materials of different specific gravity are employed. Most common is the dual media filter, where coarser anthracite grains with a specific gravity of about 1.5 rest on top of a silica sand layer with a specific gravity of 2.65. In backwashing such a filter, the larger grains of the lighter anthracite always remain on the top of the filter, permitting the full depth of the bed to be more effectively used during the water treatment process.

The rate of application to the water treatment filters ranges from 4 to 10 m/h, depending on the quality of the water. The facility water engineer selects the sizes and loadings of the pretreatment and filter units to minimize the overall cost of treatment. When raw source waters are of high quality and coagulation and sedimentation are not required, as is the case when water is drawn from upland reservoirs with low turbidity and color problems, direct filtration is used with the addition of a very small amount of coagulant and coagulant aids. Such direct filtration processes are widely practiced in the treatment

of water for swimming pools and for many industrial uses. Since filters are periodically taken out of service for washing, there must be multiple backup units. Also, because of the many valves and other fittings required in each filter, there is a limit to their size requiring larger water-treatment plants to house many separate filter units.

A preferred mode for operating sand filters during water treatment would be upflow so that the incoming source water is met initially by the largest sand grains. Such upflow filters or a combination of upflow and downflow filters with the filter drains in the center are widely used in Europe. The reluctance to adopt such upflow units in the United States arises from the fact that an upflow filter constitutes a cross-connection. In a conventional filter, the unfiltered water is always separated from the filtered water by the bed. The underdrain system contains only filtered water that is used for backwashing. The dirtied wash water on top of the filters after washing should not mix with the filtered water. Any wash water that remains on top of the filter is refiltered, so there is never an occasion when the underdrains receiving the filtered water can be contaminated by unfiltered or wash water. On the other hand, the purified effluent from upflow filters occupies the same space above the filters as is occupied by the wash water during washing, and contamination of the filtered water is quite possible. In many European plants, where filters are used primarily to remove iron and manganese from groundwaters and there is no bacterial contamination, such cross-connections are of little consequence. Also, in the reclamation of wastewaters where the production of potable water is not intended, upflow filters may be effectively utilized.

The earliest filters, introduced in the middle of the nineteenth century for use without pretreatment by coagulation and sedimentation, were slow sand filters. The rate of application to the slow sand filter is approximately 0.15 m/h, requiring an area about 50 times greater than conventional filters. The slow sand filter operates by the creation on its top layer of a film of material removed from the water including microorganisms that is termed *schmutzdecke*. It is this living filter that removes color, turbidity, and bacteria from treated water. The top layer is easily clogged, however, and the top 3–5 cm of sand are removed periodically for washing. Immediately after removal of the *schmutzdecke*, the performance of the filter may be somewhat poorer but it is quickly restored. Several cleanings take place before the washed sand is restored to the filter. To permit somewhat greater loads on slow sand filters, it is customary to precede the slow sand filtration with pretreatment by rapid sand filters or microstrainers, drums made of finely woven steel mesh that remove algae and other large particles permitting the slow sand filters to operate for longer periods between cleanings. Chemical coagulants are not used in this process.

Diatomaceous earth filters are used for industrial water supplies and many other specialized applications. The water to be filtered is mixed with diatomaceous earth and forced through a porous septum in a pressure shell forming a filtering layer several millimeters thick on the surface of the septum. When the filter is clogged, the flow is reversed and the diatomaceous earth is dislodged and washed away and a new cycle of operation is initiated. Filters of considerable capacity can be provided in a small space, and such units are particularly suitable for mobile installations, swimming pools, and many industrial water supplies. However, they are not well suited for handling coagulated waters because the filters clog quickly. More importantly, the small thickness of diatomaceous earth does not provide the security against breakthroughs of unfiltered water that is provided by the meter depth of sand in conventional filters; therefore, they have not been widely adopted in the municipal practice of water treatment.

Communities with hard water, which generally originates from groundwater, often use filters containing ion-exchange resins for softening. For treatment plants drawing upon highly polluted sources, granular activated carbon filters to adsorb chemicals are also being introduced. Such filter units, identified as "point-of-use" treatment devices, have been introduced for home use for attachment to the household supply or even to a single water faucet. These "point-of-use" treatment devices must be properly maintained. If the water treatment media are not replaced or recharged at regular intervals, the treatment devices may do more harm than good. These types of filters are of

little value in removing bacteria and may actually result in an increase in the bacterial content of water resulting from bacterial overgrowth within the filter itself. Home units for water softening are less necessary today with the availability of synthetic detergents; however, if home water softening is desired, the water softener is best attached to the household hot water tank and washing machines rather than softening the entire water supply of the household.

Disinfection. Disinfection with chlorine has been the single most important process for ensuring the bacteriological safety of potable water supplies in the United States and other industrialized nations. Water-borne epidemics from bacterial contamination have been reduced in industrialized countries as a result of this advancement, and the bacterial water-borne outbreaks that have occurred have been traced to failures in chlorination. In order to be effective in water treatment, water disinfectants need to possess the following important properties: (a) effectively destroy sensitive bacteria, viruses, and amebic cysts in water within a reasonable time despite all variations in water temperature, composition, and concentration of microbial water contaminants; (b) remain nontoxic and palatable to humans and domestic animals after treatment; (c) offer a reasonable cost and be easily stored, transported, handled, and applied safely; (d) provide determinable measurement of residual concentration in the treated water easily, and preferably automatically; and (e) offer sufficient persistence in treated water so that the disappearance of the residual would be a warning of recontamination. As it is not feasible to continuously monitor bacteriological or virological quality of water and there is a need to have the results before the water is distributed to the consumer, the ability to detect a residual concentration of a known bactericidal disinfectant after exposure for a certain time at a certain pH and temperature is a key quality-control test for disinfectants in drinking water.

The use of chlorine or one of its derivatives meets these requirements most economically; however, other alternative methods of disinfection are sought for two reasons: (a) chlorine added to some waters imparts an undesirable taste and odor, particularly where phenol is present; and (b) the reaction of chlorine with organic matter even where these organics are not themselves of health significance has resulted in the formation of a wide range of reaction by-products. The problems created by the use of chlorine as a disinfectant have been exacerbated because chlorine is a useful oxidant that can remove taste and odors economically and, when added at the beginning of a water treatment process, reduce the concentration of microorganisms that can cause difficulty in sedimentation tanks and filters later in the water treatment process. The wide use of prechlorination, particularly with waters drawn from polluted sources such as the Mississippi and Ohio rivers, has resulted in many water systems not meeting the trihalomethane standard. This problem may be effectively addressed by the use of better sources of raw water or by adequate treatment before the disinfecting dose of chlorine is added. Humic organics, phenols, and other precursors of trihalomethanes should be removed before the addition of chlorine to reduce this problem; however, this generally requires abandoning the process of prechlorination. While the removal of natural organics through coagulation, sedimentation, and filtration can be readily accomplished, the removal of synthetic organic chemicals in polluted waters is much more difficult. The adoption of substitutes for chlorine must be initiated with great care since other disinfectants may themselves produce by-products with toxicologic profiles of which far less is known than of the trihalomethanes. Also, some of the other methods of disinfection such as chloramination do not provide the same level of microbiological safety as chlorine treatment. Nevertheless, pursuit of all methods of disinfection may reveal a combination that provides the required safety of water disinfection while minimizing the undesirable side effects of by-product production. For example, the use of other methods of disinfection, such as those described below with chlorine added primarily to ensure bacterial safety by providing the water with a measurable chlorine residual, may be suitable combinations for drinking

water treatment. Boiling water will provide disinfection, but this process is suitable only as an emergency measure for individual consumers and is not a reasonable community approach to providing drinking water.

A wide range of other methods of disinfection including the use of strong oxidants is available that may be combined with chlorine. Sunlight is a natural disinfectant, and irradiation by ultraviolet light is an engineered process that can be tailored to disinfection of water. A mercury vapor arc lamp emitting invisible light of 25–37 Å applied to a water source free of light-absorbing substances, particularly suspended matter that will protect microorganisms against the light, is a useful method of disinfection. Unfortunately, there is no way of continuously monitoring the effectiveness of the process and, as such, this application has not found use in municipal potable water supply practice in the United States, although it is used in the Soviet Union. Silver ions are bactericidal at concentrations as low as 15 µg/L, but this disinfection process is quite slow. Larger concentrations that speed up the process are unacceptable because of possible side effects from silver toxicity. Furthermore, silver ions are neither viricidal nor cysticidal in appropriate concentrations, and silver is expensive as a disinfection option. Nevertheless, silver-coated sand may be appropriate for specialized installations requiring water disinfection. Copper ions are strongly algicidal and copper sulfate is often used for algae control in lakes and reservoirs; however, copper is not bactericidal. Pathogenic bacteria do not survive in highly acid or alkaline waters below a pH of 3 or above a pH of 11. A water treatment process that reduces the pH of source water to these pH levels, as might be the case through the use of lime, will accrue some disinfection benefits. Otherwise, the use of acids or alkalis as disinfectants is not feasible.

Oxidizing Chemicals. Oxidizing chemicals used for water treatment include the halogens (chlorine, bromine, and iodine), ozone, and other oxidants such as potassium permanganate and hydrogen peroxide. Potassium permanganate has found wide use as a replacement for chlorine for taste and odor control but it is not as effective as a disinfectant. The use of ozone is useful for destroying odors and color and is also an effective disinfectant but it suffers from the fact that it leaves no residual suitable for monitoring. Among the halogen compounds, gaseous chlorine and a wide variety of chlorine compounds are economically feasible for use in water treatment. Bromine and iodine have been employed on a limited scale for the disinfection of swimming pool waters as well as in tablets for disinfecting small quantities of drinking water in the field and in remote conditions.

Ozone. The combination of ozone for pretreatment while providing some disinfection followed by chlorination has become a popular sequence in Europe and is beginning to be employed in the United States to reduce the level of trihalomethanes in finished drinking water. In this process, ozone is produced on-site by the corona discharge of high-voltage electricity into dry air or oxygen. Ozone is corrosive and toxic and in conjunction with hydrocarbons from automobile exhaust is responsible for oxidant pollution and upper and lower respiratory irritation in many individuals. In the vicinity of a water treatment plant using ozone, the environmental effect can often be seen on surrounding vegetation. Nevertheless, ozone is used effectively and efficiently as an oxidant, a deodorant, a decolorant, and a disinfectant in both drinking water and wastewaters. In light of the fact that production of ozone is expensive and energy-intensive and the fact that ozone residuals disappear rapidly from water and are not available for quality control, ozone is used for special applications and not as a general replacement for chlorine in water treatment. Intensive research into the characteristics, biocidal efficiency, and reaction products of ozone continues; however, the use of ozone treatment is not expected to replace chlorine entirely because it leaves no residual for ongoing water quality monitoring.

Chlorine. Chlorinated lime (CaClOCl) was the first chlorine disinfectant used for treating public water supplies. It is a hygroscopic white powder that rapidly absorbs both moisture and carbon dioxide from the air with the resultant loss of chlorine and is rapidly replaced by hypochlorites. This technique was replaced by elemental chlorine (Cl_2) produced by the electrolysis of brine in liquid form for storage and transmission in steel cylinders. Liquid chlorine is still by far the most common form of chlorine used for water supply and wastewater disinfection. Calcium hypochlorite (Ca(OCl)_2) is stable and is used for small installations since it is easily stored in solid form in small containers with 1–3% solutions prepared as needed. Sodium hypochlorite (NaOCl) is also used for small installations and increasingly for large installations where the transportation of liquid chlorine is considered too hazardous because of the danger of leakage and environmental contamination. Chlorine is heavier than air and is extremely toxic, requiring all handling procedures and dosing of liquid and gaseous chlorine to be conducted with extreme care. Chlorine dioxide (ClO_2) is used in special instances, particularly where tastes and odors may be a problem for water treatment, and is produced directly in water by the reaction of elemental chlorine with sodium chlorite (NaClO_2). The on-site generation of hypochlorite by electrolysis of brine may be appropriate for communities in isolated locations where power is available but the delivery of chlorine may be difficult.

When chlorine or its derivatives are added to water in the absence of ammonia or organic nitrogen, hypochlorous acid (HOCl), hypochlorite ion (OCl^-), or both are formed with the distribution between the two depending upon the level of pH. These compounds are referred to in practice as free available chlorine. When ammonia or organic nitrogen is present, monochloramine (NH_2Cl_2), dichloramine (NHCl_2), and nitrogen trichloride (NCl_3) may be formed with the distribution among the species again being a function of the level of pH. Generally, the first two of these compounds prevail and are referred to as chloramines of combined available chlorine. Since the disinfecting power of each of these varies widely, the chemistry of chlorination must be fully understood so that the chlorine may be used effectively and disinfection assured in finished drinking water. Although the purpose of adding chlorine is to destroy microorganisms, most of the substances in water that react with the chlorine are inert organic materials, both natural and human-made, as well as other reducing substances. If organic matter and other chemical compounds that require chlorine demand can be removed from water by treatment before the addition of chlorine, both the required addition of chlorine and the formation of chlorinated organic compounds will be reduced.

When ammonia or its salts are present in chlorinated water during water treatment, chloramines are formed. Monochloramine is formed in the pH range of 6–8, while dichloramine predominates at lower pH values. The chloramines appear as part of the residual chlorine, but as they are a considerably less effective disinfecting agent than hypochlorous acid. To ensure adequate disinfection, a free residual must be formed and this requires the addition of more than enough chlorine to react with all the ammonia and organic compounds present in the water under treatment. The great advantage of obtaining free available chlorine is that most tastes and odors that can be oxidized by chlorine are destroyed, and rigorous disinfection, even leading to the inactivation of viruses, can be ensured as long as the proper combination of chlorine residual concentration, pH, time of contact, and temperature are conscientiously observed.

While hypochlorites used in water treatment facilities can be added with solution feeders, special equipment is required for adding elemental chlorine. Chlorine is transported in liquid form in steel cylinders, but chlorine gas also exists within the cylinder. It is this gas that is drawn off for solution by water stream feeding and delivered into the water to be treated. For significant rates of use, particularly in wastewater treatments where the amounts of chlorine used are substantially greater than in water supply disinfection, the chlorine may be withdrawn from the steel tank as a liquid and vaporized in special evaporation equipment. Below 9.5°C , chlorine combines

with water to form chlorine hydrate or chlorine ice that may obstruct feeding equipment in treatment facilities. Therefore, it is important that chlorine feeding equipment and the water that may come in contact with the gas be maintained above this critical temperature. Because chlorine is highly toxic, it must be handled with great care and under adequate safeguards. Concentrations of 30 ppm or more induce coughing, and exposures for 30 minutes to concentrations of 40–60 ppm are very dangerous with 1000 ppm being rapidly fatal in humans. Since chlorine gas is heavier than air, it may concentrate in tunnels and lower levels of buildings at the water treatment facilities, exposing workers and the public. Therefore, special facilities are provided for handling chlorine with separate entrances to feeding and weighing rooms, special automatic ventilation, and safety equipment including appropriate personal protective equipment.

Since chlorine is the most important safeguard for microbiological safety of drinking water, no breakdown in chlorine feeding can be tolerated. Thus, units must be adequate in size and be duplicated so that failure of any single unit would not interfere with continuous chlorination. An ample number of filled cylinders must be available with at least two cylinders on-line at all times so that an empty cylinder can be replaced without interfering with the chlorination process. Most chlorinators operate under vacuum to prevent leakage of chlorine gas with the vacuum created by the feed water being pumped under pressure. The pressure of water required for this feed water line must be substantially greater than the water pressure in the line being fed and this requires separate pumps. Failure of these pumps resulting from a power disruption would lead to cessation of the chlorination process. Therefore, suitable alarms with provision for standby power generation are required to ensure continuous water treatment operation. Portable chlorinators that operate off pressure in the cylinders may be used for emergency chlorination of water mains, wells, tanks, and reservoirs in the field.

After chlorine is added, sufficient contact time must be provided which depends upon the quality of the source water being treated but is generally approximately 30 minutes. In water treatment facilities, this process may be completed in a clear well, and in wastewater treatment plants special chlorine contact chambers are constructed. Chlorination is now routinely automated to permit automatic variation of dosage to account for variations in flow and chlorine demand and to maintain a constant chlorine residual. The chlorine dosages and residuals are recorded and it is common to maintain an alarm to give warning of any departure from the required chlorine residual in the water treatment process.

Corrosion Inhibition. Treated drinking water may be more corrosive because of the addition of coagulants and chlorine, both of which reduce the pH of the water under treatment. Also, many water sources in the United States are quite soft and corrosive naturally. To avoid corrosion of pipelines, hot water heaters, and plumbing fittings, it is general practice to reduce the corrosivity of finished water. This process is completed by either adding sufficient alkalinity and raising the pH to render the water noncorrosive or by adding a hexametaphosphate sequestering agent, which tends to form a light coating in the pipes and mitigates the effect of any corrosion that might result. Corrosion control is also important to minimize lead concentrations in water where lead is present in household water plumbing and may represent a health hazard.

Adsorption. Depending on the source of water for a community, a water treatment plant may use one or more of the processes described above. However, none of these processes are directed against the synthetic organic compounds that pollute many U.S. water resources resulting from drainage from urban and industrial activities. Some removal of these organics can be expected when powdered activated carbon is used for taste and odor control. The synthetic organic compounds in water were initially characterized by passing the water sample through activated carbon filters on which the organics are adsorbed and then dissolving these organics with chloroform. The 1962 U.S.

Public Health Service Drinking Water Standards had a limit of 0.2 mg/L for this carbon chloroform extract. It was recognized that many of the organics adsorbed on the filter were of no health concern and that many organics that might be of health concern were not adsorbed at all. The use of special GAC filters for treating water drawn from polluted sources is now being introduced in an attempt to remove some, if not all, of these refractory organic chemicals. Pilot water treatment plants have been built but there is little experience with the long-term full-scale use of these special GAC filters. They have limited capacity, require recharging, and may release contaminants into the finished water being treated. In time, the larger cities that draw drinking water from polluted sources, such as the lower Delaware, Hudson, Ohio, and Mississippi rivers, are likely to incorporate GAC filters into their treatment processes. Smaller communities that draw from polluted sources will be constrained in their adoption of GAC filters because of their inadequate operating and monitoring capabilities. One beneficial effect of requiring such additional treatment may be that water purveyors now drawing on polluted sources will examine other options for drinking water treatment. For example, Vicksburg, Mississippi, which had been drawing its water supply from the Mississippi River prior to passage of the SDWA, switched to groundwater. This possibility does exist for other cities facing this environmental dilemma and may be more attractive than trying to monitor and remove the myriad synthetic organic compounds present in these rivers. Also, the cost of installation and operation of GAC filters along with the cost of monitoring may make higher-quality sources a more attractive option.

Water Distribution Systems

A water supply system including a community's treatment plant is designed to meet the average demand for water on the maximum day of use for a locality. Water use varies from hour to hour and may reach a peak during an event such as firefighting activities. Accordingly, a water distribution system must be based on peak water demand requirements and include: (a) high lift pumps that deliver treated water to the distribution system, (b) transmission mains for the treated water, (c) piping in municipal streets that serves residential homes and businesses, (d) hydrants in the distribution system for firefighting activities, and (e) service reservoirs supplying the source water. Each water customer is served by a connection to the water main generally through a dedicated meter. To ensure continuity of water service, water distribution pumps are selected so that if any single pump is down for repairs, the remaining backup pumps can handle the community's water needs. Also, it is customary to provide standby power generally through diesel engines to ensure continuity of water service. Distribution system piping is most commonly comprised of cement-lined ductile cast-iron pipe and is generally 6 inches or more in diameter which is the minimum size necessary for fire protection. The water distribution pipe network is designed with sufficient interconnections so that if any one pipe breaks, water service including fire protection can be provided via other routes. Water distribution systems are designed to maintain a minimum pressure of 20 psi (about 280 kg/cm²) during peak flow demands to permit service to be maintained at least to the second floor of residences without creating a back draft that might pollute the water supply. Higher buildings need to be served by their own pumping stations in order to receive water service. Elevated service reservoirs are present in many communities to maintain these pressures by storing water for peak demand use, firefighting activities, or in emergencies.

The introduction of dual water supply systems of potable and nonpotable water requires that the two systems be kept physically separate and easily distinguishable. This is accomplished by using different materials and colors for the pipe network and hydrants and different-shaped valve boxes.⁷ The operation and maintenance of a community's water distribution system is under the responsibility of a local water supply authority so that water services are available and dependable in an emergency. It is to the credit of the water industry in the United States that power failures occur with considerably greater frequency than failure of water services.

► WASTEWATER COLLECTION AND DISPOSAL

With increasing population growth and pressure from urbanization and industrialization, human waste products have increased in volume and type, and their impact on the environment in the United States has intensified significantly. Human waste products include night soil and wastewaters and each exerts its own stressors on the environment and present unique public health challenges. Human night soil principally affects soil, and wastewaters principally affect water; but both may have a serious impact on the environment and the health and general well-being of every community in the United States.

Night Soil Collection and Disposal. The expression *night soil* is used to describe human body wastes, excreta or excrement, or the combination of feces and urine voided by humans. The term itself derives from the historical practice of carting away accumulations of human ordure at night. In most industrialized countries, night soil no longer exists as such since human excreta is flushed away by water into community or individual sewerage systems. The disposal of human night soil is a problem of economy, convenience, personal hygiene, and public health. The danger of exposure to infectious diseases is proportional to the concentration of the causative agents in night soil and it is the source of a wide variety of gastrointestinal infections. The safe disposal of human night soil has important public health implications, and necessary operations to address this public health service are commonly left to local government in the United States.

The two components of night soil—feces and urine—vary significantly in amount but only slightly in composition depending upon the diet and age distribution of the general population and the consumption of water and other liquids. Human fecal matter contains food residues, bile and intestinal secretions, cellular substances from the alimentary tract, and expelled microorganisms in large numbers. The average per capita amount of fecal matter excreted daily is estimated at approximately 90 grams, ranging up to an average of 150 grams for adult males in the United States. On the basis of wet solids, fecal matter contains about 1% nitrogen, much the same relative amount of phosphoric acid, and approximately one-fourth the weight of potash. The number of coliform organisms alone is well in excess of 100×10^9 and there are a wide variety of other microorganisms in human fecal discharges including bacterial cells that comprise approximately one-fourth of the weight of human feces. The infective capacity of human feces is illustrated by the isolation of more than 100×10^9 *Salmonella typhosa* from some carriers of typhoid fever bacilli and in the millions of cysts of *Entamoeba histolytica* from carriers of amebic dysentery. Similar numbers of virus units of poliomyelitis have been isolated in the stools of infected individuals with this virus.

The principal components of human urine are water, urea, and mineral ash. The weight of urine excreted by humans is about 1000 grams per capita daily and up to 1500 grams in adult males. Compared with fecal material, urine is richer in fertilizing elements with daily per capita production of nitrogen at 10 times that of fecal material, phosphoric acid twice that of fecal matter, and potash at eight times the production in human feces. Therefore, it is no surprise that that urine constitutes the most agriculturally valuable part of human excreta. At the same time, human urine is normally sterile and destroys many bacterial species in fecal matter when left in contact for any length of time. As chemical fertilizers became economical and standard practice in industrial parts of the world, the use of human excreta as fertilizer was abandoned during the last century. However, with increasing cost of chemical fertilizer production, primarily resulting from the high energy costs involved in manufacturing, interest in using human wastes for agricultural fertilizer is being reconsidered in the United States. The circulation of enteric human pathogens in the environment from night soil exposure is a function of many conditions including (a) the prevalence of the causative agent in diagnosed cases and secondary carriers, (b) the rate of survival of the excreted pathogen in different ecosystems and climates, (c) the nature of the infection and the minimum infective dose necessary for infection, and (d) the host

susceptibility and immune status of the population potentially exposed to the pathogen.

Wastewater Disposal and Water Pollution. In the United States, household wastes from kitchen, bathroom, and laundries are conveniently flushed away as domestic wastewater and manufacturing wastes are discarded as industrial wastewaters. The system of underground pipes and appurtenances into which wastewaters are discharged is collectively the community's sewage system. Municipalities initially constructed sewers to protect their city streets and low-lying areas from inundation by flooding rainstorms—not to carry away human body wastes. The original sewers were designed as storm-water drains—not sanitary sewers. Water carriage of human waste did not come into purposeful use until the nineteenth century. At that time, the Industrial Revolution and the explosive growth of urban communities placed a heavy burden on existing waste removal—and the manual transport of human waste from inside cities. As a consequence of this pressure, storm-water drains were pressed into service for domestic waste removal leading to a combined sewerage system. During summer periods, the streams into which the sewers emptied began “to seethe and ferment under a burning sun” as the oxygenating capacity of the natural waters had been surpassed. One resolution was the construction of intercepting sewers along the banks of larger bodies of water. These conduits were constructed to transport human waste beyond the community being serviced to other points of possible disposal. Storm waters were spilled, together with their share of municipal wastes, into the otherwise unprotected waters. This weakness in design of the combined system of sewerage is yet to be resolved in older cities in the United States. Separate systems of sewerage did not come into significant use until the beginning of the twentieth century when the treatment of wastewater was introduced resulting in (a) the protection of water reserves within the community against human and industrial pollution and (b) the treatment of all wastewaters without the complication of rainwater removal.

Understandably, the need for reducing the burden of human waste pollution imposed upon freshwaters and oceans was established initially in densely settled industrial communities in the United States. Waste removal techniques progressed from the separation of gross, generally settleable pollution constituents (primary treatment) to the separation of fine or dissolved, generally nonsettleable, pollution components by biological treatment (secondary treatment), and ultimately to the removal of the small concentration of specific classes of residual pollutants (tertiary treatment). The disposal of domestic wastewater and industrial wastes involves collection through plumbing systems of residential homes and other buildings followed by their delivery to public sewers; collection and treatment of communal and industrial wastewaters; and disposal of these treated wastes onto or into receiving waters.

Modern wastewater treatment in the United States began in the 1920s and for a half-century was devoted to protecting the best uses of the receiving waters into which the wastewaters were being discharged and included the following classifications: Class A—drinking water for human consumption and a protection of shellfish laying beds; Class B—bathing waters; Class C—aquatic life; Class D—industrial and agricultural water supply; and, Class E—navigation and disposal of wastewaters without nuisance. Standards were established for each of these classes, and the subsequent treatment required was established to maintain these standards. For example, treatment facilities discharging to class A and B waters were required to provide bacterial removal since drinking and bathing had rigorous bacterial standards that were not applicable to waters for other purposes. Dissolved oxygen levels did not need to be so high in waters used for industrial and agricultural purposes as in waters for aquatic life. Accordingly, the treatment to remove biochemical oxygen demand needed to be greater when discharges were released to Class C waters intended for protecting aquatic life than when they were released to Class D waters.

These standards were the responsibility of the individual states, and some states were more rigorous in their implementation of standards than others. Accordingly, some streams were allowed to become

highly polluted and unfit for any use. The environmental movement of the 1960s targeted this environmental problem leading to passage of Public Law 92-500, the Federal Water Pollution Control Act Amendments of 1972 with its 1977 amendments known collectively as the Clean Water Act. One of the goals of this act stated that water quality in the nation's water reserves provide for the protection and propagation of fish, shellfish, and wildlife and provide for recreation in and on the waters—all to be achieved by 1983. This eliminated prior classification of Class D and Class E. Another national goal presented in the act was that the discharge of pollutants into navigable water be eliminated by 1983, a goal that was recognized by many professionals as being potentially unattainable. Unfortunately, there was not an emphasis in Public Law 92-500 directed to preservation of receiving waters for potable water supplies. One important provision of the Clean Water Act is the requirement for National Pollution Discharge Elimination System (NPDES) permits for all sewerage, so-called point-source, discharges. The permits list the conditions that have to be met for pollution discharges, and together they provide a useful tool for wastewater management. The problems of nonpoint-source wastewaters, such as urban and agricultural runoff, however, remain less tractable.

Wastewater Drainage of Buildings. The plumbing systems of dwellings and other buildings are the terminus of the water supply and the beginning of wastewater disposal as illustrated in Fig. 48-11. The central components of house drainage systems are a vertical stack and a connecting horizontal house drain network leading to the residential sewer that leads to the street sewer or to an on-site method of disposal. For tightness, all piping with the exception of the house sewer is metallic or rigid plastic. Each fixture drains into the system through a trap in which a sealing depth of water prevents air within the piping from seeping into the building. Usually malodorous, this air may at times contain toxic and flammable contaminants and the seal of traps are intended to remain intact. To prevent their being siphoned by aspiration or blown by back-pressure from water rushing through them or past them in pipes or stacks, these traps are vented. For full safety, water inlets must discharge well above the high-water mark of the fixture to keep its waters from being sucked or forced back into the water system by backflow. If an adequate air gap cannot be provided, special backflow preventers must be installed in the supply pipe. Although water supply systems are normally under higher pressure than drainage systems, pressures are reduced drastically at times of high draft such as during fires or when water pipes break. The pressure in the water system may then drop below atmospheric pressure and the resulting negative (in relation to barometric) pressure differential may pull dangerous pollutants into the water system.

Wastewater Drainage of Towns. Sewerage systems, whether separate or combined, are in a sense vascular systems of underground conduits that collect the spent water of a community for subsequent treatment and appropriate disposal.⁵⁰ Sewers generally originate in a high-lying portion of a community, point progressively downhill, and increase in size as they accumulate more wastewaters from larger and larger tributary areas. In the United States, street sewers are at least 8 inches in diameter and house sewers at least 6 in. Sanitary and combined sewers are laid deep enough in the ground to drain the lowest fixtures in the properties serviced. However, when basements or lower levels are very deep as is the case for most tall buildings, wastewaters are lifted to the street sewer by pumps or ejectors. Sewers are generally of vitrified tile or concrete, with joints of premolded rubber or plastic to maintain water tightness. The slopes on which sewers are laid are generally set by the existing street grades. If a community is flat, sewers must still be laid on minimum grade, becoming quite deep, and pumping stations must lift the wastewater back to a minimum depth, often leading to an expensive wastewater system. Alternative systems such as vacuum or pressure sewers to avoid the need for laying sewers to grade may have appropriate application in these special situations. For inspection and cleaning, sewer access openings are generally built into the wastewater system at changes in grade and

Figure 48-11. Typical residential plumbing system and domestic wastewater disposal in the United States.

direction and also at intermediate points in long, straight runs of network lines. Rainwater enters combined or storm sewers through street inlets with catch basins necessary for combined sewerage systems. The outlets of catch basins to their sewers are trapped to contain air in the sewer and to prevent sand and gravel from entering the system; however, street inlets in separate storm systems are left untrapped.

Quantity and Composition of Wastewater. During dry weather periods, the volume of wastewater consumes about 70% of the water used by a community, with this flow fluctuating by day, week, and season.³ The maximum peak rates used by a community may be as much as 200% higher than the average daily use. Associated industrial uses may introduce still greater differences and fluctuations in demand. In wet weather and for some period thereafter, groundwater adds to this wastewater flow which is also impacted by the tightness of the sewer system and the water content of the surrounding soil. Intercepting sewers for combined sewer systems are designed to carry as much water as can be economically and technologically justified for a community system. In localities where rainfall is steady and gentle, interceptors are designed for up to six times the dry weather flow since spills are rare. However, in communities where rain and snowstorms

are intense and of short duration, the frequency and volume of storm water overflow is not altered significantly by oversizing interceptors to carry more than the peak dry weather water flow.

The wastewater deposited in sewer systems originally shares the fundamental quality of the drinking water supply but is quickly contaminated by the human and industrial waste load imposed upon it, by the influx of groundwater, and in combined sewers by the varying quantities of rainwater and street wash. The longer the wastewater flows or remains stagnant, the more the contaminant constituents disintegrate with (a) fecal matter and paper breaking down; (b) bacteria and other saprophytes multiplying significantly; (c) respiration of living organisms and incidental biochemical changes reducing the oxygen originally dissolved in the water; and (d) fresh sewerage first growing stale and then converting to an anaerobic or septic environment. Wastewater is obnoxious to the senses as it purifies, and is dangerous to public health as it contains untreated pathogenic microorganisms.

In general, wastewater is analyzed for the purpose of ascertaining or predicting the effects of discharge on bodies of water into which it is to be released and for evaluating the performance of wastewater treatment processes. A routine test for biochemical oxygen

demand (BOD) is used that measures the oxygen requirements of bacteria and other microorganisms as they feed upon and bring about the decomposition of organic matter in the wastewater. These BOD requirements are important since they determine whether the receiving body of water remains aerobic (oxygen present) or anaerobic (oxygen exhausted) after the release of wastewater. Therefore, the BOD test is a measure of the putrescible load placed on wastewater treatment works and on bodies of water into which a wastewater treatment plant empties the community's treated wastewater. In the United States, the per capita contribution of 5-day 20°C BOD to domestic wastewater averages 54 grams, of which 42 grams is in suspension, 19 grams is settleable from suspension, and 12 grams is dissolved. Industrial wastes may add to these wastewater amounts appreciably, and their relative impact on the water system is expressed in terms of the number of individuals that would exert an equivalent BOD load. Especially high BOD loads are added to municipal wastewater systems by such industries as breweries, canneries, distilleries, packing houses, milk plants, tanneries, and textile mills.

Industrial Wastewaters. Because BOD characterizes only organic wastes typical of human discharges, where industrial wastes are present, the chemical oxygen demand (COD) or the total organic carbon (TOC) determination is also a useful indicator. Where industrial synthetic organic compounds or heavy metals are released in industrial effluent, these compounds should also be monitored in wastewater streams and treatment plant effluents, particularly where industrial wastes are discharged into waters that will be subsequently used for drinking or that will provide an aquatic environment for edible fish. Many industrial wastewaters interfere with treatment processes by imposing heavy loads on the wastewater treatment plants or by impairing biological treatment resulting from the presence of toxic components in the wastewaters. Accordingly, industries may be required to pretreat their industrial wastes before being permitted to discharge them into a municipal sewerage system. In addition, these industries are often required to reimburse the local municipality for handling these industrial wastewaters, generally in accordance with their volume and toxicity.

Many industrial wastewaters are discharged directly into receiving waters, thereby requiring NPDES permits created by the Clean Water Act. Facilities covered by EPA's baseline NPDES general permit for storm water discharges associated with industrial activity are subject to reporting requirements for chemicals classified as "water priority chemicals" and must monitor their storm water discharges for these compounds.⁵¹ The Water Priority Chemicals list currently contains 234 compounds as well as corresponding methods of analysis required for sampling the facility's storm water discharges by an EPA-approved method. Therefore, two regulatory approaches have been undertaken to address this environmental problem by the EPA.⁵¹ The first is based upon the requirement for the use of the BAT economically achievable for pollution control and analysis with guidelines established by EPA for at least 20 industrial categories. The second is based upon monitoring released chemical compounds in storm water discharge that now includes a list of 234 individual "priority pollutants."⁵¹ Establishing standards for these chemical pollutants as well as monitoring procedures is a formidable and expensive task particularly since there are approximately 70,000 chemical compounds in industrial use in the United States yearly.

► WASTEWATER TREATMENT PROCESSES

With few exceptions, water purification and wastewater treatment processes are alike in concept and in technique; the two processes differ only in the amounts of pollutants that must be removed and in the degree of purification that must be accomplished at the end of the engineering process.³ The key operations in wastewater treatment processes are directed toward the separation of the imposed load of human and industrial wastes received by the "carrying" water.

Wastewater Treatment

Wastewater solids constitute sewerage sludge or residuals, and the desired phase separation or mass transfer of removable solids is set in motion during a number of different techniques including physical, chemical, and biological unit operations. Moreover, since wastewater is very rich in nutrients, air or oxygen must be introduced into treatment processes if the wastewaters are to be kept fresh and odorless during treatment. This process is also a form of aerobic mass transfer since aeration or gas transfer results in removal of the gases and odors of decomposition. By contrast, anaerobic conditions may favor the degradation of putrescible matter in the dewatering and stabilization of sewage sludge. The common unit operations of wastewater treatment and their useful combinations are as follows:

Preliminary Treatment. Screens or comminutors are often placed at the influent of wastewater treatment plants to remove or macerate materials and other large objects that may interfere with subsequent treatment unit processes farther down the line of the treatment process. Similarly, grit chambers remove heavy sand and grit that may create problems in the wastewater treatment process and be problematic in the streams or other bodies of water receiving the wastewater effluent.

Sedimentation. The main workhorse of wastewater treatment plants is the settling tank where settleable waste solids are removed by the sedimentation process. These sedimentation techniques are similar to sedimentation tanks in water purification treatment except that due to the fact that the settled waste sludge can become quickly putrescible, mechanical sludge-removal equipment is always included in this process. Primary sedimentation tanks hold waste sewage for 1–2 hours and during this time, 50–70% of the influent suspended waste solids including 30–50% of the influent BOD are deposited on the sedimentation tank's bottom. The resultant sludge is bulky since it is comprised of approximately 95% water and is putrescible because its solids are volatile.

Intermediate, secondary, or final sedimentation tanks remove the formed flocs or sludge developed in biological treatment of wastewaters. When wastewater treatment was first introduced, a recognized goal was the introduction of at least primary treatment in all the industrialized countries. In the United States, Public Law 92-500 mandates a minimum of secondary treatment (i.e., biological treatment). In general, primary sedimentation is a precursor to secondary biological treatment of wastewater.

Chemical Coagulation and Flocculation. The process of chemical coagulation and flocculation for wastewater is similar to the processes used for water purification treatment, although the amount of aluminum and iron salts required may require as much as 100 mg/L. Reductions as high as 80–90% in suspended solids and 70–80% in BOD are obtained with these processes; however, the resultant sludge from chemical wastewater treatment are generally more problematic than the sludge created by primary treatment.

Biological Treatment. Biological treatment units for wastewater treatment are designed to encourage a high rate of growth and activity of scavenging microorganisms. This method of biological treatment has dual benefits: (a) conversion of finely divided, colloidal, and dissolved organic matter into settleable cell substance by biosynthesis; and (b) reduction of the energy level of the remaining organic matter by bioanalysis, degradation, or oxidation. However, the presenting wastes must not be toxic to bacteria and other microorganisms in order for the biological treatment process to be effective in treating wastewaters. As noted previously, secondary or biological treatment is the minimum treatment required to be provided by U.S. communities with few exceptions. Biological treatment removes approximately 85% of BOD resulting in an effluent BOD of approximately 30 mg/L.

Two unique biological treatment processes are in general use in the United States: (a) trickling filtration and (b) activated-sludge aeration.

Diagrams for treatment works illustrating high-rate trickling filter treatment operations and activated-sludge treatment units are presented in Fig. 48-12. A third treatment option is a rotating biological contactor unit, which provides for the establishment of biological growths on a fixed medium without requiring the large areas necessary for trickling filters or activated sludge operations. Descriptions of the typical wastewater treatment operations used in the United States are described below and presented in the diagrams in Fig. 48-12:

- Trickling Filters.** Structurally, trickling filters are beds of stone or plastic media that are 1–4 meters deep with extensive surfaces to which microorganisms adhere as zoogeal slimes or biomasses. These biomasses are supplied with nutrients from waste products trickling over the beds from top to bottom and with oxygen from air sweeping up or down through the filter bed. The wastewaters are distributed over circular filters from arms rotating over the bed propelled by their own jets positioned horizontally from rows of nozzles. The filter effluent is collected by a system of underdrains large enough to carry the flows from the bed and to transmit enough air to the zoogeal slimes to ensure aerobic conditions. The biomass that builds up in the filters is balanced by sloughing into the filter effluent, and is captured in the secondary settling tank. The wastewater effluent is frequently recycled for dilution of wastewater influent and greater efficiency. For highly contaminated wastes or high-volume loading, two or more treatment units may be placed in series. After sedimentation, trickling filters can produce effluents containing less than 20 mg of BOD and suspended solids per liter. The performance of trickling filters is not significantly affected by transient shocks of strong or toxic wastes, implying that the filter slimes have a large reserve capacity that is not easily destroyed by serious effluent challenges. As a result, trickling filters are sometimes introduced as “shock absorbers” in advance of activated sludge units, which are less rugged in their response to taxing challenges from varied and significantly contaminated and toxic wastewaters. The sludge produced by this wastewater treatment process is approximately 0.05–0.1% of the original wastewater flow under treatment. Ordinarily, this sludge contains 92–95% water and 60–70% organic matter on a dry weight basis. Due to the large expanse of area occupied by this type of treatment plant, they are generally not used in large municipalities.
- Activated Sludge Units.** Structurally, activated sludge units are tanks that are 10–15 ft deep in which the wastewater is mixed and aerated together with previously formed biomasses or flocs that are returned to the tank wastewater influent readied for treatment. These flocs act as trickling filter slimes, and aerobic conditions are maintained by the injection of compressed air or oxygen or by absorption of oxygen from the atmosphere at the air-water interface, which is continuously renewed by mechanical stirring or air diffusion. The flocculant solids and the activated sludge are then removed in final settling tanks. The biomass that builds up in the aeration unit is maintained by returning a useful amount of sludge to the process from the final settling tank; therefore, recycling is built into the activated sludge process. Transfer of organic matter to the zoogeal flocs by adsorption and subsequent stabilization and oxidation takes several hours. Sludge return of approximately 25% by volume of incoming sewage produces about 2500 mg of suspended solids per liter of the mixed liquid. The activated sludge wasted from the process is large in bulk due to the high water content and it is highly putrescible due to the fact that the sludge consists principally of living cells.

Modern activated sludge treatment facilities are inherently flexible, allowing variation in returned sludge and air in quantities and methods that meet the changing needs of a community. Three variants of the conventional process serve as examples.

In *modified aeration*, the period of aeration is shortened and the concentration of suspended solids in the mixed liquid is reduced. Less air is required, but the degree of final treatment is also reduced. In *step aeration* or *step loading*, the returned sludge is added to a fraction of the in-flowing sewage, the remainder being introduced at equal distances along the path of the mixed liquid. In this process, the returning sludge renews its activity without being overwhelmed. In *complete mixing*, the influent is introduced transverse to the wastewater flow. This avoids “shock loading” of the sludge even more effectively than step loading. Sludge may be kept in circulation within the aeration unit until it is no longer degradable, a practice favored in small plants or when the organic substances in the wastes under treatment are completely soluble such as the treatment of milk-processing wastes.

Stabilization Ponds. A system of stabilization ponds is constructed in porous or tight soil as rude basins that are approximately 1 meter deep which allows exposure of large surfaces to air and light. Putrescible wastewaters are held in stabilization ponds for several weeks, and during this time, settleable solids sink to the bottom of the pond where organic matter decomposes as well. Under favorable climatic conditions, carbon dioxide, nitrogen, phosphorus, and other nutrients are released into the water during decomposition and stimulate profuse algal growths. During daylight hours, oxygen is produced by photosynthesis and maintains aerobic conditions in the stabilization ponds, while at night, carbon dioxide is lost to the atmosphere. In this wastewater process, seepage and evaporation are not significant.

Except in winter at high latitudes, when covered by ice, properly dimensioned stabilization ponds remain aerobic and both BOD and coliform are reduced to acceptable levels. Climatic and operational factors affect the performance of stabilization ponds so significantly that allowable wastewater loadings cannot be predicted with certainty. Depending upon environmental circumstances, winter loadings may be no more than 20 persons per 1000 m² with summer loadings as high as 400 persons per 1000 m². The green alga *Chlorella* is a common bloom and these small spherical cells are not easily separated from the wastewater effluent; however, the incentive remains to convert waste nutrients into useful algal proteins that can be subsequently harvested safely and economically as animal feed. Because of their large area requirements, stabilization ponds are introduced where waste volumes are not large and land is not too costly for placement of a wastewater treatment facility.

Tertiary Treatment. In many instances in the United States, secondary treatment is insufficient to maintain water quality in receiving streams and lakes, and tertiary treatment is required to preserve water safety. When a tertiary treatment operation involves physical and chemical processes, it is characterized as advanced waste treatment (AWT). Often the tertiary treatment is required in a community to remove additional BOD, which can be accomplished by (a) adding a second stage of biological treatment or (b) by carrying the process to nitrification, which oxidizes oxygen-demanding ammonia in the wastewater, relieving oxygen pressures on receiving streams and water bodies. Other tertiary treatment processes are designed specifically for removal of phosphorus and/or nitrogen in a community with excessive levels in their wastewater. Phosphorus is generally removed chemically, while nitrogen can be removed biologically or by ammonia stripping, a gas-exchange process. These two water-borne nutrients may stimulate eutrophication or fertilization of receiving lakes and other still or slow-moving bodies of water, and removal from effluent wastewater may control eutrophication of receiving waters. Unfortunately, these nutrients may also originate in nonpoint sources such as runoff from fertilized urban and agricultural lands, which are much more difficult to control.

Where wastewater reclamation is intended after tertiary treatment, filtration may be introduced for polishing the wastewater effluent leading to increased clarity and reduction of the chlorine demand for disinfection. In some special instances of tertiary treatment, filters may be employed with activated carbon to reduce the color and the

concentration of synthetic organic compounds in the resulting wastewater effluent. As the efficiency of removal of water-borne pollutants is increased, the cost of removing each additional unit of pollution increases exponentially. After secondary treatment achieves 85% removal, an additional 10% removal in tertiary treatment may cost more than removal of the first 40% of water contaminants. In fact, the goal of 97–99% removal may cost as much as the entire effort of 0–97%. Unfortunately, the operational and energy costs of tertiary treatment may be exceedingly high for some communities. Therefore, municipal authorities are often tasked with demonstrating ample justification in public benefits, including improved public health, before selecting tertiary treatment options.

Disinfection of Wastewaters

Disinfection of wastewater through chlorination is required only where wastewater effluents are to be discharged into waters used for drinking, bathing, or shellfish aquaculture. Chlorination of wastewater effluents may create three problems: (a) chloramines are formed during the process which may be toxic to aquatic life; (b) chlorinated hydrocarbons of potential health significance may be formed in reaction with organics; and (c) beneficial microorganisms as well as pathogens are destroyed, thereby reducing the ability of the receiving water to biochemically stabilize the organic matter remaining in the wastewater effluent being discharged. Therefore, disinfection of wastewater effluents needs to be evaluated carefully in each instance based upon the benefits versus these risks to the water ecosystem. An alternative to chlorination of wastewater effluents is ultraviolet light, which eliminates the negative impact on aquatic life and the creation of chlorinated hydrocarbons. However, to be effective, UV light requires an effluent of consistently low turbidity generally requiring tertiary filtration as well.

Sludge Management

Wastewater sludge is the settled solids removed from the wastewater flow during their passage through primary sedimentation tanks with or without the benefit of coagulating chemicals and biological treatment. Sludge accumulates most of the living organisms that find their way into wastewaters and often teems with ciliated protozoa that feed upon bacteria accelerating the die-away of bacterial pathogens in the sludge product. In addition, sludge dehydration deprives the bacterial pathogens of moisture needed for survival. Fresh primary-tank solids are the most dangerous to human health, solids from biological treatment units less so, solids that have been subjected to biological decomposition still less, and air-dried solids the least hazardous to public health. Heat-dried sludge solids are generally microbiologically safe due to the heat lability of several important microbial pathogens. Although the period of survival of enteric viruses in sludge is still unknown, enteric bacteria such as the typhoid bacillus survive for approximately one week, viable cysts of *E. histolytica* have been isolated from sludge held for 10 days at 30°C, and viable hookworm eggs have been isolated after 41 days. Even in sludge held for 6 months, a 10% survival rate for *Ascaris* sp. eggs was noted. Therefore heat-treatment of sludge is important since pulverized sludge heated to 103°C for three minutes destroyed all *Ascaris* sp. eggs.

Sludge Treatment. Generally speaking, wastewater sludge is of little economic value and generally disposed of in the cheapest fashion possible by each community. In normal circumstances, it is neither feasible nor economic to dispose of large volumes of community wastewater sludge generated without dewatering it, destroying residual organic constituents, or both. Reducing the water content of wastewater sludge is exemplified by the fact that reducing the moisture content of sludge from 96% to 98% to doubles the proportion of solid matter and consequently halves the volume of sludge to be handled and disposed. Dewatering and destruction of organic matter are the primary objectives of sludge treatment, and the wide range of options for the handling of community wastewater sludge is illustrated in Fig. 48-13.⁵²

Sludge Digestion. Wastewater sludge is an abundant source of food for saprophytic bacteria, and different groups of living organisms use

Figure 48-13. Flow diagram of handling options for wastewater treatment plant sludge with arrows indicating possible flow paths. (Adapted from Okun DA, Ponghis G. Community Wastewater Collection and Disposal. Geneva: World Health Organization; 1975.)

different types of nutrients originally contained in the sludge or available after decomposition. As the nutritive value is exhausted, the wastewater sludge becomes stable and in its final state of degradation is inoffensive to sight and smell. As the wastewater sludge is well digested, the end products of digestion are gases, liquids, and residues of mineral and conservative organic substances. Losses by gasification and liquefaction, destruction of water-binding colloids, and physical compaction of solids reduce the bulk of the sludge and prepare it for the dewatering process.

The organic solids in wastewater sludge digest under both aerobic and anaerobic conditions as is illustrated in swamps and river deposits. In the preparation of wastewater sludge for land disposal, it is simpler and more economical to digest the solids anaerobically. The principal gas released during aerobic decomposition of these types of organic compounds is carbon dioxide, while during anaerobic digestion it is combustible methane (65–80% by volume). The potential heat energy of the resultant methane is a prime factor in the economy of anaerobic sludge digestion since methane may be burned under a boiler or in a gas engine. The power released from this anaerobic process as heat and mechanical energy is used for heating buildings and digestion units in wastewater treatment facilities as well as for air compression, pumping, and minor laboratory purposes on-site. On a per capita basis, the normal daily volume of methane gas generated from this decomposition process is about 0.03 m³ from primary settling tanks and nearly the same amount again from biological treatment units. Ground garbage and some organic industrial wastes

may actually increase the methane gas yield appreciably from this operation with the fuel value of this gas at approximately 24,000 kJ (BTUs)/m³.

Anaerobic sludge digestion units are heated, covered, insulated tanks in which wastewater sludge is stored until it is dense, essentially odorless, and readily dehydrated. The temperature of the sludge mass is kept at an optimal operating value of approximately 35°C. In modern, high-volume wastewater treatment installations, digestion is promoted by stirring as well as by heating. Digestion tank capacity requirements range from 0.07 m³ per capita for sludge from primary treatment up to twice that for all the sludge from an activated sludge plant. If the selected wastewater sludge treatment is by mechanical dewatering and heat-drying or incineration, sludge digestion is not necessary; however, capacities may be much less than indicated above because digestion is completed. The destruction of organic matter at high temperatures and pressures by wet combustion is also finding some application for wastewater treatment operations.

Sludge Drying. For small wastewater treatment facilities, the most cost-effective and most common method of dewatering sludge is drying the sludge product in open air. In this scenario, digested sludge is run or pumped onto beds of sand and gravel or other suitable porous material, where part of the sludge moisture evaporates at the surface, and part seeps through the supporting bed into underdrains. Drying times vary with climate and the character of wastewater sludge. The required area is about 0.1 m² per capita for well-digested primary sludge and twice that amount for biological sludge. When the sludge has lost enough moisture to become a spadable cake, it is removed from the drying beds for final disposal. In wastewater treatment facilities of moderate to large size, it is cost-effective to dewater sludge mechanically.

Sludge Disposal. Disposal of wastewater sludge is a challenge for every community, and some disposal practices are being evaluated based upon the possibility of additional environmental pollution from some disposal practices. For example, some seacoast towns pump wet sludge to the ocean; others load partially dewatered sludge onto vessels and transport the product to dumping grounds at sea. Dewatered sludge is a suitable material for disposal in a properly designed landfill by itself or in combination with municipal refuse. Wet sludge can provide useful moisture, humus, and nutrients for composting operations. The use of properly treated sludge as a fertilizer may be warranted as a measure of nitrogen and phosphorus conservation and soil building. To this purpose, some municipalities dispose of wet sludge to local farmers for use as fertilizer; however, this practice is questioned by many professionals. Tank trucks with fixed nozzles that plow and discharge the liquid sludge into the soil have become popular. In general, only commercially dry (heat-dried to less than 10% moisture) activated sludge has been found sufficiently marketable in the United States for use on lawns and golf greens to meet the expense of dewatering and heating.

Because of the low cost and the convenience of chemical fertilizers, the production of heat-dried sludge for sale is seldom economically feasible. In the few instances where heat-dried activated sludge is marketed, as from Milwaukee, Wisconsin, the capital investment in the facilities needed for sludge preparation for sale has already proven to be financially sound. Where suitable sites for sludge disposal are not economically available, the sludge must be incinerated leaving only the resultant ash for disposal. In some communities, incineration of sludge with municipal refuse has been feasible as a disposal mechanism. The ultimate disposal of wastewater sludges, particularly if they contain infectious pathogens, heavy metals, and synthetic organic chemicals, has raised many questions and public health concerns. All of the methods of disposal, whether by discharge to sea, application to agricultural land, disposal in landfills, composting, or incineration have come under criticism. The EPA has been addressing this problem since passage of the 1977 Clean Water Act Amendments. The EPA regulations include (a) contaminant limits for heavy metals and synthetic organic compounds in sludge in milligrams per kilogram; (b) loading rates in kilograms per hectare for various land applications;

and (c) technology, monitoring, and reporting requirements. The ultimate choice for disposal will likely involve land application and landfills for communities that have such land available to them, and for larger cities that do not have these options, incineration is generally the most optimal choice. Unfortunately, the choice of application to land and disposal in landfills may result in the potential for significant impact in water reserves and supplies.

Wastewater Disposal

Outfall sewers in each community are used to discharge treated wastewater into the receiving bodies of water in the municipality. If outfall sewers are to be effective, they must be designed and positioned to disperse the treated wastewater effluent quickly and thoroughly throughout the receiving water. In running streams, this task is not difficult; however, in lakes, tidal estuaries, and the ocean it is not a simple task. Outfall sewer locations must be selected with consideration to the location of the water purification plant intakes, shellfish layings and aquaculture operations, recreational beaches, and other recreational boating areas. Proper positioning requires analysis of water movements of the water body receiving the treated wastewater effluent such as patterns of normal currents, wind-induced and tidal movements, and eddy diffusion created by differences in the density of the treated sewerage and the receiving water. Treated wastewaters are generally warmer and lighter than the water into which they are discharged. For example, disposal of treated wastewater into a receiving body of water near its surface, especially the brackish waters of tidal estuaries, may result in the wastewater laying on top of the diluting water, not mixing appreciably, and forming a contamination slick noticeable for many miles. The temperature-density equilibrium of this disposal process is so delicate that every situation and season must be handled separately to prevent these environmental complications. Under some conditions, subsurface discharge of wastewaters into a deep freshwater lake may build up a large mass of undispersed wastes around the treated wastewater outfall. However, this technique is frequently used and is often an effective method of dispersal since the lighter wastewater liquid rises like a smoke plume through the receiving body of water, resulting in appropriate dispersion. This process may be enhanced by discharging the wastes through a number of outlets or diffusers spaced apart to prevent interference.

The purification accomplished in receiving streams can be improved by engineering works that supply water for dilution during periods of low flow, lengthen the time of downstream passage of the receiving water, or introduce air into the flowing water either directly by injection or indirectly by agitation. In low-water situations, water is released from upland reservoirs in the same or neighboring catchment areas or water is pumped back or recycled from the more voluminous flows of lower river reaches or other water courses. Travel times and self-purification are normally lengthened by impoundages within a polluted stretch of the receiving stream. Compressed air has been introduced with some success into critical reaches of polluted streams from stationary compressors and piping or from floating barges.

Where running water has been introduced into kitchens, bathrooms, laundries, and outbuildings of farms and residences where there is no public sewer system, the resident wastewaters must be disposed of on-site. Usually, this is done through septic tanks or cesspools, which involve simple settling and subsurface leaching of wastewater effluents. In order for these systems to be effective, the amount of sewage cannot be large in relation to the leaching area, and the receiving soil must be porous. Where the volume of wastewater is high or the soil is nonporous, more sophisticated and costly treatment methods patterned after municipal processes must be introduced. Of special concern is the contamination from both chemical and biological agents of nearby wells. Septic tanks derive their name from the septic or anaerobic condition created by the decomposition of the settling solids or accumulating sewage sludge. All septic tanks must be emptied of accumulated sludge periodically, and this seepage is generally disposed of in community wastewater treatment plants.

The ability of soil to absorb settled sewage is explored by digging test holes, filling them with water, and clocking the time required

for the water to drop a given distance in the stratum in which leaching is to take place. In some states, soil profiles are used to determine the ability of the soil to absorb settled sewage. Septic tanks and tile fields may be suitable for truly rural areas; however, this method has also been adopted by housing developments, where tile fields may become clogged and septic tanks overflow creating a local health hazard. Housing developments constructed in peri-urban areas not accessible to municipal sewerage systems have led to the proliferation of package plants for wastewater treatment. These plants do conform to most modern practices often providing tertiary treatment and may be obliged by NPDES permits to meet exacting wastewater effluent standards. However, their operation and maintenance becomes the responsibility of the homeowner, who has limited capacity to manage such facilities. Even where private utility companies are employed to operate these package plants, their performance record may suffer. The quality of personnel and the cost of monitoring small treatment plants are often similar to running large treatment facilities. Therefore, it is preferable that new housing developments be small enough to permit septic tanks, and when greater densities are planned, sewerage service from a nearby large municipality be required. In particular, package plants should be avoided in water supply watersheds.

Wastewater Reclamation

Wastewaters are a water resource, and their reclamation for reuse serves both to conserve limited quantities of freshwater and to reduce the load of pollution on receiving bodies of water. The following water services have already been provided by wastewater reclamation: (a) irrigation, both agricultural and urban; (b) industrial use, both process and cooling activities; (c) recreational, use through establishment of lakes and ponds; and (d) nonpotable residential and commercial use, including toilet flushing. Reclamation of wastewater for potable purposes is currently not recommended as U.S. drinking water practice requires that priority should be given to the purest water sources for drinking water. However, wastewater reclamation for irrigation and land disposal of wastewaters may provide a viable opportunity for reuse since reclaimed wastewaters for irrigation of growing crops or lawns may be beneficial.

Land disposal of wastewater may be useful in smaller communities where ample land is available and soil conditions are appropriate for wastewater disposal. The nutrients in wastewaters that would be problematic if discharged to a body of water, on land may constitute an important fertilizer, particularly as chemical fertilizers become more costly. Each community situation is unique, requiring certain rates of application and requiring specific pretreatment. In addition, since wastewaters are produced year-round but cannot be applied to land during periods of heavy rainfall or freezing, seasonal storage is also required.

Where wastewaters are to be reused, the treatment needs to be tailored to the specific reuse plan with more intensive treatment and more stringent standards as the uses become of greater public health concern. The California Department of Health has prepared *Wastewater Reclamation Criteria*, which guides the regulation of many hundreds of reclamation projects in the state.⁵³ The highest degree of treatment required is for nonpotable distribution systems including urban irrigation, toilet flushing, industrial use, spray irrigation of food crops, and nonrestricted recreational impoundments (i.e., those that permit body contact). Essential to such reclamation use of wastewater is the reliability of operation of the treatment facilities and continuous monitoring of effluent quality with a capacity to automatically reject wastewater effluent that does not meet the bacterial, turbidity, and chlorine residual standards.⁵³

► PROTECTION OF WATER QUALITY AND PUBLIC HEALTH

The need for potable water is vital to basic human survival and is an essential cornerstone of public health. Water also plays a critical role in all aspects of the nation's complex industrial society, and access to uncontaminated water is essential to food processing, crop production, and livestock health. In June, 2005, the Administrator of the

Environmental Protection Agency predicted that *safeguarding the country's water supply would be one of the pressing environmental concerns of the twenty-first century*. EPA Administrator, Stephen L. Johnson, stated, "I believe water, over the next decade and further, will be *the* environmental issue that we as a nation and, frankly, as a world will be facing. Keeping the nation's water safe and secure is an area of vulnerability for the United States and also an opportunity for us." (Emphasis added.)⁵⁵ Conscientious stewardship of water requires vigorous water source protection, enduring water pollution control, and aggressive water quality management in order to ensure access to a water supply that provides both the quantity and quality necessary to preserve this environmental resource and prevent water-related disease.

Contamination of water by infectious pathogens, chemical compounds, or radiologic agents has the potential to affect the health of millions of residents in the United States. However, preservation of water quality and prevention of water-borne disease are complicated tasks requiring a coordinated effort from many diverse disciplines ranging from water engineers to practicing health-care providers. The complexity of water quality management is expansive as illustrated in this chapter and includes water source protection, water purification engineering, wastewater treatment and pollution control, and water-borne disease prevention. Any successful strategy to ensure water quality and safety in the United States must include a multidisciplinary team effort of educated partners working together to address the many significant challenges facing our nation in the future as we protect our precious resource of water.

► ACKNOWLEDGMENT

The author wishes to extend a special thanks to Ms Laura Campbell for her information technology and graphic design expertise during preparation of this manuscript.

Hazardous Waste: Assessing, Detecting, and Remediation

William A. Suk

► INTRODUCTION

The past century of industrial, military, and commercial activity worldwide has resulted in hundreds of thousands of hazardous waste sites where organic compounds and metals contaminated surface and subsurface soils, sediments, ground, and surface waters. In order to reduce risks to human and ecologic systems, considerable time and money have been spent remediating these sites since passage of major environmental legislation (e.g., Superfund). Hazardous waste management is undoubtedly one of the most important environmental issues. Despite the common agreement that industrial production without waste is our long-term goal, there will be an ongoing need for proper management of wastes for years to come. Further, there is a need to continue to sharpen the cause and effect relationships between a polluted environment and poor public health. These relationships resulting from exposure to hazardous wastes are more insidious and subtle manifestations in children and adults. The challenge is to better understand these contaminants, and to determine under which conditions and at which levels they pose a threat to human health and the environment.

► DEFINITIONS OF WASTE

Classifications and Properties of Waste

Wastes may be classified by their physical, chemical, and biological characteristics. An important classification criterion is their consistency. Solid wastes are waste materials having less than approximately 70% water. This class includes municipal solid wastes such as household garbage, industrial wastes, mining wastes, and oil-field wastes. Liquid wastes are usually wastewaters, including municipal and industrial wastewaters, that contain less than 1% suspended solids. Such wastes may contain high concentrations (greater than 1%) of dissolved species, such as salts and metals. Solid waste, as defined under the Resource, Conservation, and Recovery Act (RCRA) is any solid, semisolid, liquid, or contained gaseous material discarded from industrial, commercial, mining, or agricultural operations and from community activities. Solid waste includes garbage, construction debris, commercial refuse, and sludge from water supply or waste treatment plants, material from air pollution control facilities, and other discarded materials. Solid waste does not include solid or dissolved materials in irrigation return flows or industrial discharges. Sludge is a class of waste intermediate to solid and liquid wastes. Sludge usually contain between 3% and 25% solids, while the rest of the material is water-dissolved species. These materials, which have a slurry-like

consistency, include municipal sludge, which is produced during secondary treatment of wastewaters, and sediments found in storage tanks and lagoons.

Federal regulations classify wastes into three different categories, based on hazard criteria: (a) nonhazardous, (b) hazardous, and (c) special. Nonhazardous wastes are those that pose no immediate threat to human health and/or the environment, for example, municipal wastes such as household garbage and many high-volume industrial wastes. Hazardous wastes are of two types: (a) those that have characteristic hazardous properties, that is, ignitability, corrosivity, or reactivity, and (b) those that contain leachable toxic constituents. Other hazardous wastes include liquid wastes, which are identified with a particular industry or industrial activity. The third category from industry is classified generically as special wastes by origin, and is regulated with waste-specific guidelines. Examples include mine spoils, oil-field wastes, spent oils, and radioactive wastes. In the United States, all hazardous wastes are regulated under Subtitle C of RCRA.

Hazardous waste has been defined as myriad substances that cause toxicity to living organisms. For all practical purposes, toxic waste and hazardous waste are interchangeable. As indicated, hazardous waste is defined as solid waste that is acutely toxic or possesses one or more of the following criteria: ignitability, corrosivity, reactivity, or toxicity.¹ Traditionally, when discussing radioactive or medical waste, the term “mixed waste” is used (see the section on Radioactive and Mixed Wastes). Toxic substances occur naturally in soil, water, and air; however, thousands of toxic substances are anthropogenic. The anthropogenic substances are of particular concern because of the quantities that are produced, their dissemination and persistence, and because, historically, their release into the environment has not been well controlled. Furthermore, most anthropogenic compounds are organic and are readily absorbed by living organisms.

Hazardous Wastes

Hazardous waste is a subset of solid wastes that poses substantial or potential threats to public health or the environment. It is specifically listed as a hazardous waste by exhibiting one or more of the characteristics of hazardous waste (i.e., ignitability, corrosivity, reactivity, and/or toxicity), being generated by the treatment of hazardous waste, or being contained in a hazardous waste. Some environmental laws list specific materials as hazardous waste. For example, hazardous waste can exist in the form of a solid, liquid, or sludge and can include materials such as polychlorinated biphenyls (PCBs), chemicals, explosives, gasoline, diesel fuel, organic solvents, asbestos, acid, metals, and pesticides. Environmental laws also list materials that must be treated and managed as hazardous.

The true amount of hazardous wastes generated is not known, although the approximate amount is 400 million tons a year. The Organization for Economic Cooperation and Development (OECD) estimates that, on average, a consignment of hazardous wastes crosses the frontier of an OECD nation every 5 minutes of every day all year. More than 2 million tons of those wastes are estimated to cross national frontiers of OECD European countries annually on the way to disposal sites. Other movements, which are illegal, are motivated by the possibility of important gains in transferring the problem to places where controls or standards are less strict. Another motive may be that vast territory and scant resources in countries that import products make any attempt at serious surveillance impossible. Some countries also prefer to manage their hazardous waste problem by transporting it at lower cost to other countries.

The quantity of generated wastes of all kinds is still increasing, and the rapid pace of industrialization worldwide will necessitate careful attention. In response to growing recognition of health and environmental risks associated with hazardous wastes, governments have brought into force a series of national laws to control the generation, handling, storage, treatment, transport, disposal, and recovery of these wastes. To mitigate such potential threats, urgent measures should be taken to avoid or reduce generation of hazardous wastes, optimize environmentally sound recovery of wastes, reduce to a minimum or eliminate transboundary movements of hazardous wastes, manage wastes in an environmentally sound and efficient way, and dispose of wastes as close as possible to the place where they are generated.

In exceptional cases, exporting hazardous wastes to a country capable of eliminating them properly may be safer for human health and the environment if adequate storage or treatment is not possible in the generating country or until appropriate technology and adequate infrastructure are available. Increased international cooperation is necessary to help developing countries manage and treat the wastes they generate in an environmentally sound way. There have been a number of conferences and workshops to assess and evaluate hazardous waste exposures and to provide a framework for future research and collaborative efforts to address these problems.^{2,3,4,5}

Thousands of new chemicals are being developed and introduced annually into commerce. Only a small fraction of these substances have been tested for toxicity. Hundreds of millions of tons of hazardous waste are generated annually and the quantities are increasing.⁶ A small fraction of toxic waste in the environment is from household use; the greatest production comes from industry, particularly the chemical and petroleum industries.⁷ Another leading generator, the agricultural chemical manufacturing industry, produces chemicals, such as pesticides, that by their very nature are toxic not only to their targets, but also to other life forms. The magnitude of problems created by toxic substances is immense and ubiquitous, while the impact is, to a great extent, unknown.

► TRANSPORTATION OF HAZARDOUS WASTES

Toxic substances and other contaminants know no borders and, as such, the issues surrounding them have gained a presence in international forums. In 1972, 70 governments met in Sweden for the United Nations Conference on the Human Environment. This conference brought environmental issues to an international level. Since that time more than 170 international environmental treaties have been signed,⁸ demonstrating the global commitment to the issue. In 1976, the United Nations Environment Program's International Register of Potentially Toxic Chemicals was established. This Register collects information on hazardous waste and distributes it to anyone who requests it. The Basel Convention, 1989, established the Control of Transboundary Movement of Hazardous Wastes and Their Dispersal. With more than 100 signatories on this treaty, the movement of wastes is now managed throughout much of the world. A pivotal conference sponsored by the United Nations and held in Rio de Janeiro, Brazil, in 1992, United Nations Conference on Environment and Development (Rio Earth Summit), focused on the issues of biodiversity and sustainable

development.⁹ This report included a chapter on both toxic waste and hazardous waste, thus demonstrating the priority of the effective control and management of such releases into the environment. Protection of the environment in conjunction with economic development is closely related in any proposals that support future global welfare.

► POLICIES MANAGING THE FATE OF TOXIC SUBSTANCES

In the 1960s, the United States Congress began its journey in establishing environmentally oriented laws. In 1966, the Division of Environmental Health Science was established in the Department of Health, Education and Welfare to study the health effects of environmental agents. In 1969, it was elevated to Institute status (National Institute of Environmental Health Sciences [NIEHS]), thus emphasizing the importance of environmental implications on human health. In the same year, the United States Congress passed the National Environmental Policy Act, requiring federal agencies to assess the impact of their actions on the environment. A year later the U.S. Environmental Protection Agency (EPA) was established. EPA is responsible for working with state and local governments to control and prevent pollution in areas of solid and hazardous waste, pesticides, water, air, drinking water, and toxic and radioactive substances. Since that time numerous other acts, including the Toxic Substance Control Act (1976) (TSCA), have been passed with the goal of maintaining a healthy environment. TSCA requires that producers of toxic substances be held accountable for the release of these substances into the environment. In 1976, the RCRA gave EPA authority to control hazardous waste from "cradle-to-grave." This control includes the minimization, generation, transportation, treatment, storage, and disposal of hazardous waste. RCRA also set forth a framework for the management of nonhazardous solid wastes. RCRA focuses only on active and future facilities and does not address abandoned or historical sites. The National Toxicology Program was established in 1978 as an interagency organization to provide toxicological information on potentially hazardous chemicals to regulatory and research agencies and to the public.

The Comprehensive, Emergency Response, and Compensation and Liability Act (CERCLA (also known as Superfund)) was passed in 1980 to address immediate and long-term threats to the public health and the environment from abandoned or active sites contaminated with hazardous or radioactive materials. Under the Superfund program, EPA has the authority to clean up the nation's worst hazardous waste sites, using money from a trust fund supported primarily from a tax on chemical feedstocks used by manufacturers. Companies or individuals responsible for the wastes are identified by EPA, if possible, and made to pay for the cleanups. The Superfund Amendments and Reauthorization Act (SARA) of 1986 reauthorized CERCLA to continue cleanup activities around the country. Several site-specific amendments, definitions, clarifications, and technical requirements were added to the legislation, including additional enforcement authorities. Also under the SARA, the Superfund Hazardous Substances Basic Research Program (Superfund Basic Research Program) was established. The Superfund Basic Research Program is a multidisciplinary program administered by the NIEHS. This program is committed to advancing the state of the science reducing the amount and toxicity of hazardous substances and, ultimately, preventing adverse human health effects.¹⁰

► ASSESSING AND DETECTING ADVERSE HEALTH EFFECTS OF HAZARDOUS WASTES

Studies of the adverse health effects of hazardous waste must contend with many challenges. Exposure is usually ill defined and often misclassified, historical data may not be available or are otherwise problematic, and mixed chemical exposures are likely and may not always be uniform across a population. The exposed population is often

small or incompletely determined. Resources for study may also be limited. The endpoints to be studied may be uncertain, leading to consideration of multiple endpoints.

Sediment

Sediment—the “muck” at the bottom of rivers and other bodies of water—is composed of materials transported and then deposited by water or wind and represents a surprisingly rich and productive environment. The organisms that live in it form the base of a food chain that stretches all the way up to humans.

Areas of sediment contamination occur in coastal and inland waterways, in clusters around larger municipal and industrial centers, and in regions affected by agricultural and urban runoff. The EPA’s Report to Congress on Contaminated Sediment (prepared in conjunction with the NOAA, the Army Corps of Engineers, and other federal, state, and local agencies) states that sediment contamination exists in every region and state of the country and that approximately 10% of the sediment underlying U.S. surface waters is sufficiently contaminated with toxic pollutants to pose potential risks to fish and to humans and wildlife who eat fish. Much of the contaminated sediment in the United States was polluted years ago by improper disposal or run-off of chemicals including PCBs, pesticides, and mercury which have since been banned or restricted. Sediments constitute a major source of persistent bioaccumulative toxic chemicals which may pose threats to ecological and human health even after contaminants are no longer released from point and nonpoint sources. Documented adverse ecological effects of contaminants in sediments include skin lesions, increased tumor frequency, and reproductive toxicity in fish; reproductive failure in fish-eating birds and mammals; and decreased biodiversity in aquatic ecosystems. Threats to human health occur when sediment contaminants bioaccumulate in fish and shellfish tissues consumed by humans. Fish advisories have been issued for more than 1500 water bodies in 46 states for pollutants such as mercury, dioxins, PCBs, PAHs, and pesticides such as chlordane and chlorpyrifos.

More than 10 federal statutes provide authority to the USEPA program offices to address the problem of contaminated sediment. USEPA has ongoing efforts to prevent further sediment contamination, to develop methodologies to improve the assessment of sediment contaminants, and to design remediation technologies to clean up existing sediment contamination.

Bioavailability

The bioavailability of an environmental contaminant—the degree to which it can be assimilated by an organism—is a critical factor in decision-making processes related to both public health and remediation strategies. While it seems like a simple concept, bioavailability has the potential to affect:

Risk assessment—Incomplete understanding of the bioavailability of a contaminant is a significant factor complicating the evaluation of the risk of exposure to a toxic contaminant.¹¹ Historically, exposure to hazardous materials in the environment has been quantified through the use of standard laboratory analytical techniques geared toward determining the total amount of material found in the sample under consideration. It may not be appropriate to measure total concentrations in the environment, as different contaminants or different species of an elemental contaminant may exhibit different levels of mobility, both in the environment and once inhaled, ingested, or placed in contact with the skin. If a contaminant is sequestered in the soil or sediment, or has limited mobility in tissues, it may not represent a significant human or environmental risk.

Identification of remediation goals—Bioavailability is one of the many complex elements that may be taken into consideration when cleanup criteria are determined for a contaminated site. The question “How clean is clean enough?” is made even more difficult by an incomplete understanding of the bioavailability of contaminants at a site and the factors that influence bioavailability.

Selection of appropriate remediation strategies—Bioremediation is often less expensive and more efficient than conventional remediation techniques. However, for bioremediation methods to work, the contaminant must be available to the bacteria or plant used in the cleanup effort.

Fate and transport—Bioavailability of contaminants in soils is a complex process that is influenced by the interplay of both chemical and biological factors. For example, the chemical process of adsorption is generally thought to decrease the bioavailability of certain contaminants in soils, while some evidence suggests that the presence of bacteria in soils may increase the accessibility of soil contaminants to living organisms.

Biomarkers

The majority of diseases are the consequence of both environmental exposures and genetic factors. To understand the relationship between exposure and adverse health effects, scientists are working to identify biomarkers—key molecular or cellular events that link a specific environmental exposure to a health outcome. The identification, validation, and use of biomarkers in environmental medicine and biology will depend fundamentally on an increased understanding of the mechanism of action and the role of molecular and biochemical functions in disease processes.¹² For environmentally-induced diseases, molecular biomarkers will play a key role in understanding the relationships between exposure to toxic environmental chemicals, the development of chronic human diseases, and identifying those individuals at increased risk for disease. Although much progress has been made to identify potential biomarkers, the challenge still remains to validate, in a robust manner, the accuracy, reproducibility, specificity, and sensitivity of biomarkers, and to assess the feasibility and cost-effectiveness of applying biomarkers in large population-based studies. Such validated biomarkers will be invaluable in the prevention, early detection, and early treatment of disease.

There are three broad categories of molecular biomarkers that are commonly used in the field of environmental health:

Biomarkers of exposure quantify body burden of chemicals or metabolites and are usually applied early in the exposure-disease paradigm. These markers are powerful tools for epidemiologists, allowing relatively accurate measurement of external and/or internal dose of an environmental agent. However, the applicability of biomarkers of exposure is often limited by their relatively short half-life, providing information on exposure over a period of days to months compared to the natural history of the disease that spans years or decades. There are noteworthy exceptions to the transient nature of exposure biomarkers, such as pesticide residues in body fat and blood that can persist over months and years. Nevertheless, the timing of sample acquisition for measurement of environmental exposures and the study of interactions with genetic susceptibilities is a critical factor in study design.

Biomarkers of effect detect functional change in the biological system under study, and allow investigators to predict the outcome of exposure. DNA damage (e.g., adducts, chromosomal aberrations, loss of heterozygosity at specific chromosome loci) is frequently used as biomarkers of effect, although there is often no clear delineation from biomarkers of exposure. For example, DNA adducts can be interpreted as biomarkers both of exposure and biological effect.

Biomarkers of susceptibility indicate the interindividual variation in mechanistic processes on the continuum between exposure and effect. An individual’s susceptibility to environmentally mediated disease may arise from genetic causes or from nongenetic factors such as age, gender, disease state, or dietary intake. Genetic polymorphisms may function as biomarkers of susceptibility; but it is important to keep in mind that it is actually the phenotype that is of importance for the final response to the hazardous insult.

Agent-Specific Problems at Hazardous Waste Sites

New regulations for disposal of wastes on land require periodic monitoring not only of metals but also of organic pollutants (Table 49-1).

TABLE 49-1. MAJOR GROUPS OF ORGANIC CHEMICALS

Pollutants by Group	Origins and Comments
Aldrin/dieldrin, heptachlor, DDT/DDE/DDD lindane, toxaphene, malathion, hexachloro-2,4-dichlorophenoxyacetic acid (2,4-D) hexachlorobutadiene Benzo[a]pyrene, benzo[a]anthracene, phenanthrene	Pesticides and herbicides. Some are found in household chemicals. Many chlorinated pesticides have been banned from use.
Polychlorinated biphenyls (PCBs) Dioxins, furans	Motor oils and diesel fuel. These occur naturally as by-products of fuel combustion. Electrical and chemical manufacturing. PCBs are banned. By-products from the synthesis of phenol-based pesticides, such as 2,4-D.
Phenol	Household products and disinfectants.
Pentachlorophenol	Wood preservative. Pentachlorophenol is very persistent in the environment.
Benzene, methylene chloride, methylethyl ketone tetrachloroethylene, trichloroethylene, hexachlorobutadiene	Some household products such as paints. These chlorinated solvents are very volatile.
Vinyl chloride, bis(2-ethylhexyl)phthalate, tricresyl phosphate, dimethylnitrosamine, benzidine, 3-3'-dichlorobenzidine	Plastics and plasticizers.

Source: Title 40, Code of Federal Regulations. Part 257.

Arsenic. Arsenic is listed first on the ATSDR 2001 CERCLA Priority List of Hazardous Substances and is found at over 70% of all Superfund sites. While both natural and anthropogenic sources contribute to arsenic contamination of soil, sediment, and water, contamination at Superfund sites primarily results from the disposal of arsenic-containing compounds from industrial and mining practices. For example, due to improper industrial disposal, lake sediments from the Aberjona watershed area of Boston contain as much as 1–2% arsenic by weight.

Although exposure to arsenic has been associated with a variety of human health effects, the toxicity of arsenic is particularly difficult to characterize as a single element, because its chemistry is complex, and there are many arsenic compounds. Specifically:

- Arsenic is considered a probable human lung, skin, and bladder cancer carcinogen. Arsenic is unique in that it is the only known agent that increases lung cancer following systemic (drinking water) rather than inhalation exposure.
- Arsenic exposure has been implicated in lymphoma, nasopharyngeal, stomach, colon, kidney, and prostate cancers.
- There is a strong synergistic association between arsenic exposure and cigarette smoking for the risk of lung cancer.
- One of the major concerns is that there is not an established dose-response curve for arsenic-induced cancer.
- Arsenic can contribute substantially to the development of vascular diseases.

Remediation of arsenic-contaminated sites is complicated by several factors:

- As an element, arsenic cannot be destroyed or broken down by biological or normal physical processes into simpler, less toxic substances.
- At Superfund sites, arsenic is generally present in complex mixtures, often with high levels of organic compounds.
- Some natural geologic formations contain high levels of arsenic that can leach into groundwater.

The body of knowledge built on by research and the associated base of data concerning the potential health effects of exposure to arsenic were taken into consideration by the USEPA in its review and action to reduce the Maximum Contaminant Level (MCL) of arsenic in drinking water from 50 ppb to 10 ppb.

Lead. Lead can be found in all parts of our environment. Much of it comes from human activities including burning fossil fuels, mining, and manufacturing. Due to past major reductions and now the

elimination of lead in gasoline, there has been a significant decrease in public exposure to lead in outdoor air. Remaining air pollution sources include lead smelters, incineration of lead batteries, and burning lead-contaminated waste oil. However, the most common sources of current lead exposure come from old homes containing lead-based paints and lead-contaminated soil.

Because lead persists in the environment, it continues to be a contaminant of concern to the USEPA and ATSDR. Lead has been found in at least 70% of the National Priorities List sites identified by the USEPA. Lead is listed second on the 2001 ATSDR Priority List and is one of six “Criteria Air Pollutants” for which the USEPA has developed health-based national air-quality standards.

Lead overexposure is a leading cause of workplace illness. Exposure to high levels of lead can damage the blood, brain, nerves, kidneys, reproductive organs, and the immune system. Lead poisoning is still the leading environmentally induced illness in children. Children are particularly susceptible to the harmful effects of lead because they are undergoing rapid neurological and physical development. Even at repeated exposure to small doses, lead can be a problem because it accumulates in the body. Lower levels that are more commonly associated with current exposures can result in impaired cognitive functioning, subtle neurobehavioral effects, and developmental effects in children, and have been associated with higher blood pressure in middle-aged men.

Decades of research have been devoted to ascertaining the health effects associated with lead exposure and the underlying mechanisms for these detrimental effects. Even still, more research is needed. As the tools have become more sophisticated and sensitive, questions that could not even be considered in the past can now be studied. With this increased sensitivity, subtle health effects are now being detected. Because lead is persistent in the environment, continued research focused on low-level health effects and methods of prevention, including environmental remediation, is still necessary.

Dioxin. “Dioxin” is a term commonly used to refer to the chemical 2,3,7,8-tetrachlorodibenzo-p-dioxin or TCDD. In all, there are 210 isomers of polychlorinated dibenzodioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs)—collectively these compounds are often referred to as dioxin-like compounds or “dioxins.” The toxicity of dioxins varies with the position and number of chlorine atoms—many dioxins are only slightly toxic and some are nontoxic. However, animal studies have shown that TCDD is very toxic—it causes cancer and is a known endocrine disruptor that can alter reproductive, developmental, and immune function. Dioxins are among the 12 man-made chemicals targeted for global phase-out by the UN Treaty on Persistent Organic Pollutants (POPs).

Dioxins are chemical contaminants that have no commercial use. They are formed as by-products in the burning of chlorine-based chemical compounds with hydrocarbons. Municipal waste incineration, forest fires, backyard trash burning, and manufacturing processes to produce herbicides and paper contribute to the production of dioxins. As a consequence, trace amounts of dioxins and furans are present in virtually all global ecosystems.

Because dioxins are present in low levels as environmental contaminants in food, people are constantly exposed to them through ingestion. Even though they are not found at high concentrations in food, over time, dioxins accumulate in human tissues because they are not readily excreted or metabolized.

Factors impacting the remediation of dioxin-contaminated sites include the following:

- Dioxins are stable to heat, acids, and alkali
- Dioxins bind tightly to soil and are virtually insoluble in water. This increases the difficulty of soil remediation but decreases the extent of groundwater contamination
- Dioxins can be broken down by ultraviolet light—most have a half life of 1–3 years
- Dioxin uptake by plants from soil is limited—no detectable amounts of dioxin are found in grain and soybeans.

Polychlorinated Biphenyls. PCBs are a family of 209 chemical compounds for which there are no known natural sources. Each consists of 2 benzene rings and 1–10 chlorine atoms; PCBs vary in degrees of toxicity. Importantly, PCB-contaminated sites are usually contaminated with mixtures of PCBs, and the toxicity of any mixture is dependent upon the interactions of the individual congeners.

Because of their stability, resistance to fire, and electrical insulating properties, PCBs were widely used in a variety of industrial applications. Unfortunately, the very characteristics of PCBs that made them applicable for industrial uses make them problematic in the environment. PCBs are very persistent. They are generally unalterable by microorganisms or by chemical reaction. According to the ATSDR, PCBs have been found in approximately one-third of the National Priorities List sites identified by the USEPA.

PCBs are extremely toxic—they are listed fifth on the ATSDR's 2001 CERCLA Priority List of Hazardous Substances. PCBs have been demonstrated to cause a variety of adverse health effects in animal studies. PCBs not only cause cancer but can adversely affect the immune, reproductive, nervous, or endocrine systems. Studies in humans provide supportive evidence for potential carcinogenic and noncarcinogenic effects of PCBs as well. It has been suggested that many of the adverse health effects associated with PCB exposure are a result of its ability to mimic the body's natural hormones (e.g., estrogen), and that this "endocrine (hormone) disruption" can lead to infertility, certain types of cancer, and other hormone-related disorders.

Volatile Organic Compounds. Organic compounds that evaporate easily are collectively referred to as volatile organic compounds (VOCs). VOCs are widely used as cleaning and liquefying agents in fuels, degreasers, solvents, polishes, cosmetics, drugs, and dry-cleaning solutions. VOCs can have direct adverse effects on human health. Many VOCs have been classified as toxic and carcinogenic. VOCs of particular significance to human and environmental health include benzene, toluene, ethylbenzene, and xylene (BTEX), methyl t-butyl ether (MTBE), ethylene chloride, chlorobenzene, trichloroethylene (TCE), and perchloroethylene.

Most VOCs found in the environment result from human activity—as the result of spills or inappropriate disposal, or as uncontrolled emissions from industrial processes. When VOCs are spilled or improperly disposed of, a portion will evaporate, but some will soak into the ground. Water can transport VOCs in soil, potentially carrying them to the groundwater table. When VOCs migrate underground to nearby wells, they can end up in drinking-water supplies.

VOC contamination is recognized as a critical issue for both air and water:

- USEPA estimates that VOCs are present in one-fifth of the nation's water supplies.
- Because VOCs are considered a precursor for ground-level ozone (smog), they are one of the six "Criteria Air Pollutants" for which the USEPA has developed health-based national air quality standards.
- Remediation of VOC-contaminated soils and groundwater is complicated because it is common for the component organic pollutants to exist as separate liquid phases. Also, the migration of the dissolved plume is unique to each site. VOC contaminant transport is governed by the quantity of VOC in the plume; its relation to biological and chemical properties of soils and groundwater; the hydraulic properties of the geologic materials; and any structural features which can act as barriers or conduits for fluids. Therefore, it is difficult to generalize properties of VOC transport from one site to another.

Mercury. Exposure to mercury occurs from inhalation, ingestion, and absorption. Primary sources of exposure are spills, incineration, contaminated water and food, and dental or medical treatments. Mercury is listed third on the ATSDR 2001 CERCLA Priority List of Hazardous Substances. Mercury is found at approximately 50% of all Superfund sites.

Mercury enters aquatic and terrestrial systems from the atmosphere primarily in an inorganic form. However, under conditions that favor bacterial sulfate reduction, inorganic mercury is methylated to form methylmercury, a potent neurotoxin that bioaccumulates in fish. Wetlands, lake sediments, and anoxic bottom waters are three locations where methylmercury is rapidly formed as an incidental by-product of bacterial sulfate-reduction. As a consequence of atmospheric deposition of inorganic mercury, its metabolized form, methylmercury, can be found in fish from lakes remote from the initial point sources of contamination.

Mercury contaminants are present in the environment in three forms—elemental mercury, inorganic mercury salts (ex., chlorine, sulfur), and organic mercury compounds such as methylmercury. The nervous system is very sensitive to all forms of mercury. Exposure to high levels of elemental, inorganic, or organic mercury can permanently damage the brain, kidneys, and developing fetus. Methylmercury and elemental mercury vapors are more harmful than other forms, because more mercury in these forms reaches the brain. Effects on brain function may result in irritability, shyness, tremors, or changes in vision, hearing, or memory. The human cancer data available for all forms of mercury are inadequate to draw conclusions as to its carcinogenic potential.

On March 1, 2002, the Food and Drug Administration (FDA) announced that it will soon schedule a meeting of its Foods Advisory Committee to review issues surrounding methylmercury in commercial seafood. This review will include a reexamination of FDA's most recent Consumer Advisory for pregnant women and women of child-bearing age who may become pregnant. SBRP research will play an important role in these proceedings.

Soils contaminated with mercury present unique challenges for remediation due to the variety of chemical forms in which mercury can occur and because of the challenge in meeting cleanup concentration goals set by regulation or risk assessment. Phytoremediation is not a viable option for mercury-contaminated soils. While thermal treatment (retorting) based on the unique volatility of mercury is listed by the USEPA as the Best Demonstrated Available Technology for mercury-contaminated wastes, typically high costs, limited capacity, and potential for atmospheric releases have restricted wide application of this technology.

Mixtures. Historically, toxicity and carcinogenicity testing as well as mechanistic research on environmental chemicals have focused on

single agents. Over the years, this approach on environmental chemicals has been critical in providing information which has led to a better understanding of the interactions of exposure and susceptibility in relation to time. Indeed, the setting of standards for single substances is seen as an important and generally accepted tool in the protection of human health. However, it is becoming increasingly recognized that humans are not exposed to single chemicals. Rather, humans are exposed either concurrently or sequentially by various routes of exposure, to a large number of chemicals from a wide variety of sources over varying periods of time. Therefore, researchers, environmental policy-makers, and public health officials are faced with the challenge to design and implement strategies to reduce human disease and dysfunction resulting from exposure to chemical mixtures.¹³ Scientific approaches that have been used to assess the effects of single chemicals on biological systems are inadequate to address the potential health consequences that may arise from exposure to chemical mixtures.

Several factors contribute to the uncertainty of our understanding of the toxic effects of environmental exposure to chemical mixtures:¹⁴

- Many of the effects of exposure are subtle and difficult to quantify.
- Many environmental contaminants are changed to metabolites or conjugates in the body, and these new products may also have biologic activity that may or may not be similar to the parent compound. Thus, even a single compound may become a functional mixture.
- A single environmental contaminant may lead to different effects when exposure occurs at different ages. Researchers need to design studies that will evaluate long-term, delayed, and potential trans-generational health effects resulting from environmental or occupational exposures.
- Humans may be exposed to a nearly infinite number of combinations of contaminants, and we do not know what dose ranges or which biologic endpoints should be studied.

► RISK ASSESSMENT

Risk assessment is a structured methodology that is used to evaluate the possible effects of hazardous waste sites on human health and ecosystem health. The USEPA uses this process both to view the extent of a problem at a Superfund site and to inform decision-makers from the preremedial through the postremedial phases of a Superfund site cleanup. An integral component of risk assessment is exposure assessment, which is the process of measuring or estimating exposures to chemical contaminants. The general goal of risk/exposure assessment research is to improve and validate the measurements, modeling, and instrumentation and study designs that are used to analyze the health risks and exposure pathways from Superfund sites. Some key areas of research include epidemiological studies that evaluate the relationship between exposure and disease in a population; the development of new risk assessment tools; use of models and biomarkers to measure exposure and effect; and studies elucidating the environmental pathways in which environmental contaminants are transported from the release site to possible points of contact with humans. The advances made in these studies can assist remedial project managers and other decision-makers in protecting the environment and meeting the public health needs of the communities affected by Superfund sites.

The U.S. EPA's Superfund statutory authority mandates that it protect both human and ecological health at hazardous waste sites. The protection of human health has received more attention by the public, the USEPA, and other federal and state site managers. However, recently increased emphasis has been placed on the development of technologies and data to better assess ecological health. Now, a risk assessment is prepared for each site that includes separate assessments of human health and the ecological impacts of a site.

► REMEDIATION

Remediation research covers the spectrum of technologies being developed for the cleanup of groundwater, sediments, soil, and other environmental media contaminated with hazardous substances. With primary prevention as the goal, researchers are developing innovative biological, chemical, and physical methods that effectively reduce the amount and toxicity of hazardous wastes. Remediation research also includes development of new and improved methods of hazardous waste containment, recovery, and separation. This broad area of research includes laboratory and bench studies, and applied field research once a technology has reached an advanced level.

To develop novel remediation technologies, basic knowledge regarding the physical and chemical processes involved in each strategy is needed. For example, an in-depth understanding of sorption and desorption processes is necessary for many remediation technologies. Kinetic data, such as the rates and extent of hazardous waste conversion, are needed for thermal, chemical oxidation, and supercritical fluid technologies. The development of efficient and economical remediation strategies requires collaboration among a wide spectrum of diverse fields. For example, a microbiologist alone does not have all of the knowledge required to design and implement a bioremediation system, but requires support from experts in fields such as ecology, soil science, hydrogeology, geologic engineering, geophysics, and geochemistry.

Remediation can be very practical, frequently with direct applications to Superfund sites, including field testing and patented cleanup technologies. The knowledge gained from understanding remediation processes not only serves as the basis for subsequent basic or applied research in these areas, but also provides a foundation for practical benefits such as lower cleanup costs on hazardous waste sites and improvements in human and ecological health risk assessments.

Remediation research covers the spectrum of technologies being developed for the cleanup of groundwater, sediments, soil, and other environmental media contaminated with hazardous substances. With primary prevention as the goal, researchers are developing innovative biological, chemical, and physical methods that effectively reduce the amount and toxicity of hazardous wastes. Remediation research also includes development of new and improved methods of hazardous waste containment, recovery, and separation. This broad area of research includes laboratory and bench studies, and applied field research once a technology has reached an advanced level.

► NEED FOR MULTI-/INTERDISCIPLINARY RESEARCH

Research focused on hazardous wastes is driven by the need to protect human health; however, a positive outcome can be attained only if the full life cycle of the contaminant is understood.¹⁵ It is evident that hazardous substances are capable of moving through the environment from one stratum to another, interacting with microbes, plants, animals, and humans. Each step of the process must be elucidated and related to the steps before and after. Thus many scientific disciplines must be integrated. In doing so, the procedures of characterizing and evaluating risks of hazardous wastes can be scrutinized and revised as directed by new research findings.

From a public health perspective, disease prevention and reduction of risk and exposure is fundamentally affected by the bioavailability and transformation of hazardous wastes in various medias. Therefore, it is important to support the development of environmental technologies that allow for the treatment of environmental contaminants so that potential human health effects are ameliorated, or indeed prevented.¹⁶ Basic and applied research needs to be funded on the premise that these research developments will one day be used to decrease or prevent the risk to human health associated with hazardous wastes. It is important to recognize that the cleanup of contaminated soils, sediments, and

groundwater is not only for improvement of the environment, but it is also a means by which human exposure and human health risks can be reduced. To this end, promoting and strengthening basic and applied research in environmental technologies integrated within a framework of health-related research and development is essential.

► RADIOACTIVE AND MIXED WASTES

Approximately 800,000 cubic feet of low-level radioactive waste was disposed in 1993, a 45% decrease from the preceding year. Industry efforts to minimize waste generation and to reduce the volume of waste by compaction and incineration have contributed to the decrease. The Nuclear Regulatory Commission (NRC) has developed a classification system for low-level waste (LLW) based on its potential hazards, and has specified disposal and waste form requirements for each of the three general classes of waste—A, B, and C. Class A waste contains lower concentrations of radioactive material than Class C waste. The volume and radioactivity of waste vary from year to year based on the types and quantities of waste shipped each year.

The disposal of high-level radioactive waste requires a determination of acceptable health and environmental impacts over thousands of years. Current plans call for the ultimate disposal of the waste in solid form in a licensed, deep, stable geologic structure.

There are basically two types of by-product materials. The first type is produced by a nuclear reactor. More precisely, this is any radioactive material or material made radioactive by exposure incident to the process of producing or using special nuclear material. The second type is produced by the uranium and thorium mining process as well as the tailings or wastes produced by the extraction or concentration of uranium or thorium from ore processed primarily for its source material content, including discrete surface wastes resulting from uranium solution-extraction processes.

The radioactive waste material that results from the reprocessing of spent nuclear fuel, including liquid waste produced directly from reprocessing and any solid waste derived from the liquid that contains a combination of transuranic and fission product nuclides in quantities that require permanent isolation, is referred to as high-level waste (HLW). HLW is also a mixed waste because it has highly corrosive components or has organics or heavy metals that are regulated under RCRA. HLW may include other highly radioactive material that NRC, consistent with existing law, determines by rule requires permanent isolation.

Definitions of Radioactive Wastes

Radioactive waste is solid, liquid, or gaseous waste that contains radionuclides. The Department of Energy (DOE) manages four categories of radioactive waste: high-level waste, transuranic waste, low-level waste, and uranium mill tailings.

HLW is highly radioactive material from the reprocessing of spent nuclear fuel. HLW includes spent nuclear fuel, liquid waste, and solid waste derived from the liquid. HLW contains elements that decay slowly and remain radioactive for hundreds or thousands of years. HLW must be handled by remote control from behind protective shielding to protect workers.

Transuranic (TRU) waste contains human-made elements heavier than uranium that emit α -radiation. TRU waste is produced during reactor fuel assembly, weapons fabrication, and chemical-processing operations. It decays slowly and requires long-term isolation. TRU waste can include protective clothing, equipment, and tools.

Uranium mill tailings are by-products of uranium mining and milling operations. Tailings are radioactive rock and soil containing small amounts of radium and other radioactive materials. When radium decays, it emits radon, a colorless, odorless, radioactive gas. Released into the atmosphere, radon gas disperses harmlessly, but the gas is harmful if a person is exposed to high concentrations for long periods of time under conditions of limited air circulation.

LLW is any radioactive waste not classified as high-level waste, transuranic waste, or uranium mill tailings. LLW often contains small amounts of radioactivity dispersed in large amounts of material. It is generated by uranium-enrichment processes, reactor operations, isotope production, medical procedures, and research and development activities. LLW is usually made up of rags, papers, filters, tools, equipment, discarded protective clothing, dirt, and construction rubble contaminated with radionuclides.

Mixed waste is defined as radioactive waste contaminated with hazardous waste regulated by the RCRA. A large portion of the Department of Energy's mixed waste is mixed low-level waste found in soils. No mixed waste can be disposed of without complying with RCRA's requirements for hazardous waste and meeting RCRA's Land Disposal Restrictions, which require waste to be treated before disposal in appropriate landfills. Meeting regulatory requirements and resolving mixed waste questions related to different regulations is one of DOE's most significant waste management challenges.

► CONCLUSION

The uncertainties and unknowns surrounding exposures present a huge challenge for decision-makers, especially for those dealing with hazardous waste sites. Accordingly, a basic, mechanistic understanding of the cellular, molecular, and biochemical processes that are affected by the exposures can enhance the scientific base used in the decision process.^{15,17} There are many aspects to developing a fuller understanding of the relationship between exposures and disease processes such as the identification of the causative agent(s); determination of the minimum dose where adverse health effects are manifested; and elucidation of the mechanisms by which these substances cause toxicity. The more we learn, the better understanding we will have of carcinogenesis, cardiovascular toxicity, reproductive toxicity, neurotoxicity, and other toxic effects. Clearly, these are all important public health concerns.

Aerospace Medicine

Roy L. DeHart

Aerospace medicine is “that specialty of medical practice within preventive medicine that focuses on the health of a population group defined by the operating aircrews and passengers of air and space vehicles, together with the support personnel who are required to operate and maintain them.”¹ The practice of aerospace medicine tends to reverse the usual order of traditional or curative medicine. Normally the physician is treating abnormal physiology (illness) in a normal (terrestrial) environment. The physician concerned with the care of the aviator or astronaut most frequently deals with a normal (perhaps supernormal) individual in an abnormal (aeronautical) environment.

Since its earliest beginnings, flight has required people to adapt to or to protect themselves from multiple environmental stressors. Progress in flight has required continuing improvement in adaptation or in the devices used for protection. Such progress has always been marked by the sacrifices made by those who push the envelope of aeronautical and astronautical activity. On December 17, 1903, on a windswept beach in Kitty Hawk, North Carolina, the Wright brothers succeeded in accomplishing sustained powered flight for 12 seconds over a distance of 40 m. In less than 15 years, thousands of these powered flying machines swarmed over the battlefields of the “Great War.” During this rapid expansion of military aviation, the seed of aviation medicine sprouted, took root, and grew. The department of space medicine was officially established at the United States Air Force School of Aerospace Medicine under the directorship of Dr Hubertus Strughold on February 9, 1949.²

The first human-operated flight in space, circumnavigating the globe, was performed by Soviet cosmonaut Yuri Gagarin on April 12, 1961. In February 1962, American astronauts joined the Soviets with the successful orbital flight of John Glenn.

Biomedical oversight for the United States’ space program is headquartered at the National Aeronautics and Space Administration’s (NASA) facility at the Johnson Space Center, Houston, Texas. Following successful lunar flights and space laboratory missions, the United States entered into a nearly routine operation with the space transportation system or “shuttle.” The losses of *Challenger* in 1986 and *Columbia* in 2003, however, are a reminder of the operational hazards of space flight.

► THE SPECIALTY OF AEROSPACE MEDICINE

Shortly after World War II, the Aero Medical Association initiated activities for the establishment of a training program for medical specialists in the field of aviation medicine. In 1953, the American Board of Preventive Medicine (ABPM) approved the decision to authorize certification in aviation medicine. The first group of physicians was certified in the specialty that same year. As of 2005, 1376 physicians have been certified in the specialty.

With the advent of space flight, both the association and the specialty changed names to appropriately reflect activities in both the

aeronautical and astronautical environments. The name of the specialty was officially changed by the ABPM to Aerospace Medicine.

In 2000, the ABPM initiated the development of a Certificate of Added Competency in Undersea and Hyperbaric Medicine. This is of interest to aerospace medicine as it is related to the hyperbaric environment, an environment used to treat dysbarism or aviator’s bends.

► TRAINING AND EDUCATION

Few physicians have the opportunity to gain experience in aerospace medicine until their postgraduate years. Typically, physicians are introduced to the specialty via one of two routes. Those practitioners with an interest in aviation may turn to the Federal Aviation Administration (FAA) for orientation and training as an aviation medical examiner (AME) to support general aviation. Each year the FAA conducts postgraduate educational courses for new physicians who are becoming AMEs and refresher training for established AMEs. The second route is via the military, as the three services conduct their own training programs for flight surgeons. These courses are basically introductory and focus on the clinical preventive medical aspects of evaluation and care of the aviator. Historically, most physicians who have entered the field of aerospace medicine have done so via the military route.

Residency Programs

Aerospace medicine is one of the smallest specialty training programs in the United States, both with regard to training sites and number of residents. Its program is similar in structure to other training programs in preventive medicine. Two programs are under the Department of Defense (DoD) sponsorship. The Air Force program is headquartered at the United States Air Force School of Aerospace Medicine, San Antonio, Texas, and the Navy program is managed at the Naval Operational Medical Institute, Pensacola, Florida. There are two civilian university residency programs available: Wright State University, College of Medicine, Dayton, Ohio, and the University of Texas, College of Medicine, Galveston. Both enjoy affiliation agreements with NASA. Fewer than 50 residents are in training at any one time, with 25–30 candidates sitting for the specialty board examination annually.

► THE AEROSPACE ENVIRONMENT

The characteristic that distinguishes aerospace medicine from other medical fields is the complex environment in which flight takes place. Stressors that impinge on humans in this unique environment, either singularly or in combination, include hypoxia, reduced atmospheric pressure, thermal extremes, brief and sustained acceleration fields, ionizing radiation, null gravity fields, and maintenance of situational awareness. For men and women to perform successfully in this potentially

hazardous environment, the principles of preventive medicine apply in the selection, health maintenance, and engineering protection of the aircrew.

The Biosphere

The chemical and physical properties of the atmosphere vary with the attained altitude. Although the properties are frequently described in terms of altitude, it must be appreciated that the atmosphere is dynamic in that specific characteristics are altered by season, the earth's rotation, and latitudes. For practical purposes, the components and their relative percentage of the atmosphere remain relatively constant up to an altitude of approximately 90 km. The major constituents of the atmosphere are nitrogen (78%) and oxygen (21%). The remaining 1% of the atmosphere consists of argon, carbon dioxide, helium, krypton, xenon, hydrogen, and methane. The actual percentages of these constituents vary with the water content of the atmosphere, which is altitude-dependent. As one ascends, the air becomes dryer.

Regardless of the altitude within the aeronautical frame of reference, the percentage of oxygen available to an individual at sea level is basically the same as that found at 90 km. The difference is that the partial pressure of oxygen is much reduced at altitude. Consequently the physiological availability of oxygen is likewise reduced.

One constituent of the atmosphere has received considerable attention in recent years because of concern for potential adverse health effects should it be reduced. Ozone is produced in the upper atmosphere by the photodissociation of molecular oxygen. Ozone attains maximum density at an altitude of approximately 22 km but is present in measurable concentrations from 10 to 35 km. Reduction in the ozone concentration increases the level of ultraviolet radiation reaching the earth's surface (see Chap. 3).

At sea level, the column of air creates an atmospheric pressure of 760 mm Hg, 760 torr, or 1013.2 millibars. As one ascends in altitude, there is less of a column of air and thus less air pressure; however, this relationship is not linear: the density of the air decreases exponentially. Consequently, at a height of 5.5 km the air density is one-half that found at sea level, and at 11 km the density is one-quarter. In practice the actual heights are somewhat greater because of the effects of temperature.

Oxygen Systems

Hypoxia, which may have any one of several causes, has devastating effects on normal physiological function. In aviation, this oxygen deficiency is due to a reduction in the oxygen partial pressure in inspired air, which occurs at altitude because of reduced oxygen in the ambient air. The alveolar partial pressure of oxygen is the most critical factor in this problem. In aviation, two factors must be considered in understanding hypoxia at altitude.

Not only may the partial pressure of oxygen be low, for example, the available oxygen is reduced by half in the ambient air at 6 km, but the ambient pressure may be insufficient to permit gas exchange at the alveoli. Considering that water vapor at normal body temperature is 47 mm Hg and the residual alveolar carbon dioxide pressure is 40 mm Hg, then for any air exchange to occur in the lung, the ambient pressure must exceed 87 mm Hg. Even if the aviator is breathing 100% oxygen, if the ambient pressure of oxygen is no higher than 87 mm Hg, it would be impossible to overcome the gas pressures already present at the alveoli and thus provide oxygen.

Hypoxia is particularly dangerous because its signs and symptoms produce little discomfort and no pain. Between 2000 and 3000 m, the subtle symptoms may produce deficiencies in night vision and some drowsiness. Unfortunately, intellectual impairment can be an early manifestation of hypoxia, thus compromising the ability of an individual to behave rationally. Thinking is slow and calculations are difficult. Both memory and judgment are faulty, and reaction time is delayed. This condition can be rapidly treated by administering oxygen at altitudes between 3000 and 10,000 m and adding positive pressure oxygen up to 14,000 m or by enclosing the individual in a pressurized system with available oxygen at altitudes out to space.

To avoid discomfort and potential hazard in flying at altitude, the most logical solution is to carry your terrestrial environment with you. Although it is not the usual case, the same principle applies for many aircraft systems, particularly passenger-carrying aircraft. The body of the aircraft becomes a pressure vessel in which the air pressure and oxygen availability are similar to that at sea level. For a number of practical reasons, such as passenger comfort, avoiding clinical hypoxia for most passengers, and the additional cost of maintaining a sea level environment, the actual cabin altitude for most commercial aircraft is set at approximately 2500 m. Although passengers will note some pressure changes in the ears or sinuses, the change is gradual and rarely causes pain or discomfort. In most cases, the passenger is not even aware of these pressure changes. The altitude is set so that most passengers are able to fly without experiencing any hypoxic symptoms. Occasionally, passengers with a compromised pulmonary or cardiovascular system may require supplemental oxygen, since their reserve is inadequate to compensate for these relatively small changes in oxygen partial pressure.

In the absence of a pressurized cabin, the aviator may be forced to adapt by wearing a self-contained pressure system. Although the public is most familiar with "space suits" from television reporting, similar suits have been used for over a half century by military aviators flying high-altitude missions.

Provided the ambient pressure is adequate, supplemental oxygen systems permit high-altitude flying and provide a safety factor for passengers on commercial airliners. Most systems employ an oxygen storage system of either pressurized gas or liquid oxygen. The source of oxygen is then connected through a regulator or metering device to an oxygen mask worn by the user. Another less commonly used oxygen storage system uses solid chemicals that, when activated, release oxygen. Two devices have been developed to provide onboard oxygen generation systems. The fuel-cell concept has been developed for space flight and is basically an electrolysis system freeing oxygen from water. A second system uses the reversible absorption properties of fluomine for oxygen. In this technology, pressurized air is forced over a fluomine bed, and the pressure is then reduced, allowing the absorbed oxygen to be released. Other techniques have included the molecular sieve device, which is used to filter oxygen from air; a similar technology employs a permeable membrane that passes oxygen preferentially to other constituents of the atmosphere.

Biodynamics

The first powered-flight aviation death occurred in the United States when an army lieutenant sustained fatal injuries while flying with Orville Wright. Since that initial accident, there has been an ever-increasing sophistication in the science of aircraft accident prevention and aircrew and passenger protection.

Acceleration occurs whenever the velocity of an object changes. This change may occur either in direction or in magnitude. For convenience, transitory acceleration in aerospace applications is expressed in terms of "g" and is defined as the magnitude of acceleration when the velocity change approximates 9.8 m/s². Transitory acceleration is of such a short duration that the body does not reach a steady-state status. Protection from transitory acceleration has generally centered around two technologies: the development of restraint devices, such as lap belts and shoulder harnesses, and the design of crew space to reduce the possibility of contact.

Accident protection technology has been employed in the design of the airframe to absorb energy and improvements in the seat structure to reduce mechanical failure.

Primarily in military aviation, escape systems have been designed that often impart a new acceleration field. Ejection seats and capsules are designed to carry the occupant free of the aircraft envelope even on the ground at zero speed or in adverse conditions during uncontrolled descent. These new components of acceleration are specifically designed to remain within human tolerance.

During World War I, fighter pilots began reporting visual changes when they engaged in a pull-out or during aerial combat.

Research work using a human centrifuge demonstrated, in 1935, the effects of blackout during sustained acceleration. Sustained acceleration is achieved when the body has sufficient time to reach equilibrium with the effects of the acceleration. In this context, g has been used to reflect a ratio of weight. Consequently, a pilot flying a maneuver in an aircraft in which he or she sustains 4 g would likewise experience an increase in body weight from 175 to 700 pounds. In such an acceleration, a flight helmet with equipment weighing 10 pounds becomes a mass of 40 pounds. As any mass exposed to such a field will experience a proportionate increase in weight, this has dynamic effects on the body's hydrostatic blood column and thus on cardiovascular function. For example, the hydrostatic column from the heart to the eye in a normal terrestrial environment is 30 cm; when exposed to a plus 6 g acceleration environment, it becomes equivalent to 180 cm. In this example, the body's blood pressure would be unable to overcome the hydrostatic pressure, and blood flow to the level of the eyes would cease.

Because of the normal hydrostatic pressure of the eyeball, a pilot will experience blackout wherein vision is lost but consciousness is maintained. When tested on a centrifuge using a standard protocol, the typical aviator, relaxed and without any protective devices, experienced blackout between 4 and 5.5 g. The same aviator, when allowed to strain to increase blood pressure, is able to increase tolerance 0.5 g to 1.5 additional g. Two critical factors impact the degree of tolerance: the rate of onset of the acceleration, and its duration.

Further protection is available using mechanical devices such as an anti-g suit. The suit is basically a lower torso device with bladders to press on the abdomen, thighs, and calves. These bladders inflate when a sensor is stimulated by acceleration. Such devices increase the g tolerance by 2 g. Research performed over half a century ago demonstrated that an anti-g suit properly worn during performance of a straining maneuver can increase g tolerance from approximately 4 g to about 9 g. Another mechanism used to enhance acceleration tolerance for pilots has included body positioning to orient the long axis of the body more perpendicular to the acceleration vector. Positive pressure breathing is also shown to be helpful in increasing tolerance, as it increases intrathoracic pressure.

The biomechanical force environments in aerospace systems can be enormous, with generation of severe noise and vibration. Human exposure to these forces may affect performance and contribute to adverse health outcomes. Prevention is the key to proper management of these stressors.

Spatial Disorientation

The complex neurosensory system that we terrestrials use to maintain our orientation in the three-dimensional plane of our normal existence is inadequate for the three-dimensional dynamic environment of aerospace.

The vision sensory system is by far the most important modality for providing us input to maintain spatial orientation. Visual information processing, however, is acted on by the vestibular system and, to some degree, by proprioception and motion.

Vestibular function in maintaining spatial orientation is not as clearly defined or evident as vision. Once we are deprived of visual cues, the vestibular system becomes a major source of orientation cues in our normal environment. The visual-vestibular interface is important in fine-tuning our spatial orientation activities. However, an individual with a nonfunctional vestibular system is able to perform well as long as visual cues are adequate.

In the environment of flight, the aviator is exposed to far more complex motion inputs than the physiological system is designed to process. Not infrequently, visual cues may be in conflict with apparent motion and velocity cues processed by the vestibular system. These conflicting cues may lead to severe spatial disorientation or induce episodes of motion sickness. In flight, the visual system may be subjected to various illusions, which may cause the pilot to assume a position in free space that is inaccurate. At night or in inclement weather, the pilot may not have any external visual cues.

Vestibular illusions are often severe and may produce a fatal outcome. These illusions are generally produced by velocity changes that generate input from the semicircular canals and otolith organs.

Disorientation accidents in military aircraft account for approximately 15% of fatal mishaps. Measures that may be employed to prevent these accidents include modifying flight procedures to reduce the opportunity for disorientation; improving the ease of interpretation of information presented by flight instruments; increasing proficiency in instrument flying, which will permit the pilot to overcome false sensory input; and educating the pilot regarding physiological frailty and the need for dependence on and acceptance of flight instrument information.

Space

The transition from the terrestrial to the space environment is not a well-demarcated line but rather a continuum that varies with altitude depending upon the parameter discussed. Human operated flight and near-earth orbit at altitudes in excess of 240 km require a self-contained vehicle sealed from the near vacuum of space. At this altitude, the air density is so low that there is no practical method for compressing the gases to supply both pressure and oxygen to the craft's inhabitants. Although the sun's radiation may heat the vehicle, occupants must be protected from the extreme cold of the ambient environment. While in orbital flight, the astronaut experiences a nearly gravity-free, or weightless, environment. This occurs when the gravitational force vector is counterbalanced by the centrifugal force imparted to the vehicle as it travels tangential to the earth's surface. Long-term exposure to this near-null gravity environment has important biomedical ramifications that as yet are not fully defined.

The earth's atmosphere serves as an insulator to shield us from many of the potential dangers of space radiation. Once a person is in space, this protection is no longer available, and ionizing radiation must be a concern. Three types of radiation present hazards: primary cosmic radiations, geomagnetically trapped radiation (also known as the Van Allen belts), and radiation produced by solar flares. The environment of space is similar in many ways to the aeronautical environment; however, the duration of exposure is much more prolonged in space, and null-gravity is unique.

► OPERATIONAL AEROSPACE MEDICINE

The physician practicing aerospace medicine as a clinical specialty must be an astute clinician in the office setting and also a practitioner able to grasp the nuance of the environment of flight.

The stressors impinging on aircrew vary with the type of flight vehicle, whether a single-seat private plane or a multicrew space habitat. Consequently, the physician serving as an AME or flight surgeon (FS) must be cognizant of the aircrew's flight environment. For ease of discussion, these operational flight environments are defined as civil aviation, military aviation, and space operations.

Civil Aviation

This category of flight operations includes commercial aviation and private or recreational flying. Airlines represent an international industry with aircraft worldwide transporting nearly 1.6 billion passengers over 1300 billion air miles per year compared to 650 million passengers enplaned in the United States. With the deregulation of the airline industry in the United States, air commuter and air taxi operations have grown to fill the vacuum left when airlines pulled out of small airport terminals. Most large corporations in the United States either own or lease aircraft for business purposes. Other commercial activities include air ambulance service, flight training, aerial application, air cargo, and the new growth industry of commercial parcel delivery.³

In the United States there are approximately 460,000 active pilots, 167,000 general aviation aircraft, 10,000 air carrier aircraft, and 18,000 airports.⁴

The magnitude of preventive medicine intervention by the aerospace physician takes on added meaning when one realizes that all U.S. licensed aviators are required to have an initial medical examination prior to issuance of their license and periodic assessments as long as they continue to fly. To examine these aviators, the FAA has designated 4800 physicians as AMEs. These physicians have undergone special training conducted under the auspices of the FAA; they may have had experience as military flight surgeons and frequently are private pilots themselves. The examination is performed to a rigorous protocol, and detailed physical standards have been promulgated.

The periodicity and sophistication of the examination is dictated in part by the class of the license exercised by the aviator. The airline captain must meet a more stringent standard, more frequently, than is required of the private pilot. In all cases, the medical examination is reviewed by medical personnel at the FAA's Civil Aeromedical Institute (CAMI). Approximately 1800 medical examinations are received each business day by the office. This represents one of the largest longitudinal medical databases in the country; unfortunately, resources to use the tools of epidemiology for fully studying this wealth of data have not been available.

Another employment category required to meet flight medical standards is air traffic controller. These 15,000 federal employees stationed throughout the United States must meet, as a minimum, the physical standards required of pilots, and just as with pilots, these examinations are repeated periodically.

CAMI also has responsibility for conducting research to address issues of health and safety for flight deck and cabin crew as well as for the private aviator and passengers. Toward this goal, the institute has conducted research and recommended standards on emergency aircraft lighting, egress systems, restraint systems, breathing equipment, emergency breathing devices, and flotation systems.

Military Aviation

The Air Force has by far the widest range of aeronautical activities. Low and slow describes some Air Force missions, while others are truly into the fringes of space. Current fighter aircraft are capable of readily exceeding the physiological tolerance of the pilot with rapid onset, high g. The response of fighter aircraft is so fast that controls are now electronic rather than hydraulic or mechanical. Large transport aircraft are capable of nearly endless flight with air-to-air refueling. With rest facilities and multiple crew, the aircraft can simply keep on flying; the only restriction is the crew rest requirements of its human operators. Since the 1950s, it had been predicted that aeronautical design would take aircraft performance beyond the performance of the pilot. That time has arrived, as aeronautical engineers are now forced to curtail performance characteristics of the aircraft because the human operator can fail.

Army aviation medicine has for some years concentrated on unique facets of rotary wing operations and pilot adaptability. In past years, helicopter crashes that were survivable in terms of impact force frequently ended in fire and death of the occupants. With intense research and redesign, this hazard has been significantly reduced. The military necessity of helicopter operations in adverse weather conditions and at night has created human factor challenges that have only in part been successfully addressed by technology.

The unique challenge for naval aviation medicine is related to aircraft carrier operations. The flight surgeon is responsible not only for health maintenance of the flight crews but also for maintaining health surveillance for the 5000 people on board the carrier. The word "independent" has been used to describe a prominent characteristic of this medical service. The flight surgeon is the public health officer for this isolated community and oversees all aspects of hygiene, epidemiological surveillance, health maintenance, and medical disaster preparedness aboard ship.

The Navy has celebrated the sixtieth anniversary of the Thousand Aviator Program, one of the first large cohort, longitudinal health surveillance programs undertaken in the United States. More than 1000 aviators and aviation cadets were examined using psychological and physiological assessment procedures. This ongoing study has

reviewed cardiovascular status, overall morbidity and mortality rates, and the effects of the aviation experience on the overall health of the individual.

Space Operations

The United States piloted space program has enjoyed successes; unfortunately, it has also experienced disasters that continue to remind one that space operations are neither routine nor free from potential catastrophic failures. On February 1, 2003, the *Columbia* Space Shuttle broke up on reentering Earth's atmosphere. All seven crew members were lost. Foam insulation fell from the fuel tank during launch damaging the left wing. On reentry, hot gases entered the wing, resulting in the craft's destruction. The Soviet Union likewise has experienced success and disaster in space.

As experience has accumulated with human-days in space and monitoring of increasing numbers of astronauts in the space environment, medical concerns have focused on the physiological effects of null gravity. Based on our current experience for short duration flights, the biomedical challenges include space adaptation syndrome (space motion sickness), cardiovascular deconditioning, loss of red cell mass, and bone mineral loss. For the Space Transportation System (shuttle) operations, the first two concerns are primary. Space adaptation syndrome has been experienced by up to one-third of the shuttle crew. This syndrome occurs in the early segments of orbital flight and may adversely affect early mission performance.

Fluid shift and deconditioning effects occur even during the relatively short duration of the shuttle orbital missions. Performance during orbit does not appear to be compromised, but with the increasing g upon reentry, performance decrements are possible.

As preparations proceed for a continuous habitat in space, the remaining biomedical challenges will become important. Russia has successfully maintained cosmonauts in orbit for over a year.

The International Space Station operation introduces additional challenges for maintaining astronauts on long duration missions. The environmental control systems must be able to maintain potable water and uncontaminated air reliably for long periods. Microbe overgrowth must be prevented. Food and sanitation issues need to be addressed with resupply providing only one solution. Health maintenance surveillance and emergency medical treatment will require attention. Crew work-rest cycles and psychological considerations remain challenges, as do biologically efficient extravehicular activities.

On January 14, 2004, President Bush announced a new vision for further space exploration. First, the United States will complete work on the International Space Station by 2010, meeting our commitment to over 15 international partners. Second, the nation will begin development of a new manned exploration enterprise to explore worlds beyond our orbit—the Crew Exploration vehicle with its first mission by 2014 with a one-month stay on the lunar surface. Third, the launch of a 30-month round-trip flight to Mars will follow the lunar habitat success.⁵ With current propulsion systems, the Mars mission will require optimal employment of orbital mechanics. Approximately half of the mission will be in transit from Earth to Mars and return. The other half will be in residence on the Martian surface waiting the time window for initiating the return launch. There is an enormous gap between the nation's current knowledge and available technology and what will be required for a successful Mars trip. NASA has begun to develop the Bioastronautics Roadmap to assist in defining the problems and developing the solutions that must precede any such long-duration space flight and human habitation on a planet.⁶

In the fall of 2004, SpaceShipOne became the first civilian venture to enter suborbital space flight. A space tourism industry developed by the private sector could be in business by 2008 with up to 100,000 paying passengers a year taking suborbital flights by 2020. Anticipating this possibility, the FAA has begun the development of general medical guidance for operators of manned suborbital commercial space flights. This guidance will identify and prioritize the minimum medical requirements necessary to promote the safety of paying passengers who

intend to participate in these flights. Suborbital space flight may expose passengers to a far more hazardous environment than that experienced on traditional flights.

► PERSONNEL, PASSENGERS, AND PATIENTS

In general, the people most involved in the aerospace industry are flight crews, cabin personnel, ground staff, passengers, who represent the chief revenue source for commercial aviation, and patients, who may be transported either by an airline or air ambulance service.

Personnel

American flag carrier airlines are responsible for the direct employment of approximately 650,000 workers, including 75,000 flight deck and 90,000 cabin crew members.⁴ The remaining employees make up the maintenance teams, counter servicing and baggage personnel, and those engaged in administration and management. The preventive health surveillance and medical monitoring of these individuals are provided via a variety of health service mechanisms. A number of the larger airlines maintain modern, sophisticated medical departments providing both occupational and aviation medicine services to the workforce. Other airlines have elected to keep only a minimal medical presence in-house and to contract for or otherwise provide services to employees. Smaller airlines have found it successful to hire the periodic services of an aeromedical consultant and to contract out health services. Less common is contracting all health services without the benefit of corporate medical oversight.

Airlines providing comprehensive aviation medical services will provide many, if not all, of the services detailed in Table 50-1.⁷

Many of the activities for either flight crew or ground personnel are clinical preventive medicine services. The sophistication of the preemployment examination depends on the job description of the future employee. In part, because of the enormous training investment in pilots, airlines try to select pilots who are free of active disease, who have few precursors to chronic illness, and who do not exhibit high-risk lifestyle behavior.

Although many pilots earn their livelihood in commercial aviation, most aviators in the United States are private pilots who fly for recreation or business. Whether the aircraft is a wide-bodied, multi-engine, commercial passenger airliner, a high-performance jet fighter, or a single-engine private aircraft, the aviation environment and its potential adverse effects on human physiology remain. Although the level to which stress is imposed on the aviator is determined in large measure by the flight profile of the aircraft, all aviators are exposed to some adverse environmental factors associated with flight. Prevention or amelioration of adverse effects resulting from the flight environment continues to be a key component of the practice of aerospace medicine. Flight personnel whose health and well-being may be compromised by illness or by self-imposed stress compromise their performance as aviators and thus have a potential adverse effect on flight safety.

Illness and Disease. Aviation is among those few avocations or vocations where the incapacitation of the operator could have dire

effects. Once airborne, the aircraft is dependent on the pilot to safely complete the flight. Although there are many assists to the aviator both in the aircraft and on the ground, the number of aircraft capable of fully automated flight is small. Consequently, public safety dictates that the potential for pilot incapacitation be minimized.

There are many physical afflictions an aviator may have without undue risk to flight safety. However, certain medical conditions are currently considered incompatible with safe flight. The clinical skills of the aerospace medicine specialist are most tested in diagnosing occult disease and determining the risk such a condition may impose on flight safety and the aviation activities of the aviator.

Unexplained loss of consciousness or epilepsy are examples of conditions that may create an unacceptable risk to the pilot and to the public. Diabetes mellitus, requiring medication, and exertional angina are other examples where the risk to public safety may take precedence over the individual pilot's desire to continue flying.

Therapeutic Medications. Physicians write over 2 billion prescriptions for therapeutic medications each year in the United States. An even greater number of over-the-counter medications are purchased annually. With this degree of drug ingestion among the U.S. population, it is most probable that medication is being taken by a substantial percentage of aviators. Both therapeutic effects and adverse side effects may create situations that adversely affect flight performance. Common side effects of medications include drowsiness and loss of concentration. A pilot on a long, uneventful flight must be vigilant to fight boredom and inattention. He or she may also be experiencing mild hypoxia. If one adds to this scenario the side effects of medication, the results could be tragic. Most studies have shown that adverse effects of medications are enhanced by the flight environment.

The Department of Defense, because it supervises the health care of its pilots, simply removes the aviator from flight duty until completion of the therapeutic regimen. For long-term or chronic disease requiring therapy, such as mild hypertension, limited prescription medications are available, provided a prior trial has demonstrated that the pilot experiences no adverse side effects. In the civilian sector, such control of health care is essentially nonexistent. This is true even for commercial airlines that may attempt to monitor the health status of their pilots. Consequently both the physician providing treatment and the pilot taking medication must be educated to the potential dangers of adverse side effects in flight.

Nontherapeutic Drugs. Two commonly used nontherapeutic drugs are cigarettes and alcohol. Although the incidence of alcohol-related aircraft accidents has fallen in response to an extensive educational effort on the part of the FAA, alcohol continues to be associated with approximately 11% of general aviation accidents. Alcohol and altitude are synergistic, both in the effects upon the central nervous system and with respect to slowing metabolic clearance rates. Ground-based simulation and actual in-flight performance have demonstrated that blood alcohol levels as low as 0.04% (40 mg/dL) adversely compromise flight performance.

Habitual cigarette smokers commonly have blood carbon monoxide levels in excess of 5%. This represents a reduction in the blood oxygen level equal to that of a nonsmoker at an altitude of 2200 m. Consequently, aviators who smoke are placing their bodies physiologically at a higher altitude than indicated and this compromises altitude tolerance.

Work-Rest Cycles. Numerous factors in the aerospace environment enhance the onset of fatigue. One of the more significant of these factors is the erratic schedule many aviators maintain while flying. Weather remains the greatest cause for flight schedule disruption in private, business, or commercial aviation. Although larger, more expensive aircraft are now equipped with electronic measures to reduce the impact of weather on flight schedules, problems remain. There are regulatory controls, work rules, and common sense methods in place to reduce inadvertent or intentional fatigue factors.

National Transportation Statistics, Bureau of Transportation Statistics, Department of Transportation, 2004.

Although a pilot may fly only the prescribed number of hours over a particular time period, there is no assurance that there will be either the opportunity or ability to obtain adequate rest in the interval.

The excitement of a new place, insomnia in a strange bed, circadian rhythm asynchrony, and work-related anxiety may contribute to restless sleep and inadequate rest. Then a new workday begins, which may, in fact, be in the middle of the pilot's biological night. Such circumstances are not infrequent and do lead to both acute and chronic fatigue for aircrew members.

For the private pilot, time schedules are frequently self-imposed, which initially may have been realistic but become severely disrupted with the passage of a storm front. Frequently, the individual attempts to reach the next destination, ignoring the length of time without rest and the manifestations of fatigue. Fatigue is rarely cited as the primary cause of an aircraft accident; however, it often appears as a contributing factor.

Ageing. For a number of years, the FAA has had in place the Age 60 Rule. This rule directs that air transport pilots flying for commercial airlines may not serve as pilots beyond age 60 years. This is not a medical regulation but one promulgated through operations. There is no such age limitation for other categories of flying. All others, regardless of age, may continue aviation activities as pilots as long as a current medical certificate is maintained and other evaluation requirements of the license are met.

The Age 60 Rule had its origin in 1959 before sophisticated medical diagnostic techniques were available, and it predated the advanced simulators, which are now able to measure subtle performance decrements. It was recognized that the risk for sudden incapacitation in flight increased with age, particularly cerebral vascular accidents and heart attacks. The wisdom at the time said such a rule was necessary to reduce the potential for such events by controlling the population at risk. Although the rule is currently being sustained in the courts, considerable epidemiological evidence is being put forward in an attempt to overturn what some have described as age discrimination. Southwest Airline, Jet-Blue Airways, and the Professional Pilots Federation all pointed out to the court in 2005 that older pilots are still capable and the major overseas carriers allow pilots to fly commercial aircraft beyond age 60.

Passengers

Commercial airlines have both an obligation and a commitment to provide safe, reliable, and comfortable service to their passengers. In general this is the experience of millions of passengers flying each year. Table 50-2 provides comparative accident data for air, road, and rail travel. Terrorists took control of four large commercial passenger planes in a coordinated attack on September 11, 2001. Two aircraft were deliberately crashed into the two towers of the World Trade Center in New York City; one aircraft was crashed into the Pentagon in Washington, D.C.; and the final aircraft was crashed in a field in rural Pennsylvania. Nevertheless, travel by domestic airlines remains one of the safest forms of transportation.

Safety. Many of the safety features in modern commercial aircraft go unrecognized by the passengers. The number of emergency exits are specified to ensure rapid evacuation in case of an emergency. Both

airline seats and seat belts are designed to sustain considerable impact force in order to protect and restrain the passenger. Other than the pre-flight demonstration, few passengers have seen the emergency oxygen masks, which are available at every seat location in aircraft flying at substantial altitudes. Emergency lighting has been designed to provide illumination in case of power failure, and floor level track lighting leads to the emergency evacuation routes. The most important safety feature is not equipment but the cabin attendant. Although most passengers look to these individuals to make the flight more comfortable by providing service and assistance, the cabin attendant's primary purpose is to provide safety instructions and to help passengers in case of emergencies.

Since the events of September 11, 2001, passengers have not only been exposed to the physical stressors of flight, but to social and emotional predeparture stress as well. The "hassle factor" of flying has become everybody's burden to bear—even those in first class. The cabin crew has witnessed a significant increase in the tension, anger, and acting-out of frustrated passengers and has given the name "air rage" to this behavior. According to the largest U.S. flight attendants' union, there are 4000 reports of air rage each year. In part due to the stress related to commercial flight, it may not be the best mode of transportation for everyone, although it is recognized as the safest mode of travel. Certain pulmonary, cardiovascular, and neuropsychiatric conditions may best be left to surface travel. Medical problems are rare and in-flight deaths rarer, but untoward events do occur. A major airline reported that 1.5 medical diversions are expected for each one billion passengers flown.

In the larger commercial airliners there is a requirement that the aircraft have both a major medical kit and an automatic defibrillator on board (Table 50-3).^{8,9} In surveying its passengers, an airline was able to identify a physician among passengers on larger aircraft 85% of the time. In recent years a condition known as "economy

class syndrome” has entered the aviation lexicon. This refers to the development of deep vein thrombosis in passengers who remain seated in the tight confines of the cabin for long periods of time. As a preventive measure, the airlines are providing information about the syndrome and recommending that passengers take several preventive steps to reduce the risk. Passengers are encouraged to remove constrictive stockings, exercise the feet and legs while seated, move about the cabin as conditions permit, and maintain hydration.

Circadian Asynchronization (“Jet Lag”). Transmeridian flights commonly are disruptive to the passenger’s awake-sleep cycle. There is considerable individual variability to disruption of the normal body rhythm. Time shifts of 3–4 hours often will alter the body’s homeostasis. The recovery time is dependent not only on the number of time zones crossed but also on the direction of flight. Body cycle disruptions occurring after crossing six or more time zones appear to be relatively persistent when one is flying east, lasting upward of 11 days; symptoms from flying west persist for no more than 1 or 2 days. Measures recommended to reduce the impact of this circadian asynchronization include adjusting daily activities several days before the flight, changing meals to the new time, eating light meals, avoiding alcohol, and using hypnotics during and following the flight, as well as allowing specific rest periods on arrival at the destination. More recent work suggests bright light and melatonin may help in resetting the “body clock.”

Patients

There are few absolute contraindications to transporting patients by air. Patients who suffer from dysbarism, acute myocardial infarction, pneumothorax, or air embolism can be moved with relative safety, provided appropriate precautions are taken and preparations made. Assuming that maximum effort has been made to stabilize the patient, the question should be asked, “Are the benefits of air transportation real, and do they justify the clinical risks and financial costs?” The DoD has the greatest experience with transporting seriously ill and injured patients. The military aeromedical evacuation system employing large transport aircraft represents the nation’s main resource for fixed-wing medical transport. Commercial air ambulance services are available in all large communities in the United States. Most visible is the medical center helicopter used to transfer critically ill and injured patients and neonates to tertiary medical facilities.

Medical conditions requiring particular insight into the physiology and environment of flight are air embolism and pressure change–induced decompression sickness, or dysbarism. In the transfer of such patients, it is imperative that pressure changes routinely experienced in flight be avoided. Some aircraft, such as the Hercules C-130, can be overpressurized to maintain the cabin below sea level pressure provided flight is at a relatively low altitude.

Airline companies are frequently called upon to make special provisions for the transfer of ill or injured patients in the normal cabin environment of an airliner. Provided such a transfer does not represent a hazard to other passengers, stretchers are available that extend over three airline seats. The patient must be accompanied by at least one attendant. The expense is significant because of the block of seats required by the stretcher apparatus.

Prevention is the hallmark of aeromedical support to personnel, passengers, and patients: prevention of disease and risk behaviors that might compromise the longitudinal health of air-crew personnel; prevention of injury or death to passengers through safety design of aircraft and safe airline operations; and prevention of further complications to the air-transported patient through planning, training, and equipping aeromedical transportation systems.

► COMMUNITY AND INTERNATIONAL HEALTH

Aerospace flight operations have the potential for disrupting the environment and serving as a mechanism for the introduction of disease. Within the United States, regulations have helped reduce the impact

of flight operations on the environment. The potential for disease transmission has been reduced with the implementation of international sanitary regulations and other control mechanisms.

Disease Transmission

The spread of epidemics by movement of populations has been well documented throughout history. In days past, an infected individual traveling by land or sea usually became symptomatic, and thus the disease was apparent before the person reached his or her destination. With today’s high-speed jet traffic, it is not only possible but likely that an individual infected with a communicable disease could be asymptomatic yet incubating the disease at the time of arrival at the destination. Today it is possible to fly to nearly any destination on the globe within 24 hours. Thibeault¹⁰ implicates the aircraft in the spread of cholera, penicillin-resistant gonorrhea, influenza, rubella, and Lassa fever. Shilts, in *And The Band Played On*, describes how a flight attendant, with his ability to move rapidly from city to city, may have served as a vector of the human immunodeficiency virus.¹¹

While passengers are crowded into a small cubic air volume, the aircraft is designed with an air-conditioning and ventilation system that maintains a low bacteria count. Even with the use of maximum efficiency HEPA filters, infections have occurred among both crewmembers and passengers. Such infections have been documented for tuberculosis, influenza, and most recently severe acute respiratory syndrome (SARS). As the SARS epidemic spread and became global in the spring of 2003, commercial aircraft became identified as a major source of cross-border spread. Five commercial international flights were associated with transmission of SARS from patients with symptoms to passengers and crew. The notification of potentially exposed passengers and studies of the risk of transmission were complicated by difficulties in tracing contacts.¹² A highly effective spread of SARS occurred onboard China Air flight 112 from Hong Kong to Beijing on March 15, 2003.

Recognizing the potential importance of the aircraft as a mechanism to spread disease and vectors, the first sanitary convention for aerial navigation convened in 1933. The convention’s focus was curtailment of the spread of yellow fever, including limiting the distribution of the mosquito vector *Aedes aegypti*. This convention eventually became the World Health Organization (WHO) Committee on Hygiene and Sanitation in Aviation. International airlines are required to comply with the International Health Regulations published by WHO, which primarily address the following:

1. Promulgation of the application of epidemiological principles
2. Enhancement of sanitation at international airports
3. Reduction or elimination of factors contributing to the spread of disease
4. Elimination of disease vector transportation
5. Enhancement of epidemiological techniques to halt the introduction or establishment of a foreign disease

Vector Control

Disinfection procedures vary from airline to airline. The principal objective of these procedures is to kill mosquitoes and other insect vectors of disease. At one time, it was common when one was flying to or from tropical areas to have cabin attendants pass through the aircraft with activated aerosol cans spraying insecticide. Another procedure, which was less obvious, was to disseminate an insecticide vapor from several fixed stations in the aircraft. Current regulations permit residual treatment of the aircraft with permethrin. A common practice was the “blocks-away” disinfection technique, in which insecticide would be introduced into the passenger cabin immediately after the aircraft was closed and was taxiing to take off. An alternative method was to use aerosol insecticide prior to arrival at the destination airport. In any case, to be effective, it is necessary that insecticides be used before unloading passengers, cargo, and luggage. It is becoming more common for live animal cargo to be transported by air. The issues of disease and vectors must be addressed with such cargo.

Large pieces of expensive equipment are also being transported by air. When the equipment has been used in the field, it is extremely difficult to ensure that all fomite contamination has been removed prior to air transportation to another country. Washing and steam cleaning of the exterior of such equipment has become regular practice. The use of some form of pesticide is commonly required before the equipment is allowed to be unloaded after it has crossed international borders.

Airline Community Health

A commercial airliner, whether traveling domestic or international routes, provides a partially closed, self-contained environment. Air is brought on board, filtered, condensed, warmed, and if necessary, neutralized for irritants such as ozone and oxides of nitrogen. Potable water must be available as well as beverages safe for human consumption. The catering service must provide food items, which frequently include both preprepared meals and other items requiring some degree of preparation. Provisions must be made for the generation of solid and hazardous waste. Toilet facilities must be provided that require retention tanks to hold sewage until servicing can be provided on the ground. Arrangements for the collection of trash and sewage and its proper disposal on arrival must be made. These details may prove relatively simple in the domestic environment but may become extremely complex with international flights. In some international situations, all food products must be incinerated at the destination airport to ensure no introduction of a plant or animal disease.

► THE ENVIRONMENT

Noise

One of the more noticeable features of aerospace operations is noise. The Department of Transportation estimates that approximately 3% of the U.S. population, 9 million persons, have been exposed to a potentially hazardous level of aircraft noise. The Environmental Protection Agency (EPA) is authorized under the Noise Pollution and Abatement Act (1970) and the Noise Control Act (1972) to institute noise control abatement procedures around airports. The FAA has also been assigned responsibilities to reduce environmental noise. Regulatory requirements set goals and timelines for airport operators to submit and comply with noise compatibility programs.

Since the implementation of these laws, efforts have been undertaken by airframe manufacturers to control aircraft noise at its source. Numerous design changes have been made in engines primarily to reduce noise. Airports may require specific landing and departure patterns, including engine power adjustments, to comply with abatement controls. Some airports have found it necessary to curtail nighttime operations to satisfy objections by the community surrounding the airport. All levels of government have taken an active role in ensuring the compatibility of land use around airfields, both with regard to safety and noise control.

The "Greenhouse Effect" and Ozone Depletion

Aerospace operations contribute approximately 1% to the nation's total emissions of hydrocarbons, oxides of nitrogen, and carbon monoxide. In certain areas such as Atlanta and Chicago where aircraft operations are intense, emission levels have increased by approximately 3%. Under the Clean Air Act, airlines have markedly reduced the practice of inflight fuel dumping. Economics have also dictated a change in this policy. The principal environmental problem of the fuel is its contribution to photochemical pollution. The formation of the condensation trail, or con-trail, results from the emissions of the aircraft's engines condensing and freezing in the cold ambient temperature of altitude. It has been suggested that heavy jet traffic may cause weather changes in areas surrounding major airport hubs.

Ozone depletion is receiving an appropriate international response. In the 1970s there was much concern that oxides of nitrogen would serve as catalysts for ozone depletion at the high altitudes of the supersonic

transport (SST) flights. It was estimated that an SST fleet of 100 aircraft would decrease the ozone layer by 10%. This concern played an important role in the decision by this country to withdraw from the SST commercial competition. With additional research and a better understanding of the high-altitude atmospheric chemical relationship, the fears of ozone depletion from this source were shown to be exaggerated.

► THE FUTURE

Early in the twenty-first century, all projections point to more people flying higher and faster. The technology of aerospace systems will continue to improve, and the degree of automation of both air and space craft will continue to increase. Both British and French SST aircraft have been taken out of commercial service. A catastrophic accident may have contributed to the fleets' demise, but there were also real environmental and economic issues that played a role in the decision. In 2005, there are no SSTs flying; however, a feasibility study to consider development of a new SST is being jointly sponsored by the French and Japanese.

If bigger is better, then we should all take delight in the introduction by Airbus of their forthcoming A380. This behemoth will surpass the Boeing 747 as the world's largest passenger airliner. This new double-decker, 555 seat (or more) transport is expected to enter service in the summer of 2008. However, there are currently few airport terminals in the world that can accommodate such an aircraft. The logistics and human-factor challenges for boarding and disembarking 500–600 passengers are enormous. All of the issues addressed earlier in the chapter may be compounded by such an airborne biomass. Large numbers of men and women will be required to maintain and operate the expanding fleet of aerospace vehicles. New exotic materials will be introduced by the aerospace industry, requiring special medical surveillance programs to ensure the safety and health of those working with these new substances.

The challenges to public health and the environment will continue. With the continued expansion of international commerce via rapid air and space transport, the potential for transporting disease, vectors, and fomites will continue. Increasing air traffic in finite, three-dimensional space will result in some compromise to environmental factors. Airports will continue to expand, challenging community aesthetics and introducing social and environmental concerns.

With all of the opportunities and challenges of the future, aerospace medicine will continue to have an important niche in the ecology of health services.

Housing and Health

John M. Last

All humans need protection against the elements, somewhere to store food and prepare meals, and a secure place to raise offspring. The effects of housing conditions on health have been known since antiquity. Deplorable living and sanitary conditions in urban slums became a political issue in the nineteenth century when accounts by journalists, novelists, and social reformers aroused public opinion. Osler's *Principles and Practice of Medicine* (1892) and Rosenau's *Preventive Medicine and Hygiene* (1913) noted the association between overcrowding and common serious diseases of the time such as tuberculosis and rheumatic fever. Housing remains a sensitive political issue in many communities, because it is unsatisfactory, insufficient, inadequately served by essential infrastructure, and for various other reasons.

► OVERVIEW OF HOUSING CONDITIONS IN THE WORLD

Housing conditions have greatly improved in the affluent industrial nations throughout the second half of the twentieth century, but more than two-thirds of the households in the world are in developing countries, the great majority of them in rural areas. The most prevalent indoor environment in the world is the same now as throughout history—huts in rural communities.¹ This is changing, as urbanization transforms the distribution of populations in the developing world, where the proportion living in urban areas by the beginning of the new millennium had reached almost 50%.² The urban population will compose 65% or more by 2025 (UN World population and urbanization trends, <http://www.un.org/popin/wdtrends.htm>). Many cities are already very large (Table 51-1).

Many new urban dwellers in developing countries have terrible living conditions, crowded into periurban slums. They often lack sanitation, clean water supplies, access to health care, and other basic services such as elementary education. The proportion of people in such circumstances ranges from 20% to more than 80% in many cities throughout Africa, Latin America, and southern, southeastern, and southwestern Asia. The plight of children is especially deplorable; infant mortality rates exceed 100 in many places.³ Children may be abandoned by parents who cannot provide for them: they become street children who must fend for themselves from ages as young as 5 or 6 years. Many turn to crime and child prostitution to survive.

Shantytowns and periurban slums endanger the health and security of many millions in Latin America, Africa, and much of Asia. They are ideal breeding places for disease and social unrest. Accurate numbers are impossible to obtain because the missing services include enumeration by census-takers and because situations change so rapidly, but in Mexico City, Lima, Santiago, Rio de Janeiro, São Paulo, and Bogota, well over half the total population live in the periurban slums. In the late 1990s there were more than 40 million

periurban slum-dwellers in these six cities alone. Worldwide, an estimated 100 million people are entirely homeless, living on the streets without possessions, often from infancy onward.⁴ Although this is a problem mainly in developing countries, homeless people have increased in numbers in the most affluent industrial nations in recent decades, often forced out of their homes by hard economic times. Public health departments in large cities in North America and Europe have been obliged to spend increasing proportions of their budgets on emergency shelters for growing numbers of homeless destitute families. The weak and the vulnerable suffer disproportionately when social safety nets are inadequate, as is often the situation in the United States. One consequence is homelessness. About 842,000–850,000 people are homeless in any given week in the United States, and about 3.5 million are homeless for some period every year. Two-thirds are adults, predominantly single men, 11% are families with children, and 23% are children under 18 years. Most of the children are under 5. About 39% of homeless people in America suffer from mental disorders, and 66% have alcohol and/or substance abuse problems (http://www.nrchmi.samhsa.gov/facts/facts_question_2.asp). Many millions, 17 million refugees (<http://www.unhcr.org>) and more than 25 million internally displaced people (<http://www.idpproject.org/statistics.htm>), live in refugee communities in Africa or the Middle and Far East where housing conditions are usually worse than in periurban slums, or are homeless in cities in upper- and middle-income countries. Refugee communities may have health services, but these are seldom adequate; supplies and continuity of services are often precarious; the safety and security of the inhabitants is often threatened by hostilities, and their long-term prospects for a better life are poor. The Israeli Defense Forces policy of demolishing homes in refugee communities where suicide bombers had lived has been a deplorable example of actions by a civilized nation aggravating an already terrible social predicament. The genocidal policies of the Sudanese government toward the estimated 1.5 million displaced people in the Darfur region of Sudan have been even more deplorable.

Industrially developed nations are experiencing other challenging new health problems related to housing conditions. Rising land values and the need to provide cheap housing for expanding populations have led to proliferation of high-rise, high-density apartment housing. Publicly supported housing projects economize by restricting living space and providing few amenities. This kind of dwelling creates new sets of problems: emotional tensions attributable to living too close to the neighbors, inadequate play areas for children, poor services, and defective elevators and communal washing machines. When adverse climates make heating or air conditioning desirable, and when buildings must be sealed against inclement weather, efficient exhaust ventilation is important as a way to reduce the risk of sick building syndrome. Only a small minority of people, predominantly the educated professional classes (such as many readers of this book), enjoy comfortable, aesthetically pleasing, healthy living conditions.

TABLE 51-1. WORLD'S LARGEST CITIES (CONURBATIONS), 2000–2004

1. Tokyo, Japan (incl. Yokohama, Kawasaki)	34,000,000
2. Mexico City, Mexico (incl. Nezahualcōyotl, Ecatepec, Naucalpan)	22,350,000
3. Seoul, South Korea (incl. Bucheon, Goyang, Incheon, Seongnam, Suweon)	22,050,000
4. New York, USA (incl. Newark, Paterson)	21,800,000
5. Sao Paulo, Brazil (incl. Guarulhos)	20,000,000
6. Mumbai (Bombay) India (incl. Kalyan, Thane, Ulhasnagar)	19,400,000
7. Delhi, India (incl. Faridabad, Ghaziabad)	19,000,000
8. Los Angeles, USA (incl. Riverside, Anaheim)	17,750,000

► INDOOR ENVIRONMENT

Indoor climate and indoor air pollution, biological exposure factors, and various physical hazards encountered inside the home are encompassed by the term *indoor environment*. The indoor climate may be the same as that out of doors, or it may be modified by heating, cooling, or adjustment of humidity levels, and often in sealed modern buildings, by all of these.

Physical Hazards

Physical hazards in the indoor environment include toxic gases, respirable suspended particulates, asbestos fibers, ionizing radiation, notably radon and “daughters,” nonionizing radiation, and tobacco smoke.

Indoor air may be contaminated with dusts, fumes, pollen, and microorganisms. The principal indoor air pollutants in industrially developed nations are summarized in Table 51-2. Many of these pollutants are harmful to health. Some occur mainly in sealed office buildings, and others, such as tobacco smoke, in private dwellings.

In developing countries, indoor air pollution with products of biomass fuel combustion is a pervasive problem (Table 51-3). The fumes from cooking fires include high concentrations of respiratory irritants that cause chronic obstructive pulmonary disease (COPD) and that sometimes contain carcinogens. Premature death from COPD is common among women who from their childhood have spent many hours every day close to primitive cooking stoves, inhaling large quantities of toxic fumes.⁵

The toxic gases specified in Table 51-2 come from many sources. Formaldehyde is emitted as an off-gas from particle board, carpet adhesives, and urea-formaldehyde foam insulation; it is a respiratory and conjunctival irritant and sometimes causes asthma. It is not emitted in sufficient concentrations to constitute a significant cancer risk. Although rats exposed to formaldehyde do demonstrate increased incidence of nasopharyngeal cancer, there is only weak evidence of elevated cancer incidence or mortality rates even among persons occupationally exposed to far higher concentrations than occur in domestic settings. Nonetheless, urea-formaldehyde foam insulation has been banned in many jurisdictions on the basis of the evidence for carcinogenicity in rats. Gases and vapors from volatile solvents, such as cleaning fluids, have diverse origins. There is a wide range of other pollutants, such as many organic substances, oxides of nitrogen, sulfur, carbon, ozone, benzene, and terpenes.⁶ All such toxic substances can be troublesome, especially in sealed air-conditioned buildings and most of all when the air is recirculated to conserve energy used to heat or cool the building. In combination with fluorescent lighting, these gases and suspended particulate matter can produce an irritating photochemical smog that may cause chronic conjunctivitis and nasal congestion.

Imperfect ventilation can become a serious hazard if it leads to accumulation or recirculation of highly toxic gas such as carbon monoxide. This is especially likely when coal or coke is used as cooking or heating fuel in cold weather, and vents to the outside are closed to conserve heat.

Asbestos was used for many years as a fire retardant and insulating substance in both domestic and commercial buildings. Its dangers to health have led to restriction or banning of its use and to expensive renovations aimed at removing it (see Chap. 23). Fibrous glass insulation may present hazards similar to those of asbestos but less severe.

Ionizing radiation, in particular radon and “daughters,” can be a health hazard, especially if houses are sealed and air recirculated, in which case there is greater opportunity for higher concentrations to accumulate. Sources of radon include trace amounts of radioactive material incorporated in cement used to construct basements. Radon can also be emitted from soil or rocks in the environment where the houses are built.

Extremely low-frequency electromagnetic radiation (ELF) has attracted much attention since the observation of cancer incidence at higher rates than expected among children living close to high-voltage power lines.⁷ No convincing relationship has been demonstrated between childhood cancer and exposure to ELF from domestic appliances, with the possible exception of electric blankets.⁸ Microwave ovens and television screens are safe. The nature of the relationship, if any, between ELF and cancer remains controversial, however.

Tobacco smoke is often the greatest health hazard attributable to physical factors in the indoor environment. Infants and children are significantly more prone to respiratory infections, and nonsmoking spouses are more prone to chronic respiratory illnesses and to tobacco-related respiratory cancer when living in the same house as a habitual cigarette smoker. Cigarette smoking is a hazard in another way as well: about 20–25% of deaths in domestic fires are a result of smoking.

TABLE 51-2. SOURCES AND POSSIBLE CONCENTRATIONS OF INDOOR POLLUTANTS

Pollutant	Sources*	Range of Concentrations
Respirable particles	Tobacco smoke, stoves, aerosol sprays	0.05–0.7 mg/m ³
Carbon monoxide	Combustion equipment, stoves, gas heaters	1–115 mg/m ³
Nitrogen dioxide	Gas cookers, cigarettes	0.05–1.0 mg/m ³
Sulfur dioxide	Coal combustion	0.02–1.0 mg/m ³
Carbon dioxide	Combustion, respiration	600–9,000 mg/m ³
Formaldehyde	Particle board, carpet adhesives, insulation	0.06–2.0 mg/m ³
Other organic vapors (benzene, toluene, etc.)	Solvents, adhesives, resin products, aerosol sprays	0.01–0.1 mg/m ³
Ozone	Electric arcing, UV light sources	0.02–0.4 mg/m ³
Radon and “daughters”	Building materials	10–3,000 Bq/m ³
Asbestos	Insulation, fireproofing	1 + fiber/cm ³
Mineral fibers	Appliances	100–10,000/m ³

*Tobacco smoke, benzene, radon and daughters, asbestos, and possibly formaldehyde are carcinogens; most others on this list are respiratory or conjunctival irritants. Carbon dioxide is an asphyxiant; carbon monoxide is a lethal poison.

Biological Hazards

Biological hazards in the indoor environment include many varieties of pathogenic microorganisms. *Mycobacterium tuberculosis* survives for long periods in dark and dusty corners. *Legionella* lives in dilapidated water-cooled air-conditioning systems, stagnant water pipes, and shower stalls, especially in warm moist environments. Mites that live on mattresses, cushions, and infrequently swept floors cause asthma, as may many organic dusts and pollens. Many other infections, especially those spread by the fecal-oral route, occur most often when homes are dirty, open to flies, or infested with cockroaches or rats. Food storage and cooking facilities should be kept scrupulously clean at all times because many varieties of disease-carrying vermin are attracted by filth and because food scraps can be an excellent culture medium for many pathogens that cause food poisoning or other diseases.

Socioeconomic Conditions

Socioeconomic conditions are related to the quality of housing in many ways, some already mentioned. Crowding always is greater among the poor than among the rich; this increases risks of transmitting communicable diseases and often imposes additional emotional stress that probably contributes to domestic violence. Street accidents involving children are more common in poor than in wealthy neighborhoods because the children often have no other place than the street to play. Poor people generally live in poorly equipped and maintained homes, adding to the risk of domestic accidents ranging from falls down poorly lit stairwells to electrocution. Lead poisoning

is a particular hazard for children in dilapidated houses where they are likely to ingest dried-out flakes of lead-based paint. Emissions from factory smelter stacks contribute to environmental lead and other toxic metal contamination and are more often present in poor than in well-to-do neighborhoods because the former are more often located in or close to heavily industrialized areas.

► HOUSING CONDITIONS AND MENTAL HEALTH

Many descriptive studies by social epidemiologists and psychiatrists have demonstrated a consistent association between mental disorders and urban living conditions.⁹ There is also a close relationship between mental health and social class.¹⁰ Those who cannot cope with the competitive pressures of industrial and commercial civilization because they suffer from such disorders as schizophrenia, alcoholism, or mental retardation and have inadequate family and social support systems drift downward to the lowest depths of the slums or become homeless street people. There are estimated to be between 500,000 and 2 million homeless mentally ill persons in the United States.¹¹ Schizophrenia and alcoholism have maximum prevalence in slums and “skid row” districts, and depression, manifested by attempted and accomplished suicide, is clustered in neighborhoods where a high proportion of the people live in single-room rented apartments.¹² Adolescent delinquency, vandalism, and underachievement at school have high prevalence in dormitory suburbs occupied mainly by low-paid workers, where recreational facilities for young people are often

TABLE 51-3. INDOOR AIR POLLUTION FROM BIOMASS FUEL COMBUSTION IN DEVELOPING COUNTRIES

	GPM (mg/m ³)	BaP (mg/m ³)	CO (mg/m ³)	NO ₂ (µg/m ³)	Other

BaP = benz-a-pyrene; SPM = suspended particulate matter. Data from de Koning HW, Smith KR, Last JM. Biomass fuel combustion and health. *Bull WHO*. 1985;63:11–26. *Air Quality Guidelines*. Regional Reports series 23. Copenhagen: World Health Organization; 1987.

inadequate and schools are often of inferior quality. Bad housing does not cause these problems; they are usually symptoms of a more complex social pathology. A different set of factors contributes to the syndrome called “suburban neurosis,” which occurs among women who remain housebound for much of the time while their husbands are at work and their children are at school;¹³ this condition has been alleviated by television, which by bringing faces and voices into the house relieves loneliness. It has also been alleviated by changing work patterns, with increasing proportions of married women joining the workforce.

► HOUSING STANDARDS

Public health workers are directly concerned about the quality of housing because of the many ways it can affect health. Local health officials have special powers to intervene when health is threatened by inadequate housing conditions. A handbook frequently revised by the Centers for Disease Control and Prevention and the American Public Health Association, *Housing and Health: APHA-CDC Recommended Minimum Housing Standards*,¹⁴ sets out specific details on basic equipment and facilities, fire safety, lighting, ventilation, thermal requirements, sanitation, space requirements (occupancy standards), and the special requirements for rooming houses. This valuable reference spells out general guidelines that can be used by local authorities as the basis for regulations, but there are no universal legally enforceable standards until local jurisdictions introduce them. *Health Principles of Housing*,¹⁵ a WHO manual, gives guidance on a wide range of behavioral factors that can influence health in relation to housing conditions, for example, by providing guidelines on ways to reduce psychological and social stresses by ensuring privacy and comfort, and on the housing needs of populations at special risk such as pregnant women, the handicapped, and the elderly infirm. Both booklets should be part of the library of every local health officer.

► STATISTICAL INDICATORS OF HOUSING CONDITIONS

Health planning requires every kind of information pertinent to community health, including statistics on housing conditions. Useful information is routinely collected at the census on density of occupancy (persons per bedroom), cooking and refrigerating facilities, and sanitary conditions. Tables derived from small-area analysis of census data showing housing statistics enable health planners to identify neighborhoods at high risk of diseases associated with crowding and poor sanitation.

Census tables also enable health planners to identify less obvious health hazards, such as proportions of elderly persons living alone, whether in small apartments or multiple-room dwellings that were family homes before others in the family moved away or died, leaving an elderly person as sole resident. Once such neighborhoods are identified, public health nurses and other community health workers can more easily locate and visit individuals at risk, who may need but have not yet asked for help.

In addition to census tables, there are other useful sources of information on neighborhoods with a high incidence of social pathology. Fire departments record false alarms and fires deliberately lit; police departments record details of vandalism and calls to settle domestic disturbances; and schools record absenteeism and truancy. All can be analyzed by area, thus pinpointing high-risk neighborhoods; this method has been used as part of a program aimed at improving the chances of getting a good start in life for children from disadvantaged homes. There is a high correlation between these indicators of social pathology in a neighborhood, such as a high-rise, high-density apartment complex for low-income families, and the incidence of emotional disturbances and similar behavioral upsets among young and teenaged children.¹⁶

► HEALTHY COMMUNITIES AND HEALTHY CITIES

As part of the initiative for “Health for all by the year 2000” that followed resolutions passed at the World Health Assembly in 1977,¹⁷ health planners in many nations, notably in the European region of the World Health Organization (WHO), began active planning for health promotion (to be distinguished from disease prevention). Health promotion (see Chap. 1) requires action by many individuals and groups not usually identified with care of the sick or prevention of disease. The definition of health promotion, “the process of enabling people to increase control over and improve their health,” implies that people may often have to take action aimed at improving their living conditions. The Healthy Cities movement is a coordinated program involving community health workers, local elected officials in urban affairs, and a wide variety of community groups who collectively seek to upgrade living conditions. Initially, some of the participating cities were relatively healthy places to live (e.g., Toronto, Canada), while others (e.g., Liverpool, England) were not. The Healthy Cities initiative emphasizes activities that could be expected to enhance good health, such as provision of improved recreational facilities, services for children and their mothers (including basic education for the mothers as well as the children), and aggressive action to eradicate urban wasteland, industrial pollution, toxic dump sites, and other forms of urban blight.¹⁸ From modest beginnings, the Healthy Cities movement has spread all over the world and in some places has extended beyond cities to embrace rural communities.¹⁹ Since the environment in which people live, grow, work, and play so manifestly influences their health and happiness, the Healthy Cities initiative is potentially among the most valuable means at our disposal to make this environment healthful.

► SPECIAL HOUSING NEEDS

Elderly and disabled people require accommodation that has been adapted to enable easier access (ramps, handrails, wide doors to permit passage of wheelchairs), to facilitate storage and preparation of food (low-placed cupboards and stoves with front-fitted switches, which are inadvisable in homes where there are small children), and with special equipment for bathing and toileting (strong handrails, wheelchair access). Special accommodation of this type is often segregated, which tends to set the occupants apart in an urban ghetto for the elderly and disabled. Integrated special housing is preferable, as examples in Denmark, Sweden, and the United Kingdom have demonstrated; in this setting, elderly, infirm, and younger disabled persons live among others who are not disabled, a situation that many of them prefer and that helps to accustom these other people to making allowances for their disabled fellow citizens.

► CONCLUSION

This is a brief summary of a complex and diverse topic. The essential requirements of the domestic environment have been stressed, along with some of the obvious adverse effects of unsatisfactory housing.

The home should provide more than mere shelter and a safe place to raise children. It should be the setting in which the family lives and grows together, where bonds of affection and mutual trust are formed and strengthened, where socialization into the prevailing culture and intellectual stimulation are occurring, and where privacy is available when it is wanted and needed. Doxiadis²⁰ coined the term *ekistics*, meaning the science of human settlements, to encompass the many interactive factors that make living space compatible with good physical, mental, emotional, and social health and well-being. The arrangement of dwelling units, their relationship to the natural and to the human-made environment, and their interior structure and function all play a part in creating a housing environment conducive to good health. Many less easily described and unmeasurable factors,

such as the innumerable ways that people can interact, also contribute to the ambience of the living space. These intangible factors would receive more attention in a better world than this if we were really intent on applying all possible means to the end of promoting and preserving the public's health.

Human Health in a Changing World

John M. Last • Colin L. Soskolne

► HUMAN HEALTH IN A CHANGING WORLD

Throughout its 4-billion-year life, Earth has undergone many changes in the distribution and abundance of life forms, including human inhabitants, and in the living and nonliving features of the ecosystems with which humans interact. Early in the twenty-first century, the United Nations Millennium Assessment Report, the collective work of over 1300 scientists worldwide, painted a disturbing picture of life-supporting ecosystems that are gravely stressed by human activities to an extent that is unsustainable even in the medium-term. This conclusion has been reinforced by recent publications of the Intergovernmental Panel on Climate Change,¹ and the Millennium Ecosystem Assessment.²

Atmospheric composition and climate have changed many times. Sometimes air and ocean currents that determine climate and weather have been altered by tectonic plate movements. The impact of large meteors or massive volcanic activity that block sunlight by filling the air with dust and gases such as sulfur dioxide have occasionally produced sudden climate changes leading to great extinctions.³ Variation in solar radiation, oscillation of Earth's axis, or passing clouds of interstellar dust may induce ice ages and periods of interglacial warming.⁴ Minor seasonal fluctuations are associated with many intervening variables that make weather forecasting one of the most inexact of all sciences.

A consensus has developed among scientists in the relevant disciplines that human activity is adversely affecting Earth's climate;⁵ and there is compelling evidence that human activity is changing the biosphere in other ways besides climate.⁶ The changes represent a new scale of human impact on the world unlike anything in recorded history. Collectively, the changes endanger both human health and future prospects for many other living creatures. Global warming and stratospheric ozone depletion have attracted the most attention, but the changes go beyond these two processes.

The term *global change* covers several interconnected phenomena:⁷ global warming ("climate change"); stratospheric ozone attenuation; resource depletion; species extinction and reduced biodiversity; serious and widespread environmental pollution; desertification; and macro and micro ecosystem changes, including some that have led to emergence or reemergence of dangerous pathogens.⁸ These phenomena are mostly associated with industrial processes or result from the increased pressure of people on fragile ecosystems.⁹ All are interconnected and some are synergistic—some processes reinforce others. What makes these human-induced changes different from those through history is the rate of current change and its reach.¹⁰

Ecological integrity, the ability of ecosystems to withstand perturbations, is dependent on three factors: population, affluence, and technology.^{11–13} All three factors are interdependent and can operate synergistically, accelerating declines in systems upon which life, including human life, depends for sustenance. As declines accelerate, thresholds are exceeded as the buffering capacity of these systems is challenged, resulting in system flips or collapses. When large-scale ecosystems collapse, all life that these systems have nurtured over

centuries and millennia can then either be buffered from impacts by drawing on ecological capital from elsewhere, by migration to more hospitable locales, or by succumbing. The frail, marginalized in society, and the poor generally do not have the survival option.

Each of these three variables is interdependent and must be considered if solutions to our downward spiral are to be found. Many independently derived indicators of ecological well-being demonstrate that declines are underway and are accelerating.^{14–16} There is a need for sober debate in pursuit of solutions to grave global problems, and public health practitioners must engage in such discussions by considering all three factors in the delicate ecological integrity balance; not each one in isolation.

Population: In little more than the length of an average lifetime, the population quadrupled, from about 1.7 billion in 1900 to about 6.4 billion by 2000.¹⁷ It is not clear whether our numbers have reached or exceeded Earth's carrying capacity;¹⁸ but responsible opinion inclines to the view that we have reached the limits for comfortable human existence. Earth might sustain for a while many millions more than the present number, but life for all but a small minority would be of greatly diminished quality and long-term sustainability would be at best precarious.¹⁹

Affluence: Affluent people and nations consume renewable and nonrenewable resources far in excess of their needs, and consequently, the ecological footprint of the affluent nations far exceeds available resources worldwide.²⁰ Moreover, consumption leads to pollution from the disposal of waste, much of which ends up in the backyards of marginalized people locally^{21,22} or in low-income countries.²³ These are institutionalized practices and hence are deemed legitimate business practices.²⁴

Technology: Technologies that result in war and ecological devastation are clearly harmful both to ecosystems and human health.²⁵ In countries where environmental legislation and regulation do not permit polluting technologies to operate, polluting technology is often exported to regions of the world where stringent environmental controls are absent, while newer generation technologies are implemented in affluent nations to comply with local environmental standards.

Evidence on the causes and consequences of global change was published by the Intergovernmental Panel on Climate Change (IPCC) in 1990^{26,27} in its First Assessment Report. There was more evidence in the Second Assessment Report in 1995.²⁸ The Third Assessment Report was published in 2001¹ with graver predictions based on more refined science than just 11 years previously. The Fourth Assessment Report is appearing in installments in 2007 (see Addendum). Much of the information in this chapter is taken from the IPCC Reports, from *Climate Change and Human Health*,²⁹ (1996) and from *Climate Change and Human Health; Risks and Responses* (2003).³⁰ There have been many other reports: by national governments,³¹ scientific articles,^{32,33} and documents produced by nongovernmental agencies such as the Union of Concerned Scientists,³⁴ Friends of the Earth, the Worldwatch Institute,³⁵ and the Sierra Club.

BOX 52-1. NATURE'S SERVICES*

"The conditions and processes through which natural ecosystems, and the species that make them up, sustain and fulfil human life. They maintain biodiversity and the production of *ecosystem goods*, such as seafood, forage, timber, biomass fuels, natural fiber, and many pharmaceuticals, industrial products, and their precursors. The harvest and trade of these goods represent an important and familiar part of the human economy. In addition to the production of goods, ecosystem services are the actual life-support functions, such as cleansing, recycling, and renewal, and they confer many intangible aesthetic and cultural benefits as well."

- Purification of air and water
- Mitigation of floods and droughts
- Detoxification and decomposition of wastes
- Generation and renewal of soil and soil fertility
- Pollination of crops and natural vegetation
- Control of the vast majority of potential agricultural pests
- Dispersal of seeds and the translocation of nutrients
- Maintenance of biodiversity, from which humanity has derived key elements of its agricultural, medicinal, and industrial enterprise
- Protection from the sun's harmful ultraviolet rays
- Partial stabilization of climate
- Moderation of temperature extremes and the force of winds and waves
- Support of diverse human cultures
- Providing of aesthetic beauty and intellectual stimulation that lift the human spirit

*Daily, Gretchen C. *Nature's Services: Societal dependence on natural ecosystems*. Island Press. 1997:3–4.

In the late 1980s, when concerns about global warming and other aspects of global change began to attract widespread public interest, some contrary views and rebuttals were published,^{36,37} sometimes but not always sponsored by organizations that opposed actions aimed at mitigating global change. As the empirical evidence mounted, these contrary views have become more muted. A recent attack on climate science came from Lomborg³⁸ in *The Skeptical Environmentalist*. This book provides an example of how science can be challenged, but Lomborg is an economist and his book is devoid of sound scientific analysis.

Every component of global change merits discussion; and so do some of the complex interconnections among them. Readers are urged to consult the sources cited in the bibliography. The health, social, economic, and other impacts of global change have been the topic of many important reports.^{39–41} There are some obvious actions we should take to enhance readiness to deal with public health aspects of global change and implications for public policy generally.

A critical concern is the disconnect in most people's minds between nature and human well-being.⁴² There is a belief that should we, for instance, destroy our water supplies, clean water will be produced through technologies yet to be invented. Likewise for all of Nature's services⁴³ that humanity has taken for granted for millennia (see Box 52-1) Costanza^{44,45} has demonstrated that Nature's services, in dollar terms, amount annually to some three times global GDP. Thoughtful scientists and philosophers⁴⁶ have cautioned for decades about the folly of such expectations, even if only on the basis of thermodynamic principles.^{47–49}

► GLOBAL WARMING

Svante Arrhenius recognized in 1896 that Earth's mantle of atmosphere acts like a greenhouse, allowing passage of short-wavelength solar radiation into the biosphere, trapping longer wavelength infrared radiation. Without the greenhouse effect, Earth's surface temperature would swing from over 50°C in strong sunlight to –40°C at dawn. The concentration of greenhouse gases in the troposphere has risen rapidly since the beginning of the industrial era because several of these gases, notably carbon dioxide, are products of fossil fuel combustion and other human activities. Industrial activity and the combustion of petroleum fuels in automobiles have increased exponentially

since the 1950s, accelerated by industrial and commercial development in India, China, South Korea, Taiwan, Indonesia, Thailand, Brazil, Mexico, and other countries. Currently over 6 billion metric tons of CO₂, the principal greenhouse gas, are added to the troposphere annually, increasing amounts every year. In 2002, the last year for which a global estimate is available, the global output of CO₂ was almost 7 billion metric tons.⁵⁰ This is despite the promises made by most national leaders at the UN Conference on Environment and Development⁵¹ (UNCED) in Rio de Janeiro in 1992, to stabilize carbon emissions at or below 1990 levels. Moreover, tropical rain forests, perhaps the most important carbon sink (i.e., a biological system that absorbs carbon emissions, thus helping to counter-balance negative impacts on Earth's temperature), are being rapidly depleted often by slash-burning and this adds even more carbon gases to the greenhouse. Phytoplankton, another important carbon sink, are damaged by increased ultraviolet radiation (UVR) flux from depleting stratospheric ozone, an example of reinforcement of one form of global change by another. When they signed the 1995 Framework Convention on Climate Change, most national leaders reiterated their earlier promises, and the 1995 IPCC Reports add a sense of urgency to the need for action. Recently, support for the Kyoto Accord has exposed countries whose leadership is primarily focused on the narrow good of its own citizens, failing to embrace global concerted action to remedy a global crisis already underway.

In 1995, the atmospheric concentration of carbon dioxide reached a higher level than at any time in the last 140,000 years, and the average ambient atmospheric temperature was the highest since record-keeping began.⁵² It is estimated by global climate models using a variety of methods that the average global ambient temperature will rise by about 0.5°C in the first half of the twenty-first century and may rise 2°C by 2100.⁴ These estimates were revised upward in the Third Assessment Report to 4.5°C. Moreover these are *average* temperatures; the increase and the seasonal and diurnal swings are expected to be greater, as much as 6–8°C, in temperate zones, and even more extreme near the poles. If arctic permafrost thaws as a result, a great deal of methane will be released, adding to the existing burden of atmospheric greenhouse gases and accelerating the warming process. Polar ice caps and sea ice are melting at rates greater than the predictions suggested as recently as a decade ago, suggesting that global warming is proceeding at rates at or near the upper levels that were predicted in the earlier Assessment Reports.

Global warming has direct and indirect and predominantly adverse effects on health.⁵³ Although heat-wave deaths are dramatic and obvious,⁵⁴ for instance causing at least 10,000 excess deaths in Paris in July 2003, in terms of overall health impact a more important impact on health may be an increased incidence and prevalence of water-borne and vector-borne disease. Increased average ambient temperatures extend the range, distribution, and abundance of insect vectors such as mosquitoes, allow the pathogens they carry to breed more rapidly, and may enhance their virulence.⁵⁵ Malaria, for instance, is expected to become prevalent in temperate zones and at altitudes in tropical and subtropical regions from which it is now absent, notably large highland cities and periurban slums in East Africa (e.g., Nairobi, Harare, Soweto) where an additional 20–30 million people will be at risk; there will be many millions more at risk of malaria annually in Indonesia and other populous South and Southeast Asian nations.⁵⁶ Other tropical and subtropical vector-borne diseases also will increase in incidence, prevalence, and perhaps mortality. In North America, several arbovirus diseases (e.g., viral encephalitis and hemorrhagic dengue fever) will occur more frequently.

The indirect effects of global warming include a sea-level rise of up to 50 cm by the year 2050, due to melting of polar and alpine ice-caps and thermal expansion of the seawater mass. This will disrupt many coastal ecosystems, jeopardize coastal and perhaps some ocean fisheries, salinate river estuaries that are an important source of drinking water, and displace scores of millions of people from low-lying coastal regions in many parts of the world, including the Netherlands, Bangladesh, much of South China, parts of Japan, and small island states (e.g., Vanu Atu, the Maldives) that face inundation and obliteration. Up to 10–15 million people along the eastern seaboard of the United States may be affected. Many of those displaced will become “environmental refugees” in third-world megacities or drift into urban squalor in the rich industrial nations.

Another effect of global climate change with implications for human health is anomalous weather—notably, more frequent, severe, and unpredictable weather emergencies such as catastrophic floods, hurricanes and tornadoes, and heat waves. Atmospheric physicists and climatologists believed that some unusual weather events in the 1986–1995 decade may have been attributable to global climate change. Indeed, the warming trend is now recognized as having been in play since about 1990. These anomalous weather events have already extracted a heavy financial toll from the insurance industry and from national disaster funds in the United States and elsewhere (Table 52-1).⁵⁷ With sudden flooding, sewer backups and the potential for the contamination of drinking water supplies have been reported resulting in public health emergencies in both the United States and Canada in the recent past. The disastrous hurricanes Katrina and Rita that caused immense devastation and loss of life in New Orleans and elsewhere in Louisiana and in Texas in August 2005 may have been in part a manifestation of this trend.^{58–63}

The European summer of 2003 included severe heat waves associated with sharp increases in mortality in several large cities, notably in Paris where a conservatively estimated 10,000 out of a total excess mortality of 14,000 was directly attributable to heat-wave conditions.

The impact of global warming on food security could be very serious; here the interconnection of global warming with resource depletion and desertification is important. Global warming will jeopardize the viability of crops in some of the world’s most important grain-growing regions because it will alter rainfall patterns and soil moisture levels and hasten desertification of marginal grazing and agricultural land, as it has already done in much of the West African Sahel, parts of northeastern Brazil, and elsewhere in Africa (e.g., Ethiopia, Sudan, Angola, Zimbabwe). An increase in surface-level ultraviolet radiation flux, discussed below, will make matters worse if it impairs plant reproduction or growth. Predictions are difficult when so many variables are involved, but the models developed by agronomists suggest that, while some grain crops might benefit from warmer climate and higher levels of atmospheric CO₂, the overall impact is likely to be a decline in world grain crop production⁶⁴ (Table 52-2).

TABLE 52-1. INSURED LOSSES FROM “BILLION U.S. DOLLAR” STORM EVENTS SINCE 1987*

Year	Event	Insured Loss (\$ Billion)
1987	Windstorm (Western Europe)	4.7
1989	Hurricane Hugo (Caribbean, United States)	6.3
1990	Winter storms (Europe—four events in total)	13.2
1991	Typhoon Mireille (Japan)	6.9
1991	Akland fire (United States)	2.2
1992	Hurricane Andrew (Florida)	20.8
1992	Hurricane Iniki (Hawaii)	2.0
1993	Blizzard—“Storm of the Century” (Eastern United States)	2.0
1993	Floods (United States)	1.2
1995	Hurricane Luis (Caribbean)	1.7
1995	Hurricane Opal (United States)	2.4
1995	Hailstorm (United States)	1.3
1996	Hurricane Fran (United States)	1.8
1998	Hurricane (Georges Caribbean, United States)	3.5
1998	Ice storm (Canada, United States)	1.2
1998	Hailstorm	1.4
1998	Floods (China)	1.1
1999	Winter storms (Europe)	10.4
1999	Typhoon Bart (Japan)	3.4
1999	Hail storm (Australia)	1.1
1999	Tornadoes (United States)	1.5
1999	Hurricane Floyd (United States)	2.2

*From Munich Reinsurance Company. *Windstorm—New Loss Dimensions of a Natural Hazard*. Munich: Munich Reinsurance Company; 2000. Figures are adjusted for inflation (1999 values). (See http://www.grida.no/climate/ipcc_tar/wg2/329.htm, Table 8-3 from which Earthquakes have been omitted.) Note (1) From 1970 through 1986, no claims exceeding 1 billion US \$ are reported. Note (2) According to the United Nations Environment Programme (UNEP) (at <http://www.rolac.unep.org/cpresa/cpb43i/cpb43i.htm>), total insurance losses for 2003 and 2004 amount, respectively, to \$16 billion and \$35 billion.

Desertification is made worse by unsound and inappropriate agricultural methods. The “green revolution” that dramatically increased agricultural output in the 40 years following the end of World War II is over: many forms of agricultural output have remained stationary or have declined in the past 5–10 years, raising troubling questions about Earth’s carrying capacity.

Global warming is the principal cause of the retreat of alpine glaciers that has been observed since the late nineteenth century. This could reduce the ice-melt component of many river systems, which contribute by irrigation and/or seasonal flooding to productivity of food-producing regions. The deficit is compensated in part at least by increased rainfall, but in the long term, river flow could decline. Shortages of fresh water for irrigation and drinking may be the most critical limiting factor on further population growth in many parts of the world.

► STRATOSPHERIC OZONE ATTENUATION

In 1974, Molina and Rowland, two atmospheric physicists, predicted that chlorofluorocarbons (CFCs), a widely used class of chemicals, would permeate the upper atmosphere where they would break down under the influence of solar radiation to produce chlorine monoxide.^{65,66} Chlorine monoxide destroys ozone; each molecule of chlorine monoxide is capable of destroying over 10,000 ozone molecules. Rowland and Molina were awarded the Nobel Prize for

TABLE 52-2. SELECTED CROP STUDY RESULTS FOR 2 × CO₂-EQUIVALENT EQUILIBRIUM GCM SCENARIOS*

<i>Region</i>	<i>Crop</i>	<i>Yield Impact (%)</i>	<i>Comments</i>
Latin America	Maize	-61 to increase	Data are from Argentina, Brazil, Chile, and Mexico; range is across Global Climate Model (GCM) scenarios, with and without CO ₂ effect
	Wheat	-50 to -5	Data are from Argentina, Uruguay, and Brazil; range is across GCM scenarios, with and without CO ₂ effect
	Soybean	-10 to +40	Data are from Brazil; range is across GCM scenarios, with CO ₂ effect
Former Soviet Union	Wheat grain	-19 to +41	Range is across GCM scenarios and region, with CO ₂ effect
Europe	Maize	-14 to +13 -30 to increase	Data are from France, Spain, and northern Europe; with adaptation and CO ₂ effect; assumes longer season, irrigation efficiency loss, and northward shift
	Wheat	Increase or decrease	Data are from France, United Kingdom, and northern Europe; with adaptation and CO ₂ effect; assumes longer season, northward shift, increased pest damage, and lower risk of crop failure
	Vegetables	Increase	Data are from United Kingdom and northern Europe; assumes pest damage increased and lower risk of crop failure
North America	Maize	-55 to +62	Data are from United States and Canada; range is across GCM scenarios and sites, with/without adaptation and with/without CO ₂ effect
	Wheat	-100 to +234	
	Soybean	-96 to +58	Data are from United States; less severe or increase with CO ₂ and adaptation
Africa	Maize	-65 to +6	Data are from Egypt, Kenya, South Africa, and Zimbabwe; range is over studies and climate scenarios, with CO ₂ effect
	Millet	-79 to -63	Data are from Senegal; carrying capacity fell 11-38%
South Asia	Biomass Rice	Decrease -22 to +28	Data are from South Africa; agrozone shifts Data are from Bangladesh, India, Philippines, Thailand, Indonesia, Malaysia, and Myanmar; range is over GCM scenarios, with CO ₂ effect; some studies also consider adaptation
China	Maize	-65 to -10	
	Wheat	-61 to +67	
	Rice	-78 to +28	Includes rainfed and irrigated rice; range is across sites and GCM scenarios; genetic variation provides scope for adaptation
Other Asia and Pacific Rim	Rice	-45 to +30	Data are from Japan and South Korea; range is across GCM scenarios; generally positive in north Japan, and negative in south
	Pasture	-1 to +35	Data are from Australia and New Zealand; regional variation
	Wheat	-41 to +65	Data are from Australia and Japan; wide variation, depending on cultivar

*For most regions, studies have focused on one or two principal grains. These studies strongly demonstrate the variability in estimated yield impacts among countries, scenarios, methods of analysis, and crops, making it difficult to generalize results across areas or for different climate scenarios. (See Chapter 15, Reference 10.) Note: IPCC 2001 provides an update with more specific details according to studies with explicit global economics and/or global yields; and, by studies of yield and production in developed regions, nations, and subnational regions: http://www.grida.no/climate/ipcc_tar/wg2/212.htm#tab54.

Physics in 1995 in recognition of their work. Other atmospheric contaminants that destroy stratospheric ozone include other halocarbons and perhaps oxides of nitrogen (e.g., in exhaust emissions of high-flying supersonic jet aircraft). Volcanic eruptions sometimes release chlorine compounds into the atmosphere, so natural as well

as human-induced processes can contribute to stratospheric ozone attenuation.

Rowland and Molina's predictions soon began to come true. In 1985, Farman and coworkers observed extensive attenuation (a "hole") in the stratospheric ozone layer over Antarctica during the Southern

Hemisphere spring.⁶⁷ This has recurred annually; since 1990, seasonal ozone depletion has been observed in the Northern Hemisphere too, greatest over parts of Siberia and northeastern North America. Stratospheric ozone depletion was correlated by Kerr and colleagues at the Canadian Climate Centre in 1993 with increased surface level UVR flux.⁶⁸ Ozone depletion so far is about 3–4% of total stratospheric ozone and increasing annually.

The stratospheric ozone layer protects the biosphere from exposure to lethal levels of ultraviolet radiation. The gravity of this progressive loss of stratospheric ozone was recognized almost immediately and led many industrial nations to adopt the Montreal Protocol, calling for a moratorium on manufacture and use of CFCs.⁶⁹ CFCs were widely used as solvents in manufacture of microprocessors for computers, foaming agents in polystyrene packing, propellants in spray cans, and as Freon gas in air conditioners and refrigerators; their supposed chemical inertness made them a popular choice. But because they are inert, they have, on average, an atmospheric half-life of about 100 years, so stratospheric ozone depletion will continue to be a serious problem well into the twenty-second century. Stratospheric ozone must not be confused with toxic surface-level air pollution with ozone that contaminates fumes from some industrial processes or as a result of the action of sunlight on automobile exhaust fumes (“photochemical smog”).

Stratospheric ozone depletion permits greater amounts of harmful UVR to enter the biosphere, where it has adverse effects on many biological systems and on human health. The principal biological effects of increased UVR are disruption of the reproductive capacity and vitality of small and single-celled organisms, notably phytoplankton at the base of marine food chains, pollen, amphibians’ eggs, many insects, and the sensitive growing ends of green leaf plants. Increased UVR also has direct adverse effects on human health: it increases the risk of skin cancer, increases the risk of ocular cataracts, and probably impairs immune function.

► RESOURCE DEPLETION

The more people there are, the greater the stress on finite and scarce resources. The resources essential for survival are fresh water for drinking and irrigation, and food. Air quality is also a major concern.

Water shortages in some parts of the world are associated with conflicts, and in the next 50 years as the shortages spread to other

TABLE 52-3. PER CAPITA WATER AVAILABILITY (M³/YEAR, PER CAPITA) IN 2050

Country	1990	No Climate Change—2050	GFDL 2050	UKMO 2050	MPI 2050
Cyprus	1280	770	470	180	1100

Saudi Arabia	310	80	60	30	140
South Africa	1320	540	500	150	330
Spain	2850	2680	970	1370	1660

*Assumptions about population growth are from the IPCC IS92a scenario based on the World Bank (1991) projections; the climate data are from the IPCC WGII TSU climate scenarios (based on transient model runs of Geophysics Fluid Dynamics Laboratory [GFDL], Max-Planck Institute [MPI], and UK Meteorological Office [UKMO]). The results show that in all developing countries with a high rate of population growth, future “per capita” water availability will decrease independently of the assumed climate scenario.

countries and regions, these conflicts probably will be exacerbated (Table 52-3). Threats to water security are a primary cause of some of the most intractable conflicts in the world.⁷⁰ In fact, the United Nations Environment Programme (UNEP) and various scientists and organizations anticipate that countries will be at war over access to fresh water by about 2020 (<http://www.unep.or.jp/ietc/Issues/Freshwater.asp>; <http://www.planetark.com/dailynewsstory.cfm/newsid/26728/story.htm>; <http://www.fdu.edu/newspubs/magazine/03su/waterwars.html>; <http://www.unep.or.jp/ietc/knowledge/view.asp?id=2383>; <http://pubs.acs.org/hotartcl/est/99/jan/interview.html>).

The IPCC *Summary for Policymakers* suggests that water shortages will be an important limiting factor on growth and development in some regions, notably much of the Middle East, South Africa, parts of Brazil, and the Southwest of the United States.⁷¹ Sea-level rise due to global warming and salination of river estuaries and water tables close to seacoasts will threaten some of the largest human settlements on Earth: Tokyo, Shanghai, Calcutta, Bombay, Jakarta, and Lagos, among others with populations of 14 million or more around 1999–2001. There will be much population movement away from coastal zones that are now at or only just above sea level. Not only will some of this inhabited land be below sea level, its fresh water supplies will be compromised by seepage of sea water into subsurface aquifers; many heavily populated river estuaries will thus lose much of their carrying capacity. Desertification of grazing lands and marginal cultivated agricultural land would further threaten food security.

Another critical limiting factor is shortage of ocean and coastal fish stocks. This was seen in the early 1990s in dramatic form in the collapse of many of the world’s ocean fisheries, mainly due to irresponsible overfishing; but it was aggravated by changes in marine ecosystems accompanying the disappearance of coastal wetlands, disruption of river outflows by massive dams (e.g., the Aswan High Dam), pollution with chemicals, oil spills, and so on. Other factors were changes in ocean temperature and flow of currents such as El Niño, which affect marine ecology. Fish provide about 20–25% of human protein needs, considerably more in coastal-dwelling populations in South and Southeast Asia. It is not clear where replacement protein will come from.⁷²

Shortage of energy in industrializing nations such as India and China makes matters worse. Rising energy needs in these and other industrializing nations have led to greatly increased and often inefficient combustion of low-grade coal, which not only adds to the burden of greenhouse gases but causes considerable health-harming atmospheric pollution. Energy production and combustion have diverse impacts on health, ranging from chronic respiratory damage due to inhalation of smoke from cooking fires inside inadequately ventilated village huts in the developing world⁷³ to the after-effects of the Chernobyl nuclear reactor disaster and ill-defined and poorly understood effects of living close to high-voltage electric power lines.^{74,75}

Over 50% of the world’s population now lives in urban centers. The deterioration of air quality in these centers presents an ongoing challenge to public health because the elderly, the frail, and the hypersensitive succumb if air quality deteriorates. Allergens or other triggering factors continue to increase as demonstrated by increasing rates of asthma globally. Under global warming, large urban centers will experience more inversions, and smog day advisories are expected to increase further. In the summer of 2005, for instance, there were more than double the previous average annual number of smog days in Toronto, Canada.

► SPECIES EXTINCTION AND REDUCED BIODIVERSITY

That there have been extinctions of whole populations and of specific species in the past is undisputed.^{76,47} As a result of human activity, unique animal and plant species are becoming extinct at an

accelerating rate. Much discussion centers on the loss of species that might have great benefit for humans if they could be studied in detail and their properties exploited, for example, as anticancer agents. This view of species extinction is anthropocentric, a narrow view that considers only the possible direct benefits of biodiversity for humans. Subtle features of biodiversity matter more, especially the loss of genetic diversity.⁷⁷

It may be very hazardous to proceed on our present course of increasing reliance on monocultures of high-yielding grain crops. Entire yields could be wiped out by an epidemic plant disease to which that strain is vulnerable; whereas if a genetically diverse grain crop is struck by plant disease, some strains at least are likely to survive.

We have long understood that widespread pesticide use on insects that damage crops killed large numbers of useful arthropod species such as bees and led to death or reproductive failure of many species of birds.⁷⁸ Fat-soluble dioxins and PCBs that concentrate as they move through food chains have adverse effects on reproductive outcomes, for example, by causing lethal deformities, some of which might also occur in other vertebrates, including humans.

We have become increasingly aware of the interdependence among many diverse species that share an ecosystem. John Donne's phrase, "No man is an island" applies to the myriad species that share the biosphere; when the bell tolls for amphibia whose eggs are killed by rising UVR flux, or for monarch butterflies that die when their winter habitat disappears, the bell tolls for us all. Destruction of natural ecosystems could have many harmful, even lethal, consequences for humans as well as for spotted owls.

► DESERTIFICATION

Conversion of marginal agricultural land into desert is a widespread problem. Land that was suitable for light grazing was inappropriately used in attempts to grow crops. Thin soil on mountain slopes that held native vegetation capable of resisting erosion in annual spring snowmelt was cleared and cultivated, leading to rapid erosion—the soil slid down steep mountain slopes leaving only bare rock on which nothing grows. Trees and shrubs have been stripped from arid zone savannah and from many mountain slopes to provide fuel wood, with the same result.⁷⁹

Sometimes the climate has changed, as in parts of formerly tropical rain forests in Central and South America that have been cleared as grazing land for beef cattle or in attempts to grow soybeans, wheat, or rice. The hydrologic cycle from tropical rain forest to rivers and lakes to clouds that precipitate as heavy rain is disrupted when trees are cut. Within a decade or less, rainfall is reduced, and soil moisture levels decline precipitously.⁸⁰ The Sahara Desert was at least partly covered with rain forest as recently as 5000 years ago; once the trees were cut, conversion to desert proceeded rapidly and has shown no signs of recovery. Similar processes are at work in other parts of the world; the consequence is declining potential to produce food. Formerly bountiful land that desertifies might take from a few hundred to a few hundred-thousand years to become fertile again.

► ENVIRONMENTAL POLLUTION

Environmental pollution can be localized, regional, or global; all forms adversely affect human health and the integrity of the environment. Those that fall into the category of "global change" include major environmental disasters and catastrophes: the Chernobyl nuclear accident in the former Soviet Union;⁸¹ massive oil spills in maritime accidents involving supertankers (e.g., *Torrey Canyon*, *Exxon Valdez*); and insidious permeation of the entire biosphere by stable toxic chemicals that enter and are transmitted from one species to another through marine and terrestrial food chains. International conventions⁸² have been developed in an attempt to control pervasive chemical exposures, but some polluting countries, for economic reasons, have elected to continue business as usual, and have opted out of these conventions.

The collapse of the former Soviet Union and its satellites revealed gross environmental destruction that could take many centuries to be healed.⁸³ This regional pollution has had adverse effects on health, such as occurrence of high levels of birth defects and severe respiratory damage.⁸⁴

Some forms of chemical pollution are global in scope: PCBs, dioxins, DDT, fat-soluble chemicals, persistent organic pollutants, and endocrine disruptors that travel through food chains have permeated the entire world.^{14,85} Heavy metals, for example, lead and mercury, occur in trace amounts in emissions from coal-burning power generators and ore smelting plants (which may emit other toxic chemicals such as arsenic). These contaminants occur in trace amounts, but the total burden worldwide, falling on land and into the sea, amounts to millions of metric tons annually. These toxic chemicals all concentrate in food chains.

Lead and mercury concentration in cormorants' feathers has been assayed in museum specimens prepared by taxidermists before the Industrial Revolution and compared to present-day levels; modern levels are up to 1,000–10,000 times greater than before the Industrial Revolution.⁸⁶ Pregnant women who eat much fish risk causing mercury poisoning of their fetus.

► DEMOGRAPHIC CHANGE

Underlying all the above features of global change are several aspects of population dynamics. The most obvious is population growth, which since approximately the 1950s has accelerated in an unprecedented surge almost all over the world.⁸⁷ After many millennia of stable world population in the hunter-gatherer era of human existence, the development of agriculture about 10,000 years ago led to the first surge in population growth and subsequently to a slow, but generally steady arithmetical increase in numbers of humans. Roughly coinciding with the Industrial Revolution and European colonization of the Americas and Oceania, the pattern of growth became approximately exponential about 200 years ago, leading to the sharp increase that has occurred in the last 100 years, which was followed by a hypergeometric population explosion that coincided with and was probably in part caused by the "green revolution" and greatly increased agricultural productivity in the two to three decades after World War II. The reasons for the increase are complex and controversial. The efficacy of public health measures (e.g., environmental sanitation, vaccination) played a part, but ecological and behavioral causes, such as optimism about the future and earlier age at marriage, probably were more important. In the nineteenth and early twentieth centuries, agricultural development provided more food, and the population expanded to approach the available supply of food. Not all causes of the population explosion are well understood.^{88,89}

As well as the surging increase in numbers, unprecedented movements of people have occurred since the late nineteenth century. Long-term migration has been very large, for example, an estimated 30–40 million people from Europe into the Americas and Australasia in the period from 1850 to 1910, and perhaps larger undocumented migrations within Asia, for example, of ethnic Chinese into many parts of Southeast Asia, over a longer period dating from some time in the last millennium.⁹⁰ Seemingly perpetual wars and widespread political unrest have contributed to migrations, but the main factor has been economic: many who migrate have perceived that their opportunities for work and a good life would be better elsewhere than where they were born and raised.

Rapid urban and industrial growth is an important parallel socio-demographic phenomenon. The proportion of people living in cities exceeded 50% of total global population in 1998.⁹¹ In rich industrial nations, urban land shortage, real estate values, new building techniques, and personal preferences have led to an enormous growth in high-rise apartment dwellings. In developing nations, megacity shantytown slums with populations of 10 million or more have proliferated; these lack sanitary and other essential services and create an ideal breeding ground for disease and social unrest. This aspect of global change has far-reaching effects on health.

The movement of large numbers of people from rural to urban regions is attributable to industrialization, mechanization of agriculture, attraction of rural subsistence farmers and landless peasants to prospects for more lucrative work in cities, and in many parts of the world, flight from oppression by powerful rich landowners, banditry, or overt armed conflict.

We can regard these massive people movements as a biological process, a form of tropism that has attracted people toward places where they can grow and develop, and away from places where growth and development were inhibited. This perspective comes close to considering humans as a parasitic infestation of the biosphere,^{92,93} a harsh judgment, but one for which there is some empirical support.

Another form of movement with important health implications is short-term international air travel. International Air Transport Authority (IATA) statistics show present annual air travel between countries and continents to be 600–700 million persons; they travel on business or pleasure or for seasonal employment.⁹⁴ Rapid air travel allows people who may be incubating communicable diseases to travel to destinations where large numbers of people may be susceptible to the pathogens introduced in this way.

► EMERGING AND REEMERGING INFECTIONS

Another way in which the world has changed is in the emergence and reemergence of lethal infectious pathogens.^{95–98} The human immunodeficiency virus (HIV) pandemic is the most obvious; it is linked to a resurgence of two old plagues, tuberculosis and syphilis, which find fertile soil in immunocompromised hosts and often now are due to resistant strains of pathogens. These three diseases are endemic in sub-Saharan Africa and in megacity slums elsewhere in the developing world and in the counterpart of these slums in rich industrial nations, among the homeless, disenfranchised, urban underclass. Other emerging infections are due to organisms such as Ebola virus, hantavirus,⁹⁹ *Borrelia burgdorferi* (Lyme disease), and *Legionella pneumophila* (Legionnaires' disease). Others are due to the expansion of old diseases, such as hemorrhagic dengue fever, into regions from which such diseases had been eliminated generations ago, only to return now because of the combination of climate change and the introduction of hardy vector species such as *Aedes albopictus*, among others.^{30,100–107}

► OTHER RELEVANT CHANGES

Complex economic, social, industrial, and political factors accompany the above processes and contribute to the difficulty of finding solutions that work. Global economies have supplanted national and regional ones.¹⁰⁸ Transnational corporations, owing allegiance to no nation and seemingly driven by the desire for a profitable balance sheet in the next quarterly report, move capital and production from places where obsolete plant and equipment, tough labor and environmental laws, and political systems may impede them, to countries without these restraining influences, thus maximizing short-term profits¹⁰⁹ without accountability for potential harms to local ecologies and populations.¹¹⁰

Political revolts against local and regional taxation have undermined public health and other essential services and their infrastructures in some rich industrial nations, including the United States. For many years there have been no new investments, little maintenance, no salary increases (sometimes reductions of pay and benefits), and serious staff reductions in many public health services.

Television “sound-bites” and fragmentary news reporting deprive busy people of information that is necessary to enable them to make intelligent decisions about such matters as public health services and environmental sustainability. Many people regard elected officials with contempt, which deters them from voting—a dangerous trend

that has the potential for the political agenda to be captured by determined single-issue interests. All too frequently, those who are elected lack the political courage to make the tough decisions—such as raising taxes on fossil fuels—that the state of the world demands if the climatic trends are to be halted and ultimately reversed before irreversible harm is done.

► PUBLIC HEALTH RESPONSES

Perhaps never before have public health workers and their services faced such challenges as they do now.^{111–115} Actions of several kinds are required (Table 52-4). Some obvious and simple measures can be initiated at once, for example, the protection of fair-skinned infants and children against excessive sun exposure. We need to establish or strengthen our surveillance of insect vectors and the pathogens they can carry. It also is essential to enhance preparedness to cope with public health consequences of disasters, including an

increasing proportion that are weather related and associated with floods, hurricanes, droughts, or other extreme weather events; and we need to be prepared to cope with increasing numbers of environmental refugees. Needed research strategies are also summarized in Table 52-4.¹¹⁶

Effective responses are hampered by many factors. The decay of infrastructures and erosion of morale, as dedicated staff are laid off and salaries frozen or cut, have inhibited meaningful efforts to prepare for any but immediate emergencies. Yet some obvious preparations to cope would cost little. Disaster planning must be maintained at a high level of preparedness; nothing is more certain than that there will be increasingly frequent, more severe, and less predictable weather emergencies. Large cities and towns on flood plains or in places where there can be tidal surges are increasingly vulnerable. Insurance companies have recognized this by reluctance to insure against some natural disasters. Some public health agencies and local government departments have disaster plans, but many do not. Swiss RE is one reinsurance company that in the early 1990s, while the fact of global warming was being denied by so many other corporate entities worldwide, recognized the fact through the simple reality of increases in insurance claims. They have since been staunch advocates for a more serious acceptance to this reality and of the need for political and social action to prepare for the severe consequences of more extreme weather events into the future.⁵⁷ The insurance industry generally has been persuaded of the reality of climate change as a consequence of the great increase in claims in the past two decades.

There are many simple actions that public health services can carry out to mitigate the adverse effects of global change on human health. For instance, weather reports now often mention the level of UVR flux and offer advice about sun avoidance. In U.S. cities, for example, Chicago, prone to extreme summer heat, humidity, and severe smog, public health authorities have plans to evacuate the most vulnerable people to air-conditioned shopping malls, and the like when heatwaves occur.

► GROUNDS FOR OPTIMISM

Faced with the array of problems outlined above, it would be easy to admit defeat. But there are grounds for optimism about our predicament.¹¹⁷ Humans are robust, a very hardy species: we have demonstrated considerable ability to adapt to a wide range of harsh environments. We are resourceful, intelligent, and often at our best in a crisis. We are now, perhaps, entering the greatest crisis we have ever faced. Its insidious onset has lulled us into complacency, if we think at all about the nature of the global changes that endanger us. There is also an element of denial, akin to the reluctance of a cancer patient to accept the seriousness of the condition, or the risk-taking adolescent to whom death or permanent disability due to dangerous behavior is unimaginable.

Epidemiology and other public health sciences can do much to induce greater recognition of the need for changes in values and behavior. Precedents in the history of public health since the second half of the nineteenth century¹¹⁸ are encouraging. The field of eco-epidemiology has begun to examine ways of measuring the effect, if any, of ecological declines on population health as one way of informing policy.^{119,120} As with any new scientific path, however, the challenges are great to obtain the needed data to conduct meaningful analyses. Recommendations for future research have been offered,¹⁶ but great political will is needed to effect the recommended changes in data availability for the conduct of eco-epidemiology in this area.

The necessary sequence for control of any public health problem is awareness that the problem exists, understanding what causes it, the capability to control it, a sense of values that the problem matters, and political will.¹²¹ All but the last of these exist now. We have the basic science evidence that enables us to predict what is likely to happen. Empirical evidence to support the predictions is rapidly mounting and soon will comprise an incontrovertible body of knowledge and

BOX 52-2. MILLENNIUM DEVELOPMENT GOALS

Health, poverty, and conservation

1. Eradicate extreme poverty and hunger
2. Achieve universal primary education
3. Promote gender equality and empower women
4. Reduce child mortality
5. Improve maternal health
6. Combat HIV/AIDS, malaria, and other diseases
7. Ensure environmental sustainability
8. Develop a global partnership for development

understanding that even the most obtuse self-interested group will be unable to deny or rebut. One example of global concerted action was seen in September 2000, at the United Nations (UN) Millennium Summit, where it was pledged that by 2015, all 191 UN member states would meet all eight of the Millennium Development Goals (MDGs) (<http://www.un.org/millenniumgoals/>) (see Box 52-2).

Increasing numbers of important interest groups, such as the reinsurance industry and leaders in some resource-based industries are recognizing the need for action. Increasing numbers of thoughtful people are aware of the need to conserve resources rather than squandering them wantonly as we did in the 1950s and 1960s with “disposable” products. A few more dramatic disasters consequent to the collapse or major disruption of established weather systems would help to galvanize public opinion and lead to pressure for change that even the most complacent political leaders would be unable to ignore.

Environmental protection laws and regulations have been strengthened in many countries and in the European Union, and in the United States these laws and regulations remained substantially intact until recently when the administration weakened or revoked several important safeguards. This suggests that the change of values required as a necessary prerequisite for action to mitigate global change is already beginning. It will undoubtedly help if the health impacts of global change are given greater attention in the media. Public health workers and epidemiologists can contribute by emphasizing the health effects of global change, and actions needed to minimize their impact. (See Box 52-3.)

► ENVIRONMENTAL ETHICS AND THE PRECAUTIONARY PRINCIPLE

The change of values that we believe is already under way is leading to recognition of the need to observe a code of conduct for the environment, an ethic of environmental sustainability. Environmental movements are gathering strength in many countries and “Green” parties are seen increasingly as “respectable” and in the mainstream of politics. They are beginning to influence the political agenda despite pressure from powerful industrial and commercial interest groups that have long been able to achieve their ends by controlling political decisions. The pressure often comes first from grass-root levels, perhaps because of a proposal to establish a toxic waste dump or a polluting industry; but its origins may matter less than its increasingly successful efforts to influence the outcome. Examples such as these make for hopeful reading in Suzuki and Dressel, 2002.

Another hopeful sign is recognition of the Precautionary Principle in policy formulation: when there is doubt about the possible environmental harm that may arise from an industrial or commercial development, a nuclear power station, an oil refinery, an open-cast coal mine, or other environmentally damaging activities, people and communities who will be most affected are increasingly often given the benefit of the doubt, because of the Precautionary Principle.^{122,123} A few years ago, this almost never happened. Now it is commonplace, especially in the European Union and, to a lesser

BOX 52-3. THE EARTH CHARTER
MARCH 2000

PREAMBLE

Earth, Our Home
The Global Situation
The Challenges Ahead
Universal Responsibility

PRINCIPLES

I. RESPECT AND CARE FOR THE COMMUNITY OF LIFE

1. Respect Earth and life in all its diversity.
2. Care for the community of life with understanding, compassion, and love.
3. Build democratic societies that are just, participatory, sustainable, and peaceful.
4. Secure Earth's bounty and beauty for present and future generations.

In order to fulfill these four broad commitments, it is necessary to:

II. ECOLOGICAL INTEGRITY

5. Protect and restore the integrity of Earth's ecological systems, with special concern for biological diversity and the natural processes that sustain life.
6. Prevent harm as the best method of environmental protection and, when knowledge is limited, apply a precautionary approach.
7. Adopt patterns of production, consumption, and reproduction that safeguard Earth's regenerative capacities, human rights, and community well-being.
8. Advance the study of ecological sustainability and promote the open exchange and wide application of the knowledge acquired.

III. SOCIAL AND ECONOMIC JUSTICE

9. Eradicate poverty as an ethical, social, and environmental imperative.
10. Ensure that economic activities and institutions at all levels promote human development in an equitable and sustainable manner.
11. Affirm gender equality and equity as prerequisites to sustainable development and ensure universal access to education, health care, and economic opportunity.
12. Uphold the right of all, without discrimination, to a natural and social environment supportive of human dignity, bodily health, and spiritual well-being, with special attention to the rights of indigenous peoples and minorities.

IV. DEMOCRACY, NONVIOLENCE, AND PEACE

13. Strengthen democratic institutions at all levels, and provide transparency and accountability in governance, inclusive participation in decision making, and access to justice.
14. Integrate into formal education and life-long learning the knowledge, values, and skills needed for a sustainable way of life.
15. Treat all living beings with respect and consideration.
16. Promote a culture of tolerance, nonviolence, and peace.

THE WAY FORWARD

extent, in Canada. The principle is not widely embraced in the United States.

It is promising that Western culture is beginning to show interest in the value of "Traditional Knowledge" and/or "Indigenous Knowledge" that had provided a foundational guide for aboriginal population survival over millennia. The operating principle among some of these indigenous cultures is that of "The Seventh Generation." Under this principle, the consequences of present day decisions that could impact the environment are considered for their potential consequences seven generations hence. Any action that could negatively impact seven generations hence is not taken (http://www.iisd.org/pdf/seventh_gen.pdf; also: <http://www.ecology.info/seventh-generation.htm>. Accessed on May 1, 2007).

Finally, and also promising, is the fact that health and environment are being encouraged to communicate, both in government agencies, and in curricula on sustainability and health in university

training programs.^{8,56,124-129} Educating young people to appreciate the complexities of the link between health and environment and to move them from linear and reductionist to systems and transdisciplinary approaches to problem solving are to be encouraged.¹³⁰ Transdisciplinarity is the philosophical concept of scholarly inquiry that ignores conventional boundaries among ways of thinking about and solving problems. It is based on recognition of the inherent complexity of many problems confronting humans and has evolved into a conceptual framework that embraces and seeks to mobilize all pertinent scientific and scholarly disciplines: physical, biological, social and behavioral sciences, ethics, moral philosophy, communication sciences, economics, politics, and the humanities. Many problems in public health require an inherently transdisciplinary approach. The social, demographic, and human health problems associated with global environmental change demand the greatest degree of transdisciplinarity. This is the antonym of reductionism.¹³¹

► MITIGATION OPTIONS

The 1995⁷¹ and 2001¹ IPCC Reports discuss several mitigation options: energy-efficient industrial processes and means of transportation; reduction of human settlement emissions; sound agricultural conservation and rehabilitation policies; forest management policies and strategies, and so on. The Framework Convention on Climate Change that was adopted by most national leaders early in 1996 spells out ways in which industries that contribute heavily to greenhouse gas accumulation can and must change. These changes are not without cost, although experience has often demonstrated that conserving energy, like all other conservation measures, is cost-effective. An obvious change that would benefit all who share Earth is introduction of deterrent taxes that would discourage use of private cars for all but truly essential purposes. Political leaders everywhere are reluctant to enact this unpopular measure and are equally reluctant to spend large capital sums on new or upgraded public transport systems in an era when reducing taxes is what got many of them elected in the first place. This is unlikely to change until a climatic emergency or other environmental crisis forces large numbers to come to their senses and realize that the time for action rather than rhetoric has arrived. Public health workers should be preparing to take the initiative in the event of climatic emergencies or environmental crises and should have cogent arguments ready to state the case for action toward environmental sustainability.

Our situation resembles that depicted by the clock on the cover of the *Bulletin of the Atomic Scientists*, with hands pointing to a few minutes before midnight. The analogy is a calendar from which all but a few days near the end of the year have been torn. The need for action is urgent.

The Ecohealth program initiative at the Canadian International Development Research Centre (IDRC)¹³² introduced in 2005 the inaugural issue of Health Environment: Global Links Newsletter (www.idrc.ca/ecohealth). This four-language, biannual publication is being produced to meet a need for information and knowledge exchange globally. The purpose of the newsletter is to sustain momentum in building with the emerging global Community of Practice on health and environment. The newsletter is sponsored by IDRC, but is intended as forum for the emerging global community of scientists and development practitioners working on health and environment linkages http://www.idrc.ca/uploads/user-S/11231750941HealthEnvironment_Newsletter-English.pdf.

► ADDENDUM

Since this chapter went into production, there have been several important reports on climate change. As attention to this particular concern grows, many more reports can be expected. The amount of literature in this field is escalating, and much can be found through Google searches.

Of particular note, one influential and more recent report emerged from Britain where the government had commissioned a report by the economist Nicholas Stern, formerly of the World Bank, on the costs of action versus inaction on climate change. Stern calculated that the long-term economic cost of continuing with a “business as usual” strategy ultimately would be as much as 20% of annual GNP because of the very high cost of dealing with increasingly frequent and severe climatic extremes. In contrast, Stern calculated that the cost of action to mitigate climate change and to adapt to inevitable change would be about 1–2% of annual GNP, if action were to begin immediately. Member nations of the European Union appear to be taking the Stern Report seriously and are acting on it; the United States and Canada, as of mid-2007, do not.

In February 2007, the first of several reports from the Fourth Assessment by the Intergovernmental Panel on Climate Change (IPCC) was released. This report deals with the increasingly strong scientific evidence that climate change is occurring and is, to a considerable

extent, the result of human activity, especially the combustion of carbon-based fuels which add to the burden of carbon dioxide in the atmosphere. Further IPCC reports are expected throughout 2007, addressing impacts and adaptation to climate change.

Details of the Stern Report are accessible at http://www.hm-treasury.gov.uk/media/999/76/CLOSED_SHORT_executive_summary.pdf, and of the IPCC reports are accessible at <http://www.ipcc.ch>.

Health Behavior Research and Intervention

Kim D. Reynolds • Donna Spruijt-Metz • Jennifer Unger

Scientists from the Department of Health and Human Services, after reviewing causes of death in the United States, concluded that about half of all deaths could be attributed to a limited number of largely preventable behaviors and exposures.^{1,2} These scientists estimated external (nongenetic) modifiable causes of mortality for the year 2000 and concluded that tobacco, poor diet and physical inactivity, alcohol consumption, microbial agents, toxic agents, motor vehicle related fatality, firearms, sexual behavior, and illicit drug use accounted for the most mortality. Their analysis led Mokdad et al. to argue for increased efforts toward prevention in our health care and public health systems.²

Responding to these disease threats, several agenda-setting documents have been produced to guide the reduction of disease risk through the modification of health behavior. *Healthy People 2010* is perhaps the most critical document of this type and defines a set of comprehensive disease prevention and health-promotion objectives for the United States to be achieved by the year 2010.³ *Healthy People 2010* was designed to realize two overarching goals including (a) increase quality and years of healthy life and (b) eliminate health disparities. *Healthy People 2010* has selected a set of 10 “leading health indicators” that will be used to measure the health of the nation over the coming years and that reflect major health concerns facing the United States in the first 10 years of the twenty-first century. These leading indicators include physical activity, overweight and obesity, tobacco use, substance abuse, responsible sexual behavior, mental health, injury and violence, environmental quality, immunization, and access to health care.

Health behavior research often occurs within two broad categories. First, investigators continuously work toward a better understanding of the factors that explain and predict behavior. A better understanding of these determinants will provide guidance for the development of interventions that have a reasonable chance of producing changes in behavior. Therefore, basic research on the determinants of health behavior will ultimately improve health promotion interventions. The second broad category involves the development of intervention strategies, usually targeting changes in behavior, with the goal of modifying health behavior as well as physiological risk factors and ultimately morbidity and mortality.

This chapter will describe several intervention approaches as well as frequently utilized theories in health behavior research. We will also provide guidance to resources that may help with the development and evaluation of effective theory-based interventions.

► THEORIES OF BEHAVIOR CHANGE

Rationale for the use of theory

Theories are used in health behavior research in a number of ways. First, theory is used to identify variables that explain and predict behavior and as a result, guide studies conducted to provide empirical evidence on postulated determinants of behavior. Second, theories are used to guide the design of interventions. The selection of variables to target for intervention and the development of specific messages within interventions are both guided by theory. Below we describe a series of theories commonly used in health behavior research and recommend further reading on the utility and use of theory in health promotion and disease prevention.⁴

Health Belief Model

The Health Belief Model is one of the oldest and most widely used theoretical models of health behavior.⁵ It was created in 1958 by researchers at the U.S. Public Health Service in an attempt to understand why many people failed to take advantage of the free tuberculosis screenings.⁶ The general assumption of the model is that people will perform health-promoting behaviors if they believe that these behaviors will reduce either their susceptibility to the condition or the severity of the condition, and if they believe that the benefits of performing the behavior outweigh the barriers to performance. For example, the model predicts that people will be more likely to obtain screening tests for a disease if (a) they believe that they personally are at risk for the disease; (b) they believe that the disease would seriously compromise their quality of life; (c) they believe that the screening test can really detect the disease, and that early detection would lead to better outcomes; (d) they believe that they are not blocked from obtaining the screening by financial, schedule, transportation, or other concerns; and (e) something reminds them to obtain the screening.

The model has five main components. *Perceived susceptibility* is the individual's estimate of the probability of getting the disease. *Perceived severity* is the individual's perception of how severe the health and social consequences of the disease would be. *Perceived benefits* are the positive consequences that the individual believes will occur as a result of performing the health behavior. *Perceived barriers* are factors that make it difficult for the individual to perform the health behavior. *Cues to action* are objects or events that remind the individual about the health

behavior, such as billboards, TV news stories, or hearing that a friend or a celebrity has the disease. It is important to note that the susceptibility, severity, benefits, and barriers all refer to the individual’s *perceptions*, which may or may not be accurate. For example, people may underestimate their probability of getting a specific disease or underestimate the severity of the disease, and they may overestimate the barriers preventing them from performing a health-promoting behavior.

The Health Belief Model has been applied to numerous other screening behaviors such as mammography and HIV testing, as well as other health-related behaviors such as condom use and physical activity.⁷ In its original conceptualization, the Health Belief Model is best suited to predict one-time performance of a single health-related action, such as a tuberculosis test. It does not address the issues inherent in long-term maintenance of behavior change. To make the model more appropriate for predicting long-term lifestyle change, it was revised in 1988⁸ to include the construct of self-efficacy, or the person’s confidence in his ability to adopt healthy behaviors or discontinue unhealthy behaviors.⁹ With the addition of self-efficacy to the model, the model’s authors acknowledged that even if people feel personally susceptible to a disease, understand the severity of the disease, and are convinced that long-term behavior change will improve their prognosis, they will undertake long-term behavior change only if they believe that they have the ability to accomplish the long-term behavior change successfully.

The focus of the Health Belief Model is on the individual’s perception of susceptibility to and severity of the disease, and perception of the relative benefits and barriers of the preventive behavior. Therefore, the goal of interventions is to alter the individual’s unrealistic perceptions. For example, if a heterosexual woman believes that she is not at risk for HIV because she thinks it is a disease of gay men, the goal of counseling would be to inform her of the actual risk of contracting HIV among women who practice risky sexual or injection drug use behaviors. If she believes that HIV is not a severe health problem because some people claim to have been “cured,” the goal of counseling would be to inform her that HIV currently cannot be cured, and that people living with HIV have a compromised quality of life. If she does not believe that HIV testing has benefits, the goal of counseling would be to inform her that early detection and prompt treatment can greatly improve the health and quality of life of people with HIV. If she believes that there are too many barriers to being tested for HIV (e.g., money, no convenient place to be tested, concerns about confidentiality), the goal of counseling would be to help her brainstorm ways to overcome these barriers (e.g., free, anonymous testing services).

Social Cognitive Theory

Social cognitive theory (SCT) is a comprehensive theory of behavior that has been used to explain a wide-range of human behaviors including health behaviors.¹⁰⁻¹³ SCT is one of the most widely used theories for the development of behavioral interventions.¹³

SCT assumes that characteristics of the environment, the person, and the behavior itself influence one another in a process referred to as reciprocal determinism. The environment is typically defined as variables that are external to the individual and include the physical environment (e.g., urban design, presence of fast food establishments) and social environment (influence of family and friends, media role models). Personal characteristics include variables internal to the individual including various attitudes and beliefs. The theory supposes

that if one of the three factors changes (environment, person, behavior), it is likely to produce changes in the other two factors. For example, a person may have a network of friends who are all sedentary. In this case, meeting and getting to know a new friend (environmental factor) who is physically active may lead to the adoption of new activities that involve more physical activity such as going for walks or trying a team sport (behavior) and this change in behavior may lead to a positive change in attitudes toward exercise (personal factors).

Embedded within each of these larger factors (environment, person, behavior) are a set of more specific variables. Intervention programs are typically designed to influence one or more of these specific variables. In health behavior research, intervention developers are usually attempting to influence environmental variables, or more commonly, personal variables as a means of modifying behavior. Personal factors include behavioral capability, defined as the essential knowledge and motor skills needed to engage in a specific behavior. Outcome expectations and expectancies are the results we anticipate when a behavior is enacted and the value we attach to that outcome. For example, if a person believes that a dietary change to include less fat will make them feel less sluggish, this might be seen as a positive outcome of that behavior change. Outcomes expectancies can be both positive and negative. Goal setting and self-monitoring comprise components of self-control within the theory. That is, people frequently set goals and monitor their progress toward those goals. This is a naturally occurring process but can also be utilized by health promotion researchers by designing programs that help people set realistic yet challenging goals for health behavior change, and providing them with tools for monitoring that progress. Observational learning involves learning skills and values related to health behaviors from observing models. This is frequently used by intervention designers to help individuals learn key skills for behavior change such as the selection of healthier foods in a restaurant or the refusal of tobacco products by adolescents. Perceived self-efficacy is the confidence a person feels in their ability to engage in a behavior. Perceived self-efficacy is usually thought of in the context of the barriers that a person must overcome to perform a behavior. Self-efficacy is higher when few barriers limit an individual’s ability to perform a behavior. Finally, SCT describes a role for the influence of emotional arousal in shaping behavior.

SCT provides strong guidance in the development of interventions by identifying variables that can form the basis of intervention activities. In addition, many of the variables described in SCT (e.g., perceived self-efficacy, outcome expectancies) have been related to a diverse set of health behaviors, boosting our confidence in the use of the model to guide intervention design.

Self Determination Theory

Self determination theory (SDT) asserts that people have three basic psychological needs: competence (feeling effective), relatedness (feeling connected to others), and autonomy (perception of self as source of ones own behavior).¹⁴ These needs are assumed to hold across age, gender, and culture, although the means to satisfy these needs may differ across various groups. Social, contextual, or environmental factors may either support or thwart these basic needs. The SDT conceives of self determination as a continuum (from nonself-determined to self-determined). Levels of self-determination coincide with types of motivation (from amotivation to intrinsic motivation) and regulatory styles (Fig. 53-1).

Type of motivation	Amotivation		Extrinsic motivation			Intrinsic motivation
Type of regulation	Nonregulation	External regulation	Introjected regulation	Identified regulation	Integrated regulation	Intrinsic regulation
Quality of behavior	Non-selfdetermined		----->			Self-determined

Figure 53-1. Regulatory styles and intrinsic motivation. (Source: Adapted from Deci & Ryan, 2002.)

Cognitive evaluation theory (CET) explains effects of contextual events (such as rewards, deadlines, praise) on intrinsic motivation, behavior, and experience.^{97,98} The CET is most useful for studying behavior for which people exhibit some interest or motivation.

Organismic integration theory (OIT) examines how to transform externally regulated behaviors to self-regulated behaviors and addresses the concept of internalization especially with respect to the development of extrinsic motivation. The continuum of self-determination (Figure 53-2) is part of the OIT. *Amotivation* is a lack of intention to act. In *external regulation*, the motivation is to obtain rewards, avoid punishment, and satisfy external demands. In *introjected regulation*, behavior is performed to avoid guilt or shame, or to enhance feelings of self-worth. In *identified regulation*, behavior (or the outcomes of that behavior) is accepted as personally important. In *integrated regulation*, behavior is completely in line with personal values, goals, and needs but still done to achieve personally important outcomes. In *intrinsic regulation*, behavior is carried out purely for inherent interest and enjoyment.¹⁴

Causality orientations theory (COT) describes how people incorporate social influences into their motivational styles—i.e., whether they do things to please themselves (autonomously oriented), or because they think they “should” (controlled orientation) or without any particular intention (impersonal orientation).⁹⁹

Basic needs theory says that people have three basic needs (as discussed in the main text). According to this mini-theory, there will be a positive relationship between goal attainment and well-being only if it satisfies a basic psychological need.^{100–102}

Figure 53-2. Four mini-theories of self-determination theory.

Intrinsic motivation is considered the optimal state of autonomy and challenge, and is associated with feelings of satisfaction, enjoyment, competence, and a desire to persist. According to the SDT, the closer a behavior is to intrinsic motivation on the self-determination continuum (Fig. 53-1), the more likely people will be to participate in that behavior. At present, SDT is made up of four mini-theories that build on these core theoretical concepts (see Fig. 53-2).

The SDT is a relatively new theory; however several interventions, including interventions to reduce cardiac risk,¹⁵ improve diet,¹⁶ and enhance physical activity¹⁷ are underway. One study trained physicians to support autonomy in a practice-based smoking cessation intervention.¹⁸ Physicians employed an autonomy-supportive style in a brief intervention with half of the nicotine-dependent subjects, and a controlling style with the other half. Results showed that subjects in the autonomy-supportive MI condition were significantly more autonomously motivated to quit. Subjects who were more autonomously motivated to quit were more likely to have quit smoking at 6, 12, and 30 months after the intervention and to remain non-smoking continuously over a 30-month period.

Transtheoretical Model (Stages of Change)

James Prochaska and Carlo DiClemente originally developed the transtheoretical model (TTM) in order to integrate the principles of behavioral change from the major psychotherapy and behavior change theories.^{19–22} The model was based on observations that people appear to go through similar stages of change no matter what kind of intervention they undergo. The TTM has two basic dimensions: stages of change and processes of change. Stages of change refers to an orderly sequence of changes through which people pass. According to the TTM, people progress through six stages of change (see Fig. 53-3) in the process of changing any health-related behavior. Some people move more quickly than others do, but the order is assumed and no stage is skipped. Processes of change refer to different techniques or intervention approaches that help people to progress through stages of change in order to achieve the desired behavioral changes. The TTM has identified 10 processes of change (see Fig. 53-4). The TTM indicates which processes of change will be most effective at each stage. Matching the stage of change in which the client finds herself with the

(1) **Precontemplation** is the stage in which people are not considering changing their behavior within the near future (defined as the next 6 months).²¹

(2) **Contemplation** is the stage in which people intend to change their risky behavior soon (defined as the next 6 months).²¹

(3) **Preparation** is the stage in which people intend to change in the immediate future (defined as the next month).¹⁰³

(4) **Action** is the stage in which people have made explicit changes to their behavior, environment, and lifestyle for less than 6 months. These changes are observable and therefore seen as action-oriented.¹⁰³

(5) **Maintenance** is the stage in which people continue their behavior changes and do not relapse into a previous stage for more than 6 months.¹⁰⁴

(6) **Termination** is the stage in which people are no longer susceptible to the temptation of relapse and possess complete self-efficacy.²¹

Figure 53-3. Six stages of change.

Matching stages	Ten Processes of change
	<i>Experimental processes of change</i>
Precontemplation & contemplation	(1) Consciousness raising concerns feeling increased awareness about the risky behavior. It involves the causes, consequences, and cures for the behavior. Interventions that utilize confrontations, feedbacks, and interpretations may aid in this process. ²¹
	(2) Dramatic relief concerns increased emotions and subsequent reduced feelings after the appropriate action is taken. Personal testimonies, role-playing, and media campaigns may aid in this process. ²¹
	(3) Environmental reevaluation concerns the cognitive and affective assessments of how the presence or absence of the problem behavior affects the person's social environment. It also reflects feelings that the person can serve as a role model for others. Family interventions and empathy training may aid in this process. ²¹
Contemplation & preparation	(4) Self-reevaluation concerns the affective and cognitive assessments of self-image with and without the risky behavior. Healthy role models and imagery may aid in this process. ²¹
Preparation & action	(5) Self-liberation concerns the increase in social networking and support opportunities for people isolated by their behavior change. This is very important in marginalized and depressed people in order to maintain the behavior change. Empowerment procedures and advocacy can be especially useful in health promotion interventions with impoverished or minority populations. ²¹
	<i>Behavioral processes of change</i>
Maintenance	(6) Stimulus control involves the removal of the cues that trigger unhealthy habits and replaces them with cues for healthy habits. Stimuli that might help this change are self-help groups, avoidance of the negative stimuli, and changing the environment. ²¹
	(7) Helping relationships are defined as the combination of trust, caring, acceptance, and openness that can help people end unhealthy behaviors. Support and rapport building are important in this process, and social support is key in behavior change. ²¹
	(8) Counterconditioning involves learning the healthier alternative behaviors that substitute for the unhealthy behaviors. Such substitutes may include relaxation and desensitization. ²¹
	(9) Contingency management involves providing consequences for moving in a positive or negative direction. While this process can include punishments, self-changers are more likely to rely on rewards for good behavior changes. Reinforcements are key and may be in the form of contingency contracts and group recognition. ²¹
	(10) Self-liberation involves the belief that people can change their behavior and the commitment and recommitment to act. Public testimonies and New Years', resolutions may aid in this process. ²¹

Figure 53-4. Processes of change (matched to stages of change).

appropriate processes of change facilitates movement through the stages of change to achieve intervention goals. The construct of *decisional balance* was developed to describe the stage-related process of weighing the pros and cons of any health-related behavior.²³ Decisional balance changes as people move through the stages of change.²⁴ For instance, during precontemplation the perceived benefits of smoking outweigh the perceived risks. As the smoker progresses into the action and maintenance stages, the perceptions of the negative consequences of smoking overtake the positive. Finally, Self-Efficacy is the confidence people gain as they progress thorough the stages that they can cope with temptations that might cause them to relapse into their unhealthy habits. This construct was added from Bandura's self-efficacy theory.²⁵ Temptation is the intensity of the urge to engage in habitual behavior. Three factors cause temptation: emotional distress or negative affect, craving, and positive social situations.²¹

TTM has been used in a number of interventions to change an array of behaviors including smoking, diet, exercise, delinquent behaviors, and condom use.²⁶ Most often, TTM is used to classify subjects according to readiness to change the targeted behavior (stages of change). Intervention materials and activities appropriate for the individual's readiness to change are then delivered. The materials and activities deemed appropriate for a given stage of readiness to change are determined from the processes of change described by the framers of the TTM. For instance, a British study used the TTM to recruit and classify subjects into a smoking cessation program.²⁷ Data from a baseline questionnaire were used to categorize intervention subjects

according to stages of change for smoking cessation. Subjects received a personalized letter describing their stage of change and a packet tailored to that stage. This process was repeated three times over six months, with subjects being reclassified according to new questionnaire data at each pass.

Theory of Reasoned Action/Theory of Planned Behavior

The theory of reasoned action²⁸ and the theory of planned behavior²⁹ were created to explain and predict a wide variety of human behaviors (see Fig. 53-5). Subsequently, the theories have been applied specifically to health-risk and health-protective behaviors. According to the theory of reasoned action,²⁸ before people perform a behavior, they go through a decision-making process that leads to the formation of an *intention* to perform the behavior. The decision-making process involves making two types of judgments. The first type of judgment is the *attitude toward the behavior*, or the person's perceptions of the pros and cons of performing the behavior. Attitudes toward the behavior consist of beliefs about the *expected outcomes* of the behavior and the *importance of these outcomes* to the individual. To form an attitude toward a behavior, a person will mentally list all the positive consequences that are likely to occur as a result of performing the behavior (e.g., for exercising, these might be weight loss, enjoyment, lowered

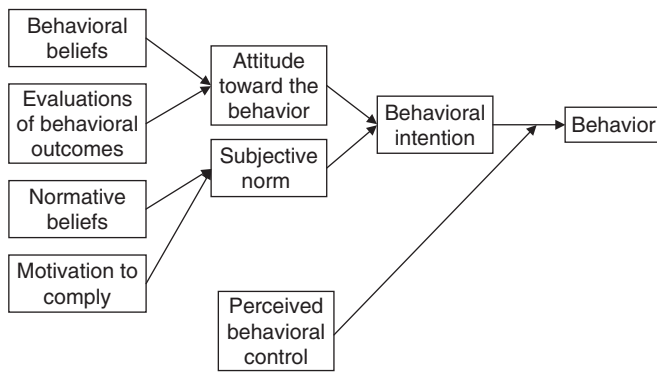

Figure 53-5. The theories of reasoned action and planned behavior.

blood pressure, increased cardiovascular endurance, etc.) and all the negative consequences that are likely to occur as a result of performing the behavior (e.g., soreness, lack of time to do other tasks, tiredness). The person will then consider the importance of each expected outcome (e.g., perhaps weight loss is extremely important to the person, but feeling sore does not bother the person much). A mental summary of all the perceived positive and negative consequences, and the importance of each, becomes the person's attitude toward the behavior.

The second type of judgment is the person's *subjective perception of the social norms* surrounding the behavior. Social norms are the person's beliefs about what other people think the person should do. For example, if a middle-aged woman has many friends and family members who exercise, she may perceive that her social network members would want her to exercise too. If she has few friends and family members who exercise, she may perceive that her social network members would not be supportive of her efforts to exercise.

Each person's social network consists of multiple individuals, including family members, friends, coworkers, neighbors, acquaintances, comembers of other organizations, etc. The opinions of some of these individuals are very important to the person, whereas the opinions of others are not as important. When thinking about social norms, the person will decide whose opinions really matter. For example, the middle-aged woman may be very concerned about whether her husband and children are supportive of her decision to exercise, but she may not care whether or not her neighbors approve. She will form her judgment about the social norms based on her perception of how her husband and children, whose opinions are important to her, would react to her decision to exercise.

The theory of reasoned action makes the assumption that intentions to perform a behavior will lead to performance of the behavior (i.e., the person who has an intention to exercise will in fact exercise). However, there are many situations in which intentions do not predict behavior. For example, a lack of time, transportation, childcare, money, facilities, etc., could prevent the person from exercising. Similarly, a person may intend to obtain regular health screening tests but may lack resources to pay for the tests. The theory of planned behavior²⁹ was created to address this issue. The theory of planned behavior is identical to the theory of reasoned action, except that it adds the component of *perceived behavioral control*. The revised theory specifies that the intentions in the theory of reasoned action will lead to performance of the behavior only if the individual perceives that he or she is capable of performing the behavior.

Interventions based on the theory of reasoned action and the theory of planned behavior can focus on one or more of the theories' components. The ultimate goal is to increase the likelihood that an individual will perform a health-promoting behavior (or decrease the likelihood of performing a health-risk behavior). According to the theory of planned behavior, the likelihood of performing a behavior can be influenced by increasing the intention to perform the behavior and by increasing the individual's perceived control over the behavior. Therefore, interventions can focus on increasing intentions and/or increasing

perceived behavioral control. Intentions can be modified by modifying the individual's attitude toward the behavior and/or the subjective norms. To improve an individual's attitude toward the behavior, an intervention would attempt to influence the individual's behavioral beliefs (e.g., the belief that exercise will increase respiratory fitness) and the evaluation of the behavioral outcomes (e.g., that increased respiratory fitness will lead to a higher quality of life). To improve an individual's subjective norms, an intervention would focus on identifying people in the social network who are supportive of the new behavior and/or helping the individual to avoid being negatively influenced by social network members who undermine their attempts to change behavior. To improve perceived behavioral control, an intervention would teach specific strategies to adopt new healthy behaviors and overcome barriers.

Like the health belief model, the theories of reasoned action and planned behavior make the assumption that humans are rational actors who carefully evaluate the costs and benefits of performing a behavior and select their course of action accordingly. These models do not specifically address impulsive, spur-of-the-moment decisions about health behaviors, nor do they address people's resistance to changing established behavioral habits. However, these models offer a useful framework to guide theory-based intervention strategies.

► BEHAVIORAL INTERVENTION STRATEGIES

Motivational Interviewing

Motivational interviewing (MI) is a collaborative counseling technique aimed at helping people increase their motivation and readiness to make behavioral changes.³⁰ MI counselors use nonjudgmental, empathetic encouragement to create a positive interpersonal collaboration that is conducive to self-examination, understanding and change.³¹ One of the goals of MI is to evoke intrinsic motivation for change.³² The counselor encourages the client to explore how their current health-related behaviors might conflict with their health goals, to evaluate their own reasons for and against behavior change, to discover behavior change strategies that are personally relevant, and to convince themselves that they can make changes. Core strategies in MI include agenda setting and eliciting change talk. In agenda setting, clients determine the goals for change so that they are active and willing participants. Eliciting change talk involves having participants generate self-motivational statements and is based on the premise that people are more likely to act on plans they develop themselves.³¹

MI interventions can be particularly effective for populations who are at a low level of readiness to change their behavior, and can be tailored to individual needs and circumstances³³ including making them developmentally appropriate.^{34,35} Additionally, MI can be used to tailor interventions for cultural competence because the client sets the goals rather than the clinician.

MI has been used in dietary and physical activity interventions, smoking cessation, substance abuse prevention, medical adherence in diabetes, psychosis, and several other chronic illnesses, and HIV-risk prevention.³⁶⁻³⁹ For instance, MI has been used successfully in interventions involving minorities to increase fruit and vegetable consumption and improve dietary compliance.³⁴ MI for addiction counseling or psychotherapy may involve multiple extended sessions. Alternatively, in public health and medical settings, patient encounters ranging from 10 to 15 minutes have proven to be effective tools for behavior change in diverse areas including problem drinking, smoking, treatment adherence in diabetes, and weight loss.^{40,41}

Classes and Curricula

Small group classes and curricula, developed for schools and other settings, are a common intervention strategy to modify health behavior. A wide range of behaviors has been targeted by curricula (e.g., violence, stress, substance use, diet, exercise habits). There are four main caveats to using a classroom curriculum: (a) both teachers and administrators

need to be supportive, (b) instructors must be properly trained, (c) the curriculum needs to be appropriate (developmentally, culturally, behaviorally) for the target group, and (d) the curriculum chosen should be known to be effective unless it is being delivered as part of an intervention study.

Identifying scientifically rigorous and effective curricula can be difficult. Some curricula are well-known and well-liked, but have not actually been proven to produce behavior change. Organizations, such as the Substance Abuse and Mental Health Services Administration (SAMHSA), offer listings of programs that have reviewed by expert panels and chosen as model programs. Model programs are defined as “well-implemented, well-evaluated programs, meaning they have been reviewed . . . according to rigorous standards of research.”⁴² In 1996, the Center for the Study and Prevention of Violence (CSPV) at the University of Colorado at Boulder, with funding from the Centers for Disease Control and Prevention and several other agencies, designed and launched a national initiative to identify what they have named “Blueprint model programs.” These programs meet a strict scientific standard of program effectiveness in reducing adolescent violent crime, aggression, delinquency, and substance abuse. Currently, more than 600 programs have been reviewed but only 11 have been deemed blueprint model programs by an expert panel.⁴³ An example of a highly effective Blueprint model program is Project Toward No Tobacco Use (TNT), developed by Steve Sussman.⁴⁴ Project TNT is a school-based intervention using a comprehensive, classroom-based curriculum designed to prevent or reduce tobacco use in youth between the ages of 5th and 10th grade. This program includes life/social-skills training, peer-resistance education, classroom-based skills development, and media education to counter alcohol and tobacco advertising. The effectiveness of Project TNT has been demonstrated in randomized controlled trials.

To date, no organization has developed a system reviewing and recognizing model programs for physical activity and nutrition although the Guide to Community Preventive Services has reviewed various approaches to the modification of physical activity.^{45,46} An example of an effective intervention to reduce obesity in children is Gortmaker’s Planet Health.⁴⁷ Planet Health is a school-based interdisciplinary curriculum focused on improving the health and well-being of 6th–8th grade students while building and reinforcing skills in language, arts, math, science, social studies, and physical education. Through classroom and physical education activities, Planet Health aimed to increase activity, improve dietary quality, and decrease inactivity, with a particular focus on decreased TV viewing. The intervention and curriculum were based on the social cognitive theory (discussed later) and the behavioral choice theory.⁴⁸ Planet Health reduced television viewing among both girls and boys, increased fruit and vegetable consumption in girls, and lowered body mass index (BMI) in girls.⁴⁹

Print Communications

Several types of print communications are used to produce behavior change and include generic, tailored, and targeted communications. General-audience print communications provide uniform health information to the broadest possible audience. Tailored print communications adapt health education messages to the characteristics, needs, and interests of *individuals*. Targeted interventions⁵⁰ provide information that is adapted for the characteristics of a particular audience based on age, gender, ethnicity, or other factors but do not provide information unique to the individual reader.⁵¹ Tailored and targeted communications typically use theoretical models of health behavior in their design. In one *tailored* intervention to increase mammography in women, participants were interviewed to assess stage of readiness, perceived barriers, and benefits for getting a mammogram, demographics, and risk status. From this information, personalized letters were generated. Each letter included a drawing of a woman matched to the age and race of the recipient and messages tailored to the recipient’s stage of readiness, personal barriers, and beliefs about mammography and breast cancer.⁵² An example of a *targeted* intervention to increase

mammography in Latina women used a large-scale population-based survey in Latina women to understand their screening behavior, knowledge, and attitudes about cancer, as well as their reading levels and other preferences. This information was used to develop a brightly colored booklet including testimonials from Latinas, based on the aggregate characteristics of this population, which was sent to all participants in the intervention.

Tailored interventions are often, although not always, more effective than generic nontailored interventions at producing changes in attitudes and behavior.^{53–55} Although more effective in many cases, tailored interventions are more costly requiring prescreening to identify levels on the selected tailoring variables, time to incorporate the tailored messages into print communications, and when larger samples are being used, a computerized “expert-system” is needed to review the tailoring algorithm and assign tailored messages. Tailoring can be costly and when delivered to large populations, may not always be practical.⁵⁶ Print communications are often more effective when combined with other intervention strategies. One study found that meeting with a health advisor along with receiving tailored print communications was more effective than receiving the printed tailored materials alone.⁵⁷

Targeted Electronic Media

A number of communication strategies have been developed to extend patient contact beyond the face-to-face clinical encounter.^{58–62} Telephone contacts by a nurse or other health care provider have been used for some time to enhance contact and intervention effectiveness in disease management and clinical care. Recently efforts have been made to automate telephone contacts for disease management and prevention with positive results.^{59–63} Email strategies, internet approaches, palm pilots, and other electronic strategies have also been used in greater frequency in recent years. Integrated systems have been developed that utilize multiple electronic sources of communication and provide an opportunity for target individuals to provide test results to health care providers as well as patients receiving targeted or tailored feedback from health care providers and health educators.^{64–66}

Electronic approaches allow repeated and more frequent contact, without the need for transportation to central health care provider locations, thereby enhancing compliance with treatment regimens and producing greater change in other behaviors of interest (e.g., smoking cessation, physical activity). In addition, these approaches take advantage of rapidly evolving electronic technology to provide new and potentially effective intervention strategies, are more possible under capitated systems of health care than under fee-for-service systems, and complement a trend toward the active involvement of patients in partnering with their health care provider.⁵⁸

Evidence has been provided for the acceptance and use of these procedures by target populations^{64–68} and for the efficacy of the approaches to modify behavior related to diabetes self-management^{60–62} and depression.⁵⁹ These approaches are still relatively new and research is needed to develop improved intervention strategies, followed by widespread dissemination of those that are most effective. The dissemination of effective strategies is dependent on a number of factors clearly described by Glasgow and his colleagues.⁶⁹ These applications must be reliable and user-friendly for clinicians and for the patients or other targets of the intervention. In addition, they must make primary care practices more efficient and allow clinicians to allocate time spent on behavioral counseling to other critical primary care responsibilities. Finally, Glasgow notes that to achieve widespread adoption, electronic intervention strategies must be cost neutral to practices. In sum, targeted electronic media hold promise for extending the availability of disease self-management and prevention intervention through clinical care settings.

Mass Media

Mass media is an important tool for health promotion and includes radio, television, and other media reaching a wide heterogeneous audience. Exposure to mass media messages can inform the public about

the importance of various health issues and give them a framework for thinking about these issues.⁷⁰ Mass media messages can affect people's attitudes and behavior by providing information and by influencing their emotions.⁷¹ The effectiveness of a particular message depends on numerous factors: the characteristics of the message (e.g., the information that the message conveys about the disease or health behavior); the source (e.g., the credibility and likeability of the spokesperson); the channel (e.g., television, radio, magazines, billboard, internet); and the receiver (e.g., the characteristics of the people viewing or hearing the message, including their demographic characteristics, health status, and awareness of health issues). For a mass media message to change people's behavior, people must notice the message, pay attention to it, understand it, remember it, retrieve the information from memory at the appropriate time, and use the information conveyed to select new behaviors.⁷¹ The advantage of mass media is that it can reach a large number of people quickly. The disadvantage is that it is difficult to create messages that are relevant and memorable to all members of the target population. The statewide antismoking media campaign in California^{72,73} is an example of a mass media intervention for health promotion. This long running, highly publicized statewide media campaign disseminates antitobacco messages through various communication channels, including television, radio, print media, and billboards. The campaign's ads vary in intended target audience (e.g., adolescents, adult smokers, specific ethnic groups) and in the tobacco-related issue addressed (e.g., preventing youth access to tobacco, encouraging smokers to call a quitline, portraying the tobacco industry as manipulative). The statewide media campaign has reached the vast majority of California youth and adults and has maintained its high visibility for over 10 years.⁷⁴

Policy

Policy change is another important tool for health promotion. New policies cause people to alter their behavior almost immediately, regardless of whether or not they have been convinced of the necessity of changing their behavior. For example, when communities implement restaurant smoking bans, the restaurant owners immediately prohibit smoking in their establishments (or risk paying a fine), and their patrons refrain from smoking (or risk being asked to leave the restaurant). In this way, nonsmokers in the restaurant are immediately protected from exposure to secondhand smoke, even before the smoking patrons and restaurant owners have changed their attitudes about smoking in restaurants. Over time, the public observes the lack of smoking in restaurants, and smoking in restaurants becomes viewed as an unacceptable behavior.⁷⁵ In the long-term, this may encourage smokers to quit or reduce their smoking so that they can dine comfortably in nonsmoking restaurants. In the short term, the policy protects restaurant staff and other customers from exposure to secondhand smoke. Policies can be set at localized levels (e.g., by specific communities, institutions, or buildings) or at higher levels (e.g., county, state, or federal governments). When policies are set at local levels, it is often easier to identify and address the specific concerns of the people who will be affected by the policy, to obtain their support for the policy, and to implement and enforce the policy. However, local-level policies affect smaller numbers of people. When policies are set at higher levels, they affect larger numbers of people, but they may be perceived as less personally relevant, and large bureaucracies may be needed to implement and enforce them. The advantage of policy interventions is that they can produce behavior change quickly, even before people's attitudes are changed. The disadvantages of policy interventions are that they may be viewed as draconian, and they require consistent enforcement to be effective.

Built Environment

Health behavior researchers have recently given more emphasis to the environment as a predictor and strategy to change health behavior. The built environment usually includes not only the physical structure of

the cities, towns, and rural settings in which we live⁷⁶ but can also include legal- and policy-level determinants of behavior.⁷⁷⁻⁸⁰

Intervention strategies that include the built environment have substantial potential to impact an entire population,^{77,78} rather than just select individuals.^{78,79} Supportive built environments can also support individual-level behavior change. For example, making more fresh fruits and vegetables available in the home, at work, and in convenience stores may help some who have recently decided to change their diet eat more fruits and vegetables. Environmental and policy approaches can continue to influence behavior over time without requiring continued and active intervention by public health professionals. For example, building neighborhoods with sidewalks and safe street crossings will increase the frequency of walking even if a health-promotion program is never delivered to people who live in those neighborhoods. Environmental and policy interventions have had success in tobacco control through programs such as taxation and bans on indoor smoking.⁸¹ In physical activity, simple interventions such as posting signage to encourage people to use stairways have been effective. In addition, urban design that fosters physical activity has been a focus of great interest for addressing the ongoing epidemic of obesity as well as increasing quality of life.⁸²⁻⁸⁵

The number of intervention strategies that have directly manipulated an environment are limited due to lack of a full understanding of the influences of environment on behavior and to the relatively high cost and long timeframe of producing changes in the built environment. The development of theories of environmental influence and of intervention strategies using the environment are emerging areas of research. Physicians and other professionals should be aware of the important role that various elements of the built environment may play on the formation of health behaviors, risk for disease, and their use in the formulation of solutions to ongoing health-related problems. Although relevant to most health behaviors, the role of the built environment on the ongoing epidemic of obesity is of particular interest.⁸⁶ Health professionals ideally will be available to influence public policy toward the creation of built environments that are more conducive to physical activity.

► INTERVENTION DEVELOPMENT AND EVALUATION

Design of Behavioral Interventions

The design of behavioral interventions involves a series of decisions at numerous levels including selection of the target behavior (e.g., helmet use, use of condoms) and target population (e.g., adults or children, specific ethnic group), the theory to use in design of the intervention, the setting where participants will be identified (e.g., schools, worksites, clinics, churches) and intervention activities delivered, the assembling of staff to design, deliver and evaluate the intervention, and finally the design of the intervention components and the development of specific intervention activities and communications. Describing a comprehensive strategy for the design, delivery, and evaluation of a behavioral intervention falls beyond the scope of this chapter. However, we will guide the reader toward source materials for the development and evaluation of a behavioral intervention.

Sources of Information for Intervention Planning

Behavioral intervention is guided by theory and by prior research on approaches that have been effective. Various approaches to intervention development have been described in the literature and we recommend consultation of these texts for assistance. A sample of these texts include the intervention planning approach by Green and Kreuter,⁸⁷ intervention mapping by Bartholomew and colleagues,⁸⁸ and approaches to intervention development for youth by Perry,⁸⁹ and Sussman.⁹⁰ Additional texts can be found providing illustrations of effective ideas and programs.^{91,92} When encountering a text, we recommend using materials that use intervention-design approaches that are theory-driven,

meaning approaches that recommend intervention based on a behavioral theory that has been empirically tested to be associated with behavior.

The development of behavioral interventions often includes art as well as science. The participation of an experienced intervention researcher can be invaluable. Some elements of intervention development can be translated across target populations and health behaviors, however, the most effective advice will likely be provided by an expert who has worked with the behaviors of primary interest to you (e.g., smoking cessation, injury prevention, obesity treatment) and in the setting in which you plan to deliver intervention activities (e.g., schools, clinics, worksites). In addition, skilled media professionals will be needed for the development of most interventions including graphic designers, professional writers or curriculum developers, and video producers to name a few.

Sources of information on effective interventions

Several sources of information are available on behavioral intervention approaches that have been demonstrated to work. The Guide to Community Preventive Services (Guide) has identified approaches to behavior change and risk reduction that work.⁴⁵ The Guide was developed by the U.S. Department of Health and Human Services to provide guidance on approaches to prevention for a diverse set of health behaviors and disease threats. The Guide reviews community intervention approaches and evaluates the evidence rating whether each approach has been demonstrated to be effective or has insufficient evidence indicating effectiveness. The Guide provides an excellent resource to those selecting or designing an intervention for disease prevention and health promotion. The Guide also refers *Healthy People 2010* objectives addressed by the intervention approaches reviewed. Recommendations provided by the Guide to Community Preventive Services are provided in book form,⁴⁵ through journal articles including summaries of reviews and recommendations in the *Morbidity and Mortality Weekly Report* and detailed information on each review in the *American Journal of Preventive Medicine*, and through a website that provides the most up-to-date information on Community Guide activities, reviews and recommendations (www.thecommunityguide.org). Guidance for chronic disease intervention can be found in the text, *Promising Practices in Chronic Disease Prevention and Control: A Public Health Framework for Action*.⁹³

A number of additional web-based resources are available describing interventions within particular content areas. The Centers

for Disease Control and Prevention and the National Institutes of Health offer a particularly rich source of information. Typically these compilations will guide individuals toward evaluated interventions within a specific domain defined by disease, target population, or setting. A number of these resources are presented in Table 53-1.

Sources of information for evaluation of interventions

We highly recommend the evaluation of new interventions, old interventions that have not been carefully studied for efficacy, and previously evaluated interventions that have been adapted for a new population or setting. Although resource constraints may preclude the use of a rigorous evaluation, when it can be developed and used, evaluation provides guidance on the effectiveness of a program, whether it should be used in the future, and how it can be adapted to increase its effectiveness. We suggest the reader consult a strong text in evaluation including those by Rossi,⁹⁴ Shadish,⁹⁵ and Valente.⁹⁶ Evaluation expertise can also be found through faculty in academic settings, and in consulting firms with a particular emphasis on educational or behavioral research. Finally, a number of web-based resources are available. Examples include the CDC Evaluation Working Group (www.cdc.gov/eval), the *Handbook for Evaluating HIV Education* (www.cdc.gov/healthyyouth/publications/hiv_handbook/index.htm), and the *Introduction to Program Evaluation for Comprehensive Tobacco Control Programs* (www.cdc.gov/tobacco/evaluation_manual/ch3.html).

Tobacco: Health Effects and Control

Corinne G. Husten • Stacy L. Thorne

In a sense the tobacco industry may be thought of as being a specialized, highly ritualized, and stylized segment of the pharmaceutical industry. Tobacco products uniquely contain and deliver nicotine, a potent drug with a variety of physiological effects.

Claude E. Teague, Jr., R.J. Reynolds, Federal Register Vol 60 (155), 1995.

Think of the cigarette pack as a storage container for a day's supply of nicotine . . . Think of the cigarette as a dispenser for a dose unit of nicotine . . . Think of a puff of smoke as the vehicle of nicotine . . . Smoke is beyond question the most optimized vehicle of nicotine and the cigarette the most optimized dispenser of smoke.

William L. Dunn, Phillip Morris, 1972, Federal Register Vol 60 (155), 1995.

Realistically if our Company is to survive and prosper, over the long term, we must get our share of the youth market . . . Thus we need new brands designed to be particularly attractive to the young smoker . . . Product image factors (a) should emphasize participation, togetherness, and membership in a group, one of the group's primary values being individuality. (b) Should be strongly perceived as a mechanism for relieving stress, tension, awkwardness, boredom, and the like. (c) Should be associated with doing one's own thing to be adventurous, different, adult, or whatever else is individually valued. (d) Should be perceived as some sort of new experience, something arousing some curiosity, and some challenge. (e) Must become the proprietary "in" thing of the "young" group.

Claude E. Teague, Jr., R.J. Reynolds. Industry documents, Bates #: 502987407–502987418 February 2, 1973.

The custom of smoking dried tobacco leaves spread from America to the rest of the world after European colonization began in the sixteenth century. Given that smoking harms nearly every organ of the body¹ coupled with its addictive properties and widespread use, it is a dangerous psychoactive drug. Its effects are soothing and tranquilizing, yet there is also a stimulant action. Physiological and psychological dependence occur, and there are severe withdrawal symptoms and a craving for tobacco that make this among the most refractory of addictions.

People start to use tobacco for several reasons. Many start for social reasons and many young people perceive tobacco use as an attribute of maturity. Nicotine is the psychoactive compound in tobacco. The nicotine is absorbed quickly and reaches the brain within seconds.² Pharmacological factors interact with stimuli

in the social environment (social reinforcers) so that after many thousands of repetitions of inhaling tobacco fumes or inserting tobacco into the mouth, tobacco use becomes firmly entrenched as a part of the tobacco-user's life. Tolerance, the need for increasing amounts to achieve the same physiological response, develops to some but not all effects of nicotine. Many tobacco users who abruptly quit experience a withdrawal syndrome of irritability, aggressiveness, hostility, depression, and difficulty in concentrating. These symptoms may last several days or even weeks and are accompanied by electroencephalographic changes; cravings for cigarettes may persist long after cessation and be stimulated by exposure to the social reinforcers previously associated with tobacco use. Many tobacco users relapse, often with days of the quit attempt.³

► TOLL OF SMOKING

Excess Mortality

Cigarette smoking has been identified as the leading cause of preventable morbidity and premature death.^{4–6} Up to two out of three lifelong smokers will die of a smoking-related disease.⁷ The estimated annual excess mortality from cigarette smoking in the United States is about 440,000.⁸ If current patterns of smoking persist, an estimated five million U.S. persons aged from 1 to 17 years in 1995 will die prematurely from smoking-related diseases.⁹ Because of its importance as a cause of morbidity and mortality in the United States, the prevalence of cigarette smoking is one of the conditions designated as reportable by states to the Centers for Disease Control and Prevention (CDC). Cigarette smoking is the first instance of a behavior, rather than a disease or illness, considered to be nationally reportable.¹⁰

Coronary heart disease (CHD), multiple cancers, and various respiratory diseases account for the majority of excess mortality related to cigarette smoking.⁸ Of the 480,000 deaths from ischemic heart disease in 2003, an estimated 80,300 (17%) were attributable to smoking. Furthermore, 156,000 (28%) of the 556,000 cancer deaths were attributable to smoking. Lung cancer caused 158,000 deaths in 2003 (28% of all cancers), and 79% of these deaths were attributed to smoking.¹¹ Other cancers caused by smoking are those of the oral cavity, pharynx, larynx, esophagus, pancreas, bladder, kidney, cervix, stomach, and acute myeloid leukemia.¹² Chronic obstructive pulmonary diseases (COPD), such as chronic bronchitis and emphysema, account annually for another 93,000 smoking-related deaths.⁸ Smokers average a 16-fold increased risk of acquiring lung cancer, a 12-fold increased risk of acquiring COPD, and a 2-fold increased risk of having a myocardial infarction (MI), compared to nonsmokers.¹³ Men and women who smoke lose 12.9 and 12.4 years of life, respectively.⁸ Historical gender differences in smoking prevalence are responsible for at least part of the gender difference in life expectancy in the United States.

It is estimated that 8.6 million people in the United States are living with a serious illness caused by smoking—thus, for each person who dies from a smoking-related disease, 20 are living with a smoking-attributable illness. About 10% of all current and former adult smokers have a smoking-attributable chronic disease. Of these, 59% are living with chronic bronchitis and emphysema, and another 19% have had a heart attack.¹⁴ Also, although nonsmokers live longer, smokers live more years with disability (2.5 years for men and 1.9 years for women).¹⁵

The good news is that smoking cessation has major and immediate health benefits.¹⁶ For persons who quit by age 30, life expectancy is essentially the same as a nonsmoker (Fig. 54-1).⁷ Even quitting late in life confers significant health benefits. Adults who quit at age 65–70 can expect to increase their life expectancy by 2–3 years.^{17–19}

Economic Costs

The annual economic toll of smoking can be divided into direct and indirect costs. Smoking-attributable healthcare expenditures totaled \$75 billion in 1998.²⁰ From 1997 to 2001, the average annual cost from lost earnings as a result of smoking-related deaths was \$92 billion.⁸ In 1995–1999, the economic costs translated into an annual cost per smoker of approximately \$3,391 or \$7.18 per pack of cigarettes sold. In addition, pregnant smokers account for a sizable economic burden on the medical care system: medical expenditures associated with smoking during pregnancy were estimated to be \$366 million in 1996, or \$704 per maternal smoker.²¹ Most studies have looked solely at the societal costs of smoking (health care and productivity, Medicare and Medicaid, etc.). A recent study estimated the cost of cigarettes, not only to society, but also to the individual smoker and his/her family, and found that smoking costs a woman \$106,000 and a man \$220,000 over a lifetime, or nearly \$40 per pack of cigarettes consumed.²² Part of the cost of smoking is due to cigarette-caused fires, although this is not included in the calculations cited above. In the United States, fires caused by smoking were the leading cause of fire death, resulting in 760 fatalities in 2003. These fires injured 1520 people and direct property damage associated with smoking-related fires exceeded \$481 million in 2003.²³

► CARDIOVASCULAR DISEASE

Coronary Heart Disease

CHD is the leading cause of excess death and disability in the United States. In 2003, 896,000 (38%) of the 2,333,000 deaths in the United States among persons aged 35 years and older were due to diseases of the cardiovascular system and 17% were attributed to smoking.^{11,24} Of cardiovascular deaths, 480,000 were due to ischemic heart disease.²⁴ In 2003, smoking was estimated to cause 39% and 34%, respectively, of ischemic heart disease deaths of men and women less than 65 years of age, with 14% and 10% being the corresponding percentages for men and women 65 years of age and older.^{11,24}

In early investigations, cigarette smoking was observed to be associated with CHD. On the basis of this observation, cohort studies examined the nature and degree of CHD risk attributable to smoking. These studies revealed a higher incidence of myocardial infarction (MI) and death from CHD in cigarette smokers than in nonsmokers. Studies demonstrated similar findings, whether in the United States, Canada, the United Kingdom, Scandinavia, or Japan.¹² In an American Cancer Society prospective study (Cancer Prevention Study II) (ACS CPS-II) with 1.2 million participants, smokers had CHD mortality approximately 85% higher than nonsmokers.¹³ Similarly, the 40-year follow-up of the British Physicians' Study reported a doubling of risk for heavy smokers.²⁵ The 1989 and 1990 Surgeon General's reports provided a summary of studies that estimated both the risk of CHD from smoking and the decrease in risk with smoking

Figure 54-1. Effects on survival of stopping smoking cigarettes at age 25–34 (effect from age 35), age 35–44 (effect from age 40), age 45–54 (effect from age 50), and age 55–64 (effect from age 60). (Source: Doll R, Peto R, Boreham J, et al. Mortality in relation to smoking: 50 years' observation on male British doctors. *BMJ*. 2004;328:1519–27. Reproduced with permission from the BMJ Publishing Group.)

cessation. The 1990 report concluded that, on the basis of both cohort and case-control studies, "cigarette smoking is firmly established as an important cause of coronary heart disease, arteriosclerotic peripheral vascular disease, and stroke. Eliminating smoking presents an opportunity for bringing about a major reduction in the occurrence of CHD, the leading cause of death in the United States."¹⁶ The 2004 Surgeon General's report reviewed studies published through 2002 and reaffirmed the conclusion that smoking causes CHD. The risk of death from CHD and cardiovascular disease increases directly with usual daily cigarette consumption.^{1,16} Even among past smokers, risk of death due to CHD and cardiovascular disease was associated with previous usual daily cigarette consumption.¹⁶

Although most early investigations of the smoking-related risk of CHD used male subjects, multiple prospective studies indicate that smoking also causes CHD among women.^{1,13,26–28} Data from the ACS CPS-II indicated relative risks of CHD of 3.0 among female smokers aged 35–64 years and 1.6 among female smokers aged 65 years and older.¹² The Nurses Health Study, which examined a cohort of 121,000 women, indicated a relative risk among current smokers of 4.13 for fatal CHD, 3.88 for nonfatal MI, and 3.93 for CHD overall. The risk increased with the number of cigarettes smoked per day: the adjusted relative risk was 1.55 for former smokers, 3.12 for women smoking 1–14 cigarettes per day, and 5.48 for women smoking 15 or more cigarettes per day, compared with lifetime nonsmokers.^{27,29}

Smokers have a higher death rate from CHD at all ages. However, since the incidence of CHD increases sharply with age for both smokers and nonsmokers, the relative risk for smoking-related CHD peaks for men at age 40–44 years and for women at age 45–49 years.^{30,31} The percentage of CHD deaths attributable to smoking is 84% for men aged 40–44 years and 26% for men aged 75–79 years. The smoking attributable percentage of CHD deaths is 85% for women aged 45–49 years and 23% for women aged 80 years and older.³²

Results from cohort studies clearly demonstrate that the risk of death from CHD is increased by early smoking initiation, number of cigarettes smoked per day, and depth of smoke inhalation. For example, data from the Nurses Health Study show that, although the risk of CHD is increased for all smokers regardless of age of smoking initiation, the risk is higher for women who started smoking before age 15. After adjustment for potential confounders, including number of cigarettes smoked daily, the relative risk of CHD for those starting to smoke before age 15 was 9.2. Among former smokers, women who started smoking before age 15 were also at highest risk for CHD, but this finding was based on a small number of cases.²⁷

Smoking in combination with other CHD risk factors appears to have a synergistic effect on CHD mortality. For example, in the Pooling project, the 10-year incidence of first major coronary event was 54 per 1000 for smokers, 92–103 per 1000 for smokers with one other risk factor (hypertension or hypercholesterolemia), and 189 per 1000 for persons with all three risk factors.³³ Diabetes also confers an increased risk of CHD that is further elevated if a person smokes.^{34,35} In studies of women using high-dose oral contraceptives, increased cardiovascular risk was reported among women who smoke.^{29,36} It is unclear if this risk occurs with the newer low-dose pills. Some studies suggest this risk does not occur with these second-generation pills,³⁷ while other studies suggest that among heavy smokers, there is an increased risk.^{38,39} Another study suggested that third generation pills might increase inflammatory markers of CHD.⁴⁰

The 2004 Surgeon General's report concluded that, because of its prevalence, smoking is a major cause of CHD, particularly at younger ages. The report also noted that smoking is associated with sudden cardiac death of all types. Smokers had a relative risk of 2.5 compared with nonsmokers and men had a higher relative risk than women.¹ A substantial proportion of the population's burden of CHD could be avoided with smoking prevention and cessation.¹ Products with lower yields of tar and nicotine as measured by a smoking machine have not been found to reduce CHD risk substantially. Additionally, by causing CHD and MI, smoking may contribute to the

development of congestive heart failure, an increasingly frequent and disabling disease with a poor prognosis.¹

Data from cohort studies show that pipe and cigar smokers generally have a lower risk of a major coronary event and subsequent CHD than do cigarette smokers. The risk of CHD-related death for pipe and cigar smokers is in the range of 1.01–1.37 compared to nonsmokers, with deeper smoke inhalation increasing the risk.^{41,42} For example, in the Cancer Prevention Study I, CHD risk was 1.23 for those who reported "slight" inhalation and 1.37 for those reporting "moderate to deep" inhalation.⁴¹ The Copenhagen City Heart Study found no difference in risk for first MI among pipe, cigar/cheroot, or cigarette smokers,⁴³ but a Swedish study reported that pipe smokers and cigarette smokers had similar risk of death from ischemic heart disease; this finding was attributed to the similar proportion of inhalers among pipe and cigarette smokers.⁴⁴ A more recent cohort study found elevated risk of CVD events (RR = 1.69) and cardiovascular mortality in pipe and cigar smokers.⁴⁵ The National Cancer Institute concluded that heavy cigar smokers and those who inhale deeply are at increased risk for coronary heart disease.⁴¹ Pipe and cigar smokers who are former cigarette smokers tend to inhale the smoke and to have much higher venous blood carboxyhemoglobin levels than do those who have never smoked cigarettes, and they are at higher risk for CHD.^{41,46,47}

Smokeless tobacco use causes acute cardiovascular effects similar to those caused by cigarette smoking, such as increased heart rate and blood pressure levels. Blood pressure is affected by the high sodium content of smokeless tobacco as well as the nicotine and licorice (which causes sodium retention).⁴⁸ A large population-based study in Sweden found that smokeless tobacco users were more likely to have hypertension.⁴⁹ In addition, some (but not all) studies of the effect of smokeless tobacco on lipids have shown a higher risk of hypercholesterolemia, lower high-density lipoprotein levels, and higher triglyceride levels.⁴⁸ This study also showed an elevated risk of diabetes in smokeless tobacco users.⁴⁸ A large Swedish cohort study found that smokeless tobacco users were 1.4 times more likely to die of cardiovascular disease than nonusers,^{49,50} and an analysis of both CPS I and CPS II reported that both cohorts showed increased death from CHD for smokeless users.⁵¹ Two case-control studies have not found an increased risk.^{48,52}

The positive effect of smoking cessation on both primary and secondary prevention of CHD has been extensively studied and validated. The 1990 Surgeon General's report evaluated this research and concluded that compared with continued smoking, cessation substantially reduces the risk of CHD among men and women of all ages.¹⁶ Subsequent cohort studies have supported these conclusions.^{53,54} The excess risk of CHD is reduced by about half after 1 year of abstinence and then declines gradually. After 15 years of abstinence, the risk of CHD is similar to the risk in those who have never smoked. Among persons with diagnosed CHD, smoking cessation markedly reduces the risk of recurrent MI and cardiovascular death. In many studies, this reduction has been 50% or more.¹⁶

Peripheral Vascular Disease

The strongest risk factor predisposing persons to atherosclerotic peripheral arterial occlusive disease is cigarette smoking,^{16,36,55} which has been shown to be directly related to lower extremity atherosclerotic disease of both large and small arteries.^{12,16} Intermittent claudication is more frequent among smokers than nonsmokers.⁵⁶ Smoking prevalence is high among victims of aortoiliac (98%) and femoropopliteal (91%) disease.⁵⁷

The 2004 Surgeon General's report concluded that smoking causes subclinical atherosclerosis.¹ The Ankle Arm Index or AAI, (the systolic blood pressure of the ankle divided by the systolic blood pressure of the arm) is a strong predictor of peripheral artery disease as well as coronary and cerebrovascular disease.^{58–60} A consistent association exists between cigarette smoking and AAI in diverse populations.¹ These new findings on the relationship between

smoking and subclinical disease demonstrate the potential for preventing more advanced and clinically symptomatic disease through cessation.

Limited studies of smokeless tobacco use have not demonstrated a high incidence of peripheral vascular disease in users, and an elevated risk of peripheral vascular disease is not evident in cigar or pipe smokers.⁶¹

Studies show a lower risk of peripheral arterial occlusive disease among former smokers than among current smokers. A recent cohort study found that current smoking was associated with a 50% increase in the progression of atherosclerosis over 3 years, and past smoking was associated with a 25% increase, when compared with never smokers.⁶² There is a consistent reduction in complications of peripheral vascular disease and improved performance and overall survival among patients who quit smoking.¹⁶ Smoking cessation also significantly reduces the risk of peripheral arterial occlusive disease for persons with diabetes, though some of the adverse effects may be cumulative and irreversible.^{62,63}

An autopsy study of atherosclerotic plaques in smokers found that the complexity and extent of plaque in the abdominal aorta increased with the number of cigarettes smoked.^{64,65} Multiple cross-sectional and cohort studies have shown that smokers have a higher abdominal aortic aneurysm mortality rate than nonsmokers.¹ The 2004 Surgeon General's report concluded that smoking causes abdominal aortic aneurysm and is one of the few avoidable causes of this frequently fatal disease.¹ Several studies have also shown an increased risk of aortic aneurysm among pipe and cigar smokers,^{12,41} and an autopsy study indicated that men who smoked cigars, pipes, or both had more complex patterns of atherosclerotic plaques than men who had never smoked cigars or pipes regularly.⁶⁴ Five cohort studies that analyzed the risk of death due to aortic aneurysm for current, former, and never smokers found that among men, risk among former smokers is 2–3 times higher than that among never smokers and about 50% lower among former smokers than current smokers. Patterns are similar for women.¹⁶

Cerebrovascular Disease

Both ischemic and hemorrhagic cerebrovascular diseases are major causes of death in the United States. Although stroke deaths have declined substantially during the past two decades, ischemic and hemorrhagic strokes accounted for approximately 158,000 (6%) of deaths in the United States in 2003.²⁴ Each year there are more than 500,000 new and 200,000 recurrent strokes.⁶⁶ The risk of stroke increases with age.

Smoking has been well demonstrated as a major cause of stroke.^{1,12} The 2004 Surgeon General's report noted that only hypertension is as consistently related to stroke risk as smoking. Smoking increases both the incidence and mortality from stroke.^{1,67,68} A meta-analysis of 32 case-control and cohort studies found that the risk of cerebral infarction was 1.9, the risk for cerebral hemorrhage was 0.7, and the risk of subarachnoid hemorrhage was 2.9 among current smokers compared with never smokers; a positive dose-response relationship between number of cigarettes smoked and relative risk for stroke was also noted.^{1,69} One study estimated that for persons younger than 65 years of age, smoking was responsible for 51% of cerebrovascular disease in men and 55% in women.¹² Smoking is also related to subclinical markers of cerebrovascular disease (white matter disease and subclinical infarcts).¹

At least two cohort studies found that pipe and cigar smoking were associated with an increased risk (RR = 1.62) of stroke events.^{45,70} Switching from cigarettes to a pipe or cigar has little effect on reducing stroke risk.⁷¹ Analysis of CPS I and CPS II showed that in both cohorts, smokeless tobacco users had increased mortality from stroke.⁵¹ Female smokers who use high-dose oral contraceptives are reported to be at increased risk of stroke.^{72,73} It has been suggested that the low-dose oral contraceptives used today might not confer the risk observed for the early high-dose formulations.⁷⁴

Compared with continued smoking, cessation reduces the risk of both ischemic stroke and subarachnoid hemorrhage. After smoking

cessation, the risk of stroke returns to the level of never smokers within 5 years in some studies, though in others, not until up to 15 years of abstinence.¹⁶

Mechanisms of Cardiovascular Disease Development Related to Smoking

Atherosclerosis is characterized by the deposition of lipid in the inner layers of the arteries, by fibrosis, and by thickening of the arterial wall. Atherosclerotic plaques develop over time, slowly progressing from early lipid deposition (fatty streaks) to more advanced raised fibrous lesions that decrease the arterial lumen, and finally to the lesions that are associated with clinical events. The process of plaque destabilization is thought to be associated with inflammatory changes and thrombotic events that obstruct the blood flow and result in clinical manifestations of disease, such as MI or stroke.¹

The highly regulated physiologic interface between blood and arterial wall components is strongly and adversely affected by the toxic products from cigarette smoke that are added to the bloodstream.¹ The smoking-related development of CHD includes at least five interrelated processes: atherosclerosis, thrombosis, coronary artery spasm, cardiac arrhythmia, and reduced oxygen-carrying capacity of the blood. The exact components of cigarette smoke that cause these changes are not known.

Endothelial Injury or Dysfunction

Data from animal studies suggest that nicotine causes endothelial damage, and data from humans indicate that smoking increases the number of damaged endothelial cells and the endothelial cell count in circulating blood.¹ Cigarette smoke exposure in dogs resulted in increased endothelial permeability to fibrinogen.⁷⁵ Young and middle-aged smokers without disease had a significant reduction in endothelium-dependent vasodilatation compared with nonsmokers.⁷⁶ Smoking also appears to stimulate smooth muscle cell proliferation and to increase the adherence of platelets to arterial endothelium. Animal studies have demonstrated that exposure of rat endothelium to blood from a person who had recently smoked two cigarettes resulted in the deposition of a large number of platelets on the endothelial surface.¹

Thrombosis/Fibrinolysis

Smoking may also increase thrombus formation. Fibrinogen levels are elevated in smokers, as is platelet-fibrinogen binding and other clotting abnormalities that tend to promote thrombus formation.⁷⁷ Plaques from smokers more frequently have thrombosis along the walls of the arteries than plaques from nonsmokers.⁷⁸ Smoking also increases tissue factor (a glycoprotein that initiates the extrinsic clotting cascade) expression.⁷⁹ The prothrombotic effect of smoking is thought to be the main underlying factor that links smoking to sudden cardiac death.⁸⁰

Inflammation

Current ideas about the pathogenesis of atherosclerosis increasingly emphasize a central role for inflammation.¹ Smoking induces a systemic inflammatory response, as demonstrated by increases in inflammatory markers such as the blood leukocyte count.⁸¹ Smoking is also associated with elevated C-reactive protein levels, another measure of inflammatory activity. C-reactive protein level is associated with risk of CHD, stroke, and peripheral artery disease.^{82–85}

Lipids/Lipid Metabolism

A substantial body of evidence has demonstrated an association between smoking and adverse lipid profiles.¹ Smokers have decreased levels of high-density lipoprotein (HDL), higher concentrations of total low-density lipoprotein (LDL) and very low-density lipoprotein (VLDL) cholesterol compared with nonsmokers.^{16,86,87} A population-based cohort study showed decreasing HDL in persons

who started to smoke and increasing HDL levels in persons who had stopped smoking.⁸⁸ Smoking may also promote lipid peroxidation, thought to be a key element in the development of atherosclerosis.⁸⁹

Increased Oxygen Demand

Cigarette smoking increases myocardial oxygen demand by increasing peripheral resistance, blood pressure, and heart rate (probably attributable to nicotine).⁹⁰ In addition, the capacity of the blood to deliver oxygen is reduced by increased carboxyhemoglobin, greater viscosity, and higher coronary vascular resistance due to vasoconstrictor effects on the coronary arteries. Reduced oxygen-carrying capacity may contribute to infarction in the presence of significant atherosclerotic narrowing of the vessels.^{1,16}

Coronary artery spasm can cause acute myocardial ischemia and may promote thrombus formation. Arrhythmias can precipitate heart attacks and can increase the case fatality rate of MI; smoking has been shown to lower the threshold for ventricular fibrillation.¹⁶

Mechanisms of Peripheral Vascular and Cerebrovascular Disease Development

The strong association between smoking and peripheral vascular disease is likely mediated by the mechanisms that promote atherosclerosis as described earlier. The peripheral vasoconstrictive effects of smoking probably also play an important role.¹⁶ The association of smoking with ischemic stroke is likely mediated by the mechanisms that promote atherosclerosis and thrombus formation.⁹¹ Cigarette smoking appears to increase the risk of stroke by decreasing cerebral blood flow.⁹² In smokers with other risk factors for stroke, cerebral blood flow is reduced in an additive manner compared with that in nonsmokers with similar risk factors.⁹³ The mechanism for the strong relationship between smoking and subarachnoid hemorrhage is currently unknown.¹⁶

► CANCER

Lung Cancer

In the United States, carcinoma of the lung is the leading cancer cause of death for both men and women.⁹⁴ Lung cancer replaced breast cancer as the leading cause of cancer death among both white and black American women in 1987.⁹⁴ Lung cancer mortality rates, as measured by ACS CPS-I from 1959 to 1965 and ACS CPS-II from 1982 to 1988, increased over this period from 26 to 155 per 100,000 women and from 187 to 341 per 100,000 men.¹³ The number of lung cancer deaths in the United States rose sharply, from 18,300 in 1950 to 61,800 in 1969, to an estimated 160,400 in 2007.⁹⁴ An estimated 89,510 men and 70,880 women will die of lung cancer in 2007.⁹⁴ In 2003, lung cancer accounted for 28% of cancer deaths and 6% of all deaths in the United States.²⁴ Of all lung cancer deaths, 79% are directly attributable to smoking.^{11,24}

Among malignant lung tumors, 90% belong to four major cell types: squamous cell, oat cell, large cell, and adenocarcinoma, which are commonly designated bronchogenic carcinoma. Smoking induces all four major histologic types of lung cancer. Initially, squamous cell carcinoma was seen most often in smokers, followed by small cell carcinoma. However, since the late 1970s, adenocarcinoma has been increasing, and is now the most common histologic type.^{95–98} It has been suggested that the increasing incidence of adenocarcinoma may be related to the switch to low-tar, filtered cigarettes, which may allow increased puff volume with increased deposition of smoke in the peripheral airways. Low tar cigarettes also have increased tobacco-specific nitrosamine (a carcinogen shown to induce adenocarcinoma) levels.^{99–104} Lung cancer has a propensity to metastasize early and widely. Five-year survival in lung cancer patients is 15%. The survival rate is 49% for localized disease, but only 16% of lung cancer is diagnosed at this early stage.⁹⁴ The survival rate from lung cancer has increased only slightly in the past 20 years.¹⁰⁵

The rise in lung cancer rates in male smokers preceded that of female smokers. In the years 1959–1961, the male/female ratio of

death rates from lung cancer was 6.7:1. Whereas the incidence rate in men appears to have peaked in 1984, the rate for women has continued to increase by 2% per year. By 1997–2001, the male/female ratio had declined to 1.7:1.¹⁰⁶ Although the 1964 Surgeon General's report¹⁰⁷ was the first official U.S. statement on the relationship of smoking and lung cancer, case control, cohort, and animal studies conducted in the 1950s showed a clear association between smoking and lung cancer.^{108,109} The study most influential in drawing medical attention to this relationship was a 1956 cohort study of 40,000 British physicians 36 years of age and older. This study demonstrated that the age-adjusted death rate for lung cancer increased from 7 per 100,000 for nonsmokers to 166 per 100,000 for heavy smokers.¹¹⁰

Other cohort studies in various parts of the world have further demonstrated the consistency, specificity, strength, and temporal nature of the association between smoking and lung cancer. The 1990 Surgeon General's report provided an outline of the lung cancer mortality ratios for current, former, and never smokers from prospective studies. Smoker mortality rates for lung cancer ranged from 4 to 27 times those of nonsmokers.¹⁶ The relative risk has increased over time, doubling for men and quadrupling for women from ACS CPS-I, 1959–1965, to ACS CPS-II, 1982–1988.¹³ Strength of association was further demonstrated by the dose-response relationship.³² Figure 54-2 demonstrates the gradient of increasing risk of death

Figure 54-2. Death rates from lung cancer among persons age 60–69, by amount and duration (in years) of cigarette smoking: Duration progresses over time. ACS Cancer Prevention Study II. (Source: Thun MJ, Myers DG, Day-Lally C, et al. Age and exposure-response relationships between cigarette smoking and premature death in Cancer Prevention Study II. In: Burns DM, Garfinkel L, Samet J, eds. Changes in Cigarette-Related Disease Risks and Their Implication for Prevention and Control. *Smoking and Tobacco Control Monograph No. 8*. Rockville, MD: National Cancer Institute, 1997 NIH Publication No. 97-4213.)

from lung cancer as the number of cigarettes smoked per day increases. Increasing the number of cigarettes smoked per day increases the relative risk for both male and female smokers.¹¹¹

There is also a direct relationship between the number of years of smoking and lung cancer mortality (Fig. 54-2). Lung cancer incidence appears to increase with the square of the amount smoked daily, but with the duration of smoking raised to a power of four or five.¹¹² Smoking mechanics, such as the degree of inhalation, also affect lung cancer mortality.¹² However, even smokers who report slight inhalation or none have a relative risk of cancer up to eightfold higher than that for nonsmokers.¹¹³ The 2004 Surgeon General's report and 2004 International Agency for Research on Cancer (IARC) report confirmed and expanded the evidence base supporting the conclusion that smoking causes lung cancer.^{1,114}

Both case-control and cohort studies have demonstrated some reduction in lung cancer risk in smokers who switched from nonfiltered to filtered cigarettes.^{12,115} For those who have always smoked filtered cigarettes, the risk of lung cancer is still very high, but may be 10% to 30% lower than that for lifelong smokers of nonfiltered cigarettes. Although initial studies suggested that low-tar cigarettes might confer reduced risk of lung cancer,^{116–118} recent reviews have concluded that any reduction in lung cancer risk associated with changes in the cigarette are small.^{101,114} The 2004 Surgeon General's report and a National Cancer Institute Monograph have both concluded that although the characteristics of cigarettes have changed during the last 50 years and yields of tar and nicotine have declined as assessed by the Federal Trade Commission test protocol, the risk of lung cancer in smokers has not declined, and changes in the design of cigarettes intended to reduce tar and nicotine yields have had no significant benefit for lung cancer risk in smokers.^{1,119}

For persons who stop smoking cigarettes, the decrease in lung cancer mortality is related to smoking history (e.g., dose, duration, type of cigarette, and depth of inhalation) as well as the number of years since cessation. Risk reduction is gradual; after 10 years the risk is about 30–50% of that for continuing smokers.¹⁶ However, even with the longest duration of quitting, the risk remains greater than for lifetime nonsmokers.¹²⁰ It is hypothesized that the absolute risk of lung cancer does not decline after cessation, but the additional risk that comes with continued smoking is avoided. For example, biopsy specimens of nonmalignant tissues show persistent molecular damage in the respiratory epithelium of former smokers.¹

Multiple case-control and cohort studies have reported an increased risk of lung cancer among those who smoke pipes, cigars, or both.^{42,45,121–123} The National Cancer Institute has concluded that regular cigar smoking causes lung cancer.⁴¹ For cigar smoking, the risk increases with the number of cigars smoked per day and with increasing depth of inhalation; depth of inhalation is the more powerful predictor of risk.⁴¹ However, studies suggest that cigar smokers who do not inhale have a lung cancer risk 2–5 times higher than nonsmokers and evidence also exists that the risk of lung cancer has increased over time for cigar smokers.¹¹⁴ Studies have reported that risk increases with the duration of cigar smoking, and decreases with cessation.¹¹⁴ In general, the risk of lung cancer is less for pipe and cigar smokers (RR = 4.35) than for cigarette smokers, but substantially greater than for nonsmokers. Former cigarette smokers who switch to cigars or pipes are at higher risk than those who have only ever smoked cigars or pipes, and the latter are at higher risk than those who quit tobacco use entirely.⁴⁷ An estimated 825 Americans died in 1991 from lung cancer as a result of pipe smoking.¹²⁴ Among pipe smokers, lung cancer death rates also exhibit dose-response relationships.¹⁶ In one study, lung cancer risk among pipe smokers decreased with time since cessation.¹²⁵

Chemical analysis of the smoke from pipes, cigars, and cigarettes shows that carcinogens are found at comparable levels in the smoke of all these tobacco products. The lower risk of lung cancer among pipe and cigar smokers compared to that in cigarette smokers is due to the smaller amount of tobacco smoked and the lower proportion who inhale.¹⁶ In Denmark and Sweden, where the style of smoking pipes and cigars involves deeper inhalation than is generally

practiced in the United States, the rate of lung cancer in pipe and cigar smokers approaches that of cigarette smokers.^{44,126}

The 2004 Surgeon General's report concluded that smoking causes genetic changes in cells of the lung that lead to the development of lung cancer.¹ Although research during the past 25 years has led to a greatly expanded knowledge of the major factors contributing to the toxicity and carcinogenicity of cigarette smoke, the mechanisms responsible for lung tumor initiation from tobacco smoke constituents are complex and not yet completely understood. Armitage and Doll¹²⁷ proposed that "k" stages are required to transform a normal cell to a malignant cell. Components of tobacco smoke are potent mutagens and carcinogens.¹ Tobacco smoke contains more than 60 known carcinogens that have both cancer-initiating and cancer-promoting activity.^{102,114} The bronchial epithelia of smokers show progressive abnormal changes; the frequency and intensity of these changes increase with the amount smoked. The number of cells with atypical nuclei decreases with an increased number of years since smoking cessation. An association between smoking and the presence of DNA adducts has also been reported.¹⁶ For example, a carcinogen in cigarette smoke (benzo[*a*]pyrene) forms adducts at specific codons on the *p53* tumor suppressor gene; these adducts are at the same locations as mutations associated with lung cancer.^{128,129} Current smokers also have significantly higher levels of PAH-DNA adducts in their lungs.¹ A large body of data links exposure to tobacco carcinogens and mutations on the *K-ras* oncogene. Mutations at codons 12, 13, and 61 are found in adenocarcinoma of the lung, and these mutations are primarily seen in smokers.¹ Recent studies have shown that DNA methylation inactivation of the promoters of tumor suppressor genes occurs frequently in smoking-related cancers. An estimated 15–35% of lung cancer tumors have inactivation of the *p16* tumor suppressor gene by DNA-methylation.¹³⁰

Oral, Laryngeal, and Esophageal Cancer

A large number of cohort and case-control studies from many countries support the conclusion drawn by the U.S. Surgeon General and IARC that smoking is a cause of oral and laryngeal cancer, and of both adenocarcinoma and squamous cell carcinoma of the esophagus.^{1,114} For the heaviest smokers, the relative risk for laryngeal cancer is 20 or more compared with lifelong nonsmokers.¹ The relative risks for male current smokers compared with lifelong nonsmokers ranged from 3.6 to 11.8 for oral cancer,¹³¹ and up to 14.1 for pharyngeal cancer.¹³² For esophageal cancer the relative risk is 7 for men and 8 for women.¹¹ The estimated numbers of deaths attributable to smoking for these cancers, other cancers, and other diseases are shown in Table 54-1, and Table 54-2 displays the attributable risks. For both men and women, most cases of these three cancers are attributable to smoking, with strong dose-response relationships at each of these sites.¹²

Smokeless tobacco causes oral cancer.^{1,133,134} The 1986 Surgeon General's Report reported a relative risk of 50 for oral cancer for smokeless tobacco users compared with nonusers.¹³⁵ Long-term use of snuff is associated with cancers of the cheek and gum. The death rates from oral and pharyngeal cancer vary more than 100-fold across countries,¹³⁶ with the highest rates among men in Sri Lanka and the western Pacific region, where tobacco is chewed in combination with betel.¹ All forms of tobacco use (cigarettes, pipes, cigars, chewing tobacco, snuff, reverse smoking [the lit end is placed inside the mouth], and "pan" [tobacco, areca nuts, slaked lime and betel leaf], chewing) increase the development of premalignant lesions and cancer of the oral cavity and pharynx.¹

Cigar smoking causes oral, laryngeal, and esophageal cancer.^{41,42,123} In one large cohort study (CPS I), the relative risk for oral cancer was 7.9 overall and 15.9–16.7 for men smoking five or more cigars per day.⁴¹ Former cigar smokers have a lower risk than current cigar smokers, but even after 10 years, the risk is three times that of nonusers.¹³⁷ Studies have shown relative risks for laryngeal cancer of 10 overall and 26 for those smoking five or more cigars per day. A relative risk of 3.6–6.5 for esophageal cancer and a dose-response relationship with the duration/intensity of cigar smoking have been demonstrated.¹¹⁴

Pipe smoking causes lip cancer and is also associated with oral, laryngeal, and esophageal cancers.^{1,114} For these sites, the mortality ratios for smokers—regardless of whether they smoke cigarettes, pipes, or cigars—are similar.^{1,12,41} A study in Brazil reported that pipe smokers have a relative risk of 11 for developing oral cancer, and this risk decreases with cessation, though it did not return to nonuser rates even after 10 years of abstinence (when it was still 3.4).¹³⁸ Another study showed an increased risk of esophageal cancer with snus (Swedish snuff) use, but the results were not statistically significant.¹³⁹

The progression from healthy mucosa to carcinoma is the result of an accumulation of genetic mutations that disrupt the normal control of cell growth.¹⁴⁰ Several carcinogens and tobacco metabolites have been measured in saliva and the oral mucosa, as well as the urine and blood, of smokers and smokeless tobacco users.¹ Studies in a number of animal species show that multiple carcinogens in tobacco smoke and smoke condensate cause premalignant papillomas and carcinomas of the esophagus and forestomach.^{1,141} Benzo[*a*]pyrene penetrates the cell membranes of the esophageal epithelium, causing papillomas and squamous cell carcinoma.¹⁴² About 50% of head and neck squamous cell carcinomas have *p53* mutations; these mutations appear to increase with the number of cigarettes smoked and are augmented by alcohol use.¹⁴³

Alcohol plays a synergistic role with smoking for each of these cancers,⁹⁴ and together, smoking and alcohol account for most cases in the United States.¹ In one study of oral cancer risk, for nonsmokers who consumed 7 oz or more of alcohol per week, the relative risk of death

from oral cancer was 2.5 compared with that for nondrinkers. Those who consumed the same amount of alcohol and smoked one-half pack of cigarettes or less per day had approximately double the risk of the nonsmoking alcohol drinkers, but the relative risk rose to 24 if the smoker consumed a pack or more per day.¹⁰⁹ Reduction in tobacco use could prevent most deaths from esophageal cancer in the United States.¹

After smoking cessation, relative risk may decrease more slowly for oral cancer than for pharyngeal cancer.^{138,144} Smoking cessation halves the risk of oral and esophageal cancer within 5 years of quitting; the risk is reduced further with longer abstinence. The risk of laryngeal cancer is reduced after 3–4 years of abstinence, but it remains higher than that for never smokers.¹⁶ Some studies (but not all) suggest that the risk of squamous cell carcinoma of the esophagus may decrease more rapidly than adenocarcinoma after cessation.^{145–147}

Bladder and Renal Cancer

Smoking is a well-established cause of bladder cancer, with 30 case-control studies and 10 prospective studies supporting this conclusion.^{1,148} As seen in Tables 54-1 and 54-2, about 45% of bladder cancer cases in men and 27% in women are attributable to smoking, accounting for more than 4800 deaths per year.¹¹ Relative risks for bladder cancer are 2 to 3, with a clear dose-response relationship. Smoking cessation reduces the risk of bladder cancer by half after only a few years.¹⁶

Centers for Disease Control and Prevention. Smoking-Attributable Mortality, Morbidity, and Economic

The relationship between smoking and cancers of the ureter and renal pelvis are even stronger: smoking accounts for 70–82% of these cases in men and 37–61% in women.¹⁴⁹ Risks attributable to smoking and the corresponding numbers of annual deaths for renal cancer are shown in Tables 54-1 and 54-2. Relative risks from a variety of studies have ranged from 1 to 5, with a clear dose-response relationship demonstrated, and reduction in risk with successful cessation.^{1,12} Both IARC¹¹⁴ and the Surgeon General¹ have concluded that smoking causes renal cancer. Some studies have suggested that pipe smoking is also associated with bladder cancer.¹¹⁴

The urinary tract is exposed to tobacco carcinogens and their metabolites as they are cleared by the body. The urine of smokers is more mutagenic than the urine of nonsmokers.¹⁵⁰ N-nitrosodimethylamine, a chemical in tobacco smoke, causes kidney tumors in a variety of animal models.¹⁵¹

Pancreatic Cancer

In 2007, there will be estimated 37,170 new cases of pancreatic cancer and 33,370 deaths.⁹⁴ The 1-year survival rate for pancreatic cancer is 24%, and the 5-year survival rate is 4%. Even for those diagnosed with local disease, the 5-year survival rate is 17%.⁹⁴ The 2004 Surgeon General's report concluded that smoking causes pancreatic cancer.¹ Dose-response relationships have been found,¹² with relative risks from 2 to 3 reported in most studies, but at the highest levels of smoking, relative risks range from 3 to 5.¹ Attributable risk and annual smoking-related mortality rates are shown in Tables 54-1 and 54-2, respectively. Evidence shows that the risk of pancreatic cancer declines with cessation.¹

The National Cancer Institute concluded that cigar smoking probably causes pancreatic cancer.⁴¹ The Veterans Study noted a 1.5 relative risk for pancreatic cancer among cigar smokers, but no increased risk for pipe smokers.¹⁵² However, other studies have suggested an increased risk of pancreatic cancer for pipe smokers.¹¹⁴ One study showed an increased risk of pancreatic cancer among snus users

(RR = 1.7) and two others among traditional smokeless tobacco users.^{139,153,154}

New studies of *ras* mutations in pancreatic cancer support a causal role for smoking. Pancreatic cancer can be produced in animals with the tobacco-specific N-nitrosamine, NNK. Aromatic amines may also play a role.¹

Stomach Cancer

In 2007, an estimated 21,260 new cases and 11,210 deaths from stomach cancer will occur in the United States.⁹⁴ Nine cohort studies and 11 case-control studies support the conclusion of the Surgeon General¹ and IARC¹¹⁴ that smoking causes gastric cancer. The Surgeon General also concluded that the evidence was suggestive, but not sufficient to infer a causal relationship between smoking and noncardia gastric cancers. The average relative risk is 1.6, with a dose-response relationship.^{12,155} Risk decreases with sustained cessation,¹⁶ with an average relative risk of 1.2 in former smokers. The risk of stomach cancer for former smokers approaches that of lifelong nonsmokers about 20 years after quitting.¹ At least two studies have reported an increased risk of stomach cancer among smokeless tobacco users, but the results were not statistically significant.^{139,156} Other data show an increased risk of stomach cancer from cigar smoking, with a dose-response relationship.¹⁵⁶

Smoking appears to increase the infectivity or add to the pathogenicity of *Helicobacter pylori*, a known cause of noncardia stomach cancer. Smoking may also lower the plasma and serum concentrations of certain micronutrients that may protect against *H. pylori* infections or gastric cancer.¹⁵⁷

Cervical Cancer

In 2007, an estimated 11,150 new cases of cervical cancer will be diagnosed and an estimated 3670 U.S. women will die from the disease.⁹⁴ Epidemiological studies have consistently shown an increased risk of

cervical cancer in cigarette smokers.¹⁶ A median relative risk of about 2.0 was found in these studies. There is a dose-response relationship with duration of smoking and number of cigarettes smoked per day.⁵⁶ Human papillomavirus (HPV) is causally related to cervical cancer and appears to be necessary to its development.^{158,159} However, two prospective cohort studies have shown that smoking was associated with increased risk in women who were HPV-positive at entry into the study.^{160,161} It is postulated that smoking may increase the rate at which cancer develops in women with persistent infection or possibly increase the risk for persistent infection.¹ Both the Surgeon General¹ and IARC¹¹⁴ have concluded that smoking causes cervical cancer. In most studies, former smokers at one year after cessation are at lower risk for cervical cancer than are continuing smokers.¹⁶ Components of tobacco smoke (including NNK and nicotine)^{162,163} have been found in the cervical mucus, and the mucus is mutagenic in smokers.¹⁶⁴ In addition, tobacco-related DNA adducts were higher in cervical biopsies of smokers compared with nonsmokers.¹⁶⁵

Endometrial Cancer

In 2007, an estimated 39,080 new cases and 7400 deaths will occur from endometrial cancer.⁹⁴ Both the 1989¹² and 2004 Surgeon General's reports¹ concluded that smoking reduces the risk of endometrial cancer in postmenopausal women. This may be due to a lower production of estrogen because of lower body weight in smokers, and altered estrogen metabolism. However, the modest decrease in the risk of endometrial cancer is far outweighed by the increase in other causes of smoking-related disease and death.^{1,12}

Acute Myeloid Leukemia

The most common type of leukemia in U.S. adults is acute myeloid leukemia, with an estimated 13,410 cases diagnosed in 2007.⁹⁴ Several literature reviews and meta-analyses noted significant association between current or former smoking and myeloid leukemia, with a dose-response relationship to the number of cigarettes smoked per day.^{166,167} There is also an association with duration of smoking. The relative risk for ever-smokers ranges from 1.3 to 1.5 compared with never-smokers. For one-pack-per-day smokers, the relative risk is 2.0. Both the Surgeon General¹ and IARC¹¹⁴ have concluded that smoking causes myeloid leukemia. Smoking causes an estimated 12–58% of acute myeloid leukemia deaths.¹

Cigarette smoke contains known substances (including benzene, polonium-210 and lead-210), which are known to cause myeloid forms of leukemia. Cigarette smoke is the major source of benzene exposure in the United States (about half of all exposure).¹⁶⁸

Other Cancers

The 2004 Surgeon General's report concluded that the evidence is suggestive, but not sufficient to infer a causal relationship between smoking and colorectal adenomatous polyps, colorectal cancer, and liver cancer. The report concluded that the evidence is suggestive of no causal relationship between smoking and risk for prostate cancer, although some studies suggest a higher mortality rate from prostate cancer in smokers than nonsmokers.¹ Several studies have found an association between smokeless tobacco use and prostate cancer.¹⁶⁹

► OTHER SMOKING-RELATED DISEASES

Chronic Obstructive Pulmonary Disease

About 12 million people in the United States have been diagnosed with chronic obstructive pulmonary disease (COPD).¹⁷⁰ In 2000, COPD accounted for more than 725,000 hospitalizations in the United States, nearly 8 million physician office visits and hospital outpatient visits, and 1.5 million emergency room visits.¹⁷⁰ An estimated 122,000 Americans died of COPD in 2003, and 76% of COPD deaths are attributable to smoking.^{11,24} The death rates from COPD

increase with age; in 2003, they were about equal for men and women.²⁴ Mortality from COPD has paralleled lung cancer mortality, increasing progressively over the past 30 years.¹² A recent decline in COPD mortality at younger ages is consistent with lower smoking prevalence among younger cohorts of Americans.¹² The 2004 Surgeon General's Report¹ summarized the studies of smoking and COPD to 2003. Data from case-control and cohort studies consistently demonstrate a higher COPD mortality among cigarette smokers than among nonsmokers, with a mortality ratio as high as 32 for persons smoking 25 or more cigarettes per day.¹⁶ In the Nurses' Health Study, the relative risk for self-reported, physician-diagnosed chronic bronchitis among current smokers when compared with women who had never smoked was 2.85.¹⁷¹ In the 40-year follow-up of the British Physicians' Study, the risk of COPD among smokers was found to be almost as high as the risk of lung cancer.^{24,25} Dose-response relationships have been consistently observed, with the risk of death from COPD influenced by the number of cigarettes smoked per day, the depth of smoke inhalation, and by the age at smoking initiation.^{126,172} The 2004 Surgeon General's report concluded that smoking causes COPD. The report also concluded that the evidence was suggestive but not sufficient to infer a causal relationship between smoking and acute respiratory infections among persons with preexisting COPD.¹

Abnormal lung function (especially expiratory airflow) occurs as early as 2 years after smoking initiation.^{173,174} Smokers exhibit a more rapid decline in forced expiratory volume at 1 second (FEV₁) with age than do nonsmokers,¹⁷⁵ and as the amount of cigarette smoking increases, the rate of decline accelerates.¹ Decline in lung function begins with inflammation in the small airways, although inflammation in the lung parenchyma is also a major factor in the development of COPD.¹ Symptoms of such inflammation are not always a reliable indicator of smokers who will subsequently have symptomatic COPD. However, those smokers with a fast annual decline in FEV appear to constitute a high-risk group for COPD development.^{1,175}

Studies have identified the likely mechanisms by which cigarette smoking induces COPD. The current model suggests that after a long latency period, COPD develops because of a more rapid decline in lung function during adulthood or because of a reduction in maximal lung growth in childhood and adolescence.¹ The age at which smoking has the greatest influence on COPD pathogenesis is unknown. Atopy and increased airway responsiveness are associated with a more rapid decrease in pulmonary function, and cigarette smoking is a cause of exaggerated airway responsiveness. Smoking also causes injurious biologic processes (oxidant stress, inflammation, and a protease/antiprotease imbalance) that result in airway and alveolar injury. If sustained, such injury results in COPD.^{1,175}

Cigar smokers and pipe smokers who inhale have a higher rate of decline of FEV₁ than cigarette smokers and a higher prevalence of chronic cough and phlegm than never-smokers.^{111,176} Several large cohort studies have found that pipe smokers and cigar smokers have approximately a twofold increase in COPD mortality compared with nonsmokers, but the case fatality rate in these groups of smokers is lower than that of cigarette smokers.^{42,175} However, former cigarette smokers who switched to cigars or pipes were at higher risk than those who had only smoked pipes or cigars, and those who quit smoking without taking up other tobacco products had the lowest risk among tobacco users.⁴⁷ A large prospective study in Scandinavia found that the apparent difference in the mortality risk associated with pipe and cigar smoking compared with that of cigarette smoking was markedly reduced after adjusting for smoke inhalation.¹²⁶ The National Cancer Institute concluded that heavy cigar smokers and those who inhale deeply can develop COPD and that the reduced inhalation of smoke by cigar smokers probably explains their lower risk of COPD compared with cigarette smokers.⁴¹ In 1991, an estimated 145 persons in the United States died from COPD as a result of pipe smoking.¹²⁴

After smoking cessation, the rate of COPD excess risk reduction is determined by prior smoking patterns (duration and daily consumption)

and the number of years since cessation. Smoking cessation reduces respiratory symptoms and respiratory infections. Smokers who quit have better pulmonary function than continuing smokers.¹⁷⁷ For persons without overt COPD, pulmonary function improves about 5% within a few months of quitting. Cigarette smoking accelerates the age-related decline in lung function; with abstinence, the rate of decline returns to that of never smokers. With sustained abstinence, the risk of developing COPD and the COPD mortality rate are lower than they are in continuing smokers,¹⁶ but do not return to the level found in nonsmokers, probably because smoking has resulted in irreversible injury to the airways and parenchyma.¹ For example, in the U.S. Veterans Study, the mortality ratio for current smokers was about 12, and was reduced to 10 among ex-smokers 10 years after cessation. After more than 20 years of abstinence, the mortality rate was still twice that of nonsmokers.¹⁷⁸ Smokers with destructive lung changes can often stabilize after cessation but do not regain lost lung function.¹⁷⁵

Smokers have more respiratory symptoms than do nonsmokers. The frequency of respiratory symptoms in children and adolescents is greater in current smokers than nonsmokers or former smokers.¹⁷⁹ The 2004 Surgeon General's report concluded that smoking was a cause of wheezing in children and adolescents, that there was insufficient evidence to determine whether there was a causal relationship between active smoking and physician-diagnosed asthma in children and adolescents, and that the evidence was suggestive but not sufficient to infer a causal relationship between active smoking and a poorer prognosis for children and adolescents with asthma.¹

The 2004 Surgeon General's report concluded that there is a causal relationship between active smoking and chronic respiratory symptoms (chronic cough, phlegm, wheezing, and dyspnea) among adults.¹ These symptoms have a dose-response relationship with the number of cigarettes smoked per day, and they decrease with cessation. Smoking contributes to these symptoms by decreasing tracheal mucous velocity, increasing mucous secretion, causing chronic airway inflammation, increasing epithelial permeability, and damaging parenchymal cells.¹⁶ The Surgeon General also concluded that there was inadequate evidence to determine whether there was a causal relationship between active smoking and asthma in adults, that the evidence was suggestive but not sufficient to infer a causal relationship between active smoking and increased nonspecific bronchial hyperresponsiveness, and that active smoking was a cause of poor asthma control.¹

Gastrointestinal Disease

Cigarette smoking is associated with symptomatic gastroesophageal reflux disease. Compared with nonsmokers, smokers have reduced lower esophageal sphincter pressure and reduced salivary function, which contribute to a longer acid clearance time.¹⁸⁰

Up to 100% of duodenal ulcers and 70–90% of gastric ulcers are associated with *H. pylori* infection.¹⁸¹ The remaining ulcers are linked to the use of nonsteroidal anti-inflammatory drugs.^{182,183} Smokers of both sexes have a high prevalence of peptic ulcer disease, with a clear dose-response relationship.^{1,56} The ACS CPS-I found that the relative risk of mortality for peptic ulcer among men was 3.1 for current smokers and 1.5 for former smokers compared with lifetime nonsmokers.¹² Duodenal ulcers heal more slowly among smokers than nonsmokers, even with therapy. Both gastric and duodenal ulcers are also more likely to recur among smokers. Smoking cessation is associated with fewer duodenal ulcers, improved short-term healing of gastric ulcers, and reduced recurrence of gastric ulcers.¹⁶

Likely mechanisms by which smoking promotes peptic ulcer disease include the potential for tobacco smoke or nicotine to increase maximal gastric acid output and duodenogastric reflux, and to decrease alkaline pancreatic secretion and prostaglandin synthesis.¹ Bicarbonate secretion from the pancreas is reduced immediately after smoking, leading to a decrease in duodenal bulb pH.¹⁸⁴ The pH level appears to be the most important determinant for the development of gastric metaplasia in the duodenum, which allows colonization by

H. pylori.¹⁸⁵ Four studies controlling for *H. pylori* infection have shown an association between smoking and ulcer.¹ The 2004 Surgeon General's report concluded that smoking causes ulcers in persons who are *H. pylori*-positive and that the evidence was suggestive but not sufficient to infer a causal relationship between smoking and the risk of peptic ulcer complications.¹

Diseases of the Mouth

Epidemiological studies from several countries have shown that cigarette smokers have more periodontal disease than do nonsmokers, and the 2004 Surgeon General's report concluded that smoking causes periodontitis.^{1,186,187} A recent study concluded that more than 50% of the cases of adult periodontitis in the United States are attributable to cigarette smoking.¹⁸⁸ A strong association has been noted between both the duration of smoking and the number of cigarettes smoked per day and the level of periodontal disease.^{1,188,189} Data from two cohort studies suggest that cigar and pipe smokers also have significantly greater periodontal disease and bone loss than nonsmokers.^{190,191} Moderate-to-severe periodontal disease occurred in 8% of nonsmokers, 13% of pipe smokers, and 16% of cigar and cigarette smokers.¹⁹² Risk decreases with sustained cessation.¹ The likely mechanism for smoking-related periodontal disease is reduction in immune response, possibly making the smoker more susceptible to bacterial infection. Smoking also impairs the regeneration and repair of periodontal tissue. The 2004 Surgeon General's report also concluded that the evidence was not adequate to determine causality between smoking and coronal dental caries, and that the evidence was suggestive but not sufficient to infer a causal relationship between smoking and root-surface caries.¹ Chewing tobacco has also been implicated in the development of root-surface caries, and to a lesser extent, coronal caries.¹⁹³

Leukoplakia or gum recession occurs in 44–79% of smokeless tobacco users^{133,194} and can occur even among young people.^{179,195} Gum recession commonly occurs in the area of the mouth adjacent to where the smokeless tobacco is held. Among adult users of smokeless tobacco or snuff, the risk of oral disease has been well documented, and changes in the hard and soft tissues of the mouth, discoloration of teeth, decreased ability to taste and smell, and oral pain have been reported.^{196–198} One study of smokeless tobacco users in a high school population reported that 49% of these teenaged users (averaging 1.7 years of smokeless tobacco use) had soft tissue lesions, periodontal inflammation, or both, or erosion of dental hard tissues.¹⁹⁹

Other Diseases

The 2004 Surgeon General's report reported several other causal relationships between smoking and disease. The report concluded that smoking causes diminished health status that could manifest as increased absenteeism from work and increased use of medical care, adverse surgical outcomes related to wound healing and respiratory complications, low bone density in postmenopausal women (the evidence was suggestive but not sufficient to infer causality in men), and hip fracture.⁵⁶ It was noted that smoking is one of the major causes of fracture in older persons that can be prevented. The report also concluded that smoking causes nuclear cataracts.¹

The 2004 Surgeon General's report concluded that the following relationships between smoking and disease were suggestive but not sufficient to infer causality: erectile dysfunction, exudative (neovascular) age-related macular degeneration, atrophic age-related macular degeneration, and the ophthalmopathy associated with Graves' disease.¹

A recent cohort study reported that smoking is a risk factor for cognitive decline from ages 11 to 64, after adjusting for childhood IQ, level of education, occupational status, and other factors.²⁰⁰ Current smoking is also associated with mental illness. In 2003, among those aged 18 or older who had serious mental illness in the past year, 44% were past month cigarette smokers.²⁰¹

In Utero Effects of Maternal Smoking

The effects of maternal smoking on the fetus have been extensively studied. It is well documented that infants born to women who smoke during pregnancy weigh an average of 200–250 g less than those born to nonsmokers.^{1,16,56} The incidence of low birth weight (less than 2500 g) in infants born to mothers who smoke is twice that of infants born to nonsmokers.^{16,56} The relationship between maternal smoking and low birth weight is dose dependent and independent of other factors known to influence birth weight, including race, parity, maternal size, socioeconomic status, sex of child, and gestational age.⁵⁶ Women who stop smoking before becoming pregnant have infants of the same birth weight as never smokers. In addition, pregnant smokers who quit in the first 3–4 months of pregnancy and remain abstinent through the rest of the pregnancy have normal birth weight infants. Pregnant women who stop smoking before the 30th week of gestation have infants with higher birth weight than do continuing smokers.¹⁶ Smoking causes both reduced fetal growth and early delivery (often from pregnancy complications).⁵⁶ However, smoking affects birth weight primarily by retarding fetal growth. The risk of a small-for-gestation-age infant is 3.5–4 times higher among women who smoke during pregnancy than among nonsmoking women. Fetal growth restriction could be reduced by an estimated 30% if all women abstained from smoking during pregnancy.¹ In 1985, the Centers for Disease Control defined the fetal tobacco syndrome as follows: (a) the mother smoked five cigarettes or more a day throughout the pregnancy; (b) the mother had no evidence of hypertension during pregnancy, specifically no preeclampsia and had documentation of normal blood pressure at least once after the first trimester; (c) the newborn infant had symmetrical growth retardation at term (37 weeks) defined as birth weight less than 2500 g and a ponderal index (weight in grams divided by length) > 2.26; and (d) there was no obvious cause of intrauterine growth retardation, such as congenital malformation or infection.¹² Several mechanisms are thought to cause the reduction in fetal growth, including impaired maternal weight gain, increased cyanide exposure (leading to impaired vitamin B₁₂ metabolism), and increased cadmium exposure. The primary mechanism, however, is thought to be intrauterine hypoxia, which is caused by increased carboxyhemoglobin production from carbon monoxide (CO) exposure, vasoconstriction of the umbilical arteries, reduced blood flow to the uterus, placenta, and fetus, and direct effectors of nicotine and other toxins in tobacco on the placenta and fetus.^{1,16} Although fetal growth is diminished among smokers, placenta-to-birth-weight ratios are larger than those of nonsmokers,²⁰² probably because of the larger placental surface necessary to provide adequate fetal oxygenation in smokers. A few studies have shown an association between smokeless tobacco and low birth weight.^{203,204}

The Surgeon General has concluded that maternal smoking causes preterm delivery (RR = 1.5) and shortened gestation. An estimated 7–10% of preterm deliveries could be prevented by eliminating smoking during pregnancy.¹

Maternal smoking is also associated with higher fetal, neonatal, and infant mortality, independent of sociodemographic factors for such mortality.¹⁶ One large study showed adjusted infant mortality rates of 15.1 per 1000 for white nonsmokers and 23.3 per 1000 for white women who smoked more than one pack per day. Comparable infant mortality rates for black women were 26.0 and 39.9 per 1000, respectively.²⁰⁵ A large retrospective cohort study found that infant mortality was 40% higher if the mother smoked during pregnancy, with a dose-response relationship, and estimated that 5% of infant deaths in the United States were attributable to maternal cigarette smoking. Among American Indians and Alaska Natives, this attributable fraction was 13%. The authors estimated that nearly 1000 infant deaths could be averted if no maternal smoking occurred.²⁰⁶ Smoking during pregnancy causes placenta previa, abruptio placentae, and premature rupture of membranes.^{1,16} Up to 10% of placental abruption could be avoided if smoking during pregnancy were eliminated.²⁰⁷ The 2004 Surgeon General's report concluded that the evidence is suggestive but not sufficient to infer a causal relationship between maternal smoking and ectopic pregnancy and spontaneous abortion. The report also concluded that smoking reduces the risk for

preeclampsia, but that this decreased risk did not outweigh the many adverse outcomes of maternal smoking.¹

The 2001⁵⁶ and 2004¹ Surgeon General's reports determined that maternal smoking during and after pregnancy causes sudden infant death syndrome (SIDS). Studies have consistently shown a two- to fourfold increased risk of SIDS among infants whose mothers smoked during pregnancy compared with infants of nonsmoking mothers, even after controlling for other risk factors. Most hypotheses about possible mechanisms center around the effects of maternal smoking on fetal oxygenation and neural development.^{1,56} One animal study reported that fetal exposure to nicotine led to reduced tolerance of hypoxic episodes and increased mortality.²⁰⁸

Although some studies suggested that smoking during pregnancy might affect physical growth, mental development, and behavior of children, studies are limited by small numbers and the infrequency of events of interest. The 2004 Surgeon General's report concluded that there is inadequate evidence to determine causality between maternal smoking and congenital malformation, physical growth, and neurocognitive development of children. The report also concluded that the evidence is suggestive but not sufficient to infer a causal relationship between maternal smoking and oral clefts.¹

Many studies have shown that smoking results in reduced fertility and fecundity for couples in which one or both partners smoke.¹ Animal studies suggest that polycyclic aromatic hydrocarbons have a destructive effect on oocytes and may affect the release of gonadotropins, corpora lutea formation, gamete interaction, and implantation.¹ Smoking also increases anovulation and shortens cycles, which may also contribute to reduced fertility and fecundity.²⁰⁹ The 2004 Surgeon General's report concluded that smoking causes reduced fertility in women, but that evidence was inadequate to determine whether there was a causal relationship between smoking and sperm quality.¹

Health Effects on Young People

Although many of the adverse health effects from tobacco occur later in life, smoking also has health implications for young people. High school seniors who are regular cigarette smokers are more likely to report shortness of breath when not exercising, cough, productive cough, or wheezing and gasping, even after adjustment for sex, other drug use, and parental education level.²¹⁰ Cigarette smoking during adolescence also appears to reduce the rate of lung growth and the level of lung function achieved. Young smokers are more likely to be less physically fit than nonsmokers. Smoking by children is also associated with an increased risk for early atheromatous lesions and increased cardiovascular risk factors. Smokeless tobacco use by children is associated with halitosis, periodontal degeneration, and soft tissue lesions.¹⁷⁹ Cigarette smoking is also associated with other high risk behaviors among young people, including other drug use, fighting, and high-risk sexual behavior.¹⁷⁹ Most young people who smoke regularly are already addicted to nicotine. For example, at least one symptom of nicotine withdrawal was reported by 92% of daily cigarette smokers and 93% of daily smokeless tobacco users aged 12–22 years who had previously tried to quit.²¹¹ Among adolescents aged 12–17 years, nearly two-thirds reported at least one indicator of dependence.⁵⁶ In another study using different measures of nicotine dependence, 91% of daily cigarette users (smoked daily for 2 consecutive weeks or more in the past year), 48% of daily alcohol users, 60% of daily marijuana users, and 79% of daily cocaine users reported one or more indicators of dependence.²¹² Although it was generally thought that addiction did not occur until after a person started smoking regularly, recent evidence suggests that nicotine addiction may begin to emerge earlier.²¹³

HEALTH RISKS OF SECONDHAND SMOKE

Constituents of Secondhand Smoke

Secondhand smoke (SHS) is a serious health hazard. In 2006, the Surgeon General concluded that SHS causes premature death and disease

in children and adults who do not smoke and that there is no risk-free level of exposure to SHS.^{213a} The Society of Actuaries has estimated that SHS costs American society \$10 billion annually in health care costs and lost productivity.^{213b} In January of 2006, the California Air Resources Board classified ETS as a Toxic Air Contaminant.^{213c}

SHS is a diluted mixture of “mainstream” smoke exhaled by smokers and “sidestream” smoke from the burning end of a cigarette or other tobacco product. It is chemically similar to the smoke inhaled by smokers and contains a complex mix of more than 4000 chemicals, including more than 50 cancer-causing chemicals and other toxic substances such as benzene, cadmium, arsenic, nicotine, carbon monoxide, and nitrogen (Table 54-3).^{114,213b,214,215} Sidestream smoke is the major component of SHS, providing nearly all of the vapor-phase constituents and more than half the particulate matter. Sidestream and mainstream smoke are different in the temperature of combustion of the tobacco, pH, and degree of dilution in air. Five known human carcinogens, nine probable human carcinogens, three animal carcinogens, and several toxic compounds such as ammonia and carbon monoxide are emitted at higher levels in sidestream smoke than in mainstream smoke.^{114,214,215} Because of their greater mass, cigars generate higher levels of indoor air pollutants than cigarettes. Smoke from one cigar burned in a home can take five hours to dissipate.⁴¹ Particulate polycyclic aromatic hydrocarbon (PPAH) levels in restaurants and bars prior to a smoking ban were higher than those at a busy intersection in rush hour or a heavily trafficked city neighborhood.²¹⁶

Considerable work has been done to develop sensitive and specific markers of exposure to SHS. Vapor-phase nicotine and respirable suspended particulate matter have been identified as markers for the presence and concentration of SHS in the environment, and cotinine (a metabolite of nicotine), and to a lesser degree nicotine, are widely used biomarkers of SHS exposure and uptake in people.^{114,213a,214,215} Levels of SHS constituents encountered indoors are large enough to be absorbed and result in measurable doses in exposed nonsmokers. However, individual biomarkers of exposure represent only one component of a complex mixture, and measurements of one marker may not wholly reflect exposure to other components of concern.^{213a} Self-reported exposure to SHS underestimates exposure and therefore the risks of such exposure.²¹⁷ For example, a study of a large nationally representative sample of persons aged 4 years and older indicated that 88% of nontobacco users had detectable levels of serum cotinine, although only 37% of adults and 43% of children were aware they were exposed to SHS.²¹⁸ The Surgeon General concluded that cotinine is the biomarker of choice for assessing SHS exposure.^{213a}

Secondhand Smoke and Children's Health

Homes are the predominant location for childhood exposure to SHS.^{213a} Exposures are decreasing over time. In 1992/1993, 43% of U.S. households had a smokefree home policy; in 2003, 72% of households had such a policy.²¹⁹ Similarly, in 2003, 4 million (16%) adolescents aged 12-17 reported being exposed to SHS in the home, a decrease from 26% in 1999. However, among households with a smoker, 40% of adolescents were exposed to SHS daily.²²⁰ Urinary cotinine concentrations in infants and young children correlate with the number of smokers in the home^{214,215} and the number of cigarettes smoked by the mother during the prior 24 hours.²²¹

More than 100 epidemiological studies have been published on the health effects of SHS exposure among children. In 1986, the National Academy of Sciences National Research Council (NRC)²²² and the Surgeon General²²³ and concluded that SHS is a major contributor to impaired respiratory health among children, especially young children. In 1993, the U.S. Environmental Protection Agency (EPA) concluded that SHS is causally associated with lower respiratory infections (e.g., bronchitis and pneumonia), increased prevalence of fluid in the middle ear, symptoms of upper respiratory tract irritation, a small but significant reduction in lung function, additional episodes and increased severity of asthma, and new cases of asthma among children

who have not previously been symptomatic.²¹⁴ The same conclusions were reached after updated reviews in 1997 and 2004 by the California Environmental Protection Agency (CA EPA).^{215,224} The 2006 Surgeon General's Report also supported these conclusions, determining that SHS causes lower respiratory illnesses in infants and children; middle ear disease (acute and recurrent otitis media and chronic middle ear effusion) in children; cough, phlegm, wheeze, and breathlessness among school-age children; ever having asthma among school-age children; the onset of wheeze illness in early childhood; and lower levels of lung function during childhood. The report concluded that the evidence was suggestive, but not sufficient to infer a causal relationship between SHS exposure and the onset of childhood asthma; and between maternal exposure to SHS during pregnancy and both preterm delivery and a small reduction in birth weight among term infants. Other diseases where the evidence was deemed to be suggestive included prenatal and postnatal exposure to SHS and cancer, leukemia, lymphomas, and brain tumors in children.^{213a} The Surgeon General's report concluded that the evidence was insufficient to infer a causal relationship between SHS and impaired cognitive development^{213a}; this issues continues to be an active area of research.²²⁵

On average, children exposed to SHS have 1.87 more days of restricted activity, 1.06 more days in bed, and 1.45 more days absent from school each year than do nonexposed children. Nationwide, this means 18 million days of restricted activity, 10 million days of bed confinement, and 7 million days of school absence each year attributable to daily SHS exposure.²²⁶ A study of 4th grade students reported that exposure to SHS led to 27% more absenteeism due to respiratory illness, and children living in a household with two or more smokers had a 77% increased risk of such absenteeism. Children with asthma were particularly at risk, but those without asthma also had an increased risk of absenteeism if exposed to two or more smokers.²²⁷

Secondhand Smoke and Sudden Infant Death Syndrome

The California EPA (1997, 2004) and the Surgeon General (2006) have all concluded that there is a causal association between SHS and SIDS, independent of the effect of maternal smoking during pregnancy.^{213a,215,224} This relationship has been found for SHS exposure from maternal smoking, paternal smoking, and smoking by others in the household. A dose-response relationship was noted with increasing numbers of cigarettes, increasing number of smokers, and increasing duration of exposure to SHS.^{215,228,229,230}

Secondhand Smoke and Adults

Among adults, exposure to SHS primarily occurs in the workplace and in the home.^{213a} Among healthy adults, the most common complaints after exposure to SHS are irritant effects in the eye conjunctiva and mucous membranes of the nose, throat, and lower respiratory tract.²²³ The 1997 and 2004 CA EPA reports concluded that SHS causes eye and nasal irritation in adults.^{215,224} In 2006, the Surgeon General concluded that SHS causes odor annoyance and nasal irritation, but that the evidence was suggestive, but insufficient to infer causality for persons with nasal allergies or a history of respiratory illness to be more susceptible to developing nasal irritation from SHS exposure.^{213b}

Secondhand Smoke and Cancer

Lung Cancer

In 1986, the U.S. Public Health Service; the NRC; and the Interagency Task Force on Environmental Cancer, Heart, and Lung Disease, each independently concluded that substantial number of lung cancer deaths among nonsmokers could be attributed to involuntary smoking;^{222,223,231} both the Surgeon General and NRC reports concluded that SHS exposure causes lung cancer in nonsmokers. The EPA reviewed the updated scientific evidence in 1993 and also concluded that exposure to SHS causes lung cancer in nonsmokers. The

^dSubstances identified as Toxic Air Contaminants by the Air Responses Board (ARB), pursuant to the provisions of AB 1807 and AB 2728 (includes all Hazardous Air Pollutants listed in the Federal Clean Air Act Amendments of 1990.)

^eReproductive toxicant.

EPA report classified SHS as a “Group A” (known human) carcinogen, a classification that includes asbestos and benzene,²¹⁴ and estimated that 3000 lung cancer deaths occur among U.S. nonsmokers each year as a result of exposure to SHS. The CA EPA (1997, 2004) also concluded that exposure to SHS causes lung cancer.^{215,244}

In 2002, IARC examined the evidence from 58 studies. Consistent findings of increased risk, a significant dose-response trend with increasing numbers of cigarettes smoked by the spouse, an increased risk in the highest exposure group, and a statistically significant trend for the number of years married to a smoker were noted. IARC also reported that all previously published meta-analyses showed a significant increased risk (relative risks ranging from 1.1-1.6) for exposure to spousal smoking. IARC did its own meta-analysis, which included more recent studies, and found a relative risk of 1.24.¹¹⁴

The 2006 Surgeon General’s report concluded that smoking causes lung cancer among lifetime nonsmokers and that there is a 20-30% increase in the risk of lung cancer from SHS exposure associated with living with a smoker. The risk is lower than that seen with active smoking due to the lower carcinogenic dose received. The report also concluded that the mechanisms by which SHS causes lung cancer are probably similar to those observed in smokers. For example, exposure to SHS causes a significant increase in urinary metabolites of the tobacco-specific lung carcinogen NNK.

The report also specifically looked at workplace exposure and noted that indoor air nicotine and/or respirable suspended particulate concentrations levels were comparable between work and residential environments, and that SHS exposures in homes and workplaces were qualitatively similar in chemical composition and concentration. The report examined 25 studies that provided information on workplace SHS exposure and the risk of lung cancer among lifetime non-smokers. The pooled relative risk from a meta-analysis of the studies was 1.22. Studies showed a trend of increased risk with increased duration of exposure, and a threefold increased risk among persons with the highest level of workplace exposure (based on both years and intensity of exposure). As a result, the Surgeon General concluded that the risk of lung cancer applies to all SHS exposure, regardless of location.^{213a}

Sinus Cancer

Both the 1997 and 2004 California EPA report concluded that SHS causes nasal sinus cancer.^{215,224} IARC noted that there have been four cohort studies and one case-control study that looked at the relationship between exposure to SHS and upper respiratory track cancers. A positive association was found in most of the studies.¹¹⁴ The Surgeon General concluded that the evidence was suggestive, but not sufficient to infer a causal relationship, primarily because of the modest sample sizes of the studies and the need to establish dose-response relationships and to characterize the risk by source and the timing of exposure.^{213a}

Other Cancers

The 2004 California EPA report concluded that SHS causes breast cancer, but there is not scientific consensus on this finding.²¹⁵ IARC noted that there have been five published cohort studies and 10 case-control studies examining this association. Two of the cohort studies were positive (but not statistically significant); three were negative. Seven of the case-control studies showed non-significant increased risk, but no studies showed a dose-response relationship with level of exposure.¹¹⁴ The Surgeon General concluded that the evidence was suggestive, but not sufficient to infer a causal relationship (due to inconsistent findings by age, the lack of an association in large cohort studies, and the lack of causal evidence between active smoking and breast cancer).^{213a}

Secondhand Smoke and Other Diseases

Respiratory Disease

The effect of SHS on chronic respiratory symptoms or disease in adult nonsmokers is difficult to measure. The EPA concluded that SHS exposure may result in increased frequency of respiratory symptoms

in adults and estimated that respiratory symptoms are 30 to 60% higher in nonsmokers exposed to SHS than in non-exposed nonsmokers.²¹⁴ Similarly, exposure to SHS has been estimated to increase the symptoms and severity of existing bronchitis, sinusitis, and emphysema by 44%²³² and respiratory work related disability by 80% (from exposure to SHS at work).²³³ The 2006 Surgeon General’s report concluded that there are multiple mechanisms by which SHS causes injury to the respiratory tract. The report concluded that the evidence was suggestive, but insufficient to infer a causal relationship between SHS exposure and several respiratory diseases: acute respiratory symptoms including cough, wheeze, chest tightness, and difficult breathing among both persons with asthma and healthy persons; chronic respiratory symptoms; adult-onset asthma; worsening of asthma control; and risk for chronic obstructive pulmonary disease.^{213a}

Both the 1986 Surgeon General’s report and the 1986 NRC report reviewed the evidence available on SHS and pulmonary function in adults. The Surgeon General’s report concluded that healthy adults exposed to SHS may have small changes in pulmonary function tests, probably because of the irritants in SHS, but are not likely to have significant reduction in pulmonary function as a result of exposure as an adult.²²³ The NRC concluded that it was difficult to determine how a single factor such as SHS affects lung function, but reported that SHS may add to the burden of environmental insults that can cause chronic lung disease.²²² The 1993 EPA report reviewed additional studies of SHS and adult lung function and respiratory symptoms and concluded that SHS exposure may result in small decreases (2.5%) in lung function among adult nonsmokers.²¹⁴ The 1997 CA EPA report concluded that the small differences in lung function were a basis for concern.²²⁴ The 2004 CA EPA report, which identified additional relevant studies, concluded that newer data supported a small but potentially biologically significant effect of SHS on pulmonary function in adults.²¹⁵ The 2006 Surgeon General’s report concluded that the evidence is suggestive, but not sufficient to infer a causal relationship between short-term SHS exposure and an acute decline in lung function in persons with asthma; and between chronic SHS exposure and an accelerated decline in lung function.^{213a}

Cardiovascular Disease

More than 20 studies have examined the association between heart disease and exposure to SHS in nonsmokers.^{213a,215} Although some negative studies have received significant press attention,²³⁴ most studies have reported an increased risk of heart disease among persons exposed to SHS. Many of the studies controlled for other cardiovascular risk factors and several demonstrated a positive dose-response relationship between exposure and disease. A large study that used data from the ACS CPS-II and controlled for other cardiovascular risk factors found about a 20% higher CHD mortality among never smokers exposed to SHS; however, a consistent dose-response trend was not found.²³⁵ A review article concluded that exposure to SHS accelerated atherosclerotic lesions.²³⁶ A recent cohort study that measured SHS exposure among nonsmokers by cotinine levels rather than self-report and followed participants for 20 years, found that the relative hazards for CHD were 1.45, 1.49, and 1.57 in the 2nd, 3rd, and 4th quartiles of cotinine levels after adjustment for other risk factors.²¹⁷ A 1999 meta-analytic review of 18 studies concluded that there was a 25% higher CHD risk among never smokers exposed to SHS than in non-exposed never smokers.²³⁷ The elevated risk was seen in men, women, those exposed at home, and those exposed at work and a significant dose-response relationship was found.²³⁷

In both 1997 and 2004, the CA EPA concluded that there was a causal association between SHS and heart disease mortality and acute and chronic coronary heart disease morbidity.^{215,224} In 2006, the Surgeon General concluded that SHS causes coronary heart disease morbidity and mortality among both men and women and estimated that there was a 10-30% increased risk.^{213a} Several observational studies have reported that hospital admissions for acute MI declined after a comprehensive local clean indoor air ordinance came into effect.^{238,238a,238b}

Various experimental and clinical studies suggest mechanisms for the cardiovascular effects of SHS. The 1997 and 2004 CA EPA reports

concluded that SHS causes altered vascular properties.^{213c,214} In 2006, the Surgeon General concluded that SHS has a prothrombotic effect, causes endothelial cell dysfunctions, and causes atherosclerosis in animal models. It was also noted that these acute cardiovascular effects occur with short duration of exposure.^{213a} Others have noted that SHS appears to cause decreased oxygen supply and increased oxygen demand—all effects consistent with the mechanisms found for active smoking. Many of the effects are believed to be caused by nicotine and carbon monoxide in SHS, but other toxins may also be important.²³⁶

In 2006, the Surgeon General also concluded that the evidence is suggestive, but not sufficient to infer a causal relationship between exposure to SHS and stroke and between exposure to SHS and atherosclerosis in humans.^{213a}

► TRENDS IN TOBACCO USE

Prevalence of Cigarette Consumption among Adults and Teenagers

Annual per capita consumption of cigarettes reached a peak of 4345 in 1963, a year before the first Surgeon General's report was published, and, except for an increase from 1971 through 1973, steadily declined (Fig. 54-3). Per capita cigarette consumption was 1691 in 2006, the lowest level since 1935.^{239,240} Overall the numbers of cigarettes sold in the United States declined from 640 billion in 1981 to 372 billion in 2006.^{239,240}

From 1964 to the late 1980s, smoking prevalence in the United States decreased an average of 0.5% per year (from 42% in 1965 to 26% in 1990; in the early 1990s, prevalence was flat,^{241,242} but then prevalence decreased from 25% in 1997 to 21% in 2005 (Fig. 54-4).²⁴³ In preliminary estimates for the first 9 months of 2006, smoking prevalence was unchanged at 21%.²⁴⁴ In the 2005 National Health Interview Survey (NHIS), smoking prevalence was higher for men (24%) than for women (18%) (Table 54-4). Smoking prevalence was highest in the 18–44 age group (24%) and lowest among Americans aged 65 years and older (8%).²⁴³ In 2002, for the first time, there were more former smokers than current smokers.²⁴⁵ Smoking prevalence varies threefold by state, ranging from 12% in Utah to 29% in Kentucky in 2005.²⁴⁶

Among both women and men, the trend in smoking prevalence has been downward. In 1965, smoking prevalence was higher for men

(52%) than for women (34%). From 1965 to 1983, the decline in smoking prevalence was greater for men (17 percentage points) than for women (4 percentage points); however, from 1983 to 2005, the decline in smoking prevalence was comparable for women and men (11 percentage points).^{241,243} In 2005, the percentage of ever smokers who had quit was marginally for men (51%) than for women (50%).²⁴⁷ The higher proportion for men has sometimes been interpreted to mean that women are less likely to quit smoking than men. However, because men are more likely than women to switch to or continue to use other tobacco products when they stop smoking cigarettes, the sex difference disappears when assessing the cessation of all tobacco use.⁵⁶ In addition, from 1965 to 2005, the percentage of ever smokers who had quit increased by 31 percentage points for women but by only 23 percentage points for men.^{241,247} The patterns of cessation among ever smokers are consistent with the historical patterns of smoking among women and men: men began quitting in greater numbers in the 1950s, but women began to quit in the 1960s. Thus, the comparable trend in conjunction with the higher absolute value for men, reflects the fact that early quitters were predominantly male.^{56,248} Other data show that women are as likely as men to quit for a day and to remain abstinent.^{249,250}

In 1978, the first year data were available from the NHIS for whites, blacks, and Hispanics, smoking prevalence was lower among Hispanics (32%) than among whites (34%) or blacks (37%).²⁴¹ In 2005, smoking prevalence was 13% among Asians, 16% among Hispanics, 22% and 32% among blacks, and whites, and 32% among American Indians and Alaska Natives.²⁴³ Smoking prevalence has declined faster for African Americans than for whites so that prevalence among African American men (formerly higher than for white men) is now comparable to that among white men, and the prevalence in African American women (formerly comparable to white women) is now lower than in white women.²⁵¹ In 2005, the percentage of ever smokers who have quit was 53% for whites, 45% for Hispanics, 44% for Asians, 39% for blacks, and 38% for American Indians. Unlike the sex differences, which are explained by historical patterns in smoking behavior, the lower proportion among blacks reflects differences in quitting behavior: blacks are more likely than whites to try to quit smoking and are less likely to succeed, even after adjustment for demographic differences.^{249,252,253} This difference remains even after adjustment for other tobacco use.¹⁶

Formal educational attainment exhibits a striking association with smoking prevalence and cessation rates. However, this relationship is

Figure 54-3. Adult per capita cigarette consumption and major smoking and health events—United States, 1900–2006. (Source: USDA Tobacco & Situation Outlook report, 2004; 1986–2000 Surgeon General's Reports.)

not linear. The “less than high school graduate” category consists of two groups with distinct smoking patterns: people with 0–8 years and those with 9–11 years of education. Smoking prevalence and cessation rates in the former group are similar to those found among people with 12 years of education, whereas a person in the latter group is

most likely to be a current, ever, or heavy smoker, and the least likely to have quit smoking. After 11 years of education, the likelihood of smoking decreases with each successive year of education. These results persist after adjustment for age, sex, ethnicity, poverty status, employment status, marital status, geographic region, and year of

survey.²⁵² In 2005, smoking prevalence was highest among people with 9–11 years of education (31%) and lowest for persons with 16 or more years of education (10%) (Table 54-4).²⁴⁷ Similarly, the percentage of ever-smokers who have quit was lowest among the group with 9–11 years of education (44%) and highest among persons with 16 or more years of education (70%).²⁴⁷

Although the percentage of employees who smoke has decreased, certain subpopulations, including blue-collar and service workers, continue to smoke at higher levels. For the years 1987–1990, roofers (58%) and crane and tower operators (58%) had the highest prevalence of cigarette smoking, and physicians (5%) and clergy (6%) had the lowest prevalence of cigarette smoking.²⁵⁴ The unemployed; the widowed, separated, or divorced; and those below the poverty level are more likely to have ever smoked or to be current smokers and to be heavy smokers (15 or more cigarettes per day).^{243,254,255}

In 2006, 25% of 8th graders, 36% of 10th graders, and 50% of 12th graders had tried cigarette smoking.²⁵⁶ The prevalence of current smoking (defined as smoking within the past 30 days) among high school seniors decreased from 39% in 1976 to 29% in 1981, and was then relatively stable until 1992, but increased to 36% by 1997 and then decreased to 22% in 2006 (Fig. 54-5). Similarly, prevalence among 10th graders increased from 21% in 1991 to 30% in 1996, then decreased to 14% in 2006. The prevalence of smoking among 8th graders increased from 14% in 1991 to 21% in 1996, then decreased to 9% in 2006. Similar patterns were seen for daily smoking. Among high school seniors, smoking prevalence was higher for girls than for boys until the late 1980s; since 1990, current and daily smoking prevalence has been comparable for girls and boys.²⁵⁶ A larger decline in current smoking prevalence occurred among black high school seniors from 1977 (37%) to 1992 (9%) than among white high school students (38% to 32%).²⁴¹ Smoking prevalence among black high school students increased from 9% in 1992 to 15% in 1998, but then decreased to 9% in 2004.²⁵⁶ The increase in smoking prevalence from 1992 to 1998 was greater for African American boys than girls, but the subsequent decline was also greater among boys than girls.^{257,258}

The Changing Cigarette

Low-Tar Cigarettes

Tar is a complex mixture of compounds, including 69 identifiable carcinogens and cocarcinogens.¹¹⁴ Nicotine is the principal constituent responsible for a smoker's pharmacological response (addiction).^{3,12} In the early 1950s, when smoking was first associated with lung cancer, a majority of Americans smoked unfiltered (plain) high-tar cigarettes, with a sales-weighted average tar and nicotine content per cigarette of 38 mg and 2.7 mg, respectively, in 1954. By 1998, the sales-weighted average content per cigarette had dropped to 12 mg tar and 0.89 mg nicotine.¹ However, these averages are based on yields from cigarettes as measured by the U.S. Federal Trade Commission (FTC) smoking machine under

standardized laboratory conditions and do not reflect the actual smoking patterns of persons who smoke filtered cigarettes.^{101,119} Filtered cigarette use increased from 0.56% in 1955 to 99% in 2003.²⁵⁹ The machine-measured tar and nicotine reductions have come through the use of efficient filters, highly porous cigarette paper, and changing the composition of the tobacco blend. Filters are generally composed of cellulose acetate, although some also have charcoal. Filters reduce the amount of tar inhaled and selectively reduce some of the volatile components of cigarette smoke. Since 1968, filters increasingly have contained perforations (which may or may not be visible) that allow air to dilute the smoke, thus reducing the machine-measured tar and nicotine yield.^{119,260} Other methods used to reduce the tar and nicotine content yields on the standard smoke assays include the use of porous cigarette paper, which lowers tar, CO, and nitrogen oxides inhaled. Use of reconstituted tobacco (made from tobacco dust, fines, particles from ribs and stems, and additives such as adhesives and cellulose fiber) decreases the tobacco content. Similarly, the use of puffed, expanded, and freeze-dried tobacco decreases the amount of tobacco needed to fill a cigarette. Increasing the length of the cigarette allows more air to enter the paper and for more of the volatile components to diffuse out of the cigarette. Increasing the filter length decreases the amount of tobacco in the cigarette, lengthening filter overwraps reduces the amount of the cigarette smoked under the FTC protocol, decreasing the cigarette circumference reduces the amount of tobacco available for burning, using a more coarsely cut tobacco means the tobacco burns less efficiently, and blending the tobacco with lower nicotine-yield strains or different leaf positions can reduce the amount of nicotine available.^{101,261}

However, low tar cigarettes have an elasticity of delivery that allows smokers to get much higher yields of tar and nicotine by altering their pattern of puffing (larger puffs, inhaling more deeply, taking more rapid or more frequent puffs), by blocking the ventilation holes in the filters with their lips or fingers, or by increasing the number of cigarettes smoked per day. These alterations allow smokers to receive much higher deliveries of tar and nicotine from the cigarette, so that most smokers who switch do not substantially alter their exposure to tar and nicotine and therefore do not significantly lower their risk of disease.¹¹⁹ Studies show that low tar cigarettes can deliver the same tar and nicotine as regular cigarettes. Although there appear to be some differences in human nicotine exposure between high- and low-yield cigarettes, these differences are small and do not correspond to the difference in the yields as measured by the FTC smoking machine. Similarly, studies have generally found no relationship between CO levels in the human body and FTC machine yields. In addition, studies suggest that the published tar-to-nicotine ratio based on the FTC machine test does not correspond to actual ratios of tar and nicotine absorbed by smokers. Thus, published tar-to-nicotine ratios cannot be used to estimate the tar exposure of smokers. Studies using biomarkers of exposure to, and doses of, tobacco smoke

Figure 54-5. Trends in cigarette smoking anytime in the past 30 days* by grade in school—United States, 1975–2006. *Smoking 1 or more cigarettes during the previous 30 days. (Source: Institute for Social Research, University of Michigan, Monitoring the Future Project.)

components have shown little relationship between biomarkers and tar/nicotine yields as measured by the FTC method.^{99,119}

In general, the FTC method underestimates human exposure to the chemicals in cigarette smoke.¹⁰¹ This machine takes 2-second, 35-mL puffs every 60 seconds until the cigarette is smoked to 3 mm of the filter overwrap, whereas humans, on average, take puffs of greater than 35 mL over 1.8 seconds, every 34 seconds. The FTC method underestimates by a greater degree the amount of smoke drawn from low-yield cigarettes than from high-yield cigarettes.¹⁰¹ In addition, since the FTC machine smokes to within 3 mm of the overwrap, lengthening the overwrap can decrease the apparent yield, even though the remaining tobacco can be smoked.¹¹⁹

Changes in smoking patterns are related to smoker's self-regulation of their blood nicotine levels and higher yields of nicotine can be obtained by alternating the frequency and depth of inhalation, increasing the number of cigarettes smoked, or mechanically compressing filter tips and blocking air channels with the lips or fingers.^{12,101,119,260} One study of participants who spontaneously switched to cigarette brands with a lower reported yield compared the smoker's cotinine levels before and after the switch. Although the FTC-measured nicotine yield was reduced from 1.09 mg to 0.68 mg, the serum cotinine levels were unchanged.²⁶² Another study found that even those smoking ultra-low-yield cigarettes could be exposed to high levels of nicotine and CO.¹⁰¹ Therefore, smokers should be informed that they may not be deriving any health benefit from low-tar products and strongly advised to quit smoking completely.

Since their introduction to the U.S. cigarette market in the late 1960s and early 1970s, the so-called low-tar and low-nicotine cigarettes have had rapid increases in market share. The market share of cigarettes yielding 15 mg of tar or less increased from 2% in 1967 to 87% in 1999, and has remained stable at 84% through 2005.²⁵⁹ In addition, since their introduction in the late 1970s, the cigarette brands with 12 mg or less of tar captured 58% of the U.S. market in 2001 and has remained at that level those with less than 7 mg tar, 12%, and less than 4 mg tar, 1%.²⁵⁹ The significant growth of the low-tar cigarette market in the past two decades is attributable to increased public awareness that cigarette smoking, particularly exposure to tar and nicotine, is detrimental to health and to the perception that low-tar cigarettes are safer.¹¹⁹ The progression from unfiltered high-tar, to filtered high-tar, to filtered middle-tar, and to filtered low-tar cigarettes has also been observed in most industrialized countries, although at a slower pace and 5–10 years after the introduction of these changes in the United States.¹⁰¹

Early studies conducted to ascertain the health consequences associated with reduction of cigarette tar and nicotine yields looked promising, with smokers of low-tar or filtered cigarettes appearing to have lower lung cancer risk. Even some later studies have also reported lower risk for lung cancer. However, these studies generally adjusted for the number of cigarettes smoked per day. If increasing the number of cigarettes smoked is a common compensatory mechanism, such adjustment would not be appropriate. In addition, later prospective studies revealed an increase in the risks associated with smoking over the period when tar and nicotine yields were decreasing. For example, lung cancer risk was higher for participants in ACS's CPS II compared with CPS I, even after adjusting for number of cigarettes smoked per day and duration of smoking.¹²⁰ Three publications recently reviewed the evidence on cigarette yield and lung cancer risk. The Institute of Medicine (IOM) found the evidence mixed, but concluded that unfiltered cigarettes probably conferred a greater risk than filtered cigarettes.²⁶³ National Cancer Institute (NCI) Monograph #13 also reported the evidence on yield and lung cancer risk to be mixed, but noted that lung cancer rates have increased over time and found no convincing evidence that changes in cigarette design have resulted in an important decrease in the disease burden either for smokers as a group or for the whole population. The NCI monograph also noted that adenocarcinoma has replaced squamous cell as the leading cause of lung cancer death in the United States.¹¹⁹ Analyses suggest that the increase in incidence parallels changes in smoking behavior and cigarette design. It has been hypothesized that the smoke from high-tar, unfiltered

cigarettes was too irritating to be inhaled deeply and was deposited in the central bronchi where squamous cell carcinomas occur. Smoke from milder filtered, low-tar cigarettes could be inhaled more deeply, allowing for the development of the more peripheral adenocarcinomas.^{99,103,104} In addition, low-tar cigarettes have higher levels of tobacco-specific nitrosamines, which have been linked to the development of adenocarcinomas.^{99,102} The 2002 IARC report concluded that any reduction in lung cancer risk associated with the changing cigarette has been small.¹¹⁴ In addition, the Tobacco Advisory Group of the Royal College of Physicians concluded "there are therefore reasonable grounds for concern that low tar cigarettes offer smokers an apparently healthier option while providing little if any true benefit."²⁶⁴

With respect to heart disease, studies are mixed. Many of these studies also adjusted for number of cigarettes smoked per day. In addition, CO is thought to be a major etiologic agent in CHD, and CO levels do not necessarily correlate with tar or nicotine levels. Differences in cigarette design can influence tar and CO yields in different directions, so studies looking at CHD by tar/nicotine levels may not measure important factors.^{1,119} The 2004 Surgeon General's Report concluded that products with lower yields of tar and nicotine have not been found to reduce coronary heart disease risk substantially,¹ and the NCI monograph concluded that there is no clear consensus on CHD risks from the use of filtered or low-yield cigarettes.¹¹⁹

Little evidence is available on the relative risks of developing COPD from the smoking of low-tar, low-nicotine cigarettes, but the existing studies generally have not found reduced risk for FEV₁ decline or COPD-related mortality from smoking lower yield cigarettes.^{115,175} The 2004 Surgeon General's Report concluded that the evidence is suggestive but not sufficient to infer a causal relationship between lower tar cigarettes and lower risk for cough and mucus hypersecretion, that the evidence is inadequate to infer the presence or absence of a causal relationship between lower yield cigarettes and reduction in FEV₁ decline rates, and that the evidence is inadequate to infer the presence or absence of a causal relationship between lower tar cigarettes and reductions in COPD mortality. The report concluded that given the strong benefits from smoking cessation on COPD, little public health benefit would be gained by further research on the relationship between cigarette type and COPD.¹ The NCI monograph concluded that there was little evidence of a substantial difference in COPD mortality among users of low-tar cigarettes and that there is equivocal evidence for a reduced rate of respiratory symptoms.¹¹⁹

Evidence suggests that the persons most likely to use low-tar cigarettes are those most concerned about smoking and most interested in quitting. Some low tar cigarettes were marketed to smokers who were thinking about quitting with such tags as "All the fuss about smoking got me thinking I'd either quit or smoke True. I smoke True."¹¹⁹ The data suggest, however, that switchers are not more likely than nonsmokers to become nonsmokers. It has been suggested that the existence of low-tar cigarettes has kept many smokers interested in protecting their health from quitting, and the net effect might have been an increased number of smoking-attributable deaths.¹⁰¹

Potential Reduced Exposure Products (PREPs)

Tobacco companies have introduced novel, nontherapeutic nicotine-delivery devices. For example, the Favor Smokeless Cigarette, a nicotine inhaler, was introduced in 1985. The U.S. Food and Drug Administration (FDA) determined that this device delivered a drug, and the inhaler was withdrawn from the market. In 1987, the Pinkerton Tobacco Company introduced Masterpiece Tobacs, a chewing gum containing shreds of tobacco. The FDA determined that chewing gum is a food product and tobacco had not been approved as a food additive and the product was withdrawn from the market. In 1987, the R.J. Reynolds Tobacco Company introduced Premier, a device that heated tobacco rather than burning it. Adverse publicity and consumer complaints about the taste and difficulty lighting the product caused the company to withdraw it before the FDA could determine whether it was a drug delivery device.²⁶¹ In 1996, the company then marketed Eclipse, which was promoted as a low-smoke cigarette and which, like Premier, heated tobacco.

More recently, other tobacco products and devices have been developed and marketed with implied claims for reduced disease risk. For example, Omni cigarettes advertise that they have “Reduced carcinogens. Premium taste.” Advance is marketed as having “a significant reduction in many of the toxins delivered to the smoker.” And Eclipse claims they “may present smokers with less risk of certain smoking-related diseases compared to other cigarettes.”²⁶⁵ The public health community is divided on whether use of PREPs is a viable strategy to reduce tobacco morbidity and mortality. PREPs have the potential to be widely adopted by smokers, much as low-tar cigarettes and filtered cigarettes now dominate the market. A recent JP Morgan survey found that 91% of smokers would be willing to switch brands if a lower risk cigarette became available.²⁶⁶ Recently, the major U.S. tobacco companies have either bought smokeless tobacco companies or developed their own product. These smokeless products are being promoted for “when you can’t smoke,” as a cessation aid, and as a harm reduction strategy.^{266a} However, there are no studies showing smokeless tobacco use increases cessation, and a recent study showed that “switchers” had a higher mortality rate than smokers who quit cigarettes and did not switch to smokeless tobacco.^{266b}

In order to conclude that PREPs reduce population risk, several assumptions would need to be met: (a) measurements suggesting reduced exposure to carcinogens and toxins would need to translate into actual reduced exposure (which did not occur with low-tar cigarettes); (b) reduced exposure would need to translate into reduced individual risk; (c) reduced individual risk would need to translate into reduced population risk (e.g., no corresponding increase in initiation or reduction in cessation that negates any reduction in individual risk); and (d) no increase in other diseases or risks (e.g., the increase in adenocarcinoma with low-tar cigarettes). Although promoting the use of purportedly lower risk products seems to make sense at some level, the reality is that none of these assumptions is necessarily true (as was clearly demonstrated by the low-tar experience) and they all need to be tested on a case-by-case basis. Also, the population effects will be determined not only by the characteristics of the products, but also by the way they are marketed and by how consumers respond to that marketing.

Several past “harm reduction” strategies have not reduced harm. For example, reducing the amount smoked by 50% may not reduce mortality from tobacco-related disease (probably because of compensation).^{267,267a} Even efforts to eliminate compensation by using nicotine replacement therapies (NRT) so smokers reduce the amount smoked have not reduced their levels of carcinogenic biomarkers as expected.^{268,269} Similarly, people who switch tobacco products use them differently than those who have always used the other products (e.g., inhalation patterns and number of cigars smoked by former cigarette smokers).¹ Finally, the experience with low-tar cigarettes suggests that they may have provided little if any reduction in individual risk and actually increased population harm.¹¹⁹

Cigarettes contain almost 5000 chemical compounds and 60 known carcinogens.¹¹⁴ It is unclear if reducing the levels of a few of these substances will reduce risk. It is also possible that methods used to reduce the level of one toxin or carcinogen could increase the level of others. For example, Eclipse has reduced levels of a few carcinogens, but increased carbon monoxide levels, which increases the risk of CHD.²⁷⁰ Also, there is often not a linear relationship between exposure and disease. For example, the risk of lung cancer is much more strongly related to duration of smoking than to amount smoked per day.²⁷¹ Also, risk of CHD increases rapidly at very low levels of exposure and then plateaus.²⁷² Any attempt to assess the probable impact of a PREP needs to look at multiple effects and outcomes, since tobacco use affects nearly every organ of the body. Even with modern cigarettes, which have been available for nearly 100 years, new causal risks are still being found.¹ Finally, people may use PREPs concurrently with cigarettes, which could expose them to multiple risk factors that may interact in complex and unpredictable ways.

Several unintended consequences could actually increase population risk. First, there might be an increase in initiation resulting from the perception that PREPs are safer. Also, some users may later switch

to cigarettes, potentially resulting in increased disease risk. For example, youth consider low-tar cigarettes to be safer, to have lower tar and nicotine levels than regular cigarettes, believe that these cigarettes take longer to cause addiction, and think that they are easier to quit than regular cigarettes.²⁷³ Second, smokers are ambivalent about quitting. The belief that they have taken a positive step to reduce their risk by switching to a PREP allows smokers to rationalize postponing quitting, as was seen with low-tar cigarettes. Thus smokers may not reduce their risk as much as they would have if PREPs had not been on the market. Third, former smokers might relapse. Finally, as was noted earlier, PREPs may introduce unforeseen new disease risks, either from increased exposure to existing toxins, exposure to new toxins, or through the simultaneous use of several products.

“Harm reduction” is being pushed as a remedy for smokers who cannot or will not quit. However, this implies that all efforts have been made to help smokers quit and that these efforts have failed. However, effective, low-cost cessation treatments are not yet widely available. This premise also ignores the fact that 70% of smokers want to quit,²⁷⁴ that 42% make a quit attempt of one day or longer each year,²⁴³ and that only about 20% use any proven therapies in their quit attempts.²⁷⁵ There is no safe form of tobacco use and there are “clean” forms of nicotine available through NRT. Even long-term use of nicotine would be preferable to the use of a different tobacco product as an alternative to quitting.

The Institute of Medicine concluded that an unsuccessful “harm reduction” strategy could lead to long-lasting and broadly distributed adverse consequences, suggesting that these interventions may need to be held to a higher standard of proof and that government should be particularly careful. The fact that it could take decades to be certain about the effects of tobacco PREPs was noted as a reason for particular caution.²⁶³ The IOM also recommended that any such strategy should occur only under comprehensive regulation of tobacco products and be implemented within a comprehensive tobacco control program that emphasizes abstinence, prevention, and treatment.²⁶³

Cigars and Pipes

In the United States, total consumption of cigars decreased yearly from 8108 million in 1970 to 2138 million in 1993, then increased to 5024 million in 2006.²⁴⁰ This increase corresponded with an aggressive marketing campaign, beginning in 1992, that glamorized cigar use.^{41,114}

A 2004 national survey found that 5% of middle school students and 13% of high school students had smoked a cigar in the past 30 day. Prevalence was 2.5 times as high for high school boys as girls.²⁷⁶ Cigar use increases steadily with grade in school, from 12% among 9th graders to 18% among 12th graders.²⁷⁷

Cigar smoking among men decreased from 16% in 1970 to 3% in 1992, then increased to 4% in 2005.^{241,278} Over the same time period, cigar smoking among women decreased from 0.2% in 1970 to 0.02% in 1992, then increased to 0.3% in 2005. A substantial number of former and never cigarette smokers are cigar smokers. In contrast to cigarettes, the increase in adult cigar use appears to have occurred among those with higher educational and income levels.⁴¹

Cigar smoke contains the same toxic and carcinogenic constituents as cigarette smoke,⁴¹ but the tar from cigars contains higher concentrations of carcinogenic polycyclic aromatic hydrocarbons (PAH) and tobacco-specific nitrosamine levels are higher in cigar smoke. Carbon monoxide and ammonia are also produced in greater quantities by cigars than cigarettes.²⁷⁹ The 1998 NCI Monograph on cigars concluded that they cause oral, esophageal, laryngeal, and lung cancer.⁴¹ Some studies suggest that cigar smoking also increases the risk of pancreatic, bladder, and colon cancer.^{114,123} The NCI report also concluded that regular cigar smokers have risks of oral and esophageal cancers similar to cigarette smokers, but lower risks of lung and laryngeal cancer, COPD, and CHD.⁴¹ However, regular cigar smokers who inhale, particularly those who smoke several cigars a day are at increased risk for COPD and CHD.^{279,280} The magnitude of risk is proportional to the type and intensity of exposure, so reduced inhalation yields lower risk. However, even those who do not

inhale are at a higher risk of disease than never-users of tobacco. Mixed smokers (those who use both cigars and cigarettes) and cigarette smokers who switch to cigars are much more likely to inhale and to use cigars regularly, and therefore remain at much higher risk for all major smoking-related diseases.^{41,43,45}

Cigars can deliver nicotine concentrations comparable to or higher than those from cigarettes and smokeless tobacco. Cigar smoke also contains a substantial proportion of its nicotine as free-base nicotine, which is easily absorbed through the oral mucosa. Thus cigar smokers do not need to inhale to ingest substantial quantities of nicotine, although oral absorption produces lower quantities and lower peak blood levels than does inhalation. Because cigars are addictive, their use by young people may potentially lead to switching to other products such as cigarettes.^{41,279}

From 1965 to 2005, the prevalence of pipe smoking among men decreased from 14% to 0.9%.^{241,247} Pipe smoking has never been common among women (0.2% or less). In 1991, men aged 35–64 years of age (3%) were the primary pipe smokers, with those 18–24 years of age being the least likely to smoke pipes (0.2%). By 2005, use varied from 0.3–0.4% among men aged 25–44 to 1.8% among men aged 45–64.²⁷⁸ Men who smoke pipes are often previous users of another form of tobacco, particularly cigarettes.¹²⁴

Pipe smoking causes lip cancer¹ and is also associated with other diseases, including oropharyngeal, laryngeal, esophageal, and lung cancer and COPD.^{43–45,61,114,126,281} Some studies have suggested an increased risk of colorectal, pancreatic, and bladder cancer with pipe smoking.^{114,281} The 1983 Surgeon General's report concluded that smokers who have used only pipes are not at greater risk for CHD than nonsmokers, but some recent studies suggest an association between pipe smoking and CHD, particularly if the smoke inhalation pattern mimics that for cigarettes.^{43,44,281} It has been estimated that pipe smoking kills 1100 Americans each year.¹²⁴

Smokeless Tobacco

Smokeless, “spit,” or oral tobacco (chewing tobacco or snuff) contains tobacco leaves plus sweeteners, flavorings, and scents. Chewing tobacco may be in the form of strands, cakes, or shreds and is either chewed or placed in the mouth. Snuff, which is marketed in a small round can, or tin, is supplied dry or moist and is held (“dipped”) between the gingiva and the lip or cheek. Whereas the smoking of tobacco has declined, the overall prevalence of smokeless tobacco use among U.S. adults has changed little during the last 20 years. The NHIS found that the prevalence of smokeless tobacco use was 5% for men and 2% for women in 1970 and 4.5% for men and less than 1% for women in 2005.^{241,282} Prevalence tends to be higher in the South and in rural regions, and higher among whites than African Americans.⁵⁶ Although the overall prevalence of smokeless tobacco use has remained low for the past two decades, the demographics of smokeless tobacco use have changed dramatically. This behavior was formerly found predominantly among older people, particularly older black men and women and older white men. Since the late 1980s, however, smokeless tobacco use, particularly snuff use, has been seen primarily among young white males.²⁴¹ In 2004, the prevalence of smokeless tobacco use among middle school boys was 4% and among high school boys was 10%. Among high school boys, use was highest among whites (14%), and lower for blacks (3%), Hispanics (8%) and Asians (2%).^{276,277}

Long-term smokeless tobacco use causes periodontal disease and oral leukoplakia, with manifestation occurring even among young people.^{135,179,195} Among users of smokeless tobacco or snuff, changes in the hard and soft tissues of the mouth, discoloration of teeth, and decreased ability to taste and smell have been reported.¹⁹⁷ There is also strong evidence that smokeless tobacco use causes cancer in humans.¹³³ The association for specific cancers is strongest for cancers of the oral cavity,^{1,133} but increased risks for cancers of the pharynx and stomach have also been reported.¹³⁹ Smokeless tobacco use causes acute cardiovascular effects, such as increased heart rate and blood pressure levels⁴⁸ and both a large population-based study

and a cross-sectional study in Sweden found that smokeless tobacco users were more likely to have hypertension.^{49,283} Some, but not all, studies of the effect of smokeless tobacco on lipids have shown a higher risk of hypercholesterolemia, lower high-density lipoprotein levels, and higher triglyceride levels.⁴⁸ One study showed an elevated risk of diabetes in smokeless tobacco users.⁴⁸ A large Swedish cohort study found that smokeless tobacco users were more likely to die of cardiovascular disease than nonusers,^{49,50} but two case-control studies have not found an increased risk.⁴⁸ An analysis of both CPS I and CPS II showed increased risk of death from CHD and stroke among smokeless tobacco users.⁵¹ Starting in 1986, smokeless tobacco products and advertisements were required by federal law to carry warning labels about the health hazards of their use. Smokeless tobacco is addictive; its use may predispose those who try it to become cigarette smokers.²⁸⁴

Other Tobacco Products

Other tobacco products, such as bidis or kreteks (clove cigarettes) are used by 2% of middle school students and 4% of high school students.²⁷⁶ When compared to filter cigarettes, bidis deliver higher amounts of nicotine (1.2 times), tar (2.2 times), and CO (2 times).²⁸⁵ Bidi smoke contains other toxic compounds, including tobacco-specific nitrosamines, phenol, hydrogen cyanide, and benzo[*a*]pyrene.^{286,287} Studies have suggested an increase in all-cause mortality among bidi smokers.²⁸⁸ Bidi smokers may have twice the risk of lung cancer as smokers of Western-style cigarettes, and three times the risk of CHD as nonsmokers.²⁸⁹ Some studies also suggest increased risk for oropharyngeal, stomach, esophageal, and laryngeal cancer and adverse reproductive effects.^{114,290–293}

► TOBACCO INTERVENTIONS

Clinical Treatment for Tobacco Use/Nicotine Dependence

The reduced national prevalence of smoking means that many millions of smokers (more than half of ever smokers) have quit smoking.²⁴⁵ In addition, 70% of current smokers want to stop smoking completely,²⁷⁴ and 42% of current daily smokers have stopped smoking for at least 1 day in the previous 12 months because they were trying to quit completely.²⁴³ Reasons to quit reported by ex-smokers as contributing to their cessation attempts and continued abstinence include: health problems; strong family pressures, both from spouses and children; peer pressure from friends and coworkers; cost of cigarettes, especially for lower-income individuals; fear of potential adverse effects on personal health or on the health of their children; the likelihood of their children starting to smoke; and concern for cleanliness and social acceptance.^{12,294}

In 2000, the Public Health Service (PHS) published updated clinical guidelines on tobacco dependence treatment that were based on a systematic review of the scientific literature from 1976 to 1998. Meta-analyses of randomized controlled trials that contained at least five months of follow-up served as the basis for the recommendations. The primary findings were that brief advice to quit is effective (30% increase in cessation rates), more intensive counseling is more effective (doubles the quit rate), counseling can be delivered via individual counseling, group programs or telephone counseling, and that FDA-approved medications double quit rates. Patients should also be encouraged to obtain social support for their quit attempt, since this increases cessation rates by 50%.²⁹⁵ Similarly, the U.S. Preventive Services Task Force (USPSTF) strongly recommends that clinicians screen all adults for tobacco use and provide tobacco cessation interventions (brief counseling and pharmacotherapy) to those who use tobacco products. The USPSTF strongly recommends that clinicians screen all pregnant women for tobacco use and provide augmented pregnancy-tailored counseling to those who smoke.²⁹⁶

For primary care providers, the recommendations emphasize the importance of (a) systematically *asking* about tobacco use (so that every patient at every clinic visit has his or her tobacco use documented), (b) strongly *advising* (in a personalized manner) all tobacco users to quit, (c) *assessing* the patient's willingness to quit, (d) *assisting* the patient in quitting and (e) *arranging* follow-up (the 5 A's). The primary care intervention is designed to be brief. Patients not yet willing to quit smoking should receive a motivational intervention to promote later quit attempts. For patients willing to make a quit attempt, the provider should help the patient set a quit date, provide key advice on dealing with problem situations, encourage the use of FDA-approved medications (nicotine patch, gum, lozenge, tablet, inhaler, nasal spray, and the nonnicotine medications bupropion and varenicline) unless contra-indicated, and refer the tobacco user to a telephone quitline or community program. All patients who attempt to quit should have scheduled follow-up in person or by telephone. These recommendations assume that office systems will be developed to assure the assessment of tobacco use and appropriate treatment.²⁹⁵

Evidence of the effectiveness for cessation interventions among youth is lacking.^{297,298} The PHS guideline gave, a "C" or expert opinion, recommendation that in clinical settings, providers should screen pediatric and adolescent patients and their parents for tobacco use and give a strong message about the importance of abstaining from tobacco use. The guideline also stated that counseling should be considered, but the content modified to be developmentally appropriate, and medications could be considered when there is evidence of nicotine dependence and a desire to quit.²⁹⁵ Similarly, the USPSTF also concluded that there was insufficient evidence to recommend for or against routine screening or interventions to prevent or treat tobacco use and dependence among children and adolescents.²⁹⁶ The Surgeon General concluded that youth smoking cessation programs have low success rates, and it is difficult to attract and keep adolescents in such programs.¹⁷⁹ One study determined, however, that in clinical settings where physicians use existing visits to provide cessation counseling, even a very low success rate could still be highly cost effective because of the low cost of such opportunistic interventions and the large potential impact. This conclusion would not extend to youth cessation programs in other settings.²⁹⁹ The PHS guideline gave a "B" recommendation to offering advice and interventions to parents to limit children's exposure to SHS.²⁹⁵

Administrators, insurers, and purchasers of health care delivery can also promote the treatment for tobacco use/nicotine dependence. Administrators can help ensure that institutional changes to promote cessation interventions are systematically and universally implemented. Insurers should make effective treatments a covered benefit, and purchasers should make tobacco use assessment, counseling, and treatment a contractual obligation. The PHS guidelines recommend that (a) a tobacco use identification system be implemented in every clinic; (b) education, resources, and feedback to promote intervention be provided to clinicians; (c) staff be dedicated to provide effective cessation treatment, and the delivery of this treatment assessed by performance evaluations; (d) hospital policies support the provision of cessation services; (e) effective smoking cessation treatment (both pharmacotherapy and counseling) be included as paid services in health insurance packages; and (f) clinicians be reimbursed for providing effective cessation treatments, and these interventions be among the defined duties of salaried clinicians.²⁹⁵ The PHS guidelines are consistent with other published recommendations.^{300,301}

Tobacco treatment is extremely cost-effective, more so than other commonly covered preventive interventions, such as mammography, treatment for mild-to-moderate hypertension, and treatment for hypercholesterolemia.³⁰²⁻³⁰⁴ An analysis of recommended clinical preventive services that ranked the services based upon disease impact, treatment effectiveness, and cost-effectiveness concluded that treatment of tobacco use among adults ranked first, along with childhood immunizations and aspirin therapy, to prevent cardiovascular events in high risk adults. It also had the lowest delivery rate among the top ranked interventions.^{304a} Some data suggest there are cost savings from

the treatment of tobacco use, even in the first year, as a result of the rapid decline in risk of acute myocardial infarction and stroke.³⁰⁵ Another study found that the cost of a moderately priced cessation program (brief clinical interventions, free telephone counseling and free NRT) paid for itself within 4 years due to lower hospital costs among successful quitters compared with continuing smokers.³⁰⁶ The managed care plan found that tobacco treatment interventions not only improved quality of care, but also decreased use of medical services: after one year of cessation, ex-smokers' medical costs dropped progressively and reached levels comparable to those of never-smokers.³⁰⁶ This plan also found that systematic implementation of tobacco treatment interventions accelerated the reduction in smoking prevalence among plan members compared with the general population.³⁰⁷ In addition, provision of preventive services in a health plan is associated with increased patient satisfaction with the plan.³⁰⁸

Telephone quitlines increase cessation rates compared to self-help materials.^{295,309,310} Quitlines have been used within health care systems to provide support for physician advice and brief counseling. When offered a choice of free group programs or free quitline support, more smokers chose quitline support. Group Health Cooperative found that a routine screening system with primary care providers giving cessation advice, medication, and encouragement to get more intensive support; marketing the program; providing quitline services; and covering counseling and medication (with the usual \$5 copay) resulted in an annual increase in use of counseling services from 0.5% to 10% of smokers in the plan,³⁰⁷ and a decrease in smoking prevalence from 25% to 15% over 10 years.³¹¹

Employers can support employees who want to quit tobacco use by offering (or referral to) a variety of cessation assistance options, including telephone quitlines, self-help programs, formal cessation programs, counseling from a health care provider, and pharmacological aids. Workplace smoking-cessation assistance can be provided on- or off-site, may be run by outside or in-house personnel, and can be an isolated activity or integrated into a comprehensive employee health promotion program. Company incentives to support employee cessation efforts may include full or partial payment of any costs, including pharmacological agents, time released from work for cessation assistance, and lower employee contributions to health benefit costs for nonsmokers.³¹² Studies have been mixed on the effectiveness of work-site programs. Although one meta-analysis suggested a modest impact, two large trials published subsequently showed either no impact or very small and nonsignificant results.³¹³⁻³¹⁵

Performance Measures for the Treatment for Tobacco Use

The Institute of Medicine identified cessation help for adult smokers as one of 20 national priority areas for health care quality improvement.³¹⁶ Treatment of tobacco use is also increasingly a performance measure for accreditation or quality assurance. For example, a majority of plans reported at least some of the measures in the Health Plan Employer Data Information Set (HEDIS).³¹⁷ A measure of a plan's smoking cessation activities was first included in December 1996, when HEDIS 3.0 was released. Under this survey measure, managed care plans report the proportion of smokers or recent quitters (within the past year) who had been seen in the plan during the previous year and who had received advice to quit smoking.³¹⁸ In 2003, the measure was expanded to include the proportions whose health care provider had discussed medications and the proportion whose health care provider had given other assistance in quitting. In 2005, 66-71% (depending on whether Medicare, Medicaid, or commercial plan). Provided advice, 32-39% recommended or discussed medication use, and 34-39% provided other assistance in quitting.³¹⁹ The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) now requires hospitals to document their provision of smoking cessation treatment for patients admitted for acute MI, heart failure, and community acquired pneumonia.³²⁰ In 2005, the Center for Medicare and Medicaid Services (CMS) began a pilot project that provides financial incentives to physicians who deliver targeted interventions.

Tobacco cessation advice and assistance were among those quality measures.³²¹

Community Interventions to Reduce Tobacco Use

Beginning in the 1970s, attention began to focus on community interventions to reduce risk factors. Examples include Finland's North Karelia Project,³²² South Africa's Coronary Risk Factor Study,³²³ the Stanford Three Communities Study,³²⁴ the Stanford Five Cities Project,³²⁵ the Multiple Risk Factor Intervention Trial,³²⁶ the Minnesota Heart Health Program,³²⁷ and the Pawtucket Heart Health Program.³²⁸ Some showed positive results, but in others, unanticipated secular changes in the control group or inappropriate or inadequate interventions led to nonsignificant results.

These were followed by the American Stop Smoking Intervention Study for Cancer Prevention (ASSIST) in 1991, a demonstration project in 17 states for community tobacco control activities. ASSIST, funded by the NCI, and conducted in collaboration with the ACS, funded state health departments to form community-based tobacco coalitions that were responsible for developing and implementing comprehensive state plans for tobacco use prevention and control. An evaluation of ASSIST reported that consumption was lower in ASSIST states than in the rest of the country.³²⁹ Around the same time, California and Massachusetts had their own statewide initiatives funded by tobacco taxes, providing further data for the evaluation of community-based interventions.

Evidence for Specific Community Interventions

As a result of community trials and other controlled studies, enough evidence is available to allow recommendations for effective community interventions. The Guide to Community Preventive Services, an evidence-based guideline, noted that: effective interventions to decrease initiation include raising the price of tobacco products, media campaigns combined with other interventions (such as price increase or community interventions), and community mobilization around minors' access when combined with other interventions.³³⁰ Effective interventions to reduce exposure to secondhand smoke include smoking bans or restrictions. Effective interventions to increase cessation include raising the price of tobacco products, sustained media campaigns (in conjunction with other interventions), telephone quitlines, and reducing the out-of-pocket costs of treatment (i.e., insurance coverage of treatment). Provider reminders alone or in combination with provider training also increased quitting, but provider training alone did not have sufficient evidence of its efficacy to be recommended.³⁰⁹

Preventing Tobacco Use

Evidence that knowledge of adverse and long-term health effects did not translate into reduced smoking among youth has led to increased attention on the development of valid theoretical models of smoking initiation and prevention programs. Five stages to smoking initiation among children and adolescents are currently recognized: (a) A preparatory stage in which attitudes and beliefs about the utility of smoking develop. Smoking may be viewed as having positive benefits even though it has yet occurred. (b) The trying stage, which includes the first two or three times an adolescent tries to smoke (usually in a situation involving peers). (c) An experimentation stage with repeated but irregular smoking, in which smoking is usually a response to a particular situation. (d) Regular use; at least weekly smoking across a variety of situations. (e) Nicotine dependence, the physiological need for nicotine.¹⁷⁹ Community-based interventions (tobacco price increases, countermarketing campaigns, minors' access restrictions, and school programs) have been the primary modalities used to prevent initiation.

Increasing Price

In 1993, an NCI consensus panel concluded that an increase in cigarette excise taxes may be the single most effective intervention for

reducing tobacco use by youth.³³¹ There is a robust body of evidence on the effectiveness of price increases on youth initiation.¹⁷⁹ The Guide to Community Preventive Services identified eight studies that specifically looked at the impact of price on youth and young adults. The Community Guide concluded that a 10% increase in price reduced youth prevalence by 3.7%, decreased initiation by 3.8%, and also decreased the amount smoked by adolescents who continued to smoke.³⁰⁹ One study concluded that youth consumption may be three times more sensitive to price increases than adult consumption.^{179,331} Another analysis of cigarette excise taxes concluded that an increase in the federal cigarette excise tax would encourage an additional 3.5 million Americans to forgo smoking, including more than 800,000 teenagers and almost two million young adults aged 20–35 years.^{331,332} Other studies have reported that for every 10% increase in price, total cigarette consumption among youth decreases 7%.^{309,331–335} Even the tobacco industry has privately acknowledged the effectiveness of price increases on reducing youth smoking: Philip Morris noted that “it is clear the price has a pronounced effect on the smoking prevalence of teenagers, and that the goals of reducing teenage cigarette smoking and balancing the budget would both be served by increasing the Federal excise tax on cigarettes.”³³⁶

Other tobacco products also respond to price interventions: increases in the price of smokeless tobacco reduce use by adolescent boys, with most of the effect coming from reduced prevalence rather than the amount used by continuing users.³³³ Studies have also shown that higher cigarette prices increase smokeless tobacco use. Increased cigarette prices also led to more cigar use in New Jersey, and the authors concluded that when excise taxes on other tobacco products do not keep pace with cigarette taxes, substitution occurs.³³⁷

Countermarketing Campaigns

Media campaigns, when combined with other interventions, are an effective strategy to reduce youth initiation.¹⁷⁹ The Community Guide determined that mass media campaigns are effective in reducing youth prevalence. Sustained (at least two years) media countermarketing campaigns reduced self-reported tobacco prevalence by eight percentage points and, for those studies reporting odds ratios, by a median of 74%.³⁰⁹ The 2000 Surgeon General's Report noted that multicomponent youth-directed programs with a strong media presence have shown long-term success in reducing or postponing youth tobacco use.³³³

Youth-focused campaigns have been developed and evaluated in several states and nationally. In Massachusetts, adolescents aged 12–13 who had been exposed to the countermarketing campaign as part of a comprehensive program were half as likely to become smokers as those who were not able to recall campaign advertisements.³³⁸ In Minnesota, when a youth-focused media campaign was ended, youth awareness of the campaign declined from 85% to 57%, and youth susceptibility to initiate smoking increased from 43% to 53% within 6 months.³³⁹ As part of the youth-focused tobacco control program in Florida that was funded by the tobacco industry settlement, the “truth” media campaign was developed. Evaluation results included a 92% brand awareness rate among teens, a 15% increase in agreement with key attitudes about smoking, a 20% decrease in smoking among middle school students and an 8% decrease in smoking among high school students.³⁴⁰ Florida teens exposed to the campaign were also more likely to agree with antitobacco industry attitudes. A longitudinal study reported that Florida teens with strong anti-industry attitudes were four times less likely to start smoking and 13 times less likely to become established smokers than teens with low anti-industry attitudes.^{341,342} In 2000, the American Legacy Foundation ran a national “truth” campaign. Evaluation results show that exposure to this campaign was associated with an increase in antitobacco attitudes and beliefs.³⁴³ Adolescents in tobacco-producing states were as responsive to the anti-industry ads as adolescents in non-tobacco-producing regions.³⁴⁴ It is estimated that 20% of the decline in youth smoking prevalence in the late 1990s was a result of the “truth” media campaign.³⁴⁵ In contrast, exposure to the

Philip Morris's "Think Don't Smoke" campaign did not cause an increase in antitobacco attitudes and those exposed to the campaign were more likely to be open to the possibility of smoking.³⁴³ Similarly a study of the Phillip Morris parent-targeted campaign "Talk. They'll Listen" found that each additional viewing of the ad was associated with lower perceived harm of smoking, stronger approval of smoking, stronger intentions to smoke in the future, and greater likelihood of having smoked in past 30 days.^{345a}

School-Based Tobacco Prevention Programs

School-based tobacco prevention programs have been shown effective when combined with concurrent, complementary community interventions.¹⁷⁹ Current recommendations on quality school-based smoking prevention programs emphasize helping children understand and effectively cope with social influences associated with smoking, highlighting the immediate negative social consequences, and inculcating youth against the effects of pressure to smoke.^{346,347} Most prevention programs focus on students in grades 6–8, the time of greatest increase in smoking experimentation.³⁴⁸ However, the effects of these programs are not sustained without additional educational interventions, media campaigns, or supportive community programs. Thus, although school-based skills' training is important for preventing smoking, more sustained and comprehensive interventions may be necessary for long-term success.¹⁷⁹

Smoke-Free Policies

Another approach to discouraging smoking among youth is the establishment of strong no-smoking policies in schools and on school grounds. Such policies not only directly discourage smoking by youth but increase the likelihood that their teachers, who are role models, will not be seen smoking.

Minors' Access Restrictions

Tobacco products are widely available to minors and commercial outlets are an important source of tobacco for them.^{333,349} Since 1986, numerous published studies involving purchase attempts by minors confirm that, despite state and local laws banning such sales, they can easily buy tobacco from over-the-counter outlets and vending machines.^{179,333,349} Active enforcement of tobacco laws increases retailer compliance.^{179,350} Studies looking at their impact on prevalence, however, are mixed.^{333,351–353} The Guide to Community Preventive Services reviewed the literature on the effectiveness of minors' access laws and concluded that they are only effective in conjunction with other community interventions.³³⁰ An evaluation in Massachusetts after the defunding of the program showed that communities that had a dramatic reduction in tobacco control funding saw an average increase of 74% in illegal sales to minors, and communities that completely lost their programs had even larger increases.³⁵⁴ It is important to keep in mind that as commercial sales to minors decrease, "social" sources (other adolescents, parents, and older friends) may become more important sources of cigarettes. Thus a comprehensive approach is needed so that smokers of all ages, as well as retailers, do not provide tobacco to minors.³³³

Eliminating Exposure to Secondhand Smoke

Clean Indoor Air Laws

Despite substantial progress, 125 million Americans are still exposed to SHS.^{213a} In 2006, the Surgeon General concluded that eliminating smoking in indoor spaces fully protects nonsmokers, but that separating smokers from nonsmokers, cleaning the air, and ventilating buildings cannot eliminate exposure to SHS.^{213a} Homes and workplaces are the primary locations for adult exposure, so interventions include smokefree homes, workplaces, and public places. Although the purpose of smokefree policies is to reduce SHS exposure, these policies also reduce consumption, increase quitting, decrease relapse, and possibly reduce initiation.^{213a, 309, 330, 333}

The entertainment and hospitality industries have particularly high SHS exposure.^{213a} One study evaluated respirable particle (RSP) air pollution and carcinogenic particulate polycyclic aromatic hydrocarbons (PPAH) in a casino, six bars, and a pool hall. SHS contributed 90–95% of the RSP and 85–95% of the PPAH in these venues. These levels were greater than the levels of these contaminants on major truck highways and polluted city streets. Another study showed that levels of SHS in restaurants are 160–200% higher, and levels in bars are 400–600% higher than in office workplaces.³⁵⁵ Yet, wait staff and bartenders are less likely to have smokefree workplaces.³⁵⁶

Both the Surgeon General's report and the Guide to Community Preventive Services evaluated the effect of smoking bans and restrictions on exposure to SHS. Both found that smoking bans reduced exposure more than smoking restrictions;^{213a,309} the Surgeon General also noted that full compliance with smoking bans eliminated exposure.

A recent study examined cotinine levels in a nationally representative survey: 12.5% of nonsmoking adults living in counties with extensive smokefree laws were exposed to SHS, compared with 35.1% in counties with limited coverage and 45.9% in counties with no law.^{356a} The health impacts of state-wide smokefree laws have also been studied. Two studies showed dramatic declines in RSP and PPAH after smoking bans were implemented;^{216,357} other studies have shown improvements in respiratory symptoms, sensory irritation, and lung function in hospitality workers.^{357a} Concerns are often raised about possible adverse economic consequences of smokefree laws on the hospitality industry. A review of the studies on economic effects showed that higher quality studies generally found a positive economic impact of smoking bans. Studies using subjective outcomes (e.g., owner expectations) tended to show a negative impact, while studies using objective outcomes (e.g., revenues, employment, restaurant sale price) usually showed a positive impact. Few of the negative studies were peer reviewed; all were funded by the tobacco industry.³⁵⁸ The Surgeon General concluded that smokefree policies do not have an adverse economic impact on the hospitality industry.^{213a}

Increasing Cessation

Increasing the Price of Tobacco Products

Price increases are one of the most effective interventions to increase adult cessation, as shown by a substantial body of evidence. The Guide to Community Preventive Services identified 56 studies in the literature. After combining those that used the same data and eliminating weak ones, 17 studies formed the basis of the Guideline conclusion that a 10% price increase decreases consumption by a median of 4.1%. For every 10% increase in price, cessation increased 1.5%.³⁰⁹ Consistent with the larger impact of price on adolescents, one study found that these effects were doubled for persons 20–25 years of age compared with adults aged 26–74.³³³ Some data suggest that men are more responsive to price than women.^{333,359} Other data have shown that less educated persons are more responsive to price increases than more educated persons, that blacks are twice as responsive as whites, that Hispanics are even more price sensitive, and that those with family incomes at or below the median were 70% more responsive than those with higher family incomes.³³³ The 2000 Surgeon General's Report concluded that the price of tobacco products has an important influence on the demand for tobacco products and that substantial increases in the excise tax on tobacco would have considerable impact on the prevalence of smoking.³³³ Another study estimated that increasing the federal cigarette tax by \$2.00 would reduce total cigarette sales by more than 4 billion packs per year, would decrease adult smoking prevalence rates by 10%, and 4.7 million smokers would quit.³⁶⁰ Even the tobacco industry has privately acknowledged the effect of price on reducing adult cigarette consumption. As Philip Morris noted, "when the tax goes up, industry loses volume and profits as many smokers cut back."³⁶¹ "A high cigarette price, more than any other cigarette attribute, has the most dramatic impact on the share of the quitting population . . . price, not tar level, is the main driving

force for quitting.”³⁶² Smuggling reduces the impact of price increases by making cheaper cigarettes available and it also reduces government revenue from a tax. Large differences in price between states or countries increases the profitability of smuggling. There is also evidence that the cigarette companies themselves have been directly involved with smuggling activities.^{362a}

Countermarketing

Evidence for the effectiveness of counteradvertising comes from both national and international data. An econometric analysis of the U.S. Fairness Doctrine (which required one antismoking message for every three to five tobacco advertising messages) concluded that counteradvertising substantially deterred smoking.³⁶³ Another study of the Fairness Doctrine concluded that the number of people who successfully quit smoking tripled during the period that the doctrine was in effect.³⁶⁴ An evaluation of a paid media campaign against smoking in Australia found that there was a marked decrease in smoking prevalence attributable to the campaign.³⁶⁵ An evaluation of a Greek media campaign showed that the annual increase in tobacco consumption was reduced to nearly zero as a result of the campaign. When the campaign stopped, consumption again rose at the precampaign rate.³⁶⁶ The Guide to Community Preventive Services found 15 high-quality studies of the effect mass media campaigns on increasing cessation. In all studies, the campaign was concurrent or coordinated with other interventions such as tax increases, community education programs, self-help cessation materials, individual counseling, or other mass media efforts. Various endpoints were measured in the various studies. The campaigns increased cessation by a median of 2.2 percentage points, reduced tobacco consumption by a median 17.5%, and reduced prevalence by a median of 3.4 percentage points.³⁰⁹

Advertising Bans

Evidence for the effectiveness of advertising bans is mixed. One study used multiple regression analysis to evaluate the effectiveness of advertising restrictions, price, and income on tobacco consumption in 22 countries from 1960 to 1986. Above threshold levels, both advertising restrictions and higher prices were effective in decreasing tobacco consumption.³⁶⁷ However, an analysis of the 1971 U.S. broadcast media ban did not show an effect.³⁶⁸ This apparent lack of effect may be due in part to these bans being frequently circumvented, such as during the promotions of televised sporting and entertainment events. For example, during a Marlboro Grand Prix telecast, the Marlboro logo was seen or mentioned nearly 6000 times and was visible for 46 minutes of the 94-minute broadcast.³⁶⁹ In addition, after the broadcast ban went into effect in the United States, tobacco advertising merely shifted to other media—newspapers, magazines, outdoor signs, transit, point of sale, and a variety of promotions—at much higher expenditure levels.²⁵⁹ Similarly, other studies have suggested that partial bans are not effective, but that complete bans can decrease consumption.^{370–372}

Quitlines

Quitlines have been shown to increase cessation rates. The Guide to Community Preventive Services found 32 high-quality studies of the effectiveness of quitlines. In all studies, telephone support was coordinated with other interventions, such as patient education, provider-delivered counseling, NRT, a cessation clinic, or a televised cessation series. Cessation rates were increased by a median of 2.6 percentage points. Six studies that examined the effect of quitlines plus patient education materials compared with patient education materials alone had a similar magnitude of effect. Five studies examined proactive telephone counseling (quitlines that make follow-up calls). These studies found a median increase in cessation of 41%.³⁰⁹ Quitlines are also offered by states as part of a comprehensive tobacco control program. Some quitline services offer free NRT with the counseling service.³⁷³ California was the first state to develop such a quitline. Both randomized clinical trials and real-world evaluation trials of the quitline have shown that it doubled quit rates over self-help materials

alone.^{374,375} It has been estimated that up to 15% of smokers would use a quitline service, but current quitlines have the capacity to only serve 1–3% of smokers.³⁶⁰

Reducing Out-of-Pocket Costs of Treatment

Reducing out-of-pocket costs for cessation treatment increases cessation. The Guide to Community Preventive Services found five high-quality studies assessing the impact of programs that reduced or eliminated costs for nicotine replacement therapy. One study reported that use of treatment increased with reduced payment level. All these studies observed an increase in cessation, with a median increase of 7.8 percentage points. One study reported an increased odds ratio for quitting of 1.63.³⁰⁹

Effectiveness of Comprehensive Tobacco Prevention and Control Programs

In the absence of the antismoking campaign, an estimated additional 42 million more Americans would have smoked in 1992. As a result of these campaign-induced decisions not to smoke, an estimated 1.6 million Americans postponed death between 1964 and 1992, gaining 21 years of additional life expectancy on average, and an estimated additional 4.1 million deaths will be avoided or postponed between 1993 and 2015.³⁷⁶ Such analyses must be interpreted cautiously, however, because they rely heavily on assumptions about what would have occurred in the absence of antismoking campaigns.

Evaluation of the California tobacco control program has shown that per capita consumption of cigarettes declined significantly in California from January 1989 through December 1993 and the decline was greater than for the United States as a whole.^{376a} From 1989 to 1993, adult smoking prevalence also declined almost twice as rapidly as the rest of the country. One study showed that the increase in youth smoking in the early 1990s was smaller in California than in the rest of the country.³³³ From 1993 to 1996, in conjunction with program cuts, the rate of decline slowed in California, but still was greater than for the country as a whole.³⁷⁷ From 1988 to 2003, tobacco consumption in California decreased 60%, and California now has the lowest per capita consumption in the United States.³⁷⁸ California has also seen improvements in health outcomes. Lung cancer incidence has declined three times more rapidly in California than in the rest of the country, and has declined among women whereas the rest of the country is still experiencing increasing lung cancer rates among women.³⁷⁹ Six of nine tobacco-related cancers have a lower incidence rate in California than in the rest of the United States (lung/bronchus, esophagus, larynx, bladder, kidney, pancreas).³⁷⁸ Reductions in cardiovascular disease have also been reported. A study of the California program reported that mortality from heart disease declined at a significantly greater rate in California (2.93 deaths per 100,000 population) than in the rest of the country, and estimated that the program was associated with 33,000 fewer deaths from heart disease between 1989 and 1997 than would have been expected without the program.³⁸⁰ Studies have estimated that the California tobacco control program saved \$11 million in the first two years and \$100 million over seven years by reducing the number of smoking-related low-birthweight babies,³⁸¹ and another \$25 million in the first two years and \$390 million over seven years through declines in smoking-related heart attacks and strokes.³⁰⁵ California has reported that for every dollar spent on the program, statewide health care costs are reduced by more than \$3.60.³⁸²

Massachusetts also experienced a persistent decline in per capita cigarette consumption since the start of its program. From 1992 to 1997, per capita consumption in Massachusetts decreased 31%, compared to an 8% decline in the rest of the country (excluding California). Prevalence declines were also greater (3 percentage points compared to 1 percentage point) than in the rest of the country. And, like California, the increase in youth smoking prevalence in the early 1990s was less in Massachusetts than in the rest of the country. The effect was particularly evident among younger adolescents.^{333,383}

Massachusetts reported that its program paid for itself through declines in smoking among pregnant women.³⁸⁴

Arizona also noted greater declines in per capita sales than the rest of the United States after implementation of its program. The state reported that adult prevalence declined at a faster rate than in the rest of the country and that young adult prevalence declined in Arizona at a time when it was increasing nationally.³³³ The program noted that the decrease in smoking prevalence among low income and low education groups meant a narrowing of disparities in tobacco use.³⁸⁵

In Oregon, trends in per capita consumption were also compared to the rest of the country (excluding California, Massachusetts, and Arizona) preprogram (1993–1996) and postprogram (1997–1998). In 1997–1998, consumption declined 11.3% in Oregon compared to 1% in the rest of the country.³³³ Oregon also noted an impact from their school program: smoking prevalence decreased faster in schools funded for prevention programs than in nonfunded schools. Even after adjustment for other risk factors, students in funded districts were 20% less likely to smoke than students in nonfunded districts. Changes in prevalence were also greater in school districts with high implementation of the program, whereas smoking prevalence in districts with low implementation stayed nearly the same as in nonfunded districts.³⁸⁶

Florida had focused an effort on youth (“truth” media campaign, youth community activities including youth advocacy groups, school programs, minors’ access enforcement, and youth involvement in the design and implementation of the program). The state documented dramatic declines in current smoking and ever smoking, and large increases in the proportion of “committed never-smokers” among both middle and high school students.³⁸⁷

Evaluations across multiple programs and nationally have also demonstrated the effectiveness of comprehensive tobacco prevention and control programs. An evaluation of the ASSIST demonstration project reported that ASSIST states had a greater reduction in smoking prevalence than non-ASSIST states, and estimated that if all states had implemented ASSIST, there would be 280,000 fewer smokers.³²⁹ A national analysis concluded that state tobacco control expenditures reduced cigarette sales over and above any price increases that occurred concurrently (and adjusting for cross-border sales). The study also noted that larger, more established programs may have a larger impact dollar for dollar, and concluded that if states had begun investing at the CDC-recommended minimum funding levels in 1994, the aggregate sales decline would have doubled (i.e., decreased an additional 9%) by 2000.³⁸⁸ A second national analysis reported that increased state tobacco control expenditures reduced youth smoking prevalence and the number of cigarettes smoked per day, and that had states spent the CDC-recommended minimum levels, youth smoking prevalence would have been between 3.3% and 13.5% lower than the observed rate.³⁸⁹

Evidence from well-funded comprehensive state programs (particularly California and Massachusetts) and from controlled studies were analyzed and developed into CDC’s “Best Practices.” In addition, the annual costs to implement comprehensive state tobacco control programs were estimated to range from \$7–\$20 per capita in smaller states (population less than 3 million), \$6–\$17 per capita in medium-sized states (population of 3–7 million), and \$5–\$16 per capita in large states (population greater than 7 million).³⁹⁰

Current Status of Tobacco Control Programs

Tobacco Excise Taxes

At the end of 2006, the federal cigarette tax was \$0.39 per pack.³⁹¹ By the end of 2006, state excise taxes ranged from \$0.07 cents per pack in South Carolina to \$2.46 in Rhode Island, with an average state tax of \$0.78 per pack (up from \$0.381 at the end of 1997). However, federal and state taxes as a percentage of retail price declined from 51.4% in 1965 to 34% in 2006.³⁹² In addition, 44 states and D.C. imposed general sales taxes on cigarettes as of 2006. In 2006, 20 states had a cigarette tax of \$1.00 or more and 5 states had a tax of \$2.00 or more per pack. New York City increased its local cigarette tax from \$0.08 to \$1.50 in 2002, and Cook County, Illinois (includes Chicago), increased its cigarette tax from \$0.18 to \$1.00 in 2004.³⁹²

In 2002, the federal tax on smokeless tobacco was only \$0.04 per can of snuff and \$0.012 per package of chew tobacco. As of January 2007, 49 states taxed smokeless tobacco.³⁹²

Media Campaigns

The 1997 Master Settlement Agreement (MSA) imposed restrictions on cigarette marketing in the United States. There could no longer be (a) brand name sponsorship of concerts, team sporting events, or events with a significant youth audience; (b) sponsorship of events in which paid participants were underage; (c) tobacco brand names in stadiums and arenas; (d) cartoon characters in tobacco advertising, packaging, and promotions; (e) payments to promote tobacco products in entertainment settings, such as movies; (f) sale of merchandise with brand name tobacco logos; and (g) transit and outdoor advertising (including billboards).³³³

Smoke-free Indoor Air

Nonsmokers are increasingly able to breathe smoke-free air in indoor environments. Federal agencies have taken action to reduce exposure to SHS. In 1987, the U.S. Department of Health and Human Services instituted a smoke-free buildings policy, and in 1994, the U.S. Department of Defense prohibited smoking in its facilities worldwide. In addition, the Pro-Children Act of 1994 banned smoking in indoor facilities that are regularly or routinely used to provide services to children (e.g., school, library, day care, health care, and early childhood development settings).^{213a} The Occupational Safety and Health Administration proposed standards to restrict exposure to SHS in workplaces, but then withdrew its Indoor Air Quality proposal in 2001, citing the substantial success states and communities, as well as private employers, were having with this issue. In August 1997, the President issued an Executive Order making all federal facilities of the executive branch smoke free, thus banning smoking in all interior space owned, rented, or leased by the executive branch unless there were separately ventilated smoking areas. In November 2004, the Secretary of the Department of Health and Human Services announced a property-wide ban on tobacco use beginning in January 2005, to be implemented as contracts came up for renewal.

Policies were also being implemented in the private sector. Effective in 1994, the Joint Commission on the Accreditation of Healthcare Organizations required hospitals to be smoke free. In 1990, smoking was banned on all U.S. domestic flights of less than 6 hours’ duration. Delta Airlines made all its flights smoke free as of January 1, 1995, and other airlines subsequently banned smoking on their trans-Atlantic flights. In 2000, legislation made all flights to and from the United States smoke free. In 1993, Amtrak made most trains smoke free.³⁹⁹

California became a leader in smoke-free environments for its citizens when all workplaces, including restaurants and bars, became smoke free on January 1, 1998. As of January 12, 2007, eight states had comprehensive indoor smoke-free policies that included all workplaces, restaurants, and bars. Five more had state-wide smoke-free policies that included workplaces and restaurants, but not bars. As of January, 2007, 2507 localities had passed some form of clean indoor air law, including Lexington, Kentucky. However, as of December 2006, 18 states had legislation that preempted localities from enacting laws to restrict smoking in public places that were more stringent than state laws.^{355, 402a} In addition to reducing the number of and degree of protection afforded by local regulations, preemption prevents the public education that occurs as a result of the debate and community organization around the issue.⁴⁰²

Workplace smoking policies, originally implemented primarily for safety reasons, are now adopted because of health concerns.³¹² The vast majority of adults recognize the danger of exposure to SHS.^{213a, 403, 404} The percentage of Americans who support totally smoke-free indoor workplaces increased from 58% in 1993 to 68% in 1999⁴⁰⁵ and 75% in 2002.^{213a} Support generally increases after institution of a ban.^{213a, 406} A 1995 survey found that 87% of work sites with 50 or more employees had a smoking policy of some kind.⁴⁰⁷ A 1994 survey of businesses with up to 25,000 employees found that 54%

had smoke-free policies and only 7% had no policy on smoking.³¹² A nationally representative survey of workers conducted in 1992–1993 and again in 1998–1999 found that 46% were covered by a smoke-free workplace policy in 1992–1993 and 70% in 1998–1999. However, significant variation existed by state in 1998–1999, from a high of 80% (Utah, Maryland) to 50% (Nevada).^{407a} Young workers (aged 15 to 19 years), men, blue-collar workers, and service workers were less likely to work in smokefree workplaces, although disparities have narrowed over time.^{213a,408} In Los Angeles, California, both patron and employee compliance with the smoke-free bar and restaurant laws increased; by 2002, 76% of patrons in freestanding bars and 98% of patrons in bars/restaurants, and 95% of employees in freestanding bars and 96% of employees in bars/restaurants were complying with the law.⁴⁰⁹ However, in 2000, only 24.5% of states, 45.5% of districts, and 44.6% of schools provided tobacco-free environments in middle, junior, or senior high schools.⁴¹⁰ In California, which enacted the first statewide smoke-free workplace law provided sustained media campaigns about the dangers of SHS, the proportion of adults with smoke-free homes increased from 38% in 1992 to 74% in 1999.⁴¹¹ The percentage of households with smoke-free rules increased nationally from 43% in 1992–1993 to 72% in 2003. In 2003, Utah had the highest proportion of homes with such rules (88.8%), and Kentucky had the lowest (53.4%).^{411a}

Exposure to SHS has been decreasing in the United States. From 1988–1991, 88% of Americans aged 2 years and older were estimated to be exposed to SHS.²¹⁸ In the third national report on human exposure to environmental carcinogens, CDC reported that from 1988–1991, the median level (50th percentile) of serum cotinine (a marker for second-hand smoke) among non-smokers was 0.20 ng/mL. From 1988–1991 to 1999–2002, the median cotinine level decreased 70% (to 0.059 ng/mL), suggesting a dramatic reduction in exposure. Exposure declined 68% in children, 69% in adolescents, and 75% among adults. Although levels declined in all age, sex, and racial/ethnic categories, exposure was still high among non-Hispanic blacks and in children and adolescents.⁴¹² After implementation of the California law creating smoke-free bars, self-reported exposure of bartenders decreased from 28 to 2 hours per week, 59% of those with previous respiratory symptoms reported they no longer had the symptoms, 78% of those with sensory irritation no longer reported those symptoms, and there was an improvement in mean lung function measurements.⁴¹³

Minors' Access

In 1992, Congress enacted the Synar Amendment. This federal statute and its implementing regulations issued in 1996 require every state to have a law prohibiting tobacco sales to minors under age 18, to enforce the law, to conduct annual statewide inspections of tobacco outlets to assess the rate of illegal tobacco sales to minors, and to develop a strategy and time frame to reduce the statewide illegal sales rate to 20% or less.^{414,415} Overall, the national retailer violation rate decreased from 41% in 1996 to 12% in 2005.^{416,417} In 2005, 48 states and DC states met the overall goal of a 20% violation rate.⁴¹⁷

Unfortunately, as states have developed minors' access laws, some have adopted weak laws that include preemptive language preventing stronger local legislation. As of January 1, 2007, 22 states had such preemptive language in their minors' access legislation.^{416a,402a} In August of 1996, the FDA issued regulations that prohibited the sale of tobacco to persons less than 18 years of age, required retailers to obtain photo identification to verify the age of all persons less than 27 years of age, banned vending machines and self-service displays except in facilities where only adults were allowed, banned sales of single cigarettes and packages with fewer than 20 cigarettes, and banned free samples.⁴¹⁸ The FDA rule was challenged in federal court by the tobacco industry, and in 2000, the Supreme Court ruled that Congress had not given the FDA authority to regulate tobacco products.⁴¹⁹ Legislation to give FDA such authority has been proposed several times, most recently in early 2007.

The MSA of 1998 also contained the following youth access restrictions: restricted free samples except where no underage persons were present, prohibited gifts to youth in exchange for buying tobacco products, prohibited gifts through the mail without proof of

age, and prohibited the sale or distribution of packs smaller than 20 for three years.³³³

Studies show that internet sales provide easy access by minors to cigarettes because many Internet vendors don't check ages or have a verification process.⁴²⁰ By the end of 2005, 29 states had passed laws prohibiting delivery of tobacco to individual consumers and/or restricting internet sales in some way.^{355,420a}

Coverage for Tobacco-use Treatment

Insurance coverage for tobacco-use treatment has been slowly increasing. In 1996, 18 states had some form of Medicaid coverage for tobacco-use treatment, but none covered all counseling modalities (individual, group, or telephone) and all FDA-approved medications. By 2005, 38 states covered some form of tobacco use treatment for all Medicaid recipients, and 1 state offered comprehensive coverage.⁴²¹ Coverage under managed care also increased from 1997 to 2002. The proportion offering full coverage in 2002 was 5% for OTC NRT gum, 9% for OTC NRT patches, 36% for NRT inhaler and nasal spray, and 41% for Zyban. The proportion offering full coverage for counseling was 16% for group counseling or classes, 19% for individual counseling for pregnant women, 26% for self-help materials, 41% for face-to-face counseling, and 52% for telephone counseling. However, 15% had annual or lifetime limits on coverage for smoking cessation interventions.⁴²² A survey of work sites having at least 10 employees and providing health insurance reported that there was at least some coverage for devices and drugs in 23% of workplaces, for counseling in 22%, but only 5% offered coverage of both drugs/devices and counseling.⁴²³ In a survey of state requirements for provision of preventive services, as of June 2001, one state mandated tobacco-use treatment coverage for group health plans only, one for HMOs only, and one for both group plans and HMOs; one required only medication coverage while the others specified cessation counseling coverage.⁴²⁴ An analysis of the extent to which states required insurance coverage for tobacco-use treatment for state employees (5 million workers) at the end of 2002 found that (of 45 reporting) 29 states required coverage for at least one PHS-recommended treatment for at least some employees, but only 17 provided coverage that was fully consistent with the PHS guideline for at least some employees, and only 7 required coverage consistent with the guideline for all state employees.⁴²⁵

Quitlines

California was first to have a state quitline (1992). As of August 2006, all states offered quitline services, although historically funding has been erratic, with some states losing and then regaining them. In 2004, the Secretary of DHHS developed a national network of quitlines. This network has a single portal number: 1-800-QUIT NOW. This portal routes callers to their state's quitline service. As part of the initiative, CDC provided funding to states without these services so that every state had a quitline. CDC also provided funding to states so they could enhance their existing quitline services.^{425a} The Secretary did not provide funding for this initiative, but in 2005, some funding was allocated by Congress for the network. However, for most states, current funding is not high enough to allow widespread promotion and provision of counseling and medication to all tobacco users interested in quitting.

Comprehensive Programs

ASSIST, funded from 1991 to 1998 by NCI and conducted in collaboration with ACS, funded 17 states to form community-based tobacco coalitions responsible for developing and implementing comprehensive state plans for tobacco prevention and control. In 1993, CDC began funding, at lower levels, the other 33 states and the District of Columbia through the IMPACT (Initiatives to Mobilize for the Prevention and Control of Tobacco Use) program. In 2000, the ASSIST and IMPACT programs were combined into CDC's National Tobacco Control Program, with funding averaging \$1 million per state. The program had four goal areas (prevent initiation, promote cessation, eliminate exposure to SHS, and eliminate tobacco-related disparities). States are expected to use community and policy interventions and

countermarketing campaigns to meet these goals and to evaluate their programs' success.⁴²⁶ In 1998, the MSA between the states and the major tobacco companies provided \$246 billion over 25 years to the states to compensate them for Medicaid costs incurred by tobacco users.⁴²⁷ Although it was expected that states would fund comprehensive tobacco control programs using this settlement, in most cases the funds have been used for other purposes, particularly as states have experienced budget deficits in the first few years of the twenty-first century.

Raising the excise tax on tobacco reduces consumption, but the effect is greater if a portion of the tax is used to fund a comprehensive tobacco control program. California was the first state to do so in 1988, when an initiative to increase cigarette taxes by \$0.25 per pack dedicated 20% of the increase to tobacco control activities.^{376a} Other states to fund programs using excise taxes included Massachusetts in 1992,³⁸³ Arizona in 1995,³⁸⁵ and Oregon in 1997.³⁸⁶ However, all four of these programs have sustained cuts. By 2004, the Massachusetts program had been virtually eliminated (a 92% cut) and the California, Arizona, and Oregon programs severely reduced (45%, 37%, and 69%, respectively).⁴²⁷ Florida's campaign, funded by its individual settlement with the tobacco industry, was cut 99%, eliminating the effective "truth" marketing campaign.⁴²⁸ Other states dedicated significant cigarette excise tax dollars or MSA funds to tobacco control programs, but from 2002 to 2005, funding for tobacco control programs was cut by 28%. The use of only 8% of excise taxes and the MSA funds dedicated to tobacco control would fund these programs at the CDC-recommended minimum level.^{390,427} By 2007, only 3 states were funding their tobacco control programs at this level, 28 states and the District of Columbia were funding at less than half the minimum level, and 5 states were not funding these programs at all.^{428a}

Protobacco Influences

Advertising and Promotion

In 1970, the cigarette industry spent \$360 million on advertising and promotion, two-thirds of which was for television and radio advertising. In the United States, broadcast media advertising was banned as of January 1, 1971. In 1975, the cigarette industry spent \$490 million on advertising and promotion, two-thirds of that for newspaper, magazine, and outdoor ads. In 1997 (the year of the MSA), the industry spent \$5.7 billion in advertising and promotion, with 80% used for promotions, specialty items, and coupons.⁴²⁹ Industry spending on advertising nearly tripled from 1997 to 2001 (to \$15.2 billion). Expenditures decreased slightly to 13.1 billion in 2005. The share used for coupons and discounts increased from 27% to 87%. Smokeless tobacco companies spent \$251 million on advertising in 2005. Price discounts and free samples accounted for 60% of the advertising budget.^{429a}

Tobacco companies maintain that their advertising and promotion are not intended to appeal to teenagers or preteen children. However, on March 20, 1997, the Liggett Group, Inc., as part of the settlement of state lawsuits, acknowledged that the tobacco industry markets to youth under 18 years of age.⁴³⁰ Similarly, documents released in January 1998 showed that in 1975, R.J. Reynolds Tobacco wanted to increase the market share of Camel filter cigarettes among young people 14–24 years of age "who represent tomorrow's cigarette business."⁴³¹ One study found that the MSA had little effect on cigarette advertising in magazines. In 2000, the tobacco industry spent nearly \$60 million on advertising in youth-oriented magazines, and advertisements for the three most popular youth brands reached 80% of young people an average of 17 times in 2000.⁴³² A Massachusetts study found that cigarette advertising in magazines with high youth readership increased 33% after the MSA,⁴³³ and another study reported that the United States Smokeless Tobacco Company (USST) increased advertising in magazines with high youth readership by 74% from 1998 to 2001 and that nearly half the company's advertising was in youth-oriented magazines.⁴³⁴ In 2002, a California judge fined R.J. Reynolds Tobacco Company \$20 million for advertising in magazines with high youth readership in violation of the state tobacco settlement agreement.⁴³⁵ The promotion of televised sporting and entertainment events heavily expose youth to tobacco

advertising as well.^{56,179,436} Moreover, the kinds of activities promoted by tobacco companies (often popular musical and sporting events) and the effort to associate smoking with maturity, glamour, and self-confidence have a strong appeal to youth. In a 2005 national survey, 81% of youth smokers aged 12–17 preferred Marlboro, Camel, or Newport, the three most heavily advertised brands. Marlboro, the most heavily advertised, was used by 48% of youth, and 40% of smokers over the age of 25.^{436a} Teens have been shown to be three times more sensitive to cigarette advertising than adults.⁴³⁷ One study reported that teens were more likely to be influenced to smoke by tobacco advertising than by peer pressure,⁴³⁸ and another showed that receptivity to advertising was associated with smoking initiation. The biggest impact comes from influencing nonsusceptible youth to become susceptible to smoking.⁴³⁹

After the Joe Camel cartoon character was introduced in 1988, Camel's share of the adolescent cigarette market increased from 2% in 1978–1980, to 8% in 1989, to more than 13% in 1993.^{179,440} One study found that the cartoon camel was as familiar to six-year-old children as Mickey Mouse's silhouette.⁴⁴¹ The Joe Camel campaign was one of the tobacco industry's most heavily criticized advertising campaigns, and there was increased pressure to drop the campaign after the Federal Trade Commission (FTC) filed suit against the company in May of 1997, alleging that the Joe Camel symbol enticed children to smoke. In July of 1997, R.J. Reynolds announced that they were discontinuing Joe Camel in the United States, although they still planned to use the cartoon character for overseas advertising.⁴⁴²

Tobacco company marketing efforts have also targeted women and minorities. The uptake of smoking among women beginning in 1967 was associated with the marketing of cigarette brands specific for women.⁴⁴³ In 1990, after the Secretary of the Department of Health and Human Services, Dr. Louis Sullivan, denounced R.J. Reynolds for "slick and sinister advertising" and for "promoting a culture of cancer," the company abruptly decided to cancel the launch of Uptown, their new cigarette aimed at blacks.⁴⁴⁴ Only a month later, the same company was preparing to introduce a new cigarette aimed at young, poorly educated, blue-collar women.⁴⁴⁵ This cigarette, called Dakota, was also withdrawn after public outcry. Another campaign, called "Find Your Voice" targeted minority women, and brands such as "Rio," "Dorado," and "American Spirit" targeted Hispanics and American Indians.³⁵⁵ In 2004, R.J. Reynolds settled a lawsuit with 13 states over Reynolds' "Kool Mixx" marketing campaign, which the states alleged targeted urban minority youth in violation of the MSA.⁴⁴⁶ In 2006, R.J. Reynolds settled a lawsuit with 38 states over their candy, fruit, and alcohol flavored cigarettes. The company agreed to a U.S. ban and to restrictions on marketing flavored cigarettes in the future. These examples suggest that new tobacco product introductions aimed at young and minority populations are likely to be aggressively attacked as exploitative.

Several studies have looked at the effect of tobacco advertising on smoking, particularly among young people. The 1994 Surgeon General's Report concluded that "cigarette advertising appears to increase young people's risk of smoking by affecting their perceptions of the pervasiveness, image, and function of smoking."¹⁷⁹ Similarly, an IOM report concluded that the preponderance of evidence suggests that tobacco marketing encourages young people to smoke.³⁵⁰ The FDA reviewed the evidence when developing the case for regulation of tobacco, and concluded that cigarette advertising is causally related to the prevalence of smoking among young people.⁴¹⁸ The U.K. Scientific Committee on Tobacco and Health also concluded that tobacco advertising and promotion influences young people to begin smoking.⁴⁴⁸

Smoking in the movies has also recently emerged as a tobacco control issue. Several studies have now shown that exposure to smoking in the movies increases youth initiation. For example, one study showed that students in the highest quartile of exposure were 2.72 times more likely to begin smoking compared with students in the lowest quartile of exposure. The effect of exposure was stronger in adolescents with nonsmoking parents. The authors estimated that 52% of smoking initiation could be attributed to exposure to smoking in the movies.⁴⁴⁹ Another study found that susceptibility to begin smoking increased with higher levels of exposure to smoking in the

movies.⁴⁵⁰ In a recent cohort study, one-third of adolescent never-smokers nominated as their favorite film stars those who smoked on-screen. These nominations independently predicted later smoking.⁴⁵¹ Although smoking in the United States has declined since the 1950s, and smoking in the movies likewise decreased from 1950 (10.7 incidents per hour) to 1980–1982 (4.9 incidents per hour), it rebounded to 1950 levels in 2002 (10.9 incidents per hour).⁴⁵² Other studies have shown that smoking is frequent even in G or PG movies.⁴⁵³

Tobacco advertising in magazines can also limit the information provided on the health effects of smoking. For example, many women rely on magazines for information about health. Yet studies have found little coverage of the serious consequences of smoking in these magazines. A recent study examined health and smoking-related coverage during 2001–2002 in 15 women's magazines (10 of which were assessed in previous studies), and found that there were only 55 antismoking articles, compared with 726 on nutrition, 424 on ob/gyn issues, 347 on fitness, 340 on diet, and 268 on mental health.⁴⁵⁴ Only six (out of 4000) articles focused primarily on lung cancer, and two of these did not address the importance of avoiding cigarettes in order to prevent lung cancer. Over the same time period, there were 176 prosmoking mentions (half of which were photographs or illustrations) and three magazines had more prosmoking mentions than antismoking messages. There were 6.4 pages of cigarette advertising for each page of antismoking ads.⁴⁵⁴

In the United States, the federal Public Health Cigarette Smoking Act of 1969 preempted most state advertising restrictions.⁴⁵⁵ In addition, as of 1998, 17 states preempted localities from passing their own laws to restrict the marketing of tobacco products.⁴⁵⁶ As of June 1997, only nine states had laws that restrict the advertising of tobacco products. These laws included restricted advertising on lottery tickets or video games, prohibited advertising within certain distances of schools, and required warning labels on billboards advertising smokeless tobacco products.^{418,455} In August 1996, the FDA issued a rule that all tobacco advertising must be in black-and-white text only except when it appears in adult publications or in locations inaccessible to young people. Billboards were banned within 1000 feet of schools and playgrounds; events, teams, and entries could be sponsored only in the corporate name, not a brand name; brand name nontobacco items, such as t-shirts, were banned; gifts and items provided in exchange for proof of purchase were banned; and the use of nontobacco names on tobacco items was banned.⁴¹⁸ The FDA rule was challenged in federal court and, in 2000, the Supreme Court ruled that the FDA did not have the authority to regulate tobacco.⁴¹⁹ In 2004, a bill giving FDA the authority to regulate tobacco failed in conference committee; a similar bill was introduced in early 2007.

Some other countries have very broad advertising restrictions.³⁷⁰ For example, Canada passed legislation in 1988 to ban all tobacco advertising in newspapers and magazines published in Canada as well as all point-of-sale tobacco advertising and promotion. In Europe a number of countries have enacted similar restrictions on the use of graphics in tobacco advertising. As of late 2004, at least 12 countries had implemented a total ban on tobacco advertising and marketing.⁴⁵⁷

Other Interventions Warning Labels

Warning labels can have an impact on consumers if they take into account consumers' previous knowledge of the risks, levels of education, and reading ability. To be effective, labels need to stand out, have a visual impact, be visible, and be content specific (not give just general information).³⁷⁰ There is some evidence that warning labels can have an impact on smoking behavior. In South Africa, tobacco consumption decreased 15% in three years after new warning labels were introduced. Stronger warning labels in Australia appear to have a larger effect on quitting behavior than the old labels, and half of Canadian smokers said that the warning labels had contributed to their desire to quit or to cut back on their consumption.³⁷⁰

Industry Lawsuits

Historically, individual lawsuits against the tobacco industry have not been successful. However, more recently there have been successful

individual suits against the tobacco industry.^{458–462} There have also been successful class action lawsuits against the tobacco industry. One of the earliest successful class action lawsuits involved flight attendants. This lawsuit, brought in 1991, sought damages for diseases in and deaths of flight attendants caused by exposure to SHS in airplanes. The settlement included waivers of all statutes of limitations, thus enabling flight attendants whose exposure happened decades earlier to pursue their claims. It also included the establishment of the Flight Attendant Medical Research Institute as a not-for-profit medical research foundation with funding by the tobacco industry of \$300 million.⁴⁶³ Another class action lawsuit that originated in Florida, sought damages against cigarette companies and industry organizations for alleged smoking-related injuries. Initially the class action lawsuit verdict awarded \$12.7 million in compensatory damages to three individual plaintiffs, and \$145 billion in punitive damages.⁴⁶⁴ In May of 2003, the Florida appeals court threw out the verdict, concluding that each smoker's claim was too unique and individualized to be tried collectively in a class action suit. In 2006 this finding was upheld by the Florida Supreme Court, but the court also ruled that the companies are negligent and their products are defective, unreasonably dangerous and addictive. In their individual cases, the plaintiffs must only prove that smoking caused their disease.⁴⁶⁵ Another class action lawsuit claimed that Philip Morris had defrauded "Lights" smokers by suggesting that light cigarettes were less hazardous than full-flavor cigarettes. In 2003, the Madison County (Illinois) Circuit Court awarded compensatory and punitive damages totaling \$10.1 billion. The Illinois Supreme Court overturned this verdict and U.S. Supreme Court let that ruling stand. Lawsuits in other states over "light" cigarettes are still pending.^{465,466} States have also sued the tobacco companies and some have filed class-action lawsuits over light cigarettes.⁴⁶⁷ In 1994, Mississippi became the first state to sue the tobacco industry for medical expenses incurred by Medicaid for the treatment of tobacco-related illnesses. In January 1998, the industry had settled with three states (Florida, Mississippi, and Texas) for amounts ranging from \$3.4 billion to \$15.3 billion. Minnesota also reached a settlement with the tobacco industry.

Under the MSA in 1997, the remaining states settled with 11 tobacco companies. Under the MSA, the companies agreed to pay \$246 billion over 25 years. Other provisions of the MSA included the significant marketing and minors' access restrictions mentioned earlier, prohibited the industry from supporting diversion of settlement funds to nonhealth use, restricted the tobacco industry from lobbying against restrictions of advertising on or in school grounds, prohibited new challenges by the industry to state and local tobacco control laws enacted before June 1, 1998. The MSA also required the tobacco industry to contribute \$25 million annually for 10 years to support the American Legacy Foundation, to contribute \$1.45 billion over five years to support the National Public Education Fund for a national sustained advertising and education program to counter youth tobacco use, and then to contribute \$300 million annually to the fund so long as the participating companies hold 99.05% of the market.³³³ As of early 2007, because of market share losses, there will be no further annual payments to the fund.

In 1999, the Department of Justice sued the largest tobacco companies under the Racketeer Influenced Corrupt Organization Act (RICO), charging the tobacco companies with conspiring to conceal the health risks and addictive powers of cigarettes. The government sought the "disgorgement" of \$280 billion in "ill gotten gains" that the industry has received by selling cigarettes to people who got addicted before the age of 21 (since the enactment of the act in 1970). The judge found the defendants guilty in late 2006, but said that a district court ruling prevented her from imposing any penalties. As of early 2007, the tobacco industry had announced their intention to appeal the ruling.^{468,468a}

► TOBACCO ECONOMICS

In 2003, consumers in the United States spent nearly \$87 billion on tobacco products, equal to 1.1% of personal disposable income.^{240,469}

One recent study estimated that smoking is associated with lower net worth, even after adjusting for a variety of demographic factors. Heavy smokers had a reduction in net worth of more than \$8300 and light smokers had a reduction of \$2000, compared to nonsmokers. Each adult year of smoking was associated with a 4% reduction in net worth, and the author concluded that smokers appear to pay for tobacco expenditures out of income that is saved by nonsmokers. The author also concluded that a reduction in smoking would boost wealth, especially among the poor.⁴⁷⁰

The industry directly accounted for about 260,000 jobs in 1993 (tobacco growing, warehousing, manufacturing, and wholesaling).³³³ In 2005, U.S. tobacco farmers produced an estimated 647 million pounds of tobacco leaf with a value of 1.1 billion, and in 2005 U.S. cigarette manufacturers produced an estimated 496 billion packs of cigarettes, 16% of which were exported.²⁴⁰ In monetary value, domestic tobacco exports (cigarettes, other manufactured tobacco products, and unmanufactured tobacco) accounted for 0.1% of the total export earnings of the United States in 2004.^{471,471a} Cigarette production in the United States is highly concentrated; four major cigarette manufacturers produce nearly all cigarettes in this country.²⁴⁰

In the twentieth century, the importance of tobacco to the overall U.S. economy declined, although its regional and local importance remains high. A 1996 study that looked at the impact of tobacco at the regional level estimated that eliminating spending on tobacco products would have led to 300,000 fewer jobs in the Southeast, but would have increased jobs in all other regions by about the same number. They further estimated that by 2000, the loss of jobs in the tobacco region would fall to about 220,000 while the net impact nationally would be an increase of 133,000 jobs.⁴⁷² Similarly, a USDA report found that the large declines in tobacco production in the 1980s had a relatively minor impact on the macroeconomy of the major tobacco-growing regions.⁴⁷³ This was attributed to the relatively small share of tobacco (less than 1% of total income) in these regional economies.

Until late 2004, a tobacco price support program that was first introduced during the Depression regulated both the number of tobacco producers and the quantity of tobacco produced through a complex system of quotas. This program led to a higher price of tobacco for farmers. In 2003, the estimated gross income per acre for tobacco was \$3851, compared with \$232 for corn and \$242 for soybeans (U.S. Department of Agriculture, unpublished data, 2003). Although the price support program increased prices only marginally (0.52%), it provided a political constituency of quota owners and tobacco farmers who opposed tobacco control interventions. Studies of the impact of the farm support program suggested that the overall impact of the program on tobacco control was probably negative.^{333,474} In 2004, Congress passed a law that eliminated the price support system and provided a \$10.14 billion payout (over 10 years) to tobacco farmers and quota holders; the cost of the buyout will be paid by the tobacco industry.⁴⁷⁵

Trade Policies

In 2003, 70% of tobacco production occurred in six countries: China, India, the United States, Brazil, Indonesia, and Turkey, with most being used to make cigarettes.⁴⁷⁶ Cigarette production largely occurs in China, the United States, and the European Union. World trade in cigarettes has been continually expanding, and U.S. companies increased exports from 24.3 billion cigarettes per year in the late 1960s to 240 billion in 1996; exports then declined to 111 billion pieces in 2006.²⁴⁰ In the 1990s, 30% of U.S. cigarettes were exported. This amount probably would have been higher except for trade policies that protected domestic tobacco growers and producers. In addition, the laws that apply to domestic cigarettes, such as warning labels and advertising restrictions, do not apply to exported cigarettes. U.S. policies and programs, particularly the Trade Act of 1974, have helped growers and producers expand into foreign markets. The threat of retaliatory trade sanctions under this act successfully opened some foreign markets to U.S. manufacturers. Under the Doggett Amendment of 1998 and guidelines distributed by the Clinton

administration, the U.S. government stopped promoting the sale or export of tobacco or tobacco products or seeking the removal of nondiscriminatory restrictions on the marketing of tobacco or tobacco products (discriminatory practices could still be challenged). U.S. diplomats were also encouraged to assist and promote tobacco control efforts in host countries.³³³ However, adherence has varied over time.

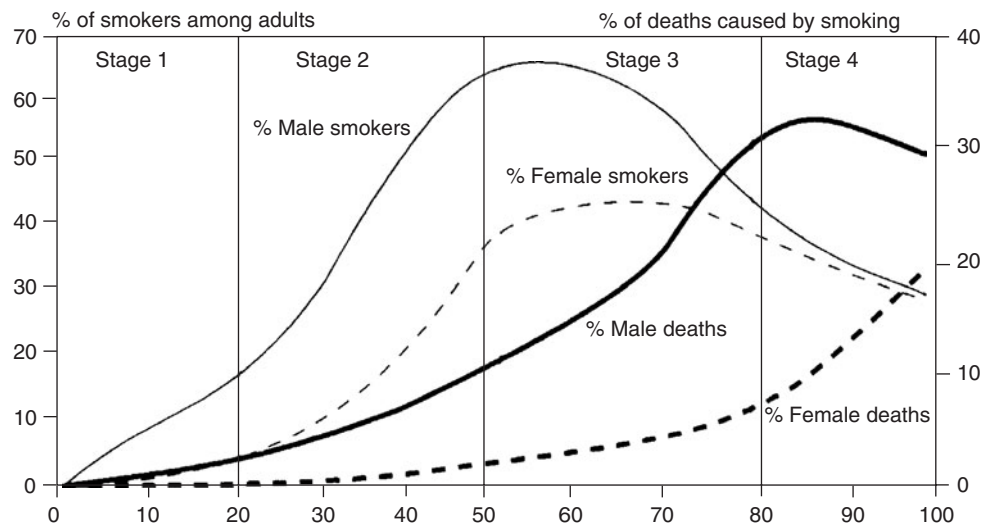

► SMOKING AND THE WORKPLACE

Employee smoking is very costly. Smokers increase absenteeism, health insurance and life insurance costs and claims, worker's compensation payments and occupational health awards, accidents and fires (and related insurance costs), property damage (and related insurance costs), cleaning and maintenance costs, and illness and discomfort among nonsmokers exposed to SHS. Smokers also take more breaks, averaging 18 days per year on breaks⁴⁷⁷ and are less productive. One study reported that former smokers are 4.5% more productive than current smokers.⁴⁷⁸ Former smokers also have less absenteeism than current smokers, but more than never-smokers. Among former smokers, absenteeism decreases with years of cessation.⁴⁷⁸ Male smokers are absent four days more than male nonsmokers each year (female smokers miss two more days).⁴⁷⁹ Male smokers incur \$15,800 and female smokers incur \$17,500 (in 2002 dollars) more in lifetime medical expenses than nonsmokers.⁴⁸⁰ The economic cost of smoking for the United States, including direct medical costs and loss of productivity from smoking-related deaths, is about \$167 billion per year.⁸ The health-care expenditures attributable to smoking were \$75 billion in 1998, or 7.1% of direct medical expenditures for the United States.²⁰ It is estimated that a 1% reduction in health care costs for businesses could increase retained profits by 5%.⁴⁸¹

► INTERNATIONAL PERSPECTIVE ON TOBACCO

Tobacco use is a major preventable cause of death worldwide. The World Health Organization (WHO) estimates that there are about 1.2 billion smokers in the world.⁴⁸² Most of these smokers are in developing countries (800 million), and are men (1 billion). Smoking prevalence for men ranges from 29% in the Africa region to 61% in the Western Pacific region. Prevalence for women ranges from 5% in the Southeast Asia region to 21% in the Region of the Americas (Fig. 54-6). Smoking prevalence varies by level of economic development: for men the prevalence is 34% in developed countries, 50% in developing countries, and 54% in transitional countries. For women the respective percentages are 21%, 7%, and 14%.⁴⁸² For men, prevalence was highest in Kenya (67%), Republic of Korea (65%) and the Russian Federation (63%) and lowest in Sweden (17%). For women, prevalence was highest in Argentina (34%), Norway (32%), Kenya (32%), Denmark and Germany (30%) and lowest in the United Arab Emirates (1%), Thailand (2%), Singapore (3%), China (4%), and Egypt (5%).⁴⁸³ It should be noted, however, that South Asia has high bidi (a type of hand-rolled cigarette) prevalence (21% for men and 4% for women). Low-income and middle-income countries, have four-fifths of the world's population, and 82% of the world's smokers.³⁷⁰ Current cigarette smoking among youth aged 13–15 years, according to a survey that assessed 224 sites in 118 countries and 1.7 million students was 9.8% in the Africa region, 18.4% in the Americas region, 4.1% in the Eastern Mediterranean region, 16.2% in the European region, 4.5% in the Southeast Asia region, and 11.8% in the Pacific region.⁴⁸⁴ Current use of any tobacco product by youth aged 13–15 years, according to a survey conducted in 75 sites in 43 countries and the Gaza Strip/West Bank, ranges from 3% (Goa in India) to 63% (Nagaland in India). Current cigarette smoking in this group ranges from less than 1% (Goa in India) to 40% (Coquimbo in Chile), with nearly 25% of students who smoke having smoked their first cigarette before age 10.⁴⁸⁵ Other findings included a lack of gender differences in tobacco use among youth and a high rate of use of tobacco products other than cigarettes.⁴⁸⁶ From

Figure 54-6. A model of the cigarette epidemic. (Source: Lopez AD, Collinshaw NE, Piha T. A descriptive model of the cigarette epidemic in developing countries. *Tobacco Control*. 1994;3:242–7. Reproduced with permission from the BMJ Publishing Group.)

1970–1972 to 1990–1992, per capita cigarette consumption decreased in the Americas (an average annual decrease of 1.5%), remained unchanged in Europe, and increased in Africa (average annual increase of 1.2%), the eastern Mediterranean (1.4%), Southeast Asia (1.8%), and the Western Pacific (3%). China is a good example of the size and scope of the smoking problem because it is the largest producer and consumer of cigarettes in the world. An estimated 300 million Chinese smoke (53% of men and 3% of women),⁴⁸⁷ the same number as in all the developed countries combined. By 2025, an estimated 2 million Chinese men will die annually from smoking.⁴⁸⁸

Before the middle of this century, very few developing countries either produced tobacco or had significant consumption of manufactured cigarettes. In the late 1950s, cigarette manufacturers sought to establish new markets in the developing countries. These countries, with more than half of the world's population, who may be unaware of the health problems associated with tobacco use, represented a huge, potentially untapped resource for tobacco cultivation, cigarette manufacture, and cigarette marketing. In 1995, 6 low income and 18 lower middle income countries were classified as either net (consumes more tobacco than they produce) or full (does not produce any tobacco but consumes it) importers of tobacco. In these countries reduced expenditures on tobacco imports could have impacts on economic development through improving and increasing trade balance and foreign exchange reserves to fund other essential development projects.^{370,489,487}

Currently, tobacco is grown in more than 100 countries, including 80 that are developing. From 1975–1998, production in developed countries decreased by 31%, and production in developing countries increased 128%. Asia increased its share of world tobacco production from 40% to 60%. The four major tobacco producing countries are China, the United States, India, and Brazil. These four countries account for about two-thirds of world production. The top 20 countries account for 90% of the world's production. However, in only three countries does the employment as a percentage of the total labor force exceed 1% (Malawi at 2.03%, Turkey at 1.29%, and the Philippines at 1.24%). The average across the 28 highest countries is 0.63%.³⁷⁰ Export earnings from tobacco exceed 1% of total export earnings in nine countries. Two countries are particularly dependent on tobacco exports as a major source of earnings: in 1998, 61% and 23% of export earnings came from tobacco for Malawi and Zimbabwe respectively.³⁷⁰ Thus, even very stringent tobacco control policies would likely have minimal negative long-term economic impact, with the largest effect in those few countries that earn a significant share of foreign earnings from tobacco such as Malawi and Zimbabwe.³⁷⁰

Trade liberalization was estimated to have increased global cigarette consumption by 5%.³⁷⁰ Another study calculated that markets opening in Japan, Taiwan, South Korea, and Thailand increased cigarette consumption by 10%. Two factors are thought to account for this: first, opening the markets decreased the price of both domestic and imported cigarettes, and second, cigarette advertising increased. For example, in Japan, cigarette advertising by U.S. companies doubled, and the domestic companies responded with their own increased advertising.³⁷⁰

Many tobacco-producing countries are poor and lack the resources to grow or import sufficient quantities of food for their populations, yet they divert agricultural land that could be used for growing staple crops such as sorghum and maize to tobacco cultivation. They may perceive tobacco production as (a) a relatively simple mechanism for raising substantial revenue from taxation of tobacco products, (b) an easy way to generate the foreign exchange necessary to buy commodities from abroad and to improve their balance of trade, and (c) a significant source of rural employment and wage production.⁴⁹⁰

The short-run economic advantages of tobacco growth and consumption come at a high cost. Most obvious are the direct, well-documented health problems associated with tobacco use. Indirect effects of tobacco production include destruction of agricultural lands and forests and improper use of insecticides by rural farmers. According to United Nations sources, the deforestation problem in many developing countries may soon become a "poor man's energy crisis."⁴⁹¹ This problem is traceable in large part to the wood burned to flue-cure many varieties of tobacco at high temperatures. Tobacco farmers in developing countries, most of whom depend on wood as their sole source of energy, use the trees from approximately 2 hectares for each ton of tobacco cured, equivalent to two trees for every 300 cigarettes, or 15 packs of cigarettes, produced.⁴⁹² A direct result of deforestation is soil erosion, which in hilly rural areas may lead to silt-filled rivers and dams during the rainy season and denuded croplands during growing seasons. In addition, because tobacco grows well in sandy soils and many developing countries are located in semiarid lands, tobacco is often grown on agricultural fringe land that borders deserts. As trees in nearby forests are cut down to fuel the curing process, desertification is accelerated and tobacco farmers are forced to move into other, less arid regions. Thus, cultivation of tobacco displaces staple food crops, leading to lost food production.⁴⁹¹

Further, the lack of adequate education among rural area tobacco farmers on the proper use of modern insecticides often leads to their indiscriminate dispersal in lakes and rivers. The resultant pollution

endangers water sources of rural villagers and surrounding wildlife. Failure to use the gloves and protective garments needed to limit exposure to toxic chemicals in insecticides also increases rural tobacco farmers' long-term risk of occupationally related diseases such as skin, lung, and bladder cancer.⁴⁹²

The major health consequences associated with smoking (e.g., cancer, heart disease, and COPD), which are well established in developed countries, are becoming increasingly prevalent in the developing world. In 1995, an estimated 1.4 million men in developed countries and 1.6 million men in developing countries (more than half from China) died from smoking-related diseases. Tobacco use also caused an estimated 475,000 deaths among women in developed countries, and an estimated 250,000 deaths among women in developing countries (including 20,000 to 30,000 deaths from smokeless tobacco) in 1995. WHO estimates that smoking caused 3.8 million deaths globally in 1995 (7% of all deaths).⁴⁸⁹ It is estimated that China will see a dramatic increase in lung cancer deaths, from 30,000 per year in 1975 to 900,000 per year by 2025, and total tobacco deaths will increase to one million before 2010, and to two million by 2025. Similarly, it is estimated that 80 million Indian males currently aged 0–34 will be killed by tobacco. Tobacco is expected to cause 500,000 million deaths among smokers alive today, and before 2020, deaths will average 8–10 million per year or 12% of all deaths. Most of these deaths will be in developing countries.^{370,489} It has also been estimated that tobacco will kill a billion people in the twenty-first century (10 times more than in the twentieth century).³⁷⁰

There are disturbing parallels between the advertising and promotion techniques used to sell cigarette smoking in the United States and other developed countries in the early twentieth century through the 1920s and the current efforts to promote smoking as a pleasurable status symbol in developing countries. There is also a tragic difference. In the 1920s, producers, consumers, and governments did not know about the adverse health effects of tobacco use. Today, the scientific evidence is incontrovertible. In 1986, the World Health Assembly unanimously adopted a resolution for member states to consider a comprehensive national tobacco control strategy containing nine elements: reducing exposure to SHS; reducing initiation by young people; reducing smoking among health personnel; eliminating those socioeconomic, behavioral, and other incentives that maintain and promote tobacco use; placing health warnings on all tobacco products; establishing educational and cessation programs; monitoring tobacco use and tobacco-related diseases, and the effectiveness of interventions; promoting viable economic alternatives to tobacco production; and establishing a national focal point to coordinate all these activities.⁴⁸⁹

In 1990, the World Health Assembly passed another resolution urging all member states to implement multisectoral comprehensive tobacco control strategies that contain the nine elements previously listed plus legislative action to protect from SHS in indoor workplaces, enclosed public places, and public transport, with special attention to risk groups such as pregnant women and children; progressive financial measures to discourage the use of tobacco; and progressive restrictions and concerted actions to eventually eliminate all direct and indirect advertising, promotion, and sponsorship concerning tobacco.⁴⁸⁹

In 1992, the World Bank developed a formal five-part tobacco policy. (a) World Bank activities in the health sector discourage the use of tobacco. (b) The World Bank does not lend directly for, invest in, or guarantee investments or loans for tobacco production, processing, or marketing. For those countries where tobacco constitutes more than 10% of exports, the World Bank is more flexible, but works toward helping these countries diversify. (c) The World Bank does not lend indirectly for tobacco production activities, to the extent practical. (d) Unmanufactured and manufactured tobacco, tobacco-processing machinery and equipment, and related services are not included among imports financed with World Bank loans. (e) Tobacco and tobacco-related producer or consumer imports may be exempt from borrowers' agreements with the World Bank that seek to liberalize trade and reduce tariff levels.⁴⁹³

In 1996, the World Health Assembly passed a third resolution requesting the director-general to initiate the development of an International Framework Convention for tobacco control (FCTC).⁴⁹⁴ The FCTC became a top priority for WHO in 1998, due to concern for the growing disease burden from tobacco worldwide. In 1999, the World Health Assembly established an intergovernmental negotiating body to draft and negotiate the FCTC. This negotiating body met six times from October 2000 to March 2003. The World Health Assembly adopted the FCTC in 2003 and within the one-year time frame provided, 167 countries (including the United States) signed the treaty. The treaty came into force for ratifying countries in February 2005, after the required 40 countries had ratified it. As of early 2007, the United States had not yet ratified the treaty. The FCTC calls on countries to:

1. Adopt a nonpreemption clause, making FCTC a floor, not a ceiling for action.
2. Develop and implement a comprehensive, multisectoral national tobacco control strategy and establish focal points for tobacco control; cooperate, as appropriate, with other parties in developing appropriate policies; protect public health policies from commercial and other vested interests of the tobacco industry in accordance with national law.
3. Report on rates of taxation and trends in tobacco consumption.
4. Adopt "in areas of existing national jurisdiction as determined by national law" effective measures to protect from SHS exposure in indoor workplaces, public transport, and indoor public places. Promote adoption of these measures at other jurisdictional levels.
5. Adopt effective measures for the testing of tobacco products and for regulation "where approved by competent national authorities."
6. In accordance with national law, adopt and implement measures to disclose to government authorities "information about the contents and emissions of tobacco products."
7. Adopt measures to promote access to educational programs on the health risks of tobacco use and SHS, information about the tobacco industry, training on tobacco control, and involvement of public and private organizations in tobacco control programs.
8. Develop and disseminate guidelines and promote cessation of tobacco use; implement cessation programs in a variety of environments, including national health and education programs and health care facilities; collaborate with other parties to facilitate the accessibility and affordability of treatment, including pharmaceutical products.
9. Adopt and implement measures at the appropriate government level to prohibit sales of tobacco to "persons under the age set by domestic law, national law, or eighteen."
10. Initiate and coordinate research; promote research that addresses the consequences of tobacco consumption and exposure "as well as research for identification of alternative crops."
11. Establish, as appropriate, programs for surveillance of tobacco consumption and exposure.
12. Establish a national system for epidemiologic surveillance of tobacco consumption.
13. Subject to national law, "promote and facilitate exchange of publicly available information relevant to the convention; endeavor to establish and maintain an updated database of laws and regulations on tobacco control."⁴⁹⁵

In the 1990s, about 13 high-income countries and 30 low-income countries had laws prohibiting the sale of cigarettes to minors, 11 high-income countries and 6 low-income countries banned vending machines, and 14 high-income and 15 low-income countries had minimum age restrictions for purchase of cigarettes.³⁷⁰ However, few countries effectively enforced these laws. Many jurisdictions also had laws that banned or restricted smoking in public places, workplaces, and transit vehicles. For example, 24 high-income and 74 low-income

countries required smoke-free public places, 9 high-income and 19 low-income countries required smoke-free restaurants, 9 high-income and 11 low-income countries required smoke-free cafes, 18 high-income and 32 low-income countries had workplace smoking restrictions, and 20 high-income and 23 low-income countries required smoke-free health establishments.³⁷⁰ Enforcement was again the issue. Some 75 countries have at least some type of advertising restriction,⁴⁸⁷ but the number with comprehensive bans is much lower,⁴⁸⁹ and such restrictions are frequently circumvented unless they are comprehensive. For example, after a 1976 law in France banned tobacco advertising, it was replaced by advertisements for matches and lighters with the tobacco brand names and logos, until a law was passed banning both direct and indirect advertising.

By the end of the 1990s, about 137 countries required health warnings to appear on tobacco product packages. However, in most countries, the warnings were small and ineffective. By the mid-1990s, a number of countries had adopted more stringent warnings, including more direct statements of risk, multiple messages, and large and rotating messages. Beginning in 2000, some countries started putting graphic pictures on warning labels (Canada, Brazil, Norway, Thailand, and the European Union).⁴⁹⁶

In 2002, taxes on cigarettes in the United States ranged from 17% of price (lowest state) to 38% of price (highest state) (Table 54-5). Prices also include \$0.46 per pack to cover the MSA. If this cost were also considered a tax, the percentage of price in New York would be 47% and in Kentucky 31%. In comparison, in Europe, New Zealand, Australia, and Hong Kong, tax as a percentage of price ranged from 52% (Hong Kong) to 82% (Denmark).⁴⁹⁷ A number of countries use part of the revenue generated to operate their comprehensive tobacco control programs.⁴⁸⁹

Many countries have had difficulty implementing comprehensive tobacco control measures. However, Finland, Iceland, Norway, Portugal, and Singapore have comprehensive tobacco control policies developed since the 1970s. Australia, New Zealand, Sweden, Poland, and Thailand have more recently implemented tobacco control programs. One study used multiple regression analysis to evaluate the effectiveness of advertising restrictions, price, and income on tobacco consumption in 22 countries from 1960 to 1986.⁴⁹⁸ Above threshold levels, both advertising restrictions and higher prices were effective in decreasing tobacco consumption. Moreover, programs that included high prices, comprehensive bans on advertising, and stringent health warnings decreased tobacco consumption most. This analysis estimated that banning tobacco advertising, requiring strong and varied health warnings on packages, and implementing a 36% increase in real price would decrease tobacco consumption by 13.5%.

In 2006, New York City mayor Bloomberg announced a \$125M initiative to reduce tobacco use in low and middle income countries with a particular focus on China, India, Indonesia, the Russian Federation and Bangladesh (which have half the world's smokers).^{498a} However, powerful economic forces will continue to militate against a strong tobacco control policy in developing countries. Only a concerted effort by international organizations (i.e., the WHO, the International Monetary Fund, the Food and Agriculture Organization, UNICEF, and NGOs) is likely to be effective in helping developing countries assign a high priority to tobacco prevention and control.

► CHALLENGES IN TOBACCO USE PREVENTION AND CONTROL

Despite considerable progress, smoking remains the largest cause of preventable death in the United States and most of the industrialized world, and it is rapidly becoming a major cause of death in developing countries as well. Lessons from the considerable progress achieved in tobacco use prevention and control during the past 25 years can help us successfully confront the remaining challenges. The growth of knowledge about the adverse health effects of tobacco has been substantial. Public education campaigns have helped to translate scientific knowledge into improved public awareness

TABLE 54-5. AVERAGE RETAIL CIGARETTE PRICE AND TOTAL TAXES PER PACK (U.S./DOLLARS/PACK OF 20), SELECTED INDUSTRIAL COUNTRIES, JUNE 17, 2002

Country	Price	Tax Incidence
Norway	\$7.56	79.2%
United Kingdom	\$6.33	79.5%
United States (Highest-NY)	\$5.32	38.4% ^a
Canada (Highest-Saskatchewan)	\$4.76	77.3%
Ireland	\$4.46	79.0%
Australia	\$4.02	68.9%
Hong Kong	\$3.97	51.9%
New Zealand	\$3.88	74.5%
Canada (sales-weighted average) ^c	\$3.80	71.6%
Denmark	\$3.77	81.7%
Sweden	\$3.64	70.5%
Finland	\$3.53	79.0%
Canada (Lowest-Ontario)	\$3.48	69.0%
United States (Lowest-Kentucky)	\$3.27	16.9% ^b

Nonsmokers Rights Association Smoking and Health Action Foundation.

All figures given in U.S. dollars, for equivalent of 20-cigarette pack in most popular price category.

Tax incidence refers to the portion of the total retail price made up of applicable taxes and fees, including excise, sales, VAT Exchange rates as of May 31st, 2002. European Union. "Tax Burden on Tobacco"; U.S., budget/tax documents; Canada, Australia, New Zealand, Hong Kong, Norway, Tobacco Journal international.

^aNote that U.S. prices include approx. \$0.46 per pack to cover the cost of the November 1998 settlement with State Attorneys General. If this amount were considered a tax, tax incidence in New York would be 47%. No municipal taxes are included in this tabulation.

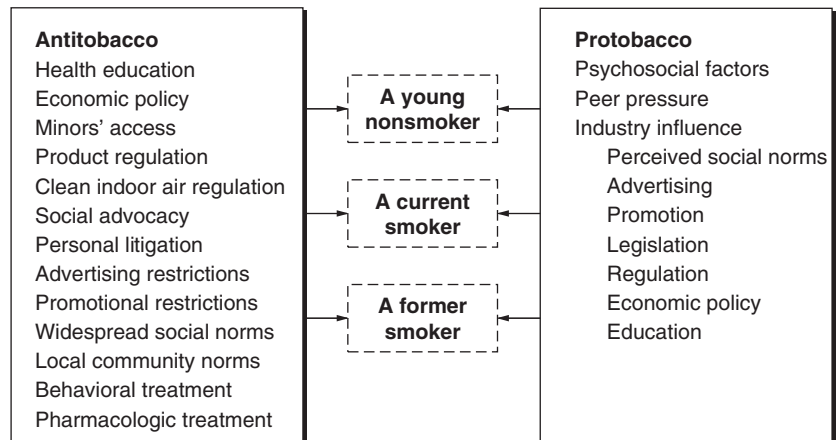

^bU.S. prices include approx. \$0.46 per pack to cover the cost of the November 1998 settlement with State Attorneys General. If this amount were considered a tax, tax incidence in Kentucky would be 31%.

^cCalculated by provincial proportion of total 2001 cigarette sales. Note that Canadian prices include June 17th, 2002 tax increases.

of some smoking-caused problems, such as lung cancer and cardiovascular disease, but awareness of other smoking-caused cancers, COPD, and reproductive effects is still limited. SHS is increasingly appreciated as a health problem: By 1992, 97% of nonsmokers and 79% of current smokers agreed that exposure to SHS was harmful to healthy adults.⁴⁹⁹ Smokers are concerned that their addiction is likely to adversely affect their health. In the United States, more than half of all persons who have ever smoked have quit,²⁴⁵ and most continuing smokers have tried.⁵⁶ Market responses to consumer concerns have included the filter cigarette, substantial reductions in average tar and nicotine content, and new delivery systems. However, because these innovations were perceived as "safer," it appears that smokers concerned about health issues switched to such products rather than quit tobacco use entirely¹¹⁹ and derived little or none of the purported health benefit due to compensation (e.g., increased number of cigarettes smoked, increased depth of inhalation, smoking more of the cigarette, vent blocking). It is imperative that tobacco users realize there is no safe way to use tobacco and they need to quit.

Tobacco companies spend huge sums to advertise and promote cigarettes (\$13.1 billion in 2005).²⁵⁹ Although the effect of this

Figure 54-7: Influences on the decision to use tobacco. (Source: *Tobacco and Situation Outlook Report, 2004;1986–2000 Surgeon General's Report.*)

activity on overall cigarette consumption is difficult to assess, advertising and promotion likely make smoking more attractive to youth, make continuing smokers less motivated to attempt cessation, and perhaps increase recidivism by providing omnipresent cues that smoking is fun and relaxing and contributes to conviviality (Fig. 54-7). It also appears that advertising was specifically increased to counteract tobacco prevention and control funding of comprehensive tobacco control programs.³³³ The inverse correlation between the percentage of a magazine's health articles that discuss smoking and cigarette advertising revenue as a percentage of the magazine's total advertising revenue suggests that tobacco money also affects editorial decisions.⁵⁶

Counteradvertising decreases consumption, reduces initiation, and increases cessation, even in the presence of several-fold greater brand-specific, procigarette advertising.³⁰⁹ Some data also suggest that broad bans on tobacco advertising are also effective in reducing tobacco consumption.⁵⁰⁰ From 1970 to 2002, the percentage of cigarette advertising expenditures allocated to promotions increased from 15% to 87%.²⁵⁹ Promoted cigarette sales have increased since the MSA and are higher in areas with higher cigarette taxes and areas with more comprehensive tobacco control programs.^{500a} Some of these promotional dollars sponsor sports events associated with being healthy, being fit, and being outdoors. The subliminal message is that smoking contributes to health and fitness. Other tobacco company promotional money goes to exhibitions at leading art museums, promoting the association of smoking with culture, sophistication, and artistic achievement. This support may also buy silence, or active opposition to smoking control proposals. In 1994, arts organizations in New York that had been recipients of tobacco philanthropy spoke out against an ordinance to ban smoking in public places.^{501,502}

Continuing the process of changing the social norms of acceptability of tobacco use offers the greatest promise. Nonsmoking is an accepted norm in many socially defined groups in the United States. Rapid growth of community, state, and federal legislation and administrative actions that limit or ban smoking in places of public assembly, coupled with growing and increasingly stringent public and private employer restrictions on workplace smoking, should further limit smoking opportunities and increase the likelihood of quitting. Public health agencies and preventive medicine practitioners can help accelerate social pressure to not smoke by supporting enactment of strict clean indoor air legislation and its enforcement.

Economic incentives are one of the most effective strategies to reduce cigarette consumption, prevent initiation, and increase cessation.^{309,333} Lower-income Americans, overrepresented among current smokers, are especially sensitive to price increases in tobacco products. Health and public health professionals can support initiatives to raise tobacco taxes.

Since 70% of current smokers want to quit smoking,²⁷⁴ and 42% attempt cessation each year,²⁴³ both public and private health organizations should be prepared to assist them. Health care professionals should routinely assess tobacco use and advise users to quit. Use of medication and telephone quitlines should be strongly encouraged. Treatment should be fully covered under both public and private insurance.

Prevention programs have demonstrated the ability to delay smoking initiation for students in grades 6–10. However, these programs are only effective when they are reinforced by additional educational interventions and supportive community programs. Such programs could include mass media efforts that make smoking appear unattractive, socially unpopular, and sexually unappealing. Communication should also stress that tobacco is an addictive drug. The fact that tobacco use is associated with increased risk of other drug use¹⁷⁹ is a potentially powerful message for parents and youth.

With the budget deficits of the early twenty-first century, funding for tobacco control programs in states was slashed. If we are to meet the *Healthy People 2010* goal of an adult smoking prevalence of 12% and a youth smoking prevalence of 16%, substantially increased funding for comprehensive tobacco control programs that use proven policy, countermarketing, and community interventions will be required. The enactment of an increase in cigarette taxes in California and Massachusetts, with all or part of the revenues used for tobacco control and education, has led to an accelerated decrease in cigarette consumption.^{333,378} In addition, two national studies have shown that comprehensive tobacco prevention and control programs reduce cigarette consumption overall and smoking prevalence among youth, over and above the effect of any tax increase that funded the program or occurred concurrently. Comprehensive programs are needed that reduce barriers to and involve the widespread use of known effective strategies. Furthermore, new and innovative strategies, particularly that address tobacco use among youth, are also needed.

The decrease in cigarette consumption has been termed one of the greatest public health achievements of the twentieth century, but it is only half achieved.⁵⁰³ The challenge of the twenty-first century is to accelerate progress so that the morbidity, mortality, and disability caused by tobacco use no longer occurs either in the United States or internationally.

Alcohol-Related Health Problems

Brian L. Cook • Jill Liesveld

► INTRODUCTION

The abuse of alcohol is more common than any other form of drug abuse throughout the world. The consequences of alcohol use are pervasive in society. From a public health perspective, alcohol use presents a unique dilemma, referred to as the “prevention paradox.”¹ This paradox stems from the observation that health and economic consequences resulting from alcohol use are far greater due to hazardous drinking than drinking patterns that constitute a formal diagnosis of alcohol dependence.² This paradox is further complicated by findings that suggest that low to moderate levels of alcohol use may play a role in reducing mortality for certain disorders, such as cardiovascular disease.³ To better understand this paradox and the risk of alcohol use, it is helpful to stratify alcohol use and risk along a continuum. This continuum stretches from abstinence to alcohol dependence.

► CATEGORIES OF ALCOHOL USE ALONG THE DRINKING CONTINUUM

Safe (Low-Risk) Drinking

Based on the concept of a continuum of risk, some organizations have proposed guidelines for “safe” (low-risk) drinking, some of which include both the characteristics and circumstances of the drinker as well as levels of consumption. American guidelines for safe drinking generally recommend no more than 2 drinks per day for men, and 1 drink per day for nonpregnant females.⁴ Slightly higher limits are proposed by U.K. authorities.⁵

One example of safe drinking guidelines, which also include characteristics of the drinker as well as levels of consumption, is contained in the report of the Australian National Health and Medical Research Council (NHMRC).⁶ “Is there a safe level of daily consumption of alcohol for men and women?” Recommendations regarding responsible drinking behavior, in which it is recommended that responsible drinking be considered as the consumption of the least amount of alcohol that will meet an individual’s personal and social needs and in any case:

- a. that men should not exceed 4 units or 40 g of absolute alcohol per day on a regular basis, or 28 units per week; that 4–6 units per day or 28–42 units per week be considered as hazardous and that greater than 6 units per day or 42 units per week be regarded as harmful
- b. that women should not exceed 2 units or 20 g of absolute alcohol per day on a regular basis, or 14 units per week; that 2–4 units per day or 14–28 units per week be considered as hazardous and that greater than 4 units per day or 28 units per

week be regarded as harmful because of the biological differences between men and women

- c. that abstinence be promoted as highly desirable during pregnancy
- d. that persons who intend to drive, operate machinery, or undertake activities in hazardous or potentially hazardous situations should not drink
- e. that in any given situation it is difficult to say that there is an absolute safe level of consumption and thus in situations of any doubt people should not drink

In this report, a unit or standard drink was equivalent to 8–10 g of alcohol compared with Canada and the United States, where one unit or standard drink contains approximately 13.6 g of alcohol.

In essence, no level of alcohol consumption will always be safe for all individuals under all conditions. Rather, increasing levels of consumption hold a progressively increasing risk of causing either acute or chronic damage. Moreover, the level at which risk occurs and its significance are influenced by a combination of personal and environmental factors that render the individual more or less vulnerable to damage from alcohol.

Hazardous Drinking

The term “hazardous drinking” has been used to describe levels of alcohol consumption that expose the drinker to a high risk of physical complications.⁷ Under certain circumstances, relatively low levels of consumption on isolated occasions may result in damage to the individual drinker. There is evidence as well that levels of consumption far below those found in people diagnosed as alcohol dependent are linked with increased risks of adverse health consequences.^{8,9} A special case involves the survival and normal development of the fetus of the drinking pregnant woman.¹⁰ In this instance, some authorities would assert that there is no safe level of consumption, or that it may be impossible to define such a level.¹¹ As information grows on how alcohol is hazardous to health we find ourselves less secure in defining what is safe.^{12,13} Rather, alcohol use involves a continuum of risk, defined by host and environmental factors as well as by the levels of alcohol consumption.

► ALCOHOL ABUSE AND ALCOHOL DEPENDENCY DEFINITIONS

The definitions of alcohol abuse and dependency have evolved over time, and differ somewhat among various organizations (e.g., the World Health Organization (WHO), American Psychiatric Association [APA]). The WHO has recently published its 10th edition of the International Classification of Diseases (ICD-10),¹⁴ while The APA recently

published its fourth edition, text revision of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR).¹⁵ The definitions differ primarily in the number and definition of symptoms required before a diagnosis of alcohol abuse or dependency are met. The ICD-10 and DSM-IV were compared in a study by Caetano.¹⁶ The one-year prevalence rate of alcohol dependence was higher (5.5% vs. 3.9%) when ICD-10 criteria were applied as compared to the DSM-IV criteria. Predictors of meeting ICD-10 versus DSM-IV criteria were slightly different in the study, thus highlighting differences in these two criteria sets which should be considered in epidemiological research. The DSM-IV definition is most widely used in alcohol use disorder research in the United States at this time.

The DSM-IV¹⁵ defines alcohol abuse as a “maladaptive pattern of alcohol use leading to clinically significant impairment or distress, as manifested by one or more of the following, occurring within a 12-month period: (a) recurrent alcohol use resulting in failure to fulfill major role obligations at work, school, or home; (b) recurrent alcohol use in situations in which it is physically hazardous; (c) recurrent alcohol-related legal problems; (d) continued alcohol use despite having a persistent or recurrent social or interpersonal problem caused or exacerbated by the effects of alcohol.”

The DSM-IV¹⁵ defines alcohol dependence as a “maladaptive pattern of alcohol use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following occurring at any time in the same 12-month period: (a) tolerance; (b) withdrawal; (c) alcohol use in greater quantity or for a longer period than intended; (d) persistent desire or unsuccessful efforts to cut down or control alcohol use; (e) a great deal of time is spent acquiring, using, or recovering from alcohol’s effects; (f) important social, occupational, or recreational activities are given up or reduced because of alcohol use; (g) alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused by or exacerbated by alcohol use.”

In the DSM-IV¹⁵ classification, once an individual meets dependency criteria, the diagnosis of alcohol abuse should no longer be used for that individual. Course specifiers should be used to describe the individual after no criteria for dependence have been met for at least one month. The course specifiers include early full remission, early partial remission, sustained full remission, sustained partial remission, on agonist therapy, or in a controlled environment.

Several observations are important regarding the DSM-IV classification system. The DSM-IV classification emphasizes the central role that alcohol comes to play in the life of a dependent individual, not simply the physiological changes associated with heavy alcohol use. Thus, an individual can be classified as alcohol dependent without classical signs or symptoms of physical tolerance and resultant withdrawal upon abrupt discontinuation of alcohol. Also, complete abstinence is not required before the remission course specifiers can be used. If none of the seven dependence criteria symptoms are met during a period of a month or longer, a form of remission is reached which is defined as either partial or full. If continued drinking does not result in full return of three or more dependence criteria symptoms, but does cause at least one dependence symptom, the remission is considered partial. If the full dependence criteria are not met for 12 months or more, the remission category is considered sustained. The utility and predictive validity of these categories remain to be established.

► EPIDEMIOLOGY OF ALCOHOL ABUSE AND DEPENDENCY

Alcohol is regularly consumed by slightly more than half of the adult United States population. In the 2003 National Survey on Drug Use & Health (formerly called the National Household Survey on Drug Abuse [NHSDA])¹⁷ 50.1% of all Americans over age 12 reported consuming alcohol. The prevalence of past month alcohol consumption was higher for men (57.3%) than for women (43.2%). 54.4% of nonblacks and 37.9% of blacks admitted to past month use of alcohol. A total of

22 million people in the United States used alcohol in the past month in 2002 compared to 21.6 million in 2003. For those in the over age 18-year group, 62.4% of males and 46.0% of females were current drinkers. While male drinking percentage remained the same as in 2002, for females there was a 2% decrease from the 47.9% identified in 2002. Of interest is that in the age 12–17 age group, 17.1% of males and 18.3% of females were identified as current drinkers, closing the gender gap. In another study by SAMHSA using data from 2002 to 2003, 50.5% of those surveyed had a drink within the past month and 7.6% of those age 12 and over were identified with alcohol abuse or dependence.^{18,22}

Large population-based studies have demonstrated that the lifetime prevalence of alcohol use disorders (abuse and dependence) is even more common. The Epidemiologic Catchment Area study demonstrated that among community-dwelling, nontreatment seeking individuals, that the lifetime prevalence of alcohol dependency was 13.7%.¹⁹ Results from the National Comorbidity Survey (NCS) by Kessler et al. demonstrated a lifetime prevalence of alcohol abuse plus dependency of 14.6% in females and 23.5% in males.²⁰

Given these prevalence rates, a conservative estimate of the number of individuals directly affected by alcohol use disorders is at least 20–30 million in the United States at any given time. Additionally, it should be remembered that the number of individuals affected by those with alcohol use disorders through marriage and family, the worksite, and the highways is far greater than the number of individuals with alcohol use disorder.

Surveys done in health care settings present a startling example of alcohol-related costs. In a primary care outpatient setting, problem drinking rates of 8–20% are seen, and between 20–40% of patients admitted to general medical hospitals have a history of alcohol use disorders.²¹ Medical morbidity of this extent obviously translates into significant mortality. United States data from the National Center for Health Statistics indicate 85,000 deaths due to either excessive or risky drinking in the U.S., making alcohol the third leading actual cause of death in 2000.²² This estimate is considered an underestimate, as many deaths which are associated with alcohol use are not coded as such on death certificates. A review of studies across multiple nations examining alcohol-related mortality demonstrated that alcoholics lose on average more than 20 years of potential life.²³

In 1998, the estimated economic cost of alcohol abuse exceeded \$184 billion in the United States, equivalent to roughly \$638 for every man, woman and child living in the United States.²⁴ Economic costs to industry alone in the United States have been estimated at \$136 billion for 1990.²⁵ Such costs include absenteeism, sick leave, decreased worker efficiency, and employee replacement costs through workers quitting, being fired, or dying prematurely.

These summary statistics can be further broken down into risk indicators, which are more useful for preventive health purposes, such as targeting screening and prevention efforts. Alcohol use disorders are more common in males than females, with the ratio of affected males:females being approximately 2–3:1. While rates of females affected with alcohol use disorders are lower, health-related consequences of alcohol use in females who do not meet diagnostic criteria for alcoholism are more severe than in males. Review of health-related consequences of alcoholism in females later in this chapter will include medical risks associated with alcohol use in non-alcohol dependent drinkers.

Age is another factor which can be used to characterize risk. Alcohol use disorders typically are most common in those under 45 years of age. Health-related morbidity is different across the age span, with more unnatural deaths (e.g., accidents, suicides, homicides) observed in younger age groups and more chronic disorders seen in the older age groups. Screening tools and definitions of alcohol use disorders in the elderly are less satisfactory than in middle age, and thus rates of alcohol use disorders in the elderly may be underestimated. A study in the International Journal of Geriatric Psychiatry, focusing on a review of different screening instruments, found that the AUDIT-5 has had promising results over other instruments such as the CAGE and MAST. No studies of alcohol use disorders in

elderly people with cognitive impairment were found, indicating a need for research in this area.²⁶

Alcohol use disorders are seen across all socioeconomic groups. Alcohol use disorders cluster weakly in lower socioeconomic groups, but this may simply be secondary to alcohol's contribution to poor school and job performance. Persons of Asian descent have lower rates of alcohol related disorders, presumably related to decreased levels of alcohol-metabolizing enzymes leading to flush reactions, tachycardia, and headache. Differences between blacks and nonblacks are significant, generally with nonblack rates being lower in both males and females. Drinking is most prevalent in urban America, and geographically in the Northeast.

The comorbidity of alcohol use disorders and other psychiatric disorders is very common. The ECA study found that about half of individuals with alcohol use disorders had a concomitant psychiatric disorder.¹⁹ In the 2003 NSDUH study, those with a serious mental illness had a 21.3% rate of alcohol dependence and abuse and those without a serious mental illness had a dependence/abuse rate of 7.9%.¹⁷ The most commonly observed psychiatric comorbidities include antisocial personality disorder, mood disorders, and anxiety disorders.

► GENERAL MECHANISMS OF ALCOHOL-RELATED DYSFUNCTION AND DAMAGE

A general schema of the mechanisms involved in alcohol-related tissue injury is provided in Fig. 55-1. Tissue in this context refers to either a single type of cell or a single organ. Besides having direct toxic effects on target tissue, alcohol also may act indirectly through a variety of mechanisms. Other alcohol-associated behaviors involving tobacco, risky sexual behavior, illicit drugs, and other drugs and chemicals as well as nonalcohol-related disease processes, may contribute as cofactors to the development, course, and outcome of alcohol-induced primary damage. In addition, alcohol may act as a factor influencing the development, course, and outcome of coincidental diseases.

Much of the tissue damage that occurs in association with alcohol use has been attributed, at least in part, to direct toxic effects; for example, alcoholic hepatitis, cardiomyopathy, and neuronal degeneration. New findings however suggest that excitotoxicity mediated through alterations in glutamate neurotransmission may be responsible for many of the central nervous system (CNS) degenerative processes associated with alcoholism (e.g., Wernicke-Korsakoff syndrome, cerebellar degeneration, dementia associated with alcoholism).²⁷ The effects on the CNS are of also of great importance in the development of various alcohol-related problems associated with acute intoxication and withdrawal from alcohol, as well as alcohol dependence.^{27,28} Acute effects are particularly important in circumstances under which drinkers may injure themselves or others.²⁹

Alcohol also may act indirectly through the production of metabolic disturbances, endocrine changes,³⁰ immune system changes,³¹ aggravation of obstructive sleep apnea,³² and displacement of dietary nutrients or impairment of their absorption or use,³³ as well as through the effects of diseases caused by alcohol.

Obstructive sleep apnea, a complication of alcohol use that occurs as a result of acute intoxication, is potentially important as a direct cause of morbidity and mortality.³² It may contribute also to the course and outcome of other alcohol- as well as nonalcohol-related diseases. This disturbance and its precipitation and aggravation by alcohol have been recognized only recently.³⁴⁻³⁶

When an alcohol-related health problem does occur, its course and outcome may be influenced by whether or not the affected individual continues to be exposed to alcohol and alcohol-related hazards. Furthermore, course and outcome may be influenced by whether or not he or she seeks, has access to, receives, and adheres to effective treatment, not only for the complications of alcohol use but also for the drinking behavior itself.

A summary of the etiological significance of alcohol and associated variables that contribute to the excess mortality of heavy drinkers is provided in Table 55-1.

Figure 55-1. Schematic representation of the general mechanisms involved in the development of alcohol-related tissue injury.

Morbidity and Mortality

The important health problems related to alcohol use were reviewed by the Institute of Medicine.³⁷ The major health problems associated with alcohol use named in this report included alcohol withdrawal syndrome, psychosis, hepatitis, cirrhosis, pancreatitis, thiamine deficiency, neuropathy, dementia, and cardiomyopathy. Alcohol use also plays a key role in injury and accidents, suicide, and homicide. Also

important is a range of adverse pregnancy outcomes and fetal abnormalities caused by the embryotoxic and teratogenic effects of alcohol.

The most common medical problems in alcohol-dependent and heavy drinking men, in terms of decreasing lifetime incidence, are trauma, acute alcoholic liver disease, peptic ulceration, chronic obstructive lung disease, pneumonia, hypertension, gastritis, epileptiform disorders, acute brain syndromes, peripheral neuritis, ischemic heart disease and cirrhosis (Table 55-2).³⁸ This pattern of lifetime

Heavy alcohol consumption and physical health problems. A review of the epidemiologic evidence. In: Smart RG, Cappell HD, Glaser FB, et al (eds). *Research Advances in Alcohol and Drug Problems*. New York: Plenum Press, 1984, vol 8, pp 149–182. The median mortality ratio, in parentheses, is shown after each cause of death.

^cBased on analyses of percentages of excess mortality in alcohol-dependent and heavy drinking men attributable to selected causes. From Ashley MJ, Rankin JG. Hazardous alcohol consumption and diseases of the circulatory system. *J Stud Alcohol*. 41:1040–1070, 1980. The median percentage value for excess mortality, in parentheses, is shown after each cause of death.

morbidity contrasts greatly with the ranking in terms of excess mortality, namely, cardiovascular disease, suicide, accidents, cirrhosis, malignant neoplasms, pneumonia, and cerebrovascular disease.³⁹ These differences in patterns of morbidity and mortality are related to the lethality of the conditions, the risk of this population dying from these disorders compared with the community-at-large,⁴⁰ and the frequency of the conditions in the general adult population. The three most common causes of excess mortality, that is, cardiovascular disease, suicide, and accidents, occur as acute problems, associated with sudden and usually unexpected death, whereas cirrhosis of the liver is the main chronic physical health problem in terms of incapacity and excess morbidity.

Alcohol use in females results in exposure to all of the risks reviewed for men. Several consequences of drinking are more common in females, often with less quantity of alcohol use than in males. In females, accidents and suicidal mortality predominate in adolescence and young adulthood as health consequences of drinking. In middle age, breast cancer and osteoporosis become issues of concern. Compared to nondrinkers, women who consume an average of one drink per day, increase their risk of breast cancer by approximately 7% while those who consume an average of 2–5 drinks per day increase their risk by 50%.⁴¹ Drinking appears to be more detrimental to women than men with respect to liver disease. Higher cirrhosis rates among female alcoholics as compared to male alcoholics, with females having lower consumption rates has been observed in a variety of studies.^{42–44} Alcohol is also the most widely used substance associated with domestic violence. Females are most commonly the battered party, and both their use of alcohol and their partner's use of alcohol appear to increase risk. The risk of HIV/AIDS and alcohol use presents similar concerns in females as well as males. Use of alcohol may influence the risk of acquiring HIV infection both through direct effects on the immune system, as well as increased likelihood of unsafe sexual behavior during periods of intoxication.

► ESTIMATING THE PUBLIC HEALTH IMPORTANCE OF ALCOHOL-RELATED PROBLEMS

In alcohol-consuming nations the public health importance of alcohol-related health problems usually is considered by each country to be significant.⁴⁵ There are differences, however, from country to country, concerning the impact of alcohol-related health problems on the total burden of ill health.

The impact of alcohol-related health problems is felt, both directly and indirectly, by many different groups. This includes those with alcohol-related health problems, their families, other individuals or groups who may suffer injury or loss due to the use of alcohol by others, those who provide services for the prevention and treatment of alcohol-related problems, and the community at large. Many of the effects are tangible but immeasurable, such as the pain and suffering experienced by the alcohol-damaged individual and his or her family. However, other manifestations of alcohol-related problems are suitable for empirical study, for example, the incidence and prevalence of alcohol-related health problems, the costs of health and social services attributable to these problems, the number of people who are disabled or die from alcohol-related problems, and the economic costs of illness, disability, and death.

It may be possible to make reasonably good estimates for specific aspects of mortality and morbidity, for example, the burden of alcoholic psychoses in specialized institutions. Unfortunately, such direct consequences are only a small part of the total problem. This is illustrated in a report on alcohol-related deaths in Canada in 1980 (Table 55-3). Of the almost 18,000 such deaths (10.5% of all deaths), the vast majority (88%) were classified as indirectly related, that is, they were due to accidents, cancers, and circulatory and respiratory diseases in which alcohol was a contributing factor.⁴⁶ This problem is further exemplified by U.S. studies in which only about 3% of recorded deaths were officially attributable to alcohol, 1.9% were attributable to an alcohol-related condition, and the remaining 1.2% had an alcohol-related condition listed along with the specified cause of death.⁴⁷ These figures are small when compared with estimates that alcohol-dependence is responsible for 1 in 10 deaths in the United States,⁴⁸ and when follow-up studies demonstrate high alcohol-related mortality.⁴⁹

Despite such shortcomings in available statistics, there is no doubt about the serious toll of morbidity and mortality that alcohol use exacts from alcohol-consuming societies, such as the United States and Canada. These countries rank as moderate consuming nations, and one can assume that the toll is higher in heavier consuming nations. Selected indicators of the public health impact of alcohol use in Canada (Table 55-3)^{46,50} illustrate this clearly.

In the period of these studies, 1979–1980, of Canadians 15 years and over, at least 12% regularly were consuming enough alcohol to be at increased risk of health consequences, 5% of current drinkers were alcohol-dependent and almost 10% experienced at least one alcohol-related problem. More than one in 10 deaths were alcohol-related. In an earlier study of premature deaths and potential years of

TABLE 55-3. SELECTED INDICATORS OF THE PUBLIC HEALTH IMPACT OF ALCOHOL USE IN CANADA

<i>Indicator</i>	<i>Year</i>	<i>Selected Findings</i>	
Population 15 years and over drinking 14+ drinks per week ⁵³	1978–1979	Overall 12%	Males 19.4% Females 4.8%
		Age group 20–24	Males 31.0% Females 8.1%
Alcohol-dependent persons ⁴⁹	1980	600,000 persons; 1 in 19 (5.3% of) current drinkers	
Current drinkers 15 years and older with alcohol-associated problem ⁴⁹	1978–1979	Tension or disagreement with family or friends	6.1%
		Problems with health	2.3%
		Difficulty with driving	1.5%
		Injury to self or other	1.3%
		Trouble with the law	1.3%
		Trouble with school or work	1.2%
Current drinkers 15 years and over with at least one alcohol-associated problem ⁴⁹	1978–1979	Overall 9.7%	Males 12.4% Females 6.1%
Alcohol-related deaths ⁴⁹	1980	17,974 (10.5%) of all deaths Directly related deaths: 2,110 ^a Indirectly related deaths: 15,864 ^b	

^aDeaths due to alcohol-related cirrhosis, alcohol dependency syndrome, the nondependent abuse of alcohol, alcoholic psychoses, and accidental poisoning by alcohol.

^bDeaths due to motor vehicle accidents, falls, fires, drownings, homicides, suicides (5,554 in 1980), as well as circulatory and respiratory diseases and certain types of cancer (e.g., oral, esophageal, and laryngeal) totaling 10,310 in 1980.

TABLE 55-4. ESTIMATED COSTS OF ALCOHOL-RELATED PROBLEMS IN THE UNITED STATES IN 1983

		\$Billion	%
■ Core Costs

DHHS Publication No. (ADM) 871519. Rockville, MD: U.S. Government Printing Office, 1987 and U.S. Bureau of the Census: *Statistical Abstract of the United States*, 106th ed. Washington, DC: U.S. Bureau of the Census, 1985.

Gross national product (GNP) in 1983: \$3305.0 billion; costs of alcohol-related problems: 3.54% of GNP.

Total costs of health services in 1983: \$355.4 billion; cost of direct services for alcohol-related problems: 4.22% of total costs of health services.

life lost in Canada in 1974, it was concluded that no other risk factor was responsible for more premature mortality than either smoking or hazardous drinking.⁵¹ The adverse health consequences of drinking remain a major health problem, despite evidence since this period of study and in association with a plateauing and modest fall in alcohol consumption, that there has been a significant decline in various indicators of alcohol-related health problems in Canada.^{52,53} Furthermore, tobacco and alcohol continue to rate first and second as risk factors responsible for premature mortality.

A different approach to quantifying the effects of alcohol-related health problems is to express them in monetary terms. Such an approach is useful because it provides an estimate of the relative distribution of the costs, for example, across organ systems or various health and social services, as well as a measure of total costs. Thus, these figures can be used to compare the costs of alcohol-related problems with other health problems as a basis for focusing the attention of the community or making policy decisions regarding the funding of prevention, treatment, and research.

An example of an economic approach to measuring the magnitude of alcohol-related problems is contained in Table 55-4, which provides an estimate of the costs of alcohol-related problems in the United States in 1983.^{54,55} First, notice that the total cost is large, \$116.875 billion. Of this amount, 89.0% was attributable to core costs, including losses in productivity associated with disability and death (76.2%) and costs incurred in the treatment and care of people with alcohol-related health problems (12.8%). Total alcohol-related health costs ranked a close second to heart and vascular disease, as the prime health cause of economic loss and were well ahead of cancer and respiratory disease. In this analysis, other related costs covered nonhealth alcohol-related costs attributable to motor vehicle crashes and fires, highway safety and the fire protection, and the criminal justice and social welfare systems. The costs of alcohol-related problems were equal to 3.54% of the gross national product, and the direct costs for health services were equal to 4.22% of the total costs of health services. Although these figures are

large, very likely they are underestimates of the true economic costs of alcohol-related problems.

Prevention Strategies

The public health approach to disease prevention was first classified in 1957 as proposed by the Commission on Chronic Illness.⁵⁶ Primary, secondary, and tertiary prevention techniques were defined. In this model, primary prevention is geared towards efforts to decrease new cases of a disorder (incident cases), secondary prevention is designed to lower the rate of established cases (prevalent cases), and tertiary prevention seeks to decrease the amount of disability associated with existing disorder or illness. Gordon^{57,58} later proposed an alternative classification system which incorporated the concept of the risks and benefits in the evaluation of prevention efforts. His categories of prevention strategies consisted of universal measures, selective measures, and indicated measures. Universal prevention measures are measures of low cost, and low risk for which benefits outweigh costs when they are applied to everyone in an eligible population. Selective measures are desirable only for a select population at above average risk of development of a disorder. Indicated preventive measures are applied to individuals who, upon screening examination, demonstrate high risk of development of a disorder.

The Institute of Medicine (IOM) noted that both of these classification systems were designed and worked best for traditional medical disorders⁵⁹, but that their application to mental disorders was not straightforward. An alternative system was proposed by the IOM, which is referred to as the Mental Health Intervention Spectrum for Mental Illness. This system incorporates the whole spectrum of interventions for mental disorders, from prevention, through treatment, to maintenance. Table 55-5 outlines this spectrum. The term prevention is reserved for those interventions that occur before the initial onset of the disorder, and it incorporates many of Gordon's concepts such as universal, selective, and indicated measures.

Universal Prevention Efforts

A significant amount of evidence suggests that early use of alcohol along with under-achievement, school problems, and aggressive behavior predict future problem drinking. While some of this risk may be due to genetic vulnerability to alcohol use disorders (covered under selective prevention efforts below), clearly genetic-environmental interactions are likely. Broader community context factors external to the individual are also strong predictors of alcohol use and problems. Community use patterns, availability of alcohol (including legal drinking age, cost, and enforcement), and peer group behavior affect the use and abuse of alcohol.

Universal prevention efforts have been tried in various forms. Community-based programs for the prevention of alcohol abuse and alcohol-related problems were recently reviewed by Aquirre-Molina and Gorman.⁶⁰ This review summarized studies concerned with changing the behavior of individuals rather than environmental changes such as altering availability. Data analysis for many such studies is ongoing and hence their ultimate impact is unknown.

Community-based studies designed to change behavior of individuals are difficult to design, implement, and complete. A more direct universal prevention strategy involves limiting availability, increasing enforcement of laws pertaining to alcohol use, legislating stricter laws, improving community standards, and increasing the cost of alcoholic beverages through taxation.

A substantial body of evidence now supports the view that increases in overall or per capita consumption are associated with higher rates of heavy drinking and, consequently, with increased frequencies of alcohol-related health problems.⁶¹⁻⁶⁵ Studies of relationships between per capita alcohol consumption and alcohol-related morbidity and mortality have focused on cirrhosis, where a strong positive correlation has been established.⁶⁶ Per capita consumption also has been correlated positively with total mortality in men,⁶⁷ international variations in deaths from diabetes mellitus,⁶⁸ deaths from alcohol-related disease,⁶⁹ alcoholism death rates,⁷⁰ and hospital admission for alcohol dependence, alcoholic psychosis, liver cirrhosis, pancreatitis,⁷¹ Wernicke's encephalopathy, and Korsakoff's psychosis.⁷²

Recognition of the relationships among per capita alcohol consumption, rates of heavy use, and the incidence of alcohol-related health problems has focused attention on universal prevention strategies aimed at the drinking population, generally with the principal objective of reducing per capita alcohol consumption. Critical reviews suggest that measures addressing the economic and physical accessibility of alcohol are among the most effective in this regard.⁷³

Economic Accessibility

Numerous studies, reviews, and reports have examined the use of price control via taxation in reducing alcohol consumption and alcohol-related problems. The accumulated evidence indicates that price control could be effective and, in some instances, powerful, both in relation to other measures and in combination with them.^{7,54,74-77} According to Cook^{78,79} and Cook and Tauchen,⁸⁰ doubling the federal

tax on liquor in the United States would reduce the cirrhosis mortality rate by at least 20%. An effect on automobile fatalities also was postulated.⁷⁸ Holder and Blöse⁸¹ used a system dynamics model to study the effect of four prevention strategies; raising the retail price of all alcoholic beverages by 25% once, indexing the price of alcoholic beverages to the consumer price index (CPI) each year, raising the minimum drinking age to 21 years, and reducing high-risk alcohol consumption through state-of-the-art public education on alcohol-related family disruptions and alcohol-related work problems, against a background of business as usual in three counties of the United States. Although both outcome measures were modestly sensitive to one-time changes in price, the largest effect was obtained by instituting a community education effort concurrently with indexing the prices of alcoholic beverages to the CPI. From an analysis of the price of beer and spirits, other economic and sociodemographic factors, and various regulatory control variables, Ornstein⁸² concluded that price was the most important policy tool available to regulators in the United States. A similar conclusion arose from a study of the effects of various regulatory measures on the consumption of distilled spirits in the United States over a 25-year period.⁸³ Levy and Shefflin,⁸⁴ using methods intended to overcome the problem of beverage substitution when price control is not directed at all beverages, estimated that the price elasticity for total alcohol consumption, although less than one (implying that demand is inelastic), was large enough for price policies to be effective in reducing alcohol consumption. Others,⁸⁵⁻⁹⁰ however, have been more guarded in their support for price manipulation as a control measure, pointing out the methodological limitations in econometric analyses, the modest or conflicting implications of some findings, and the possible role of countervailing forces.

In a study of individual drinkers, Kendell and colleagues^{91,92} found that overall consumption and associated adverse effects fell 18% and 16%, respectively, among 463 "regular drinkers" in the Lothian region of Scotland when prices were increased via the excise duty. Heavy and dependent drinkers reduced their consumption at least as much as light and moderate drinkers, with fewer adverse effects as a result. Clinical data also show that alcohol-dependent persons reduce their alcohol consumption as a function of beverage costs.^{93,94} Further, in an experimental study of price reductions during afternoon happy hours, Babor and associates⁹⁵ found that such reductions significantly increased alcohol consumption by both casual and heavy drinkers. With the reinstatement of standard prices, drinking in both groups returned to previous levels. These findings and others^{75,79,80,96} seriously challenge the previously held view that a reduction in overall consumption does not affect consumption by the heaviest drinkers. Further, liver cirrhosis mortality rates, which are considered the most accurate indicator of the prevalence of heavy drinking, respond directly and rather quickly to major restrictions on availability, including economic ones, that produce declines in per capita consumption.^{7,62,80} It is reported that 4% of deaths worldwide are due to alcohol, putting alcohol deaths on a par with the 4.1% deaths caused by smoking and the 4.4% of deaths caused by high blood pressure. Aldridge reported that if prices for alcohol increase by 10%, deaths in cirrhotic males decrease by 7%, showing that price increase is effective in reducing harm.⁹⁷

Price elasticities of alcoholic beverages vary by type of beverage, across time, and among countries.⁷ In the United States, as in Canada and the United Kingdom, beer tends to be relatively price inelastic.^{62,98,99} However, this general inelasticity does not hold in certain age groups. Grossman and colleagues¹⁰⁰⁻¹⁰³ estimated the effects on young people of increases in alcoholic beverage prices with regard to alcohol use and motor vehicle mortality. They showed that for beer, the alcoholic beverage of preference in the young, the price elasticity was considerably higher than that usually reported, a 10 cent increase in the price of a package of six 12-ounce cans resulting in an 11% decrease in the number of youths drinking beer and a 15% decrease in the number of youthful heavy beer drinkers (3-5 drinks per day).¹⁰⁰ Further, they predicted that a national policy simultaneously taxing the alcohol in beer and distilled spirits at the same rates and offsetting the erosion in the real beer tax since 1951 would reduce the number of youths 16-21 years old who drink beer frequently (4-7 times a week, about 11% of youths) and fairly

frequently (1–3 times a week, about 28% of all youths) by 32% and 24%, respectively.^{104,105} Additional analyses showed dramatic effects of excise tax policies on motor vehicle accidents in youths.^{101–103} In a multivariate analysis, it was estimated that a policy that fixed the federal beer tax in real terms since 1951 would have reduced the number of motor vehicle fatalities in youths ages 18–20 in the period 1975–1981 by 15%, and a policy that taxed the alcohol in beer at the same rate as the alcohol in liquor would have lowered fatalities by 21%. A combination of the two policies would have caused a 54% decline in the number of youths killed. In contrast, the enactment of a uniform drinking age of 21 years in all states would have reduced such fatalities by 8%, with considerable additional costs in enforcement. Since the principal objective of price control in the public health context is universal prevention, differentially higher price sensitivity among young drinkers for beer is an especially important finding.

Price control via taxation has been recommended repeatedly as a strategy for stabilizing or reducing per capita consumption and, thereby, preventing alcohol-related health problems.^{77,106–108} In the United States, recent public opinion polls indicate clear, majority support for excise tax increases on alcohol for public health purposes.⁷⁷ However, federal excise taxes on distilled spirits, wine, and beer remained constant in nominal terms (current dollar value) between November 1, 1951, and the end of fiscal year 1985.¹⁰¹ In 1985, the federal excise tax on distilled spirits was raised slightly (as a deficit reduction measure), but federal tax rates on beer and wine were not changed. Thus, the real price of alcoholic beverages has actually declined in recent years, such that between 1960 and 1980 the real price of liquor declined 48%, beer 27%, and wine 20%.⁷⁸ A similar situation has been documented in Ontario, Canada, where a taxation policy that would maintain a reasonably constant relationship between the price of alcohol and the consumer price index has been a key element in a long proposed, but unimplemented prevention strategy.¹⁰⁶

Examples of increased taxation and improved health outcomes can be seen in two more recent studies. In 2000, Switzerland imported 2 million bottles of “alcopops” but that jumped to 39 million bottles in 2002. In 2004, Swiss officials quadrupled taxes on alcopops and slowed consumption and decreased sales to young people by half in doing so.¹⁰⁹ In the United States on January 1, 1991, the federal excise tax on beer increased for the first time since 1951.¹⁰⁹ The rates of STDs, violence, and traffic fatalities decreased when the price of beer increased.¹¹⁰

Physical Availability

The relationship between the physical availability of alcohol and alcohol consumption and related problems is multifaceted and complex. It is difficult to show the effect of small changes and to untangle the effects of changes in physical availability that take place simultaneously with others, either nonspecific changes (e.g., in the general economy) or specific changes (e.g., in the economic and legal accessibility of alcohol). It is not surprising, therefore, that the evidence concerning the effectiveness of limitations on physical accessibility is mixed.^{7,45,61,104,105,111–114} Taken together, there is considerable evidence that controls on physical availability can reduce alcohol-related problems and that the consumption of both heavy and moderate drinkers can be reduced.

Prohibition is successful in reducing consumption and attendant health risks.^{7,45,61,105} Such a situation prevails in some countries today.¹⁰⁵ With the institution of Prohibition in the United States earlier in this century, cirrhosis mortality rates fell dramatically and remained well below their former levels during the earlier years and to a considerable extent even in the later years, indicative of greatly decreased consumption.⁶¹ On repeal of Prohibition and the subsequent increase in the availability of alcohol, consumption rose, and cirrhosis mortality rates gradually increased toward previous levels. Similar trends have been observed in the face of other severe limitations on availability, for example, in Paris during the two World Wars^{7,65} and during some strikes and periods of rationing.^{45,104,105,111} Under such conditions, the consumption of both heavy and moderate drinkers is reduced.^{104,105,111,112}

Similarly, sudden, marked relaxation in the availability of alcohol is associated with increases in overall consumption, heavy drinking, and alcohol-related problems. The Finnish experience, which included a very marked increase in overall consumption in connection with liberalizing legislation that led to an extensive and rapid increase in outlets in previously dry areas, has been detailed¹¹⁵ and summarized¹⁰⁵ elsewhere.

A number of additional factors play a role in physical accessibility to alcohol. These factors include the times of sale permitted, the types, characteristics, and location of outlets, and the distribution system of alcoholic beverages. Different positive and negative consequences may be seen as a result of even subtle changes. For example, while restricting the number of outlets may lead to decreased consumption, a rise in automobile crashes associated with alcohol use can be seen due to driving after acquiring the beverage of choice, as location of purchase is related to where it is consumed.¹¹⁶ The rapidity with which community changes are made also of importance upon the outcome of the change.^{45,105,111} If multiple outlets for alcohol sale are added in formerly dry areas, the subsequent marked increase in overall consumption has been previously discussed.^{111,115} These examples all point to the need for careful consideration and monitoring of changes made in the physical availability of alcohol in society.

Legal Accessibility

Age limitations represent a legal barrier to alcohol. Most countries have age restrictions on its purchase or consumption or both.⁴⁵ Although the data are neither unflawed nor entirely consistent, there is much evidence that the lower the drinking age, the higher the consumption of alcohol^{45,101,117–120} and the higher the incidence of alcohol-related problems, particularly among teenagers.^{45,105,112,117,118,121,122} Lowered blood alcohol content (BAC) limits for legal driving have recently been instituted in most states in the United States. The effect of such measures on automobile crashes and automobile fatalities will be an important outcome measure. The tradeoff of increased costs, potential social stigma, and consequent increased rates of alcohol use disorder diagnoses for individuals caught with the lowered alcohol blood levels has not been factored into decisions to lower the legal driving limits, but obviously some price will be paid.

Selective Intervention Efforts

Selective intervention efforts are those efforts geared towards individuals at greater than average risk of development of alcohol use disorders. The strongest predictor of who will develop alcohol dependency comes from the genetic literature. Family studies of alcoholics have clearly demonstrated that alcohol dependency is familial.¹²³ First-degree offspring of an alcohol dependent parent are threefold to fourfold more likely to develop alcohol dependence than those without such a parent. Family studies are not useful in separating environmental factors from genetic factors important to the development of alcohol dependency. Studies of twins^{124,125} and adoptees^{126,127} have produced evidence for such genetic factors, although at this time no alcohol dependency gene has been found. While a gene for alcohol dependency awaits discovery, the results of the adoptee studies have demonstrated that heterogeneity in alcohol dependency exists, that is, there exists at least two types of alcohol dependence. The two types of alcoholism have been referred to as milieu-limited alcoholism, which requires the presence of environmental factors for alcoholism to develop (Type I alcoholism), and male-limited alcoholism (Type II alcoholism), which does not.¹²⁸ These forms of alcohol dependency differ in terms of age of onset and associated symptoms. Type II alcoholism has an early age of onset, and often serious legal manifestations such as driving while intoxicated and fighting. Furthermore, there is evidence of various biological markers that potentially may prove valuable for targeting high-risk populations for intervention trials that have been discovered through various family and genetic studies of alcoholism.¹²⁹

If a strong family history of alcohol dependence is discovered, it is important to educate unaffected individuals in the pedigree of their enhanced risk. This educational component should be added to the other interventions to be described later in this chapter.

Indicated Intervention Efforts

Indicated intervention efforts are targeted towards high-risk individuals who are identified through screening to have hazardous drinking or early symptoms of alcohol dependence that have gone undetected. Screening methods are also important to uncover undiagnosed individuals with alcohol dependence, but who are able to mask such symptoms from others.

Screening for Alcohol Dependence

Assessing patients for alcohol use disorders in a busy primary care setting is difficult. The importance of screening for alcoholism in primary care settings is essential to public health efforts to reduce the burden of alcohol-related problems. To ascertain a full history of alcohol use, and to assess whether an individual meets DSM-IV criteria for alcohol abuse or dependency, is generally considered too time consuming by many clinicians, and some doubt exists among clinicians of the validity of self-report regarding use of alcohol. In 2000, only 37% of family physicians felt that their intervention could change an alcoholic's drinking habits despite 88% of physicians asking new outpatients whether they drank alcohol and 13% using formal screening tools.¹³⁰ Because of these concerns, a variety of screening tools have been proposed. The most commonly used tools are screening questionnaires and laboratory values. The most common screening questionnaires include the Michigan Alcoholism Screening Test (MAST),¹³¹ the abbreviated Brief-MAST,¹³² and the CAGE instrument.¹³³ Several newer instruments include the Alcohol Use Disorders Identification Test (AUDIT)¹³⁹ and the TWEAK instrument.¹⁴⁰ Laboratory screening tests include blood alcohol levels, liver enzymes elevations, erythrocyte mean corpuscular volume, lipid profiles, and carbohydrate-deficient transferrin.

Screening Questionnaires

A number of review articles are available which describe the use of alcohol use screening questionnaires. The U.S. Preventive Services Task Force's *Guide to Clinical Preventive Services*, 2nd Edition¹³⁶ provides a detailed review of the sensitivity and specificity for the MAST (84–100% and 87–95% respectively), Brief-MAST (66–78% and 80% respectively), CAGE (74–89% and 79–95% respectively for alcohol abuse and dependence; but only 49–73% sensitivity for heavy alcohol use), and the AUDIT¹³⁴ (96% and 96% respectively in an inner city clinic; but only 61% and 90% in a rural setting). These sensitivity and specificity figures are for middle-aged adults. Adolescents and the elderly may not be as adequately screened by these instruments. Other limitations of these screening instruments include the MAST being rather lengthy for routine use (25 questions), the CAGE being most sensitive for alcohol abuse or dependency and not heavy drinking, and both the CAGE and MAST fail to distinguish current from lifetime problems due to alcohol. The AUDIT is very sensitive and specific for "harmful and hazardous drinking," but uses a one-year timeframe for screening and hence is less sensitive for past drinking problems.

Allen et al.¹³⁷ offer guidelines for selection of screening tests in primary care. Based upon their review of the literature, use of the AUDIT, CAGE, or MAST was recommended. Because of time constraints in primary care, the AUDIT or CAGE were first choice recommendations, and the TWEAK was recommended for pregnant women.¹³⁵ For adolescents, the adolescent drinking index (ADI)¹³⁸ was suggested as a good option.

In the elderly, two studies^{139,140} point to deficiencies in the CAGE as a screening tool, and suggest the need for more sensitive and specific tools in this population. Adams et al.¹⁴⁰ suggests asking about quantity and frequency of alcohol use in addition to the CAGE to

increase the detection of elderly hazardous drinking. O'Connell, et al. reported that the AUDIT-5 has had promising results as well in the elderly.²⁶

The National Institute on Alcohol Abuse and Alcoholism (NIAAA) in collaboration with the American Medical Association offers the *Helping Patients with Alcohol Problems: A Health Practitioner's Guide* free to help primary care physicians with patients who are risky drinkers. A growing body of research has shown that primary care practitioners can promote significant reductions in drinking levels of problem drinkers who are not alcohol dependent.¹⁴¹

Laboratory Screening Tools

Alcohol induces a number of laboratory abnormalities. Unfortunately, to date laboratory tests for screening have not been as sensitive nor as specific for alcohol use disorders when compared to the screening questionnaires reviewed above.

Liver enzymes, including gamma glutamyltransferase (GGT), aspartate aminotransferase (AST), alanine aminotransferase (ALT), and alkaline phosphatase have all been used as screening tests. The GGT is the most useful of the liver tests. It demonstrates a sensitivity of between 50–90% for ingestion of 40–60 g of alcohol daily (3–4 standard drinks).¹⁴² The GGT rises most rapidly in response to heavy alcohol use, and with abstinence it returns to normal most rapidly. Other liver enzyme tests such as the AST, ALT, and alkaline phosphatase are less specific and sensitive than the GGT. Some have suggested use of the AST:ALT ratio of 1.5–2:1 as being an indicator of liver damage being more likely due to alcohol than other causes. While the AST and ALT are not adequately sensitive or specific to be recommended as screening laboratory tests, they have some utility as supportive tests. The GGT may be most useful as a marker for return to heavy drinking after a period of abstinence in which the GGT has returned to normal. If the GGT rises by 20%, a high likelihood for return to drinking can be assumed.

Increase in mean corpuscular volume (MCV) is less sensitive to alcohol use than elevation in the GGT, but it is quite specific to heavy alcohol intake (up to 90%).¹⁴³ Utility of the MCV is much like that of the AST and ALT, that is, helpful as supporting evidence, but not as a screening tool.

The blood alcohol concentration (BAC) is useful, and can even support a diagnosis of alcohol dependence as outlined by the National Council on Alcoholism (NCA).¹⁴⁴ A BAC of 100 mg/100 mL is considered a legally intoxicated level in most states, and is conclusive evidence for a driving while intoxicated charge. Individuals nontolerant to alcohol will generally appear intoxicated at such levels. A BAC of 150 mg/100 mL without gross evidence of intoxication suggests significant tolerance to alcohol, and fulfills criteria for alcohol dependence according to the NCA. A BAC of 100 mg/100 mL during a routine physical examination is highly suggestive of alcohol use problems according to the NCA. Thus, screening of BAC in patients who may appear intoxicated or smell of alcohol during a clinic visit can be very useful. A breath analysis of BAC is also a useful tool, and can be used to screen for individuals too impaired to drive home from emergency rooms or clinic visits if intoxication is suspected, and serum BAC cannot be readily performed or if patients refuse blood drawing.

Carbohydrate-deficient transferrin (CDT), a protein associated with iron transport, appears to effectively distinguish alcoholics consuming large amounts of alcohol from light social drinkers or abstinent individuals. CDT levels (which elevate due to few conditions other than heavy drinking) decrease the probability of false positives and elevate substantially earlier with heavy drinking than GGT levels. While excellent sensitivity and specificity could be demonstrated, disadvantages include lower sensitivity in women and adolescents, and the high cost of the laboratory analysis.¹⁴⁵

Presently, none of the laboratory markers reviewed offer advantages in sensitivity or specificity over the screening questionnaires reviewed. However, in a general medical setting, liver enzymes and

MCV are often ordered as part of the medical work-up for individuals presenting for care. The laboratory studies in combination with screening questionnaires can be useful in discussions with patients regarding the health consequences of their alcohol use.

Treatment Interventions

This chapter is devoted primarily to prevention strategies. While this is the focus of the chapter, unless primary care clinicians become aware of their potential impact on reducing hazardous and problem drinking, it is doubtful that prevention strategies will be emphasized. Similarly, physicians are unlikely to inquire about alcohol use if they feel they lack the skills to intervene or if they feel interventions are unsuccessful. In a survey of Australian medical trainees in internal medicine, psychiatry, and general practice, there was a high level of agreement that alcohol use history should be obtained from all patients, and that problem drinking should be managed, but views on treatment were less positive.¹⁴⁶ There was considerable uncertainty regarding treatment modalities most readily available to the primary care physician, that is, brief advice and cognitive-behavioral therapies. In this study, the trainees were most certain that alcoholics anonymous (AA) techniques for treatment were well supported in the literature.

While AA has been a well-supported and beneficial treatment for alcohol-dependent individuals since its beginnings in 1935, its fellowship is most appropriate for individuals who are alcohol-dependent and less likely to be an acceptable treatment modality for patients who are nondependent, but who are displaying hazardous drinking styles. This distinction is imperative, as the hazardous drinking population far exceeds the dependent population of drinkers, and as previously noted contributes greatly to the societal burdens of alcohol use problems. The hazardous, but nondependent, population of drinkers is also more likely to respond to brief interventions for alcohol problems. Another reason the primary care physician should be familiar with brief intervention techniques involves the lack of many alcohol-dependent individuals to follow through on recommendations to seek more formal treatment on referral. In a study of 1200 emergency room patients diagnosed as alcohol dependent advised to seek treatment, only 5% did so.¹⁴⁷ A similar finding was noted in a study of U.S. veterans screened for at-risk drinking. Of those who were identified as having at-risk drinking, only 5% followed advice to return for a single consultation session regarding their drinking.¹⁴⁸ These studies point to the need for the primary care physician to be skilled in office-based techniques to help patients modify and reduce or stop their alcohol use.

Effective Intervention

Recent evidence strongly suggests that brief interventions in the early stages of heavy drinking are both feasible and effective.^{148,149} Edwards and colleagues,¹⁵⁰ in a controlled clinical trial of intensive inpatient-outpatient treatment versus brief advice for alcoholism, found the latter to be more effective in nondependent alcohol abusers after two years of follow-up,¹⁵¹ whereas physically dependent patients achieved better results with more intensive treatment. In a randomized controlled trial of general practitioner intervention in patients with excessive alcohol consumption, Wallace and associates¹⁵² showed that advice on reducing alcohol consumption was effective. If the results of their study were applied to the United Kingdom, intervention by general practitioners in the first year could reduce to moderate levels the alcohol consumption of some 250,000 men and 67,500 women who currently drink to excess. Other studies have shown the effectiveness of brief intervention in socially stable, healthy, problem drinkers who do not have a high degree of alcohol dependence and whose histories of problem drinking are short.^{153–157} A careful assessment of alcohol dependence in detected heavy drinkers underpins the determination of the appropriateness of brief intervention.¹⁵⁸

To examine whether brief intervention has benefits beyond one year, investigators in Norway¹⁵⁹ reassessed 247 adults who in 1986 had been drinking at least 2–3 times per week, had elevated GGT levels and had entered a randomized trial of brief intervention. They received either a 10-minute discussion of possible reasons for elevated GGT or 15 minutes of counseling regarding decreasing drinking and monthly visits until GGT levels normalized or no intervention. Nine years after the original trial (70% follow-up) those who had received brief intervention, had significant decreases in GGT levels. The better outcomes among drinkers with high GGT levels than among those with lower levels suggests that the intervention played a role. This study suggests that brief intervention for risky drinking may be more effective than previously thought.

The degree of alcohol dependence also is crucial in determining whether the treatment goal should be moderation (i.e., controlled drinking) or abstinence.^{149,158,160} Moderation appears to be a realistic alternative in problem drinkers who are not heavily alcohol dependent, as is often the case in the early-stage heavy drinkers.^{149,154,158,161–163} It may be a more acceptable treatment goal, particularly in environments where alcohol use is especially diffuse¹⁶³ and among young drinkers, who may perceive the costs of abstinence to outweigh the risks from continued drinking.^{158,164}

A five-step early intervention and treatment strategy for use in clinical practice settings has been developed¹⁵⁸, along with self-help manuals¹⁴⁹ and procedures for teaching moderate drinking and abstinence.¹⁶⁴ Evaluations of brief interventions conducted as part of a general health screening project,¹⁶⁵ among problem drinkers in a general hospital,^{166,167} in community referral centers for referred problem drinkers,^{161,168} and in a family practice setting¹⁶⁹ are promising. This approach may be applicable beyond the clinical setting, for example, in the workplace, with considerable potential for public health impact.^{153,161} A review of 32 controlled studies of brief interventions demonstrate effectiveness of such techniques across 14 nations.¹⁴⁸

Skinner¹⁷⁰ has discussed the reasons why early detection and effective intervention strategies deserve major emphasis. To summarize: most heavy drinkers do not seek treatment for their alcohol problems, socially stable persons at early stages of problem drinking have a better prognosis, health professionals in primary care settings are in an excellent position to identify problem drinkers, and brief intervention by health professionals can be effective in reducing heavy alcohol use. Skinner cited reasons why early detection and effective intervention are not occurring, namely, widespread pessimism among health professionals about being able to intervene effectively, confusion regarding responsibility for confronting alcohol problems, uncertainty about the target population, lack of appreciation of what are appropriate interventions, and deficiencies in the practical skills and techniques to carry them out. He suggested that training materials and opportunities be readily available and incorporated into core education programs, and that strenuous efforts be made to convince key people in the health professions to give early detection and effective intervention a high priority.

► SUMMARY

Alcohol use problems are not restricted to those with alcohol abuse or dependency. Recognition of hazardous drinking as being linked to many health-related and societal burdens of alcohol is a first step towards a rational public health policy. Primary care providers are asked to screen for and be able to treat many different disorders. Alcohol use problems have, for too long, been viewed as either untreatable, or in all cases needing specialty management. Evidence exists that office screening tools, combined with relatively brief interventions, can be powerful methods to help assist a large population at risk. While the alcohol screening must compete with many disorders for primary care providers' attention, it is hoped that the data presented in this chapter will raise the priority of alcohol use disorder in the minds of those caregivers.

Prevention of Drug Use and Drug Use Disorders

Elizabeth B. Robertson • Wilson M. Compton

Drug use and drug use disorders interfere with the normal, healthy functioning across the lifespan but are fundamentally preventable. In considering the opportunities for preventing drug use and drug disorders, it is important to consider that the initiation of drug use, a necessary precursor to drug disorders, is in most cases a voluntary activity. However, the onset of drug disorders (namely abuse and dependence) is much more dependent on genetic variation in combination with specific environmental factors. The onset of drug use is most common during the late childhood and adolescent years. Proximal and distal biological, psychological, social, and environmental precursors originating as early as the prenatal period play a large role in whether experimentation occurs and use persists. On the other hand, for some individuals, the initiation of drug misuse and illicit use of drugs extends well beyond adolescence into adulthood, even in late adulthood. What follows is a review of basic information about drug use and drug use disorders and a review of prevention opportunities.

► PHARMACOLOGY OF DRUGS OF ABUSE

An understanding of the pharmacological properties of drugs is essential to the understanding of the development of drug abuse and dependence and hence the design of prevention interventions. Four processes are important to the development of drug abuse and dependence: (a) exposure, including timing of exposure and genetic susceptibility; (b) physical dependence, an adaptive state that manifests itself as intense physical disturbance when drug use is suspended; (c) psychological dependence (or “addiction”), a condition under which there is a drive toward periodic or continuous administration of the drug to produce pleasure or avoid discomfort; and (d) tolerance, or the need for increasingly higher doses of a drug to recapture the original effects of the drug. Drug abuse may occur as the result of exposure only, as in the case of binge drinking on the first occasion of alcohol use or driving a vehicle under the influence of an illicit drug.

Processes of abuse and dependence reflect characteristics of the drug, the individual user and the context of use. Among the goals of psychopharmacology, epidemiology and etiology research is to gain a better understanding of the processes implicated in the development of dependence based on the drug, the user and their interactions with one another. For example, initial use of a psychoactive drug often results in a pleasurable response. This response is reinforcing or rewarding leading to the desire to use the substance again, thereby maintaining the behavior. The more reinforcing the drug is the more likely the individual will seek the drug and abuse it. This characteristic of the drug is called its abuse liability and has been assessed for

numerous drugs through animal self-administration research. In most cases, this research has shown strong correlations between drugs animals will self administer and those that humans will abuse. In other cases, animals will not self administer drugs humans use, but the value of the animal studies is still great in that it allows for the determination of the general pharmacology and abuse liability of many substances that are then classified according to the Controlled Substance Act (CSA). Classification by the CSA provides one route to prevention as it is intended to curb the distribution of classified substance, thus making them less available to the public.

Prevention interventions approach the relaying of information concerning classes of drug in several ways. First, some interventions, especially those for general populations of young children, provide very little or no information on drugs of abuse. Instead they concentrate on skill development and other proven prevention strategies. Other interventions concentrate on targeting a specific group of drugs for a specific population. Drugs to target are typically determined through epidemiologic studies of the population of interest. Finally, some interventions target one specific drug that is a serious problem for a specific population again determined through epidemiologic studies. Some examples of these are steroid abuse among athletes and inhalant abuse among Native Americans.^{1,2}

Cannabinoids

Cannabinoids are obtained from the flowering top of the hemp plant. More than 60 cannabinoids have been isolated from the hemp plant, and 1-delta-9-tetrahydrocannabinol (delta-9-THC) has been identified as the constituent responsible for most of the characteristic effects of this category of drug. Cannabis affects cognition, memory, mood, motor coordination, perception, sense of time and, under some conditions, produces feelings of relaxation and well-being. Tolerance is clearly seen after high doses and/or sustained use. Differential tolerance occurs with various effects as well as cross-tolerance to some hallucinogens. Disruption of performance and withdrawal symptoms have been noted after discontinued use of delta-9-THC.³ In particular, withdrawal symptoms characterized by irritability, restlessness, nervousness, decreased appetite, and weight loss have been reported. Cannabis affects the cardiovascular system by increasing heart rate and differentially altering standing and supine blood pressure.

Depressants

Depressants generally share sedative and hypnotic properties and are used medically to produce drowsiness, sleep, and muscle relaxation and to prevent convulsions. In addition, barbiturates have anesthetic properties. The effects of these drugs are dose dependent, progressing

from relaxation to sedation through hypnosis to stupor. In the 1950s, depressants were developed with high anxiolytic and low central nervous system (CNS) depressant properties. These are the benzodiazepine agents, which allow relief of anxiety symptoms with less impairment of respiratory, cognitive, attention, and motor functions than the barbiturates. Depressants have complex effects. For instance, the relative degree of safety, tolerance, and dependence vary from the benzodiazepines, assigned to schedule IV, to those barbiturates, assigned to schedule II, which are associated with toxicity and high abuse liability. Tolerance for and dependence on the various drugs of this class generalize within the class and across classes to some opiates and alcohol. This is termed cross-tolerance and cross-dependence. Since, in our society, alcohol often is not recognized as a depressant drug, its use with sedative-hypnotic drugs results in stupor and death more frequently than might be the case were alcohol's depressant characteristics more fully appreciated.⁴

Dissociative Anesthetics

Dissociative Anesthetics include drugs such as PCP (phencyclidine), ketamine, and dextromethorphan. PCP was initially developed in the 1950s as an intravenous general anesthetic for surgery. However it has never been approved for use with humans, although it is used in veterinary medicine. Its sedative and anesthetic effects are trance-like and patients experience a feeling of being "out of body". Other effects are distorted perceptions of sight and sound and feelings of detachment or dissociation from the environment and self. These mind altering effects are not hallucinations. PCP and ketamine are therefore more properly known as dissociative anesthetics. The dissociative drugs act by altering distribution of the neurotransmitter glutamate throughout the brain. Glutamate is involved in perception of pain, responses to the environment, and memory. PCP is considered the typical dissociative drug. Ketamine was developed in 1963 and is currently used as an anesthetic in both humans and animals in an injectable liquid form. For illicit use, the drug is typically evaporated to form a powder that is odorless and tasteless, resulting in some cases of its use as a "date rape" drug.^{5,6,7}

Hallucinogens

Hallucinogens, unlike many abused drugs, have no accepted medical use. These drugs share an ability to distort perception and induce delusions, hallucinations, illusions, and profound alteration of mood. Mescaline and psilocin-containing plants have been used ceremonially for centuries, and LSD was synthesized 1925. Under certain conditions, drugs from a variety of classes show hallucinogenic properties. Because of similarities between experiences of persons ingesting hallucinogens and those of mentally ill persons and persons reporting profound religious experiences, these drugs also are called psychotomimetics or psychedelics. Their effects reflect activity at receptors of the serotonergic, cholinergic, and possibly other systems. Tolerance occurs with repeated use of all hallucinogens. As is true for other psychoactive substances, differential tolerance to their various effects can be demonstrated. For example, tolerance to the subjective effects of hallucinogens is greater than that seen for the cardiovascular effects. Considerable cross-tolerance exists among drugs in this category. Symptoms of physical dependence after abrupt withdrawal of phencyclidine have been described, but similar reports for LSD do not exist.^{7,8}

Opioids and Morphine Derivatives

Opioids and Morphine Derivatives are drugs that cause analgesia, sedation, and euphoria. Opioids stimulate the higher centers of the brains and slow down the activity of the CNS. The term opioid refers to natural drugs produced from the opium poppy such as opium, morphine, and codeine. Some semisynthetic opiates include heroin and methadone. Many opiate preparations are used in medical practice to manage pain, diarrhea and cough, with therapeutic doses being carefully managed to minimize side effects. Opioids can produce euphoria and are highly addictive, thus there are legal restrictions on their sale and use.^{9,10}

Stimulants

Stimulants generally are classified as excitatory in recognition of their main effect on the CNS; specifically the increase in levels of dopamine and inhibitory neurotransmitter. These include cocaine, amphetamines, methylphenidate, and related substances. At low doses, stimulants are associated with feelings of increased alertness, euphoria, vigor, motor activity, and appetite suppression. At high doses, they can cause convulsions and changes in thought characterized on a continuum from hyper-vigilance to suspicion to paranoia. Amphetamine and cocaine-induced psychoses are described in chronic abusers. Paranoid ideation generally is reported in persons with histories of chronic stimulant abuse, but transient psychotic symptoms have been reported with initial use of high doses, and instances of psychoses associated with use of medically prescribed doses also have been reported. With repeated use, tolerance to some drug effects occurs, for example, euphoria and appetite suppression, convulsion, whereas there are increases in other effects such as motor activity, stereotypy, and possibly paranoia. Cocaine has various toxic effects especially upon the cardiovascular system and when cocaine and alcohol are taken together; cocaethylene is produced, which is even more lethal than cocaine.^{11,12}

Inhalants

Inhalants are a diverse group of chemicals that easily evaporate, such as solvents, aerosols and gases that cause intoxication when their vapors are inhaled. Vapors of liquid solvents can be sniffed directly from a container, may be poured on a rag and held over the mouth, or may be emptied into a bag that is held over the mouth and nose for inhalation. The rebreathing of exhaled air causes an oxygen deficiency, which can intensify the intoxicating effects. Inhaled vapors enter the bloodstream rapidly and are distributed to the organs with large blood circulation (e.g., liver, brain) and are absorbed quickly into the CNS, depressing many bodily functions. Particularly concerning are the hydrocarbon inhalants, such as solvents, gasoline, paint thinner, etc. These agents are CNS depressants and in moderate doses result in intoxication similar to that caused by alcohol (i.e., giddiness, disinhibition, muscle weakness, lack of coordination, slowed reflexes and slurred speech). High doses can cause severe breathing failure and death. Chronic abuse can lead to irreversible liver damage, brain damage and other health problems.¹³

Other Compounds

Other Compounds that do not fall into the above categories but are abused include anabolic steroids and some over-the-counter (OTC) drugs. *Anabolic steroids*^{14,15} are synthetic substances related to the male sex hormones (androgens) that promote the skeletal muscle development (anabolic effect) and the development of male sexual characteristics (androgenic effects). Medical uses of anabolic steroids include treating conditions where the body produces abnormally low amounts of testosterone (e.g., delayed puberty) and treating body wasting (e.g., AIDS and related diseases). These drugs are obtained illegally through diversion from pharmacies; illegal imports from other countries and production in clandestine laboratories. The use of these substances is widespread among athletes motivated, in most cases, by the desire to build muscle and improve sports performance. Anabolic steroids are injected, taken orally or are rubbed into the skin in an ointment form. Most abusers take doses of up to 100 times greater than a therapeutic dose. In addition, many abusers take multiple anabolic steroids together and administer them in multiple ways; sometimes mixing them with other drugs such as stimulants and painkillers. Health consequences associated with abuse of anabolic steroids include: reduced sperm production, shrinking of the testicles, impotence, difficulty and painful urination, baldness, and irreversible breast enlargement in males. In females, health consequences include: development of masculine characteristics such as decreased body fat and breast size, deepening of the voice, excessive body hair, and loss of scalp hair. For adolescents of both genders, abuse can result in termination of the adolescent growth spurt permanently stunting growth. Other severe health, social, and psychological consequences occur for

abusers of both genders at all ages and include: liver cysts and cancer, clotting, cholesterol changes, heightened aggression, depressed mood, insomnia, loss of appetite, and muscle/joint pain.^{1,14}

Over-the-counter (OTC) drugs

Over-the-counter (OTC) drugs include a variety of preparations with which people self treat for minor ailments from the common cold to pain relief or to improve *performance* in some way, for example, stimulants, sleep enhancers, and weight control products. Many of these products include a combination of drugs that interact with one another to produce the most positive effect. Taken as directed most OTC drugs are safe, however prolonged use or excessive dosages of some of these drugs can be problematic. For example, long-term or excessive use of analgesics increases the likelihood of gastrointestinal irritation (aspirin) or liver damage (acetaminophen). Excessive dosages of a caffeine product can cause anxiety, increase in general metabolism, elevated heart rate and blood pressure and gastrointestinal irritation. Dextromethorphan, a widely available cough suppressant can, when taken in high doses, produce effects similar to the dissociative anesthetic effects of PCP and ketamine.⁵

► EPIDEMIOLOGY OF DRUG USE

Understanding the nature, extent, and patterns of use and abuse of psychoactive drugs and compounds is a necessary prerequisite to the development of efficacious and effective prevention interventions. Two epidemiological studies, the National Survey on Drug Use and Health (NSDUH)¹⁶ and the Monitoring the Future¹⁷ survey (MTF), are particularly helpful in tracking drug use over time. Examples from these two data sets are used to demonstrate trends in drug use over time.

Comparison of National Survey on Drug Use and Health (NSDUH) and the Monitoring the Future (MTF)

The NSDUH, formerly known as the National Household Survey on Drug Abuse is the primary source of statistical information on the use of illegal drugs by the overall U.S. population and has been conducted by the federal government since 1971. The survey collects data by administering questionnaires to a representative sample of the population 12 years of age and older through face-to-face interviews at their place of residence. Residence is defined as: residents of households, noninstitutional group quarters (e.g., shelters, rooming houses, dormitories), and civilians living on military bases. Homeless persons who do not use shelters, active military personnel, and residents of institutional group quarters, such as jails and hospitals, are excluded.

Prior to 1999 the NSDUH's sensitive data sections were collected using a self-administered answer sheet that the respondent sealed in an envelope, to maximize the sense of privacy, thus facilitating the accuracy of reporting. Nonsensitive sections were administered by the interviewer. Since 1999, the NSDUH interview has been carried out using computer-assisted interviewing (CAI) methodology. The survey uses a combination of computer-assisted personal interviewing (CAPI) conducted by the interviewer and audio computer-assisted self-interviewing (ACASI). Sensitive questions previously administered using respondent-completed answer sheets are now administered using ACASI, a procedure designed to be highly private and confidential for sensitive questions thereby increasing the level of honest reporting.

The MTF study uses a multistage nationally representative sampling design of secondary schools in the 48 contiguous United States. Data have been collected annually from high school seniors beginning in 1975. From 1991 to the present, data also have been collected yearly from 8th and 10th grade students. The study uses a three stage sampling strategy: (a) geographic region, (b) approximately 420 schools per year, and (c) between 42,000 and 49,000 students per year.

Weights are assigned to each student to account for school sample sizes and any potential variations in selection throughout the sampling process.¹⁷

There are numerous important methodological differences between the NSDUH and the MTF study when it comes to the youth population. Chief among them are differences in setting and method of survey administration. The MTF is conducted in the school setting whereas the NSDUH collects data in homes. Collection in the school setting is thought to provide youth a greater sense of privacy and to promote more accurate reporting; household-based collection is generally thought to yield underreporting of sensitive behaviors such as drug use.

Additionally, the NSDUH universe includes school dropouts, who are not represented in the MTF sample. The parental consent procedures are quite different between the two surveys with NSDUH requiring signed parental consent (obtained in person in the household) and MTF using either *passive* or signed active consent with documents sent from the school to the parents. The second major difference is that MTF uses self-administered paper-pencil questionnaires for data collection while the NSDUH uses interviewer and computer-administered verbal questions. Finally, NSDUH data are collected throughout the year while MTF data are collected primarily in February through May.

Figure 56-1 compares data from the NSDUH and MTF on past month use of marijuana by high school seniors.¹⁸ Note that the trend lines are very similar in shape over time; however, the MTF data indicate somewhat higher use than the NSDUH. This is thought to be the result of differences in data collection methodology described previously. Figure 56-2 presents comparative data for the same time period for use of cocaine in the past month by 12th grade youth.¹⁸ Note that the levels of cocaine use are much lower than those for marijuana and interestingly the trend patterns are quite different. Marijuana use peaked in 1979 and then made a steady decline until the early 1990s whereas cocaine use peaked at about the same time but levels of use remained relatively high until the mid-1980s. Difference in drug use trends are evident for many drugs of abuse and typically relate to factors such as availability and popularity of a particular drug in a particular region or among particular subpopulations.

Etiology

Understanding the causal factors that lead to exposure, initiation, progression, and maintenance of drug abuse is fundamental to the development of prevention interventions. Substance use, abuse and dependence result from complex interactions between biological, psychological, and sociologic factors such as the interaction styles of individuals, family members, peers, and other significant others in combination with features of the social context or environment.

The life course bio-psycho-social developmental perspective suggests that individual and environmental factors interact to increase or reduce vulnerability to drug use, abuse, dependence, and associated problem behaviors. Vulnerability can occur at many points along the life course but peaks at critical life transitions. Thus, prevention researchers pay particular attention to the significance of timing interventions to coincide with important biological transitions, such as puberty; normative transitions, such as moving from elementary to middle school; social transitions, such as dating; and traumatic transitions, such as the death of a parent. In addition, because vulnerability to drug abuse involves dynamic intrapersonal (e.g., temperament), interpersonal (e.g., family and peer interactions) and environmental (e.g., school environment) influences, prevention intervention research must target interactions between individuals and social systems across the life span. To address this complexity, intervention research needs to test strategies designed to alter specified modifiable mediators to determine which are most related to and effective in reducing drug use initiation and escalation, with what audiences, and under what conditions. An appreciation for the complexity of this work can be gleaned through examining a graphic depiction of spheres of influence on and from the developing human across time (see Fig. 56-3).¹⁹

NSDUH has two points in 1994 and a discontinuity from 1998 to 1999 due to different survey methods.

Figure 56-1. Trends in past month marijuana use by 12th-, 10th-, and 8th graders by survey.

This meta-theoretical perspective provides a broad view of the complex forces and interactions that influence developmental, in general, and problem behaviors in particular. In addition, drug abuse and drug-related HIV prevention programs utilized a number of more discrete theoretical perspectives for predicting differential drug use trajectories and elucidating developmentally grounded mediators, or risk and protective factors, malleable to change. Basing an intervention on theory is essential because it guides the development of the intervention content, length of exposure and for whom the intervention should work. It also provides the basis for the development of hypotheses and information critical to the development of a comprehensive evaluation design. Three commonly used theories in prevention are behavioral theory, social learning theory, and social cognitive theory.

Behavioral Theory²⁰

Behavioral theory,²⁰ including information processing, places emphasis on learning skills and knowledge and assumes that behavior is based on cognition rather than external forces. Major foci of this

theoretical perspective are that learning occurs through making cognitive connections between stimuli and responses and that when rewarded, especially in close temporal proximity to the response, the connections are reinforced. Additionally, active participation in the learning process is critical. A number of steps in the learning process are delineated that begin with shaping or making successive approximations to the parts of or the whole behavior with increasing accuracy over time. This stresses the importance of repetition, reinforcement, and raising standards to produce successful learning. Behaviors that are not reinforced are not learned.

Social Learning Theory²¹

Social learning theory²¹ emphasizes learning that occurs within social contexts: the family, school, the neighborhood, and community. The basic premise is that people learn from interacting with and observing other people. People who are most salient to the learner (e.g., the parent in early childhood, peers in adolescence) tend to have the most impact on both social knowledge and behaviors. Social learning that translates to changes in behavior occurs through

Figure 56-2. Trends in past month cocaine use by 12th graders in monitoring the future and national survey on drug use and health surveys (Source: Data from Glantz MG, et al. Personal Communication; 2005).

Figure 56-3. Bronfenbrenner's four ecological settings for developmental change.

modeling and imitation, but not all social learning results in behavior change. When behavior is modeled or imitated it is more likely to become integrated into the individual's repertoire of behaviors if it is positively reinforced by a significant other or a significant other receives strong reinforcement leading to the experience of strong vicarious reinforcement. In other cases the behavior itself can be reinforcing for example through sensory stimulation that is satisfying.

*Social Cognitive Theory*²¹

*Social cognitive theory*²¹ is an offshoot of social learning theory emphasizing the cognitive processes that occur during learning. Attention is a critical cognitive feature of this paradigm in that it is associated with expectation of rewards or negative consequences (e.g., when a parent asks "Do you want to do the dishes?" there is no implied consequence for saying no). Individuals develop cognitive expectation about associated behavioral consequences based on verbal and nonverbal reactions they have experienced. Other cognitive strategies related to the development of behaviors, including skills, self-monitoring, self-talk, and self-reinforcement.

Risk and Protective Factors

The bio-psycho-social perspective and theories related to prevention implicitly recognize the role of risk and protective factors in shaping developmental trajectories. The concept that risk is associated with increased vulnerability and protection is associated with decreased vulnerability to disease has been a central and longstanding concept in medicine. This paradigm has been adapted for behaviorally-based diseases with one major caveat; for many medical conditions a single source is associated with causation, whereas with behaviorally-based diseases such as substance abuse it is commonly accepted that there are multiple factors associated with disease causation. The bio-psycho-social perspective recognizes that the course of development is affected by multiple factors at multiple contextual levels over time. However it also places the individual at the center because so much of

what occurs during the developmental process is determined by individual characteristics such as temperament, learning and communication styles, and genetic vulnerability to disease.¹⁹

The study of behavioral genetics provides a framework for one line of etiologic investigation of risk and protective factors. These studies use standard research designs to look at relationships among individual genetic and environmental factors that appear to influence behavioral outcomes. For example, twin studies compare identical and fraternal twins for similar behavioral endpoints. Adoption studies compare biological and adoptive parents. Heritability, a statistical description of the portion of variability in the behavior that can be ascribed to genetic factors, can be determined by these approaches and can clarify the contribution of genetic and environmental factors to behavioral outcomes that have been demonstrated to be related to familial factors. Intelligence, personality, temperament, psychopathology, alcoholism, and to a lesser extent drug abuse have been shown to be heritable. However, few complex behaviors are under the control of a single gene; rather it appears the multiple genes in combination with environmental influences are responsible for the expression of familial-related characteristics.

Over the past two decades other studies have tried to determine constellations of behavioral and environmental risk factors associated with the origins and pathways to drug abuse. Many of these studies have successfully identified factors that help differentiate those more vulnerable to drug abuse from those less vulnerable. Risk and protective factors can affect children through establishing and/or reinforcing a negative developmental trajectory. A trajectory captures how individual children adapt either positively or negatively to their circumstances and is affected by intrapersonal, interpersonal, and environmental factors encountered at different developmental stages over the life course.^{22,23,24}

There are several basic concepts pertaining to risk and protective factors that help to put into perspective their role in development in general and in the development of substance abuse in particular. First, there are many types of risk and protective factors and they occur at all levels of the human ecosystem, but some may be more potent for some individuals than for others or may be more potent at

Figure 56-4. Risk and protective factors by context.

one particular developmental stage than another.^{25,26} Most risk factors have nonspecific effects and a major question is “Do different risk constellations result in particular patterns of negative behaviors and if so what are the mechanisms that account for this?” Many individuals experience multiple risk factors and this places them at greater risk. This is due in part to the fact that after a certain threshold of risk is attained or exceeded there appears to be an accumulation effect. Figure 56-4 illustrates this principle. Note that those individuals with 4–10 protective factors exhibit relatively few risk factors and very low prevalence of 30-day marijuana use. On the other hand, at the 6–7 risk factors threshold there is an absence of protective factors and a steep incline in the prevalence of marijuana use.²⁷

The same principle holds for protective factors, the greater the number of protective factors relative to risk factors the less likely the individual is to experience negative outcomes. In this example (see Fig. 56-5)²⁷ prevalence of academic success, a variable highly associated with low levels of drug use, is highest when there are many protective factors and few risk factors. Note as the number of risk factors increases academic success declines steeply.

A key concept is that some risk and protective factors can not be changed at all (such as genetic vulnerability and gender) and others are not easily changed (such as socioeconomic status). Because these factors are not malleable, they are not good targets for prevention. Rather factors that can be modified, such as specific behaviors and skills are more appropriate intervention targets.^{25,26}

Perhaps the most important consideration about risk for substance abuse is that not all individuals at heightened risk actually use or abuse drugs. For example, a young person with a strong family history of substance abuse and a chaotic home environment who has strong extra-familial support systems such as a positive peer group, a supportive school environment, a community with low tolerance for use, and low availability of drugs may never initiate use.

Figure 56-6 provides a framework for characterizing risk and protective factors in five contexts. These contexts often serve as foci for prevention practices. As the second examples suggest, some risk and protective factors may operate on a continuum. That is, in the family domain, lack of parental supervision, a risk factor, indicates the absence of parental monitoring, a key protective factor.²⁶

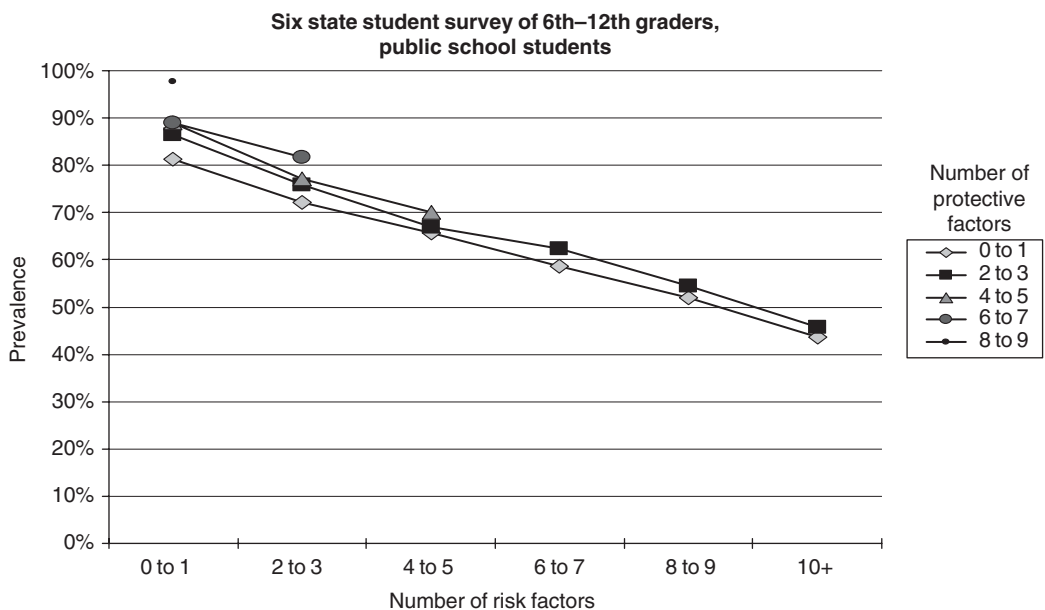

Figure 56-5. Prevalence of 30-day marijuana use by number of risk and protective factors.

Risk factors	Context	Protective factors
Early aggressive behavior	Individual	Impulse control
Lack of parental supervision	Family	Parental monitoring
Substance abuse	Peer	Academic competence
Drug availability	School	Antidrug use policies
Poverty	Community	Strong neighborhood attachment

Figure 56-6. Prevalence of academic success by number of risk and protective factors.

However, in most cases risk and protective factors are independent of each other, as demonstrated in the examples in the peer, school, and community contexts. For example, in the school domain, a school with strong “antidrug policies” may still have high availability of drugs if the policies are weakly enforced. An intervention to strengthen enforcement of school policies could create the intended school environment.

Because development takes place in context, it is important to consider the ways in which developmental contexts can influence risk and protective factors and life course trajectory. Children’s earliest interactions occur within the family and factors that affect early development are crucial to development. Families foster optimal development when strong bonds are established between parents and the child, parents are involved in the child’s activities, parents meet the child’s material needs (e.g., food, clothing and shelter) and emotional needs (e.g., support and warmth), and firm, clear and consistent limits for behavior are set and enforced in a nonhostile, matter-of-fact manner. On the other hand, children are more likely to experience negative developmental outcomes when there is a lack of mutual attachment and nurturing by parents or caregivers, parenting is inconsistent or harsh, the home environment is chaotic, or the caregiver abuses substances, suffers from mental illness, engages in criminal behavior, or has other severe behavioral or mental health problems. These latter developmental environments, such as households where parents’ abuse of drugs can impede bonding to the family and threaten feelings of security that children need for healthy development.²⁸ For young children already exhibiting serious risk factors, delaying intervention until late childhood or adolescence makes it more difficult to overcome risks because attitudes and behaviors have become well established and not easily changed.²⁹

One of the most well-delineated risk trajectories for subsequent substance abuse is out-of-control aggressive behavior in very young children.^{30,31,32} If not addressed through positive parental actions, this behavior can lead to additional risks when the child enters school—including heightened aggressive behavior which leads to peer rejection, punishment by teachers, and academic failure. If not successfully addressed through preventive intervention within the home and school contexts, over time these risks can lead to more distal risk behaviors for drug use, such as truancy, delinquency, and associating with drug-abusing peers. This example illustrates several important aspects of successful prevention that will be reiterated later. First, intervening early increases the likelihood of success.²⁸ Second, life transitions, in this case school transitions, are points of vulnerability and provide opportunities for intervention. Finally, interventions that address the problem in multiple contexts are more successful than those confined to a single context.³³

Implicit in this example is the idea that later in development, settings outside the family, such as school, with peers and teachers, and in the community, increasingly affect the quality of children’s development. Difficulties in these contexts influence children’s physical, emotional, cognitive, and social development. During the preadolescent and adolescent years, association with drug-using peers is often the most immediate risk for exposure to drug abuse and other delinquent behavior. But other factors such as drug availability, perception that drug abuse is accepted, and inflated misperceptions about the extent to which same-age peers use drugs can influence adolescents to initiate drug use. Even in the adolescent years when youths spend a great deal of time outside the home, parents and caregivers can

provide protection through age-appropriate parental monitoring of social behavior, including establishing curfews, ensuring adult supervision of activities outside the home, knowing the children’s friends, enforcing household rules, facilitating and valuing success in academics, involvement in extracurricular activities, and fostering strong bonds with prosocial institutions, such as the school, recreation activities, and religious institutions. Moreover, research demonstrates that while peers are a major force in determining immediate behaviors, such as choice of clothing styles, activities to participate in and people with whom to associate, parents remain the most important source of information and decision-making around long-term life choices such as school and career.³⁴

Elements of Effective and Ineffective Programs and Strategies

Much research has gone into determining what elements of preventive interventions are effective. There is much more to be learned about intervention strategies that do and do not work and about general principles of effective delivery. Thus, an area of research for which there is particular interest is the translation of basic science findings for the development of innovative interventions. To date the program content strategies that have been demonstrated to work typically involve the development of skills. Some of these have been mentioned previously and it was noted that the program or strategy should reflect the needs of the target population. In this section effective and ineffective programs and strategies will be more fully described and related to the pertinent social contexts with some attention to developmental timing.

At the intrapersonal level the most important strategies are those that build skills and competencies. Obviously these become more complex over the course of development. For the very young child learning to conform to rules, to behave in prosocial ways, to identify and appropriately express feelings and to control impulses are some of the important skills to learn. During the school years these skills remain important and more skills are added to the repertoire, including academic competence, social resistance, social emotional learning, and normative education.

*Family-Based Interventions*³⁵

So how does family-based prevention programming aid in building these skills? For the very young the emphasis is on the parent and targets training parents to have developmentally appropriate expectations for their children, adjusting these as the child matures. One universal program teaches the important strategy of reinforcing appropriate behaviors that the child naturally expresses and to the extent possible, ignoring inappropriate behaviors. The program developers call this strategy “catching them being good.”³⁶ Reinforcing weak but existing skills is extremely important because it gives the child a sense of control over her environment while emphasizing that the child has the ability to behave in socially acceptable ways. Of course some children exhibit problem behaviors from a very young age and more targeted approaches are needed. For example, the high pitched cries of prematurely born infants often illicit negative reactions from caregivers, which in turn results in poorer care of these very vulnerable infants. Thus, teaching parents strategies to cope with these and other early problems such as difficult temperamental characteristics can prevent

the escalation of problem behaviors, help the parents to accept the reality of the problem, and to be patient in training the child in more appropriate reactions, thus providing the parents with the sense of efficacy they need in parenting a difficult child.^{36,37,38,39}

As mentioned, transitions are points of vulnerability and the transition to school and to each additional school level after that are major periods of risk. New expectations for academic and social performance escalate over the school years and these can be very threatening to some children. Parental support and interest is important during these transitions. This generally means becoming familiar with their child's friends, their friends' parents and their teachers, monitoring their school work and social opportunities, and taking an active interest in their developing autonomous life.

School-based Interventions

At school a number of programs and strategies have also been demonstrated to make for successful transitions and academic careers. One important strategy is appropriate classroom management. Classroom management trains teachers in building strategies for rewarding positive behaviors and over time has the effect of reducing the bulk of negative classroom behaviors.^{40,41,42} This results in an environment where learning is the primary goal and the primary source of reward. While this may seem self-evident, many beginning teachers are not equipped to manage the types of classroom problem behaviors that take away from the priority of the school—learning. Thus, training teachers to use consistent, easy to learn routines that are fun for the children can enhance learning and bonding to school—two important protective factors. This type of strategy is called an environmental change strategy because it changes the classroom environment from one centered on reducing negative behaviors to one focused on promoting positive behaviors and learning.

Another type of classroom management approach, typically used with students in grades K through 3 is called social emotional learning.^{30–32,43,44} This approach helps children to identify their feelings, such as frustration, anger, and over-stimulation and then provides them tools to manage these feelings. Because this is a classroom-based intervention, all of the children know the approach and understand when a particular child is signaling that he or she are having a difficult time and respects his or her efforts to overcome the problem in a prosocial manner. Developing social emotional awareness at a very young age has long term positive effects on both academic and social performance across the school years and into adulthood.

The other type of intervention that can take place with young students is promoting academic competence. While this is not restricted to the early grades it can have the most profound effects at that developmental period in fostering a positive attitude toward learning, a sense of accomplishment, and of course, an understanding of the basics necessary for future learning.⁴⁵ These are all protective factors leading to a greater likelihood of a positive life trajectory. For example, one very potent risk factor for subsequent substance abuse, delinquency, school drop out, and under employment is the inability to read by the end of the second grade.^{39,40} By ensuring that children get the additional support they may need to achieve reading by this critical period helps to ensure on-going academic success. Of course academic problems can occur throughout an individual's school career and providing the necessary academic support is an important responsibility of schools. However, parents often need to be the driving force in seeing that this occurs.

The transition to middle school or junior high school is typically the transition most proximal to exposure to and/or experimentation with drugs. For this reason several program components have been developed that target this age group in particular. The first is social resistance skills. Resistance skills training is based on the social learning theory and stresses the importance of social factors in the initiation of drug use. Thus, the intervention paradigm focuses on teaching youth skills to handle peer pressure to experiment with drugs. This often includes either role play or video vignettes where an offer

is made and then strategies for rebuffing the offer are taught. Given the developmental status of this age group and their need to conform and maintain peer friendships, resistance strategies that do not alienate peers are taught. Social resistance programs applied in a regular classroom setting are highly successful. For example, in one randomized controlled trial, youths in the intervention groups were 30–40% less likely to initiate tobacco use compared to those in the nonintervention group.^{46,47} Interestingly, recent findings indicate that six years after this drug abuse prevention intervention was completed, those who received the intervention during junior high school were significantly less likely to have driving violations and points on their Department of Motor Vehicles records than those who did not receive the intervention. This finding illustrates relatively common phenomenon in long-term follow-up studies of interventions—cross-over effects—positive effects on behaviors not addressed in the original intervention.⁴⁸

Normative education is another strategy that has some positive effects but only when used in conjunction with skills development strategies. The goal of normative education is to correct misperceived positive norms about the actual use and acceptance of drug use. One strategy used is to actually survey students in a school about their perceptions of drug use among their peers, their perceptions of their peers' acceptance of use, and their own drug use. In most cases students' perceptions of use and acceptance of use are much higher than actual use and acceptance. These data are then reported back to students placing the "real school drug climate" in perspective and allowing students to feel that they are the norm rather than the outliers. It also reinforces the perception of the school as a safe and nurturing environment.^{46,49,50}

Community-based Interventions

At the community level and beyond, prevention strategies typically involve policy and media interventions. Policy interventions include activities such as training shopkeepers on how to request identification from purchasers of tobacco and alcohol products and how to refuse sales to those that do not meet the minimum age requirements. Other policy approaches include enforcing college campus rules about the underage use of illicit drugs and any use of illicit drugs.^{51,52}

Media can be a successful tool in reducing the initiation and progression of drug abuse when it is appropriately used. One risk factor for substance abuse is a personality trait called high sensation seeking. For youth with this trait, a media strategy that works is offering alternative activities. In one media intervention study, young adult marijuana users with the high sensation seeking trait were targeted with media messages that offered alternative activities with high sensation value such as rock climbing. Spots were aired in one community; a second community did not receive the media spots. Identified groups of high sensation seekers were followed over time. The intervention community group had a 27% reduction in marijuana use compared to the control community group after 6 months.^{53,54,55}

Ineffective Intervention Strategies

Unfortunately, prevention programs and strategies that have been demonstrated to be effective are not always used. The strategy that has been demonstrated to be the least effective is fear arousal.^{56,57} One way of introducing this strategy is through testimonials from former substance abusers. These types of testimonials can actually have the unintended negative effect of making the drug-dependent life sound romantic. Other fear-inducing strategies include media spots that inaccurately portray the harmfulness of drugs. Youths tend to discount these and substitute the negative information with information that is unrealistically positive.

Other ineffective strategies do not have unintended negative effects; however, they are ineffective in the absence of effective strategies. For example, information is an important component of most interventions; however information alone is not effective in altering behaviors. Similarly effective education where children are

involved only in activities to build self-esteem, while not harmful, is not effective in developing positive behaviors. Finally, alternate programming only, for example extracurricular activities, is not effective. Thus, these types of strategies should be looked at as “add-ons”.

Program Delivery

The state of the knowledge at this point clearly shows that the skills/competency development interventions are the most potent in terms of effectiveness. In addition, there are some general principles of delivery that are often the determining factors in whether an intervention is successful or not. Delivery refers to the way in which the program or strategy is implemented with the target population. Programs that involve interactive activities providing participants with skills practice and then reinforce those skills over time have been found to be the most successful in facilitating the desired behavior change; on the other hand, didactic strategies in which information is delivered in a lecture format have been found to have little effect.^{56,57,58}

Dosage is also critical. That means that a significant amount of the “active ingredients” of the intervention must be delivered and received for it to have the desired effect. In the same vein, providing “booster sessions” in the months and years postintervention to reinforce the important skills that have been developed help to maintain positive behavior change and skills. This implies that the intervention was delivered with fidelity to the program or strategy as originally designed and validated. At this time, little is known about what defines the “active ingredients” of behavioral interventions, thus deviations in the delivery of a program or strategy can inadvertently leave out the most important features of the intervention. Finally, it is critical that prevention efforts be consistent across contexts. That is, efforts at the individual, family, school, and community levels should reinforce one another. Inconsistency across contexts creates confusion and may result in the discounting of all efforts.⁵⁹

▶ A FINAL MESSAGE TO HEALTH CARE PROVIDERS

This chapter is intended to give an overview of the current state of drug abuse prevention interventions and the knowledge on which they are based. Absent is the role of the physician and other health care providers in reducing the initiation and progression of drug use. Health care personnel have the unique opportunity to interact one-on-one with patients about their health behaviors. However, few take the opportunity to screen patients for substance abuse or risks that may subsequently lead to substance abuse. A small but growing body of research is developing and being tested in medical offices, clinics, and hospitals. One approach being investigated is the use of technology-based tools to screen for potential drug-related problem behaviors. For example, one of the most developed research-based tools at this time is for women who have been raped. The intervention is intended to reduce the trauma caused by the rape itself and the postrape forensic evidence collection procedures. Following these experiences substance abuse may begin or be exacerbated. The intervention is provided through a two-part video presentation that addresses the process of the forensic examination to reduce stress and future emotional problems. It also provides information and skills to reduce postrape substance use and abuse. Early findings suggest reductions in alcohol and marijuana use among women who were active users prior to the rape compared to the nonviewers.^{60,61} Another example of medically-oriented tools being developed and tested is for drug abuse risk and screening among youth. The goals of developing and testing these tools are to involve the primary care physician or physician’s assistant in identifying patients at risk, providing brief interventions, and potentially providing referrals for more intensive intervention. As with all interventions, life transitions may be critical periods for physicians to screen their patients, for example, during school physicals and/or pregnancy examinations.

Community Health Promotion and Disease Prevention

Stephanie Zaza • Peter A. Briss

► INTRODUCTION

In 1988, the Institute of Medicine (IOM) released *The Future of Public Health*,¹ a seminal report that found the national public health infrastructure to be in disarray. The IOM committee defined the mission of public health as fulfilling society's interest in assuring conditions in which people can be healthy. It then developed clear statements about the role of government in three core public health functions: assessing health status, developing policy, and assuring that necessary services are provided. Finally, the committee made specific recommendations for responsibility and action at the national, state, and local levels to achieve the core functions.

The 1988 IOM publication was ultimately complemented by the 1994 report of the Department of Health and Human Services (DHHS) Public Health Functions Steering Committee, which described 10 essential public health services that corresponded to the IOM core functions (Table 57-1²). The core functions and essential services focused on the roles and responsibilities of governmental public health organizations at the national, state, and local level and were important for refocusing public health organizations and for promoting organized approaches to public health.

With the publication in 2003 of *The Future of the Public's Health in the 21st Century*,³ the IOM expanded its definition of public health to include all of society's efforts to achieve improved health. Recommendations addressed health policy at every level of American society and expanded efforts to enlist all sectors in improving health outcomes. For example, in this later report, recommendations for responsibility and action in public health are made not only for governmental entities but also for community representatives and organizations (e.g., congregations, civic groups, and schools), the health care delivery system, employers and business, the media, and academia.

In 2005, the Task Force on Community Preventive Services (a nonfederal committee supported by the U.S. Centers for Disease Control and Prevention) released the *Guide to Community Preventive Services*⁴ to assist communities in realizing the expanded version of public health suggested by the IOM report. The *Community Guide*, which provides syntheses of the best available scientific information to support health programs and policies, can help make delivery of the 10 essential health services more effective at the local level.⁵

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Taken together, these four reports illustrate the need for a holistic public health approach—one that includes several important emerging themes. First, the reports call for a holistic public health approach that comprehensively and fairly marshals the skills and resources of the entire community to promote health and prevent disease. In addition, they underline the principles of widespread community participation and building of partnerships in public health planning and action. Finally, they highlight the importance of taking an organized and thoughtful approach to the planning and implementation of health programs, which should include using the best available evidence to support decisions and action. This chapter will describe the holistic approach proposed in these seminal reports and provide specific examples of how such an approach is being implemented. In addition, the chapter will provide examples of making the link between different kinds of public health decisions and the best types of evidence to support those decisions.

► THE HOLISTIC APPROACH

In the holistic approach to public health, communities are the public health agents, and they must concentrate on the needs, preferences, and assets of the entire community. In doing so, they must consider a broad range of health conditions (e.g., chronic diseases such as diabetes and atherosclerosis, viral and bacterial infections, accidental injury), risk factors (such as smoking and inactivity), and protective factors (e.g., education, exercise programs). They must also consider the distribution of life stages within the community, cultural differences, the array of health organizations in the community, and the various assets available in the community to promote health and prevent disease.

Organized holistic approaches improve efficiency by allowing programs within the community to leverage each other's strengths or by allowing programmatic activities to address multiple related outcomes (e.g., reduced levels of smoking, fewer complications of diabetes, improved cardiovascular health). Through broad-based public health activities that involve key stakeholders throughout the community, a richer and more detailed body of information is provided for decision-making. With these relationships and the information they provide, the likelihood that these issues will go unrecognized is reduced, problems can be identified earlier in their natural course, or more proximate solutions might be identified.

Socioecologic Model

The socioecologic model is useful for explaining a holistic approach to public health.⁶ This model describes patterned behavior, such as

TABLE 57-1. THE CORE FUNCTIONS AND TEN ESSENTIAL SERVICES OF PUBLIC HEALTH

Core Functions	Essential Services
Assessment	1. Monitor health status to identify health problems. 2. Diagnose and investigate health problems and health hazards in the community.
Policy Development	3. Inform, educate, and empower people about health issues. 4. Mobilize community partnerships to identify and solve health problems. 5. Develop policies and plans that support individual and community health efforts.
Assurance	6. Enforce laws and regulations that protect health and ensure safety. 7. Link people to needed personal health services and assure the provision of health care when otherwise unavailable. 8. Assure a competent public health and personal health workforce. 9. Evaluate effectiveness, accessibility, and quality of personal and population-based health services.
Serving all Functions	10. Research for new insights and innovative solutions to health problems.

Source: Institute of Medicine. *The Future of Public Health*. Washington, DC; National Academies Press; 1988.
Public Health Functions Steering Committee. *The Public Health Workforce: An Agenda for the 21st Century. Full Report of the Public Health Functions Project*. Washington, DC: U.S. Department of Health and Human Services; 1994.

health risk behaviors (e.g., diet, smoking patterns, drinking), as the outcome of interest; these outcomes are determined by individual, interpersonal, institutional, community, and public policy factors. The model makes explicit the importance of coordinated public health actions at each level to effect change in health behaviors.

The focus of the socioecologic model on multiple interacting levels of influence on behavior is consistent with taking broad approaches to public health programming that are not limited to any one agency or sector; indeed, the model allows for and even assumes the need for input and action across the community. A holistic approach that involves all of the stakeholders in an issue is more likely to be accepted by the target population and to identify and avoid unintended consequences. Finally, a holistic approach allows the linking of health promotion activities across different conditions and risk factors to achieve both increased efficiency and greater sustainability.

Infrastructure

Realizing the benefits of taking a holistic approach to community health requires a well-organized infrastructure (preferably with predictable and sustainable funding) that can serve as the interface for various community sectors (e.g., schools, work sites, and health care delivery organizations). This infrastructure can serve as the focal point for convening and planning public health activities, securing and distributing funding for these activities, and communicating with staff of other programs and with the public. The infrastructure can consist of both formal and informal networks, paid staff and volunteer experts, leadership teams, and large community coalitions. The infrastructure is only useful, however, insofar as it develops, implements, and supports programs and policies that achieve health goals the community considers important. The inputs to public health activities provided by the infrastructure are important elements in describing those activities and their impacts. Thus, it is also important to document all of the components of the infrastructure as part of the record describing how public health programs were accomplished.

Steps to a HealthierUS

A modern example of a federally funded program that follows a holistic approach is Steps to a HealthierUS (www.healthierUS.gov/steps). The program's purpose is to develop an integrated program of chronic disease prevention and health promotion in each funded community. A range of sectors—public health, education, business, health care delivery, and community and social services—are represented in an infrastructure that is created by Steps to a HealthierUS for each community. The infrastructure provides overall strategic planning and leadership; offers an interface through which sectors can interact; communicates the program to community leaders and residents; and integrates the program with other statewide initiatives, particularly those that are federally funded. Together with sector partners, the program develops, implements, and coordinates programs and activities to accelerate progress toward established Healthy People 2010⁷ objectives for health behavior and health outcomes in six focus areas: diabetes, asthma, obesity, nutrition, physical activity, and tobacco.

Clearly, involving multiple sectors and community partners is needed to make progress in the focus areas listed. For example, achieving the public health objectives of improving the quality of care for diabetes, reducing hospitalizations from exacerbations of asthma, or increasing the use of appropriate health care services cannot be achieved without direct improvements to the health care delivery sector. Similarly, complex health risk behaviors, such as smoking, binge drinking, and combining a high-calorie diet with inactivity, will not be addressed in the health care sector alone. There is, therefore, a growing recognition of the importance of school, work-site, and community settings for health promotion activities. For example, activities such as tobacco cessation and nutrition programs as well as organized recreation may require the involvement of the school, business, philanthropic, faith-based, and community-based sectors of the community. Furthermore, these sectors may have less opportunity to meet their objectives if they work independently rather than cooperatively. Ideally, programs should be coordinated across the sectors. For example, some school-based programs have been shown to be more effective if conducted in the context of broader community efforts (such as supporting school smoking bans with community cessation programs for students, faculty, and staff). The Steps to a HealthierUS program adds value by helping to flexibly integrate efforts across the community and across various health challenges.

► EVIDENCE-BASED DECISION-MAKING IN A HOLISTIC COMMUNITY APPROACH

While local community needs and preferences are driving forces in public health decision-making, other types of evidence are required for long-term sustainability of outcomes, including scientific evidence. Unfortunately, community control may be seen as antagonistic to the recent trend to use the best available science to inform public health decisions, creating tension between public health scientists and on-the-ground practitioners. The tension may be more apparent than real, however. For many public health problems (e.g., type 2 diabetes, smoking, heart disease), we have a good deal of knowledge about their prevalence and causes as well as effective solutions; this information can be learned across communities and then applied in specific contexts. This is similar to the case in clinical medicine, in which a generalizable science tells us about the causes of problems and the solutions that work for most people, but where individual patients and providers must still make decisions about how to proceed. Recent developments in the fields of “evidence-based medicine” and “evidence-based public health” have not only improved the science but have also helped to improve its credibility while speeding its way to the bedside or the community. In communities as well as at the bedside, however, locally appropriate decisions can be informed but not solely determined by this science.

Evidence

In common usage, “evidence” is simply “A thing or things helpful in forming a conclusion or judgment.”⁸ As in the courtroom, some forms of evidence are more persuasive than others, and different types of evidence apply to different types of decisions or questions. In public health we make hundreds of decisions every day, informed by various types of evidence. A call for improving or increasing evidence-based decision-making in public health should, therefore, focus on transparently and reliably matching appropriate types of evidence to the various types of decisions.

Four Decisions

In establishing programs for promoting health and preventing chronic disease, four primary decisions must commonly be made: (a) Should something be done? (b) What should be done? (c) How should it be done? (d) Is it working or does it need to be modified? As shown in Table 57-2, in each case there are related questions that should be posed⁹ for each decision. Approaches to making these decisions can be found in a variety of health promotion and planning models and tools, such as Mobilizing for Action through Planning and Partnership (MAPP) and the PRECEDE-PROCEED model.¹⁰⁻¹¹ This section

TABLE 57-2. A FRAMEWORK FOR USING DIFFERENT TYPES OF EVIDENCE TO MAKE DECISIONS IN PUBLIC HEALTH

<i>Decision</i>	<i>Type of Evidence</i>
Should something be done?	
What is the burden of disease?	<ul style="list-style-type: none"> • Surveillance data (measuring morbidity, mortality, years of potential life lost, incidence, prevalence) • Survey data • Vital statistics data • Medical utilization data • Cost data
What is the urgency?	<ul style="list-style-type: none"> • Basic medical data (e.g., does the condition or risk factor progress rapidly or have serious complications?) • Trend data
Is it a priority for the community? What is the perceived need?	<ul style="list-style-type: none"> • Degree to which the problem is understood (e.g., emerging issues such as avian flu or environmental hazards might merit more attention than can be justified based on current burden) • Perceived interest or importance based on surveys, focus groups, political processes, or other information
What should be done?	
What is the nature of the problem?	Information gleaned from analysis of conceptual and empirical information on causes, natural course of the problem, and possible points of intervention
What works?	<ul style="list-style-type: none"> • Scientific evidence of effectiveness from individual evaluation studies • Systematic reviews of evaluation studies
What is acceptable to the community?	<ul style="list-style-type: none"> • Information about community members' understanding and approval of possible intervention strategies from: <ul style="list-style-type: none"> • Focus groups • Key interviews • Town hall meetings • Anecdote • Political processes
What can be afforded?	Information based on a comparison of typical costs and cost-effectiveness (gleaned from economic analysis) and local assets
What is feasible?	<ul style="list-style-type: none"> • Organizational assessment • Experience, interviews, etc.
How should it be done?	
What steps are needed to implement this intervention?	<ul style="list-style-type: none"> • Documentation from previous implementation of the specific intervention and other related interventions • “Best process” information • Anecdotal experience from others who have implemented the intervention
What barriers must be overcome to implement this intervention?	<ul style="list-style-type: none"> • Documentation from previous implementation • Anecdotal experience from others who have implemented the intervention • Complex systems modeling • Focus groups
Is it working or does it need to be modified?	
Is it being implemented well?	<ul style="list-style-type: none"> • “Process” measures from checklists, interviews, and other data collection tools • Achievement of behavior or health outcomes from evaluation and program monitoring efforts
What does the community think?	<ul style="list-style-type: none"> • Focus groups • Interviews • Less formal data collection • Political processes
Is it improving health risks or outcomes?	Achievement of behavior or health outcomes from evaluation and program monitoring efforts

focuses on the types of evidence that are used to make decisions and points out the wide variety of information, from scientific to anecdotal, that is applicable.

The first decision, “Should something be done?” is the essence of community-based planning for promoting health and preventing disease. Often, the decision about whether to take action relies on surveillance data, surveys, or other studies that indicate the burden of the disease or risk factor in question, frequently expressed as years of potential life lost or costs incurred. Here, communities must also consider the urgency of the issue: Is there an increasing trend? Is the problem particularly severe or disabling? Finally, communities must also consider whether addressing the problem is a priority. In some cases, the level of understanding about the problem will drive priority (e.g., issues that seem more novel may be given higher priority); the perception of risk and the acceptability of potential solutions may also determine priority.

In addressing “What should be done?,” communities must first consider the essential nature of the problem. In the PRECEDE portion of the PRECEDE-PROCEED model, Green and Kreuter point out that, “The determinants of health must be diagnosed before the intervention is designed; if they are not, the intervention will be based on guesswork and will run a greater risk of being misdirected and ineffective.”¹¹ For example, a mass media campaign to improve the population’s coverage for a vaccine is unlikely to increase immunization rates if the real problem is that people do not have access to clinics where the vaccine is offered. In brief, a detailed analysis of the local situation is required to understand how the problem should be addressed.

Failing to take advantage of the best available generalizable knowledge in addressing local priorities can also result in ineffective or misdirected efforts. The second part of the “what should be done” decision is an understanding of what works. Scientific evidence is the most reliable and generally most appropriate type of evidence for determining what works; scientific evidence consists of individual studies and reviews that synthesize those studies. Ideally, this evidence will show how much change can be expected in the outcomes of interest based on work from other communities or contexts.

Individual studies can be an excellent basis for making recommendations; they are relatively easy to find, can provide specific “recipes” for what to do, and are easy to understand. On the other hand, in many cases there will be numerous studies that seem potentially relevant, making it difficult for practitioners to keep up with them, and their results may conflict. In addition, they typically provide little information on which characteristics of the intervention or context contribute most to effectiveness.

Literature reviews are helpful for identifying and summarizing the vast scientific literature, but each approach to performing these reviews has disadvantages as well as advantages. Expert or narrative reviews are carried out by experts who gather information based on their own experience and knowledge. These reviews are useful for giving a conceptual overview of a subject but can be subject to conscious or unconscious bias in how information is collected and assembled and how the conclusions relate to that information.

In contrast, systematic reviews are based on *a priori* rules that lay out the study question, a search strategy, criteria for including or excluding studies, parameters that will be applied to judge the quality of each study, and methods for analyzing data. Meta-analyses, a subset of systematic reviews, allow for the calculation of an overall effect size (i.e., the quantifiable effect of the intervention on desired outcomes) for the group of studies included according to specific statistical methods. The advantages of systematic reviews (e.g., reduced bias and improved transparency) come at a cost, however, as they require greater time and technical expertise to conduct, resulting in fewer of these types of reviews being available.

Two examples of systematic reviews used to support recommendations for preventive medicine and public health are the *Guide to Clinical Preventive Services*¹² and the *Guide to Community Preventive Services*.⁴ The *Guide to Clinical Preventive Services*, developed by the U.S. Preventive Services Task Force (USPSTF), provides reviews and recommendations about individual clinical services, such as screening tests, counseling on health behavior, and

chemoprophylaxis (www.ahrq.gov¹²). The *Guide to Community Preventive Services*,⁴ in contrast, provides reviews and recommendations about a variety of public health interventions, such as strategies that use education, policy, system change, or environmental approaches to effect change (www.thecommunityguide.org). Together, the two references provide a broad range of interventions that have been shown through extensive scientific study to be effective.

Reviewing scientific studies to know what works is necessary for decision-making, but determining “What should be done?” means that additional questions must be asked: (a) What is acceptable to the community? (b) what can our community afford? and (c) what is feasible given our resources and capacity? These questions are answered through focus groups, interviews with key informants, and economic and systems analyses.

To address the third major decision, “How should it be done?” communities may be able to consult practice guidelines that provide additional information about how to implement recommended interventions, such as policies to ban smoking, standing orders for routine delivery of vaccinations, or campaigns to enforce laws on safety belt use. With increasing frequency, developers of guidelines and other public health practitioners are developing tool kits and materials to help move recommended interventions into practice. In addition, communities can review “best processes” to obtain information and advice about the ways of implementing programs that have been most successful across studies, as found, for example in the “Community Toolbox” developed by the University of Kansas (<http://ctb.ku.edu>). Finally, community leaders and members can draw on personal experience and anecdotes as well as documentation from previous implementations to answer the question of how things should be done.

The last of the major decisions, “Is it working or does it need to be modified?” is tied to program management, as evaluation of a program is used to determine a program’s effectiveness and, where possible, to improve performance. Ideally, this evaluation process should involve a broad range of stakeholders. The Centers for Disease Control and Prevention (CDC) has outlined a basic framework for evaluating programs that is used widely in public health and consists of just six steps: (a) engage stakeholders; (b) describe the program; (c) focus the evaluation design; (d) gather credible evidence; (e) justify conclusions; and (f) ensure use and share lessons learned.¹³ The developers of the CDC framework emphasized that the evidence gathered in step 4 must be perceived by stakeholders as relevant in addition to being believable. Thus, a variety of types of evidence might be needed, ranging from systematically collected data obtained through a well-controlled experiment to the results of document review, focus groups, and interviews with key informants.

For all of the decisions that have been discussed here, debates are ongoing about what evidence is most appropriate, how to improve the quality of that evidence, and when a body of evidence is sufficiently credible to support action. It is important to report that the need to improve the quality and transparency of the science that supports public health decisions has been recognized and that efforts to make those improvements are ongoing.

► CONCLUSION

To be successful, initiatives to promote health and prevent disease require a holistic approach, a commitment from the entire community, and a reliance on credible information. The approach described here incorporates all of these elements.

Risk Communication—An Overlooked Tool for Improving Public Health

David P. Ropeik

One thousand and eighteen more Americans died in motor vehicle crashes October through December 2001 than in those 3 months the year before, according to researchers at the University of Michigan's Transportation Research Institute. As those researchers observed "... the increased fear of flying following September 11 may have resulted in a modal shift from flying to driving for some of the fearful."¹ One thousand and eighteen people dead, more than one-third the number of people killed in the attacks of September 11, in large part because they perceived flying to be more dangerous and driving less so, despite overwhelming evidence to the contrary.

In 1971, President Richard Nixon signed the National Cancer Act and declared "War on Cancer." In 2004 the National Cancer Institute had a budget of \$4.7 billion.² In 2002, cancer killed 557,271 Americans. That same year, heart disease killed 696,947.³ Yet the National Heart, Lung, and Blood Institute spent approximately \$1.8 billion on cardiovascular diseases, including heart disease, in 2004.⁴ And there is no National Heart Disease Act, nor a national "War on Heart Disease", despite the fact that heart disease kills roughly 25% more Americans each year than cancer, roughly 140,000 more deaths in 2002 alone.

Chronically elevated stress is known to weaken the immune system, contribute to cardiovascular and gastrointestinal damage, interfere with fertility, impair the formation of new bone cells, impede the creation of long-term memory, and contribute to a greater likelihood and severity of clinical depression.⁵

What do these three cases have in common? They demonstrate the threats to public health caused by gaps between risk perception, informed by the intuitive reasoning by which humans gauge the hazards they face, and risk realities based on science. The examples above demonstrate the vital role risk communication can play in advancing public health, by helping narrow those gaps.

► RISK COMMUNICATION DEFINED

Currently, there are multiple definitions of risk communication; however, most embody the basic idea that by providing people with more information, they will be able to make smarter choices about their health.

But that was not always true. The term "risk communication" arose largely as a result of environmental controversies in the 70s, when public concern was high about some relatively lower threats to human and environmental health. Scientists, regulators, and the regulated

community described people as irrational, and their frustration gave rise to efforts to educate the public and defuse those controversies.

Early risk communication was viewed as a one-way process in which experts would explain the facts to the ill-informed lay public in ways that would help people behave more rationally, especially about such issues as air and water pollution, nuclear power, industrial chemicals, hazardous waste, and other environmental hazards. Thus, the goal of early risk communication was not always to enlighten people so they might improve their health. Instead, it was frequently a tool to reduce conflict and controversy, and often it was simply an effort by administrators, regulators, or company representatives to diminish opposition to particular product or technology or facility-citing proposal. One researcher defined risk communication as "a code {word} for brainwashing by experts or industry."⁶

But risk communication has evolved. This chapter will use the following definition:

Risk communication is a combination of actions, words, and other interactions responsive to the concerns and values of the information recipients, intended to help people make more informed decisions about threats to their health and safety.

This definition attempts to embody the ways that risk communication has evolved and matured over the past 15 years or so. Most importantly, the consensus among experts in the field now rejects the one-way "We'll teach them what they need to know" approach. A National Research Council committee effort to move the field forward produced this definition in 1989. "Risk communication is an interactive process of exchange of information and opinion among individuals, groups, and institutions. It involves multiple messages about the nature of risk and other messages, not strictly about risk, that express concerns, opinions, or reactions to risk messages or to legal and institutional arrangements for risk management."⁷ In other words, risk communication should be considered a dynamic two-way interaction. Both sides express their perspectives, and both sides have to listen and respond to information from the other.

Perhaps even more fundamental, and intrinsic to the idea of the two-way street, is the growing acceptance among risk communication experts that risk means something inherently different to the lay public than what it means to scientists and regulators. When laypeople are asked to rank hazards in terms of mortality rates, they tend to

generally agree with the vital statistics. But ask them to rank what is *risky* and their responses change, with some lesser hazards, such as nuclear power, moving toward the head of the list, and some relatively larger risks, like smoking, moving further down.⁸ “Risk” is perceived as more than a number by the general public. Other attributes, like trust, dread, control, and uncertainty, also factor into the judgments people make that subsequently influence the nature and magnitude of their fears.

As risk communication has evolved, there is increasing (but by no means, universal) acceptance by practitioners that both the science-based view of experts and the intuitive view of risk among the general public are valid, and both must be respected and incorporated if communications about risk is to be effective.

This evolution is summed up in Risk Communication and Public Health, edited by Peter Bennett and Kenneth Calman:

“... there has been a progressive change in the literature on risk:

- from an emphasis on ‘public *misperceptions*’, with a tendency to treat all deviations from expert estimates as products of ignorance or stupidity
- via empirical investigation of what actually concerns people and why
- to approaches which stress that public reactions to risk often have a rationality of their own, and that ‘expert’ and ‘lay’ perspectives should inform each other as part of a two-way process.”⁹

People are not being *irrational* when their fears don’t match the expert view of a potential high-risk situation. While they may not be exclusively relying on evidence from toxicology, epidemiology, statistics, economics, and the other sciences of risk assessment and risk analysis, research from a number of fields has established that the lay public’s perception of risk develops under conditions of “bounded rationality.”¹⁰

As it is applied to the perception of risk, bounded rationality essentially describes the process individuals use to make judgments when they have less information, time, or cognitive skills than a fully rational judgment would require. As Reinhard Selten writes “Fully rational man is a mythical hero who knows the solutions to all mathematical problems and can immediately perform all computations, regardless of how difficult they are. Human beings are in reality very different. Their cognitive capabilities are quite limited. For this reason alone, the decision-making behavior of human beings cannot conform to the ideal of full rationality.”¹¹

Gigerenzer and Selten refer to bounded rationality as “the adaptive toolbox,” the set of “fast and frugal rules” or mental processes humans have evolved to apply fact, feelings, instinct, and experience to the choices we face about threats to our survival.¹² Neuroscientists have determined that some of the processing of threat information may be determined by aspects of human brain structure. Psychologists have identified a set of affective characteristics that make some risks seem larger and some smaller, the scientific data notwithstanding. Others have described a number of common heuristics and biases, mental shortcuts that turn complicated choices into simple ones, sometimes leading to judgments that seem suboptimal, based solely on “the facts”.

These are powerful insights into more effective risk communication. By understanding the biology and psychology of how humans perceive risk, we can understand why and how lay and expert definitions of the very concept of risk vary. Such insights provide critical tools for effective risk communication because they help communicators both understand and *respect the validity* of the “intuitive reasoning” people use to gauge risk. By understanding and respecting lay perceptions of risk, the risk communicator can choose content, tone, and information delivery processes that increase the likelihood that their audience(s) will be more receptive, and their information will have more utility for the people with whom they are interacting.

The Greek Stoic philosopher Epictetus said “People are disturbed, not by things, but by their view of them.” Understanding the roots of what shapes those views allows the true dialogue of modern risk communication to take place.

► THE BIOLOGY OF FEAR

Neuroscientist Joseph LeDoux and others have made remarkable discoveries about how the human brain processes raw sensory data into perceptions of threat and hazard. They have found that what we consciously describe as fear begins in the amygdala. External sensory information travels from end organs along neural pathways that send the information to the amygdala and the cortex. But the amygdala, where fear begins, responds before the cortex has a chance to process the information and add its analysis to the risk perception process. This same time lag (LeDoux estimates it at about 20 milliseconds) applies to non-sensory inputs as well, such as thoughts, memories, etc. In very simplified terms, this means that information is processed in the part of the brain where we fear *before* it is processed in the part of the brain where we think. That alone has profound implications for risk communication since it appears that the hard wiring of the brain, in managing fear, may favor rapid response (i.e., fight-or-flight) over deliberation of the best course of action. Thus, biology may help to explain why risk means one thing to experts and another to the lay public.¹³

► RISK PERCEPTION PSYCHOLOGY

Some of what we are commonly afraid of seems instinctive; snakes, heights, the dark. Indeed, Charles Darwin recognized this and visited the London Zoo’s poisonous snake exhibit, repeatedly tapping on a glass window to provoke a strike by the snake inside, trying to teach himself not to recoil in fear. His effort in self-delivered risk communication failed. The innate fear, and the adaptive “fear first, think second” construction of the brain’s hazard perception systems could not be overcome.

But how do people subconsciously *decide* what to be afraid of, and how afraid to be, when the threat does not trigger an instinctive reaction? When people hear about a new disease, product, or technology; when individuals try to gauge the risk of something against its benefits; when persons learn new information about a potential hazard and try to fit it into what they already know. How does the human mind filter incoming data and translate it into our perceptions of what is risky and what is not?

The answers are to be found in two literatures, both of critical relevance to risk communication. The first is the study of how people generally make judgments of any kind, including judgments about risk, under conditions of uncertainty. This work has identified a number of systematic biases that contribute to what seem to be suboptimal *irrational* choices. The second is the specific study of the psychology of risk perception, which has identified more than a dozen affective attributes of risk that tend to make us more or less afraid, even when our apprehension doesn’t seem consistent with the scientific data.

General Heuristics

The discovery of systematic biases that lead to suboptimal choices was championed by, among others, Daniel Kahneman, a social psychologist who was awarded the 2002 Nobel Prize in Economics for his work. Kahneman, Amos Tversky, and others, identified a number of heuristics—mental shortcuts that simplify decision tasks when time, complete information, or both are unavailable. This field has direct relevance to risk communication, as noted in a seminal paper on risk perception: “When laypeople are asked to evaluate risks, they seldom have statistical evidence on hand. In most cases, they must make inferences based on what they remember hearing or observing about the risk in question.” “These judgmental rules, known as heuristics, are employed to reduce difficult mental tasks to simpler ones.”¹⁴

Here are some of the heuristics and biases of greatest relevance to risk perception, and therefore to risk communication.

Optimism. Many studies have found that people believe their personal risk is lower than the same risk faced by others in similar circumstances. A greater percentage of people think an adverse event might happen than think it will happen to them.¹⁵ These biases are often strongest when the risk involves personal choice, such as lifestyle risks including

smoking, obesity, or wearing safety belts. This underestimate of personal risk poses obvious challenges to achieving effective risk communication about some of the major threats to public health.

Availability. Individuals assess probability based on how readily similar instances or occurrences can be brought to mind of conceptualization. The risk of terrorism in the United States is statistically quite low. But apprehension is high since September 11, 2001, in part because such an event is more “available” to our consciousness. The availability heuristic explains why, when a risk is in the news, (flu vaccine issues, West Nile virus, child abduction, etc.) it evokes more fear than when the same risk is around, at the same level, but not making headlines.

Framing. The way a choice is presented can shape the judgment that results. Imagine you are the mayor of a city of one million people and a fatal disease is spreading through your community. It is occurring mostly, but not exclusively, in one neighborhood of 5000 residents. With a fixed amount of money, you can either (a) save 1000 of the 5000 residents in that neighborhood, 20%, or (b) save 2000 people out of the entire city of 1 million, 0.2%. What do you do?

A sizable number of people in risk communication classes choose option A, which produces a greater percentage effectiveness, but condemns 1000 people to death. Reframed, the choice would be: You can spend a fixed amount of money and save 1000 people or 2000. Presented that way, the choice is obvious. But the framing of the question in terms of percentages skews the judgment.

Anchoring and Adjustment. People estimate probabilities based on an initial value and adjust from that point. In one experiment, separate groups were asked how many nations there are in Africa. Before giving their answer, each group spun a wheel of chance. The group for which the wheel settled on the number 10 estimated 25 nations. The group whose wheel landed on 65 estimated 45 nations.

In another experiment, two groups of high school students estimated the sum of two numerical expressions they were shown for just 5 seconds, not long enough for a complete computation. The median estimate for the first group, shown $9 \times 8 \times 7 \times 6 \times 5 \times 4 \times 3 \times 2 \times 1$, was 2250. The median estimate for the second group, shown the same sequence but in ascending order— $1 \times 2 \times 3 \times 4 \times 5 \times 6 \times 7 \times 8 \times 9$ —was 512.¹⁶

Representativeness. Kahneman and Tversky describe this as “the tendency to regard a sample as a representation . . .” of the whole, based on what we already know.¹⁷ They offer this illustration. Consider a person who is “very shy and withdrawn, invariably helpful, but with little interest in people, or in the world of reality. A meek and tidy soul, he has a need for order and structure, and a passion for detail.” Then consider a list of possible professions for this person; farmer, salesman, airline pilot, librarian, or physician. Without complete data by which to make a fully informed choice, the representativeness heuristic gives you a simple mental process by which to judge, and leads to the choice that the person is probably a librarian.

Applied to risk communication, this suggests that if you describe “an industrial chemical used to kill pests,” people are likely to associate it with the universe of industrial chemicals and regard it as a risk, without regard to the details about that specific chemical.

Kahneman and Tversky also found that people think a short sequence of events generated by a random process, like coin tossing (or, in the case of risk communication, random natural events like floods, earthquakes, etc.) will represent their understanding of the basic characteristics of the whole process. People think that when tossing a coin, H-T-H-T-T-H is more likely than H-H-H-T-T-T because the second sequence isn’t random, which they expect coin tossing to be. They disregard statistical rationality (both coin toss sequences are equally as likely) because of the heuristic of representativeness.

Risk Perception Characteristics

Work in a related field, the specific study of the perception of risk, has gone further and identified a number of attributes that make certain risks seem more worrisome than others.

These “risk perception factors” are essentially the personality traits of potential threats that help us subconsciously *decide* what to be afraid of and how afraid to be. They offer powerful insight into why “risk” means different things to the lay public than it does to experts. The following list has been reviewed by Paul Slovic, one of the pioneers in the field of risk perception research. It includes examples to demonstrate each factor, and in some cases, suggestions of how awareness of the factor can be used to guide more effective risk communication.

Trust. The more individuals trust, the less they fear, and vice versa. When persons trust *the people informing them* about a risk, their fears go down. When individuals trust *the process* deciding whether they will be exposed to a hazard, they will be less afraid. When they trust *the agency or company or institution creating the risk*, they are less afraid. Most critically, when people trust *the agencies that are supposed to protect them*, they will be less afraid. If people *don’t* trust the individuals informing them, the process determining their exposure to a risk, the institution(s) creating the risk in the first place, or the people protecting them, they will be more afraid.

Trust comes from openness, honesty, competence, accountability, and respecting the validity of the lay public’s intuitive reasoning about risk. Trust is the central reason why two-way risk communication, in language that validates the feelings and values and heuristic instincts of the audience, is likely to be more effective than one-way communication that only offers the facts.

Risk versus Benefit. From taking prescription drugs that have side effects to picking up a cell phone to make that important call while driving, people intuitively measure hazards by comparing risks and benefits. The more they perceive a benefit from any given choice, the less fearful they are of the risk that comes with that choice. This factor explains why, of more than 400,000 “first responders” asked to take the smallpox vaccine in 2002 fewer than 50,000 did. They were being asked to take a risk of about one in a million—the known fatal risk of the vaccine—in exchange for no immediate benefit, since there did not appear to be an actual smallpox threat. Imagine if there was just one confirmed case of smallpox in a U.S. hospital. The mortality risk of the vaccine would still be one in a million, but the benefit of the immunization would appear tangible.

Control. If a person feels as though he or she can control the outcome of a hazard, that person is less likely to be afraid. This can be either physical control as when a person is driving and controlling the vehicle, or a *sense* of control of a process, as when an individual feels that he or she is able to participate in policy making about a risk through stakeholder involvement through hearings, voting, etc.

This is why *shared control*, from the one-on-one relationship between doctor and patient, up to community empowerment in the citing of potentially hazardous facilities, is an effective form of risk communication. This is also why, whenever possible, risk communication should include information not just about the risk (“The risk of terrorism has gone from Code Yellow to Code Orange”) but also offer information about what audience members can do to reduce their risk (“Have a family emergency plan in place, just in case”).

Imposed versus Voluntary. This is the *choice* of taking a risk, not the physical *control* over what happens next. People are much less afraid of a risk when it is voluntary than when it is imposed on them. Consider the driver using his cell phone who looks over at the car in the lane next to him and sees *that* driver on *his* phone, speeding up and slowing down and not staying in his lane. Driver A, voluntarily engaged in the same behavior, is angry at Driver B for imposing the risk.

Natural versus Human-made. If the risk is natural, people are less afraid. If it’s human-made, such as nuclear radiation, people are more afraid. Radiation from the sun evokes less fear in some people than radiation from a nuclear power plant, or from a cell phone tower.

Here is an example of how to use this principle in risk communication. Resmethrin, the chemical used to kill mosquito larvae to

reduce the risk of West Nile virus, is a pesticide, and its use often evokes community concern. When the minimal risks of resmethrin are described, community resistance is largely unchanged. But when told that resmethrin is essentially a manufactured form of chrysanthemum dust, in essence a natural pesticide, concern (among some people) about the spraying goes down.¹⁸

Dread. We are more afraid of risks that might kill us in particularly painful, gruesome ways than risks that might kill us less violently. Ask people which risk sounds worse, dying of a heart attack or dying in a shark attack, and they will say shark attack, despite the probabilities.

This principle helps to explain why the United States has a “War on Cancer” but not “War on Heart Disease”, a greater killer. Cancer is perceived as a more dreadful way to die, so it evokes more fear, and therefore more pressure on government to protect us, though heart disease kills far more people each year.

Catastrophic versus Chronic. People tend to be more afraid of threats that can kill many in one place at one time (e.g., a plane crash) as opposed to events such as heart disease, stroke, chronic respiratory disease, or influenza, which cause hundreds of thousands more deaths, but spread out over time and distance. This helps to explain the substantial risk communication challenge of getting people to modify behaviors that contribute to these major causes of death. It also suggests how risk communication that frames these killers as cataclysmic might have more impact. An example of such messaging would be, “On September 11, 2001, when catastrophic terror attacks killed roughly 3000 people, 2200 Americans died of heart disease. We don’t see those deaths because they are spread out over the whole country, but heart disease is causing tremendous loss of life in America every day.”

Uncertainty. The less people understand a risk, the more afraid they are likely to be. Sometimes uncertainty exists because the product or technology or process is new and has not yet been thoroughly studied, such as nanotechnology. Sometimes uncertainty exists because of unpredictability, as with the sniper in Washington D.C. in 2003, or acts of terrorism. Sometimes scientific answers are available but uncertainty remains because the risk is hard for people to fully comprehend, as with nuclear power or industrial chemicals. Sometimes uncertainty exists because the risk is invisible, as with radon.

This is why risk communication should reduce uncertainty by making the risk easier for people to understand. This principle makes clear why risk communication should avoid jargon, and why risk numbers should be conveyed in ways people can relate to (“A one in ten risk is like the risk to one player on a soccer team, excluding the goalie”).

When uncertainty exists because all the scientific questions haven’t been answered, the fear that results must be acknowledged and respected.

Personal Risk. Understandably, a risk that people think can happen to them evokes more concern than a risk that only threatens others. This is why numbers alone are ineffective as risk communications. One in a million is too high if you think you could be the one.

As a demonstration of this, consider how the attacks of September 11th made clear the risk of terrorism not just to Americans anywhere but in America, and the subsequent anthrax attack put the potential threat of bioterrorism into every American mailbox. The idea of “The Homeland” took on a whole new meaning.

When the first case of mad cow disease in America was found on a Washington farm in 2003, beef sales barely changed nationwide, but they fell sharply in the Northwest, where people thought the risk was more likely to happen to them.

Risk communication that offers only numbers to show that a risk is low is less likely to be trusted, and therefore won’t be as effective as communication that acknowledges that the risk is not zero and accepts that some people might still be concerned.

Familiar or New. When people first learn of a risk, and don’t know much about it, they are more afraid than after they have lived with

that risk for awhile and adjusted to it. For example, West Nile virus evokes more fear in communities in which it first appears than in those where it has been around for awhile.

Using this perception factor in their risk communication, local health officials in one section of Arizona had some success in helping local residents deal with the onset of West Nile virus in 2004 by pointing out that although the risk of West Nile virus was new to them, other communities where the same risk had existed for a few years were far less worried.¹⁹

Future Generations. Any risk to children evokes more fear than the same risk to adults. When the Washington D.C. sniper wounded a 13-year-old boy, after having murdered five adults, the local police chief said “He’s getting personal NOW!” The EPA requires all schools in the United States to be tested for asbestos, but not all offices, factories, or other adult workplace locations.

This powerful fear must be appreciated in communicating about any risk that involves children.

Personification. A risk made real by the identification with of a specific victim particularly when depicted with an image, such as news reports showing someone who has been attacked by a shark or a child who has been kidnapped, becomes more frightening than a risk that may be real, but is not described with an individual to personify it. So, risk communication to encourage healthier lifestyle choices that uses numbers (e.g., “60% of Americans are overweight or obese, representing an important risk factor for heart disease”) may not be as effective as communication that uses those numbers *and* includes names and faces of actual victims of heart disease, to personify the risk.

Fairness/Equity. People are more upset by risks when those who suffer the peril get none of the benefits. Individuals are more upset by risks to the poor, the weak, the vulnerable, the handicapped, than they are about the same risk to the wealthy, or the powerful. An example might be that the developers of a potentially hazardous facility guarantee that local residents get preference in hiring for the jobs at the facility, so that those bearing its risks share in some of its benefits. Risk communication, in actions more than in words, should address this issue.

There are a few important general rules about the heuristics and biases mentioned earlier, and the risk perception factors listed immediately above. Several of these factors are often relevant for any given risk. (e.g., cell phones and driving, where issues of risk-benefit, control, optimism bias, and familiarity all play a part.)

And, while the research suggests that these tendencies are apparently universal and that people tend to fear similar things for similar reasons, any given individual will perceive a risk uniquely depending on his or her age, gender, health, genetics, lifestyle choices, demographics, education, etc. For example, most people fear cancer, but men fear prostate cancer, and women fear breast cancer. As with population-based risk estimates, risk perception has underlying generalities which are overlaid by individual differences. This means that while it is good risk communication practice to consider the emotional concerns of the audience, not everyone in a large audience shares the same concerns. As the National Research Council report suggests, “For issues that affect large numbers of people, it will nearly always be a mistake to assume that the people involved are homogeneous . . .” It is often useful to craft separate risk communication approaches appropriate for each segment.²⁰

► RECOMMENDATIONS

As the National Research Council report noted, “. . . there is no single overriding problem and thus no simple way of making risk communication easy.”²¹ Therefore, this chapter provides general guidance on the fundamentals of risk communication that need to be applied with good judgment and tailored to each particular situation. The following are widely accepted general recommendations:

Include risk communication in risk management. Far more is communicated to people by what you do than what you say. “Risk

communication . . . must be understood in the context of decision making involving hazards and risks, that is, risk management.” (NRC)²² Consider the example cited above of the modest response to federal first responder smallpox vaccination policy. Had the risk perception factor of “risk versus benefit” been considered when the policy was being discussed, officials might have developed a different implementation plan with stronger risk communication strategies.

Information that affects how people think and feel about a given risk issue is conveyed in nearly all of the management actions an agency or a company or a health official takes on that issue. All risk management should include consideration of the risk perception and risk communication implications of any policy or action under review. Quite specifically, this means that *organizations should include risk communication in the responsibilities of senior managers, not just of the public relations or communications staff.* As the NRC report finds, “Risk managers cannot afford to treat risk communication as an afterthought,” that comes at the end of the process after risk assessment has been completed and policy implemented.

Recognize that *the gaps between public perception and the scientific facts about a risk are real, and lead to behaviors that can threaten public health. These gaps are part of the overall risk that must be managed.* Whether people are more afraid of a risk than they need to be or not appropriately concerned, this perception gap is a risk, in and of itself, and must be included in dealing with any specific risk issue and in all risk management and public health efforts, generally. Accepting that these gaps are part of the overall risk is perhaps the key step in recognizing that risk communication is integral to risk management.

Consider this example. When the first case of mad cow disease was found in the U.S. in December 2003, the federal government quickly moved to recall from the market all muscle meat that was processed in the region where the sick cow was found. This despite studies in the U.K. that did not find muscle meat to be a vector for spreading bovine spongiform encephalopathy (BSE), the animal version of the disease, into variant Creutzfeldt Jacob Disease (vCJD), the human form. Yet even though the science suggested the physical risk from the meat might have been negligible, the government recognized that public apprehension was part of the overall risk and ordered the recall. It was an intelligent *action* of risk management that had powerful risk communication impact on public judgments about the threat of mad cow disease. Public reaction to that first case of mad cow disease was surprisingly mild. (Wendy’s, the number three-hamburger chain in the U.S., reported January 2003 sales up 8.3% compared to the previous year. Smith & Wollensky’s, which operates 17 steakhouses in the U.S. reported annual January sales up 7.2%.²³

The principles of risk communication pertain to all public health issues, not just the environmental issues around which the discipline began. The dichotomy between risk communication, which has generally been thought of as trying to get people to calm down, and health communication, which is often thought of as trying to get people to be *more* concerned and take action to improve their health, is false. *Any action or message that conveys information relevant to someone’s health, ergo his or her survival, triggers risk perception biology and psychology, and the principles of risk communication should be applied.* Even an individual doctor describing a treatment or medication or a surgical procedure to a patient in order to get “informed consent” is a form of risk communication. The principles described in this chapter are tools that can make that consent more truly “informed”.

Trust is fundamentally important for effective risk communication, and it is on the line with everything you do. “. . . messages are often judged first and foremost not by content but by the source: ‘Who is telling me this, and can I trust them?’ If the answer to the second question is ‘no’, any message from that source will often be disregarded, not matter how well-intentioned and well delivered.” (Bennett and Calman)²⁴

Trust is determined in part by who does the communicating. When the anthrax attacks took place in the fall of 2001, the principal government spokespeople were the Attorney General, the Director of the FBI, and the Secretary of Health and Human Services, and not the director of the CDC or the U.S. Surgeon General—doctors likely to be more trusted than politicians. Indeed, a survey by

Robert Blendon et al. of the Harvard School of Public Health, 10/24-28/2001, found that 48% of Americans would trust the director of the CDC as a source of reliable information in the event of a national outbreak of disease caused by bioterrorism. Only 38%, however, would trust the Secretary of Health and Human Services (HHS), and only 33% would trust the director of the FBI.²⁵ Had risk communication been considered as the anthrax issue was beginning to develop, and incorporated into the deliberations of how to manage the overall anthrax risk, the more trusted officials would have done the majority of the public speaking. This might have helped the public keep its concern about the risk of bioterrorism in perspective.

But trust is more than just who does the talking. Trust also depends on competence. If people believe that a public health or safety agency is competent, they will trust that agency to protect them and be less afraid than if they doubt the agency’s ability. When the first mad cow case was found, the U.S. Department of Agriculture and the Food and Drug Administration were able to point out the effective regulatory actions they had taken for years to keep the risk low. Thus, the *actions* taken by those agencies, years before that first case, established trust, thereby affecting the public’s judgment about the risk.

Trust is also heavily dependent on honesty. Honesty is conveyed in many different ways. In some instances, it can even mean apologizing and taking responsibility for mistakes. When leaks developed in underground tunnels that are part of a major transportation project in Boston, press attention and public criticism focused on the contractor responsible for the tunnels until the chairman of the company said at a tense public hearing “We apologize for our mistakes”.²⁶ (Note that the apology was made ‘sincere’ by offering to put money behind it.) Attention thereafter focused less on the company’s culpability.

Another example of honesty is avoiding the desire to over-reassure. Again, the way the USDA handled mad cow disease illustrates one example. In the years prior to that first sick cow being found, top officials never said there was “zero” risk of mad cow disease, either in animals or in humans, just that the risk was very low. Had they followed the initial inclination of senior USDA officials and promised that the risk was *zero*, that single case would probably have provoked a more worried public reaction because people might rightly have feared that the government wasn’t being honest and couldn’t be trusted.

Obviously, honesty includes not keeping secrets, and not lying. In early 2005, Boston University received local and state approval to build a biocontainment level 4 (BL4) laboratory to study highly dangerous pathogens. But news reports surfaced that the university had hidden from local and state approval authorities the fact that workers had mistakenly been contaminated with tularemia in a BL2 lab at BU. Under public pressure, the government approval and review processes had to be reopened.

Establish mechanisms to empower real community input. Give people control—a say in their fate. Such mechanisms are a concrete way to follow the widely-accepted recommendation that risk communication is more effective when it is an interaction, not a one-way process. It is even more effective to do this proactively, so shared control and real input into decision-making are well-established should a risk crisis arise.

This input must be given more than perfunctory attention. Many government public hearing processes allow people to speak, but prevent officials conducting the meeting from answering the public’s questions and concerns. Such an interaction fails to give the audience a sense of control, and more importantly, can destroy trust since it seems disingenuous to claim an interest in public input but then fail to acknowledge it.

Making risk communication an intrinsic component of risk management requires fundamental cultural change. Sharing control, admitting mistakes, acknowledging the validity of intuitive reasoning, accepting that a realistic goal for risk communication is to help people make better judgments for themselves, assuming a nondirective approach, even being open and honest . . . are counter-intuitive and perhaps even counter-cultural to institutions and people who are used to control. These principles may seem foolish in a litigious society. They conflict with the myth of the purely rational decision-maker. As risk communication researcher and practitioner Peter

Sandman has observed “What is difficult in risk communication isn’t figuring out what to do; it’s overcoming the organizational and psychological barriers to doing it.”²⁷

Nonetheless, countless examples demonstrate how adoption of the principles of risk communication are in the best interests of most organizations, as well as the interest of public health.²⁸ These institutional benefits include: reduced controversy and legal costs, increased support for an agency’s agenda or a company’s brand and products, political support for a candidate or legislation, and more effective governmental risk management that can maximize public health protection by focusing resources on the greatest threats. While these benefits may not be readily quantifiable, and only realized over the long-term, they are supported by numerous case studies, and justify the cultural change necessary for the adoption of risk communication principles.

Finally, *within constraints of time and budget, any specific risk communication should be systematically designed and executed, and should include iterative evaluation and refinement.* “We wouldn’t release a new drug without adequate testing. Considering the potential health (and economic) consequences of misunderstanding risks, we should be equally loath to release a new risk communication without knowing its impact.”²⁹

An empirical process by which to do this has been labeled the “Mental Models” approach. As its developers say “. . . in the absence of evidence, no one can predict confidently how to communicate about a risk. Effective and reliable risk communication requires empirical study. Risk messages must be understood by recipients, and their effectiveness must be understood by communicators.”³⁰ The basic components of the Mental Models approach are:

1. Create an expert model, based on review of the scientific literature and in consultation with experts in the field, that describes in detail the nature of the risk; its hazards, where exposures occur, the range of consequences, and the probabilities.
2. Conduct open-ended interviews to find out what your target audience already knows or doesn’t know about the risk.
3. Based on this smaller interview sample, create a questionnaire to administer to a larger sample to see how well the mental model of the smaller group corresponds to what the larger sample knows and doesn’t know about the risk.
4. Draft risk communication messages that address incorrect beliefs and fill in knowledge gaps between what people don’t know and what the expert model indicates they need to know. Pay attention to the tone and affective qualities of the messages.
5. Evaluate and refine the communication using one-on-one interviews, focus groups, closed-form questionnaires, or problem-solving tasks, trying to develop messages that have the most impact on the greatest number of recipients. Repeat the test-and-refine process until evaluation shows the messages are understood as intended.³¹

► CONCLUSION

Whether terrorism or avian influenza nanotechnology or mad cow disease, risks continually arise. Old ones may fade and our attention to them may wane, but new ones will certainly develop, and our awareness of these new threats will be magnified in an age of unprecedented information immediacy and availability.

The human imperative of survival will compel people to use their “adaptive toolbox” to make the best judgments they can about how to stay safe from this evolving world of threat, even though those judgments might sometimes create greater peril. Populations need to understand the risks around them as thoroughly as possible to be able to make sound decisions. It is critical that effective risk communication become an intrinsic part of how government, business, the public health sector, and the medical care system design and execute risk management policy, so that, armed with accurate information, we can make wiser and safer choices for ourselves and for our fellow citizens.

Health Literacy

Rima E. Rudd • Jennie E. Anderson • Sarah C. Oppenheimer
• Lindsay E. Rosenfeld • Carmen Gomez Mandic

► INTRODUCTION AND OVERVIEW

Health literacy has been used as a metaphor as is *science literacy* or *computer literacy*, referring to knowledge about and facility with a particular area or process. However, most references to *health literacy* in scholarly articles move beyond the metaphor and highlight the importance of literacy skills applied in health contexts. Literacy skills encompass a set of related activities that include reading, writing, engaging in oral exchange, and using basic math. Adults apply these skills to numerous health-related activities at home, at work, in the community, and in social service and health care settings. The Institute of Medicine (IOM) report, *Health Literacy: A Prescription to End Confusion*, proposed that an individual's health literacy capacity is mediated by education, and its adequacy is affected by culture, language, and the characteristics of health-related settings.¹

Health literacy is firmly established as a field of inquiry in medicine and public health. Improved health literacy was included as a communication objective in Healthy People 2010 and the US Department of Health and Human Services (DHHS) articulated an action plan for reaching this objective in its report *Communicating Health: Priorities and Strategies for Progress*.² Studies linking health literacy to health outcomes were examined by the Agency for Healthcare Research and Quality (AHRQ) and its report, *Literacy and Health Outcomes*,³ concluded that the weight of evidence supported a link between literacy and health outcomes. The IOM was asked to examine the scope and rigor of health literacy research. The IOM issued a report offering recommendations for policy makers, researchers, government agencies, and the private sector for needed action and further research.¹

Evidence for increased interest in health and literacy links may be found in the published literature. The approximately one dozen published journal articles of the 1970s grew to three dozen in number in the 1980s and burgeoned in the 1990s after the publication of findings from the first National Adult Literacy Survey (NALS). By the end of the century, the published literature addressing health literacy consisted of approximately 300 studies.⁴ An additional 300 articles have been published between 2000 and 2004.⁵ Most of the published studies are focused on the reading level of health materials such as patient package inserts, informed consent materials, and patient education pamphlets and booklets. Over time, assessments of materials have included examinations of the match between the reading level of printed health materials and the reading skills of the intended audiences. More recent studies have expanded beyond print materials and are examining health information delivered through various channels of communication including television, websites, and other computer-based technologies. Overall, findings continue to indicate that the demands of health materials and messages exceed the average skills of the public and of the average high school graduate.^{4,1}

A smaller section of the literature has focused on health outcomes. Supported by the development of rapid assessment tools, researchers in the 1990s and beyond were able to explore links between approximations of reading skills and a variety of health outcomes. Most of these outcome studies differentiate between those with high and low scores on rapid assessment tools such as the Rapid Estimate of Adult Literacy in Medicine (REALM)⁶ and the short form of the Test of Functional Health Literacy in Adults (TOFHLA),⁷ both of which correlate well with short tests of reading skills. Researchers, in approximately 50 studies, report differences in a wide range of health-related outcomes based on readings skills. Outcome measures included awareness and knowledge of disease and/or medicines, participation in healthful activities (such as screening or breastfeeding), ability to follow a regimen (for a variety of chronic diseases), hospitalization, and indicators of successful disease management (such as glucose measures for diabetes control).

► HEALTH LITERACY AS AN INTERACTION

Various definitions of health literacy were put forth in the 1990s when the term *health literacy* started being used in abstracts, key word listings, and conference titles rather than *health and literacy*. The following definition used in *Healthy People 2010* was most frequently cited:

“the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions.”⁸

HHS and the IOM adopted this definition. At the same time, reports issued from both noted that the focus on the “capacity of individuals” needed to be balanced by a concurrent understanding of the communication delivery side as well. Consequently, the IOM committee report states that health literacy is an interaction between social demands and individuals' skills.¹ The IOM report notes that culture, language, and processes used in health care settings were unfamiliar to and often erected barriers for adults seeking advice and care.¹ The report also cites findings that the demands of public health and medicine are burdensome and may erect unnecessary barriers to access and care.

Health Demands

People engage in a wide range of activities when they take health-related action at home, at work, and in the community. In all of these health contexts, adults are provided with materials and tools they are expected to use as they access information and resources and as they

participate in decisions and actions that influence their health and that of their families.^{9,10,11}

Health information is communicated in a variety of ways. Sometimes it is conveyed via continuous text (prose) such as in the explanatory paragraphs on an informed consent sheet, a discussion of air quality in a newspaper editorial, or a description of the etiology of a particular disease in a patient education brochure or pamphlet. Documents, which include graphic displays, tables, and lists, comprise another type of material used to convey health information. These include weather charts, graphs of health-related trends over time, nutrition labels, as well as tables provided on packages of over-the-counter medicines for determining dose. In addition, documents, such as the open-ended forms ubiquitous in health and social service institutions, serve as the vehicle for information gathering for a wide range of activities including those related to health history, insurance, or research. Critical public and personal health information is also communicated in speech, whether over the airways or in conversation between a care provider and a patient.

Social demands in health contexts include the following:

- Assumptions made about the public's background knowledge, culture, and skills;
- Reading level of health-related materials designed to provide both background information and tools for action;
- Specialized processes used in detection and treatment protocols;
- Time limitations on interactions between patients and providers;
- Expectations related to priorities and behavior;
- A pervasive use of professional jargon and scientific terms in print and oral communication.

Researchers have developed and applied several tools for assessing the readability of written materials such as the simplified measure of Gobbledygook (SMOG)¹¹ and other readability formulas, the suitability assessment of materials (SAM)¹² and other text assessment approaches, and the PMOSE/IKIRSCH tool which assesses lists and tables.¹³ However, as of 2005, no studies of health literacy have reported on the development and use of tools to assess and quantify the ease or difficulty of open entry forms, visuals, or oral discourse.

Skills

Accessing, comprehending, and acting on health information and services requires individuals to have and use a full range of literacy skills. Individuals' skills include, but go beyond, word recognition and reading comprehension to encompass a broader range of linked literacy skills such as writing, speaking, listening, and basic math. The 1992 national adult literacy survey (NALS) focused attention on adults' ability to use print materials for everyday tasks.¹⁴ Materials used on the NALS were drawn from six contexts of everyday life including home and family, health and safety, community and citizenship, consumer economics, work, and leisure and recreation. Questions were based on the use of these materials and approximated the tasks adults would undertake in everyday life. Tasks included, for example, determining the price of a food item on sale for a 10 % discount, figuring out the correct dose of medicine to give a child, and filling out a bank deposit slip. Materials included a variety of prose materials (such as narratives, expositions, description, argumentation, and instructions) and documents found in everyday life (such as records, charts, tables, graphs, entry forms, and lists). Both the materials and the tasks associated with the materials were calibrated for level of difficulty. NALS scores were based on adults' ability to accomplish tasks using printed texts and ranged from 0 to 500.

The average NALS score for U.S. adults was 273. Analysts examining both national and international assessments of adult literacy

skills in industrialized nations indicated that scores above 275 reflect an ability to meet the demands within industrialized nations.¹⁵ The U.S. findings indicate that about half of U.S. adults have difficulty with complex materials and are limited in their ability to integrate information from complex text.¹⁴

A 2004 follow-up analysis of adult literacy skills as applied specifically to health materials and tasks indicates that a majority of adults encounter difficulties with materials such as labels on medicines, health benefit packages, product advertisements, and discussions of health policy issues in newspapers.⁹ The health activities literacy scale (HALS) yielded scores that are essentially the same as those for NALS, after all, the HALS was based on a sub-set of materials and tasks drawn from the NALS and the international assessments known as the international adult literacy survey (IALS). However, the focus on health materials and tasks grounds the discussion in a health context. New analyses yielded insight into the importance of a number of variables including the importance of access to wealth and its influence on literacy. Scores for the HALS varied by critical factors such as educational attainment, age, wealth, race/ethnicity, and nativity.

Educational attainment is the strongest predictor of literacy skills. Overall, those with less than a high school degree or general educational development (GED) certificate have more limited literacy skills than do those with a diploma or education beyond high school. Both the NALS and HALS analyses found that persons over the age of 60 were significantly more likely to have limited functional and health literacy skills than were younger working adults. Older adults' literacy limitations may be attributed to a number of factors including less schooling than younger adults, visual and cognitive impairments, and lost literacy skills due to diminished use.^{16,17} Those who are without resources (defined as interest from savings accounts or income from dividends) are also more likely to have limited literacy skills. Table 59-1, drawn from the Education Testing Service (ETS) policy report, *Literacy and Health in America*, illustrates the interplay among population groups by educational attainment, age, and wealth variables. Overall, the average score for those without a high school diploma or a GED is lower than the scores for others. However, the additional impact of resources may be seen in the difference between the average score of elders who have access to resources and those who do not.

Underserved populations such as minorities and immigrants are more likely to have limited literacy skills than are native-born whites.^{14,9} In addition, one analysis of the NALS offered a portrait of inmates and concluded that prisoners have literacy skills well below those of nonincarcerated persons. However, these skill levels match those of the communities from which they came.^{18,19}

Unfortunately, population groups with limited literacy skills may also have more frequent interactions with social service agencies, legal services, and health care institutions. These environments are saturated with print. Thus the mismatch between the demands of the systems and peoples' general skills becomes all the more troublesome.

Health Activities and Literacy Challenges

A broad notion of health literacy serves to move attention from the clinical encounter to the health-related tasks adults grapple with in the multiple contexts of everyday life. *Literacy and Health in America* offers a schema for examining health materials, tasks, and skills within five commonly used groupings: health promotion, health protection, disease prevention, health care and maintenance, and navigation. Table 59-2, offers a brief description of each of these groups of activities with examples of a range of materials that adults use and the associated tasks they undertake. While the materials and tasks needed within health care settings and for navigating health and social service systems are arduous, so too are many of the materials and tasks needed for mundane health-related activities at home, at work, and in the community.

TABLE 59-1. AVERAGE HALS PROFICIENCY BY WEALTH STATUS AND LEVEL OF EDUCATION

<i>Wealth Status</i>	<i>Less than High School</i>	<i>High School or GED</i>	<i>Beyond High School</i>
1. Working adults with high likelihood of having savings or dividends, low likelihood of poverty	273	291	321
2. Young adults with low likelihood of both poverty and additional assets	218	267	293
3. Retired adults with high likelihood of additional assets	216	257	285
4. Adults with high likelihood of poverty and receiving food stamps, low likelihood of additional assets	217	264	281
5. Retired adults on social security with high likelihood of poverty, low likelihood of additional assets	188	240	261

Proficiency refers to the average score based on the NALS range of a low of 0 to a high of 500. The mean score for U.S. adults is 273. Education and economic scholars note that literacy scores in the range of 275 and above are needed for participation in the economy of the 21st century.

TABLE 59-2. HEALTH ACTIVITIES, MATERIALS, AND TASKS

<i>Health Activities</i>	<i>Focus</i>	<i>Materials Adults are Expected to Use</i>	<i>Tasks Adults are Expected to Accomplish</i>
Health Promotion	Enhance and maintain health	Label on a can of food or recipes Articles in newspapers and magazines Charts and graphs such as the Body Mass Index Health education materials [such as a well baby booklet]	Purchase food Prepare a dish from a recipe Plan exercise Maintain healthy habits [re: nutrition, sleep, exercise] Take care of one's health and that of family members
Health Protection	Safeguard health of individuals and communities	A newspaper chart about air quality A water report in the mail A health and safety posting at work A label on a cleaning product	Decide among product options Use products safely Vote on community issues Avoid harmful exposures
Disease Prevention	Take preventive measures and engage in screening and early detection	Postings for inoculations & screening Letters re: test results Articles in newspapers and magazines Graphs, charts	Take preventive action Determine risk Engage in screening or diagnostic tests Follow up
Health Care & Maintenance	Seek care and form a partnership with a health professional such as a doctor or dentist or nurse	Health education Health history forms Labels on medicine Develop plan for taking medicine as described Health education booklets Directions for using a tool such as a peak flow meter Schedule and keep appointment	Seek professional care when needed Describe symptoms Follow directions Measure symptoms Maintain health with chronic disease [follow regimen, monitor symptoms, adjust regimen as needed, seek care as appropriate]
Navigation	Access needed services, and get coverage and benefits	Application forms Statements of rights and responsibilities Informed consent forms Benefit packages	Locate facilities Apply for benefits Fill out forms Offer informed consent

► IMPLICATIONS

The AHRQ report, *Literacy and Health Outcomes*, indicates that the new field of health literacy has established links between literacy and health outcomes.³ Approximately 50 such studies are focused on medical settings but have not yet included other health areas such as dentistry, mental health, social work, or pharmacy, for example. Nor have any studies examined outcomes related to activities undertaken at home, at work, or in the community.⁹ The field of inquiry is broad with a good deal of work yet to be done. Some of this work will contribute to an understanding of health disparities.

Opportunities for Research

Health literacy research findings offer important implications for investigators. The very process of research, and the accepted language in and format of documents and questionnaires used for research must be examined through a literacy lens. More rigor must be applied to the development of questionnaires and interview protocols which form the foundation for research. Health researchers have long collected information on income and health as indicators of social status, and the links between income and/or education and health are well-established.²⁰ A new focus on education and its component parts will shed light on pathways between education and health outcomes and more clearly establish the role of literacy. Inquiries into socioeconomic and racial/ethnic disparities in health outcomes must include attention to the added barrier of poorly designed materials. For example, parents must grapple with small font and jargon as they attempt to enroll in health insurance programs or to make sense of the handouts and materials they are given for chronic disease management. Furthermore, studies of literacy demands in various contexts such as health care, housing, or employment settings may shed light on how the impact of limited health literacy on health can be modified by access to resources and supports within social environments.²¹

The differences in health literacy skills by age, race/ethnicity, poverty status, and immigrant status⁹ may well reflect long-standing discrimination with respect to access to education and other resources for human development especially among older cohorts, racial/ethnic minorities, impoverished communities, and immigrants from underdeveloped countries. Health disparities are also seen between these populations groups and majority population groups in the U.S. The extent to which these differences in health literacy skills are causally related to observed disparities in health outcomes—and thus, the extent to which attention to health literacy in medical and public health interventions can ameliorate such disparities—is a critical area of current and forthcoming health literacy research.

Implications for Practitioners

Health literacy is intimately tied to client and practitioner interactions. Studies indicate that many long standing practice recommendations serve to lower literacy demands.^{22–24} Health educators, for example, have long emphasized the importance of pilot testing materials and programs with members of the intended audiences.²⁴ Public health program developers often engage members of the community as participants in the design and evaluation of programs.^{25,26} The activated patient model is supported as an important approach for the management of chronic diseases.²² Several approaches hold promise but have not yet been fully evaluated. For example, the American Medical Association suggests that health providers speak with their patients using plain, everyday language.²⁷ Health practitioners are urged to use teach-back approaches, for example, asking patients to describe how they will tell others what they just learned.

Effective innovation and progress in this field cannot be made without the ongoing participation and leadership of practitioners and policy makers. The development of all health communications must be appropriately designed with the audience in mind, based on accurate assessments of the public's knowledge and skills, and be

designed for use. Rigorous formative process and outcome evaluations must be undertaken for health communication efforts whether the focus is on print materials or oral delivery, or interpersonal or mass media channels. Plain language, well designed materials and documents, and educational approaches that go beyond a reliance on the written word will improve health literacy.

While the education sector maintains responsibility for building literacy skills, health policy makers and practitioners maintain responsibility for health materials, messages, and procedures. The recommendations for action outlined in the HHS and IOM reports call for the development and testing of programs and materials, and evaluations of new approaches and technologies. This work can be supported through partnerships among and between health professionals, K-12 teachers, adult educators, librarians, and social service agency staff.

Screening for Early and Asymptomatic Conditions

Robert B. Wallace

► DEFINITION OF SCREENING

The typical natural history of diseases and conditions dictates that at some point the biological onset of the disease occurs and progresses at varying rates until they become clinically evident. These rates may be as short as instantaneous, as in acute trauma, or could be life-long, as in a genetic risk factor for Alzheimer's disease. Primary prevention attempts to intercept the conditions that lead to disease onset, while secondary prevention generally relates to the early and asymptomatic detection of disease; that is, disease screening, in the hope that the trajectory toward clinical illness can be stopped or mitigated in a helpful way. When overt clinical illness is present, tertiary prevention refers to rehabilitative and other factors that deter disease progression and help return the patient to a healthier state.

Disease screening usually takes two general forms: (a) screening for proven, biological, or behavioral risk factors for diseases that lead to interventions or treatments in themselves, such as abnormal blood cholesterol or blood pressure levels; or (b) screening directly for evidence of the disease itself, followed by provision of effective treatment to cure or to prevent the progression of pathophysiological processes that will cause overt clinical manifestations. This implies that screening may be done in stages, for instance by screening for general disease susceptibility first, such as for certain demographic or anatomic characteristics, or only if informed consent for the screening procedure is obtained. Disease screening may be applied to general populations irrespective of receipt of medical care (i.e., mass screening), or to clinical populations with various characteristics.

In general, disease screening is applied to populations with a relatively low risk of the condition of interest. Because of the great increase in types of screening that have been developed, the general definition of disease screening does not fit all situations. For example, the *disease* may be overt and the screening is to determine the cause, as in the detection of family violence, or the condition may be overt, but not clinically explored at a primary care visit, as in the case of cognitive impairment or depression.

► THE ASSESSMENT OF SCREENING TESTS

There are several criteria that aid in selecting and applying an appropriate screening test.¹ (a) The disease should be common enough to warrant a search for its risk factors or latent stages because screening for excessively rare diseases may result in unacceptable cost-benefit ratios; (b) The morbidity or mortality (i.e., burden of suffering) of the untreated target condition must be substantial; (c) An effective

preventive intervention or therapy must exist and should not encumber a more beneficial outcome when applied to the presymptomatic rather than to the symptomatic stage; (d) The screening test should be acceptable to the population and suitable for general, routine application. Many other criteria for an effective screening test could be added, such as maintenance of test accuracy over time and freedom from screening-related adverse effects.

Even with concerted application of these screening criteria, major pitfalls may cause an erroneous assessment of a screening program's value. An example is *lead time bias*, the interval between presymptomatic disease detection by a screening test and symptom onset.² If the natural history of a disease is variable or not thoroughly understood during the presymptomatic and symptomatic stages, a screening test may identify a presymptomatic condition earlier and increase the interval to overt morbidity but not change the ultimate outcome. *Length bias* occurs when there is a correlation between the duration of disease latency and the natural history of the symptomatic phase.² If the mild form of a disease has a longer latency and is hence more easily found on screening than are more severe forms of disease, the screening test may appear falsely beneficial. In general, the validity of a screening test depends on the evidence base to justify the screening intervention. Many screening tests may be proven only through one or more randomized clinical trials. Excellent examples of creating the evidence base for screening tests can be found in the work of the U.S. Preventive Services Task Force, part of the Agency for Healthcare Research and Quality.³ Selection and interpretation of screening tests require a combination of subjective and objective criteria. Objective criteria include operating characteristics, predictive value, and cost-effectiveness of the tests, which are tempered by subjective evaluations of individual and public acceptability and financing.

The operating characteristics of a screening test are its sensitivity and specificity. These are general test characteristics that can apply to any laboratory or diagnostic test data as well as other information collected from the medical history and physical examination. *Sensitivity* is the proportional detection of individuals with the disease of interest in the tested population, expressed as follows:

$$\text{Sensitivity (\%)} = \frac{\text{True positives}}{\text{True positives} + \text{False negatives}} \times 100$$

True positives are individuals with the disease and whose test result is positive. False negatives are individuals whose test result is negative despite having the disease. *Specificity* is the proportional detection of individuals without the disease of interest, expressed as follows:

$$\text{Specificity (\%)} = \frac{\text{True negatives}}{\text{True negatives} + \text{False negatives}} \times 100$$

True negatives are individuals without the disease and whose test result is negative. False positives are those who have a positive test result but do not have the disease. Sensitivity is limited by the proportion of cases missed by the test (false negatives) and specificity is limited by the proportion of noncases found to be positive (false positives). Ideally, a test would have a 100% sensitivity and specificity, but few if any tests have achieved this. Unfortunately, sensitivity and specificity are often inversely related. This relationship has been expressed as the receiver operating characteristic (ROC)⁴ of a numerically continuous test result. The ROC allows optimal specification of test sensitivity and specificity. The sensitivity, or true-positive ratio, is displayed along the ordinate, and the specificity, or false-positive ratio, is exhibited on the abscissa. As the sensitivity increases, so does the false-positive ratio in most instances. When a ROC has been established for a test, any one of several sensitivity and specificity combinations may be evaluated for suitability in test application and contrasted with potential alternate tests. Further information on the application of ROC curves is available.⁵

Sensitivity and specificity values from the literature are most applicable to populations and test conditions similar to those under which the values were established. However, it is possible that test properties may differ according to mode of administration (e.g., telephone vs. mail questionnaire) or by any demographic feature of the target population, and thus, further generalization or extrapolation of these values can be misleading. For example, it has been suggested that the increasingly common use of hormone replacement therapy among postmenopausal women may decrease the sensitivity and specificity of mammographic screening.⁶

Whereas the operating characteristics of a test are of major help in selecting a screening test, the predictive value of a test is a major aid in interpretation of a result. The *predictive value of a positive test* is the proportion of all individuals with positive tests who have the disease and is expressed as follows:

$$\text{Positive Predictive Value (\%)} = \frac{\text{True positives}}{\text{True positives} + \text{False positives}} \times 100$$

The predictive value of a negative test is the proportion of all individuals with negative tests who are nondiseased. This is expressed as follows:

$$\text{Negative Predictive Value (\%)} = \frac{\text{True negatives}}{\text{True negatives} + \text{False negatives}} \times 100$$

Predictive values are dependent on both the operating characteristics and the prevalence of the disease in the target population. For any given set of operating characteristics, the positive predictive value is directly related to prevalence, and the negative predictive value is inversely related to prevalence. Therefore, in screening situations where the prevalence is relatively low, the operating characteristics must be very high to avoid low positive predictive values. In most screening situations for serious fatal conditions, such as cancer, the test or test sequence offering the highest sensitivity ordinarily will be preferred. This has the effect of finding as many cases as possible but may correspondingly increase the number of false positives. The effect of sensitivity, specificity, and prevalence on predictive values has been clearly demonstrated.⁷

Cost-effectiveness is especially important in screening programs because of the number of asymptomatic individuals who must be evaluated for the relatively small number of diseased cases. Formal cost-effectiveness analysis⁸⁻¹⁰ should be undertaken before program initiation. The program's value must include an assessment of all costs and a realistic appraisal of effectiveness. Positive predictive values are usually well below 50% for most initial screening situations, so that secondary diagnostic evaluation is nearly always required to eliminate false positives, adding substantially to program cost.

Exhaustive reviews of the efficacy of clinically applicable screening programs have been undertaken by the U.S. Preventive Services Task Force³ and several other disciplinary, specialty and international groups, with recommendations offered in part with consideration of cost-effectiveness. On the other hand, public screening, or mass screening, may have inherent advantages from the standpoint of efficiency. The tests and procedures selected for use are often highly standardized and can be administered more inexpensively than they can in clinical or more specialized settings, and generally they can be applied without the need for direct physician supervision. To enjoy the efficiency of mass screening, such programs must be carefully organized and managed. Recipients of both normal and abnormal test results must be considered. Those with abnormal test results must have a properly organized follow-up evaluation protocol, and those with normal results should be informed of the predictive value of a normal test to avoid false reassurance. Even with the inherent efficiency of mass screening, most such programs must still be focused on populations with sufficient disease or risk factor prevalence to maximize program efficiency.

Another application of screening programs is in the clinical context where patients have active clinical problems. Examples include screening on the first evaluative ambulatory clinic visit or at hospital admission. Comprehensive clinical screening with routine physical examinations or laboratory tests, or both, remains controversial, largely because there is very little if any evidence in the scientific literature concerning the efficacy or effectiveness of standard screening tests in the face of existing comorbid illness. For example, is mammography effective in persons with active insulin-dependent diabetes, or cholesterol screening in the face of an active carcinoma? These are questions yet to be adequately addressed in research. In the past, so-called "multiphasic" screening programs had been proposed for persons being admitted to the hospital. It now appears that these procedures have limited utility and high cost primarily because of numerous false-positive tests and irrelevant findings and should be discarded in favor of diagnostic and therapeutic activities directed at the immediate clinical problems.¹¹⁻¹³ However, inpatient hospital services have been used as opportunities for categorical screening programs such as undiagnosed human immunodeficiency virus infection,¹⁴ alcoholism,¹⁵ or nutritional problems among the elderly.¹⁶ Multiphasic biochemical screening is still being proposed as a useful inpatient tool.¹⁷

Another important issue that has arisen is screening for genetic conditions. This is covered elsewhere in this text.

Cancer

Leslie K. Dennis • Charles F. Lynch • Elaine M. Smith

Neoplasms are diseases characterized by abnormal proliferation of cells. If the proliferating cells invade surrounding tissues, the resultant tumor is malignant; if they do not, it is benign. Some benign neoplasms may be fatal, including histologically benign brain tumors that grow and displace normal brain tissue in the confined space of the skull, and hepatocellular adenomas that rupture and cause bleeding into the peritoneal cavity. Some benign tumors such as intestinal polyps are considered premalignant lesions and confer a high risk of progression to malignancy. The term cancer usually implies a malignant tumor (malignancy), but refers also to brain tumors and some other benign neoplasms.

► DESCRIPTIVE EPIDEMIOLOGY

Classification

Cancers are classified according to their organ or tissue of origin (site or topography code) and histological features (morphology code). A number of classification schemes have been developed, the most recent and widely used of which appears in Chap. 2 of the *International Classification of Diseases*, 10th revision (ICD-10), which is largely a topography code,¹ and the *International Classification of Diseases for Oncology*, 3rd edition (ICD-O), which contains an expanded version of the topography code in ICD-9 as well as a detailed morphology code.²

Sources of Incidence and Mortality Rates

Mortality rates are calculated from death certificate records and population census data. Mortality rates from various countries have been compiled periodically.³ Cancer mortality rates for the United States are published by the United States' National Cancer Institute (NCI) and Centers for Disease Control and Prevention (CDC).⁴⁻⁶

Population-based cancer registries, which have been established in many countries, provide information on incidence rates. These have been compiled in *Cancer in Five Continents*, which is jointly published periodically by the International Agency for Research on Cancer (IARC) and the International Association of Cancer Registries (IACR).⁷ The best source of cancer incidence rates for the United States is the Surveillance, Epidemiology, and End Results (SEER) program of the NCI, which supports a network of 18 population-based cancer registries throughout the country. Results from this program are published annually and more detailed monographs are published periodically.^{8,9} Both incidence and mortality statistics for the United States are summarized for the lay public and published annually by the American Cancer Society.¹⁰

A North American Association of Central Cancer Registries (NAACCR) was established in 1987, and beginning in 1991 the CDC made funds available to individual states for cancer registration. The

cost of collecting high-quality data on a sufficiently large proportion of all cases in a defined population is considerable; however, utilization of these data for research or cancer control purposes justifies cancer registration efforts.

Magnitude of the Cancer Problem

In the aggregate, cancer is second only to heart disease as a cause of death in the United States and accounts for about 23% of all deaths.¹⁰ Approximately 190 deaths from cancer occur per 100,000 people per year, compared with about 232 per 100,000 from heart disease, 53 per 100,000 from cerebrovascular diseases, 43 per 100,000 for chronic lower respiratory diseases, and 37 per 100,000 from accidents.¹⁰ Based on U.S. incidence and mortality rates for 2001–2003, the lifetime probabilities of developing cancer have been estimated to be 45.3% in men and 37.9% in women; the lifetime probabilities of dying of cancer are estimated at 23.4% in men and 19.8% in women.^{4,10} The National Cancer Institute estimates the direct medical costs of cancer to be \$72 billion annually, or about 5% of the total health-care costs in the United States.¹¹

Relative Importance of Specific Neoplasms

Age-adjusted incidence and mortality rates, as well as 5-year survival rates, in men and women in the United States are readily available, and Table 61-1 shows such rates for 1998 through 2003.^{4,10} The most common cancers in men are those of the prostate, lung, and colon and rectum; the cancers causing the most deaths in the United States are lung, colon and rectum, and prostate. In women, breast cancer is by far the most common neoplasm, followed by cancers of the lung, and colon and rectum.¹⁰ However, because of the more favorable survival of women with breast than lung cancer, mortality rates of female lung cancer exceed those for female breast cancer in the United States.

Another way to judge the importance of a malignancy is by the number of years of life lost due to its occurrence in a population. This measure reflects the incidence of the cancer, the fatality rate in those who develop it, and the age at which the cancer tends to occur. This measure gives more weight to childhood cancers than overall mortality rates, and because of economic implications, it can be of value in setting priorities for research and prevention. In order of estimated years of life lost, the 10 most important cancers in the United States are lung, female breast, colon and rectum, pancreas, leukemia, non-Hodgkin's lymphoma, brain, prostate, ovary, and liver.⁴

The estimated age-standardized incidence rates of all cancers vary among the various regions of the world, and the cancers of most importance in developing countries are different from those in developed countries such as the United States. In order by numbers of cases, the 10 most common cancers across the globe are those of the

TABLE 61-1. AVERAGE ANNUAL AGE-ADJUSTED (2000 STANDARD) INCIDENCE AND MORTALITY RATES (1998–2003) AND 5-YEAR RELATIVE SURVIVAL RATES (1998–2002 CASES) BY PRIMARY SITE AND SEX, ALL RACES, SEER 13 AREAS COMBINED

lung, stomach, liver, colon and rectum, breast, esophagus, lymphomas and myeloma, mouth and pharynx, prostate, and leukemia.¹²

Age

Cancers most probably arise from DNA-damaged cells that are capable of mitotic division and differentiation. In adults, most cancers are carcinomas that arise from basal epithelial cells of ectodermal or endodermal origin. In children, most cancers are of mesodermal origin and consist largely of leukemias and lymphomas that arise from hematopoietic and lymphoid stem cells and sarcomas that probably develop from undifferentiated cells of embryonal origin.

Incidence rates for the most common childhood cancers in the United States are shown in Table 61-2.^{4,10} The mortality rates for even the most frequent cancers in children are many times lower than the rates of comparable tumors for all ages (Table 61-1), which largely reflect rates in adults.

Cancer is primarily a disease of older adults. With some notable exceptions (e.g., cancers of the female breast and uterine cervix), there is an exponential increase in incidence rates with age. The median age at which cancer was diagnosed from 2000 to 2003 was 68.0 for males and 67.0 for females, and most cancers develop in the sixth, seventh, and eighth decades of life.⁴

Sex

Most major cancers occur more frequently in men than in women, exceptions being carcinomas of the breast, thyroid, gallbladder, and other biliary.¹⁰ Smoking-related cancers, described in detail subsequently, occur more frequently in men, at least in part because of their earlier and greater exposure to tobacco smoke. Some other cancers, such as carcinomas of the bladder and mesotheliomas, are more frequent in men, at least in part because of their greater occupational exposure to various chemical carcinogens and asbestos, respectively. Other cancers that occur more frequently in men include the lymphomas and leukemias, malignant melanomas, sarcomas of the bone, and carcinomas of the nasopharynx, stomach, kidney, pancreas, colon, rectum, parotid gland, and liver. The reasons for the excess of these cancers in males are uncertain. Women could be either constitutionally less susceptible to these neoplasms or less exposed to whatever environmental factors contribute to their development. Recently, a higher number of new cases of colon cancer were reported among women in the United States.¹⁰ It is unclear if this is a change in risk factors, screening activity, or age differential between men and women in the United States.

Race and Geography

Within individual races, incidence and mortality rates of all cancers vary considerably from one geographic region to another; migrants from one country to another, or their descendants, tend to eventually develop most cancers at rates more similar to those in their country of adoption than to those in their country of origin, suggesting an important role for environmental risk factors in most cancers.¹³ In the United States, the patterns of cancer occurrence in recent immigrants reflect the cancer patterns in their countries of origin and become less distinct as these groups become more acculturated with the passage of time. The frequency of occurrence of many cancers also varies among racial groups residing in the same country. This variation may be due to factors related to their distinct cultural patterns, social behavior, or economic status, but in some instances may be due to genetic differences among the races.

Some cancers appear to be related to a “Western” lifestyle. Cancers that tend to occur at lower rates in developing countries and

migrants from these countries than in lifelong residents of such areas as North America and Western Europe include cancers of the colon and rectum, which may be related to diets rich in animal products; cancers of the prostate, ovary, corpus uteri, and breast, which have to some extent also been related to high consumption of meats and fats, as well as to endocrinological and reproductive factors; Hodgkin's disease, which has been hypothesized to be due to a common infectious agent, probably the Epstein-Barr virus that, like polio viruses, may cause clinically overt disease with a frequency directly related to age at initial infection; and non-Hodgkin's lymphomas and neoplasms of the brain and testis, the causes of which are largely unknown. Other cancers occur more frequently in developing countries and in migrants from these countries. For example, compared to white populations of the United States and Western Europe, migrants from Asian countries have higher rates of stomach cancer, possibly related to intake of preserved foods and infection with *Helicobacter pylori*; liver cancers, which may, in part, be caused by the production of aflatoxins in contaminated foods and by hepatitis B and C viruses; cancers of the nasopharynx, caused in part by the Epstein-Barr virus (EBV); and cancer of the uterine cervix, which is caused by some types of human papillomaviruses.

Cancers that are strongly related to smoking occur with a frequency commensurate with the smoking habits in the population. Thus, cancers of the lung, larynx, bladder, kidney, and pancreas have tended to occur more frequently in developed than developing countries, but rates of these neoplasms are increasing in developing countries where more widespread cigarette smoking has accompanied economic changes. The overall incidence and mortality rates and the ratio of mortality to incidence in various racial and ethnic groups in the United States for 1998–2003 are shown in Table 61-3.⁴ Compared with data from 1988 to 1992, rates in all racial/ethnic groups have increased with the possible exception of American Indian/Alaska natives, which have the lowest cancer rates. Differences among specific Asian or Pacific Islander groups are available elsewhere for the 1988–1992 rates by racial/ethnic group.¹⁴ Similar data from the United States 2000 Census are not available yet. Variations in overall cancer incidence reflect the mix of cancers in the different groups. Variations in mortality are due to differences in both incidence and survival. The differences in the ratio of mortality to incidence rates provide a rough indicator of differences in overall survival from cancer. These are a reflection of both the types of cancer that predominate in the different groups and the level of utilization of screening and treatment services by their members. Less advantaged groups have the highest ratios of mortality to incidence, clearly indicating that improvement of services could have an impact on the cancer burden in these populations.

Time Trends

Figure 61-1, A and B, shows trends in incidence rates for various cancers in the United States from 1975 to 2002 for men and women, respectively.¹⁰ Figure 61-2, A and B, shows trends in mortality rates for the most common cancers in the United States from 1930 to 2002, for men and women.¹⁰ The striking increase in rates of lung cancer is largely due to cigarette smoking. The reason for the marked decline in rates of stomach cancer is unknown but may be related to changes in dietary habits, with consumption of less preserved and more fresh and frozen foods. The decline in mortality from uterine cancer is probably due to the decrease in incidence resulting from screening. Breast and prostate cancer incidence increased dramatically in the 1980s and early 1990s as a result of mammography and prostate-specific antigen (PSA) screening, respectively. Recently, there have been declines in mortality rates of these two cancers. Dating back to 1990, mortality rates for all cancer sites have been declining in the United States for the first time in recorded history. Incidence rates have not shown a similar declining pattern, supporting

TABLE 61-3. AGE-ADJUSTED INCIDENCE AND MORTALITY RATES OF ALL CANCERS COMBINED IN RACIAL AND ETHNIC GROUPS IN THE UNITED STATES, 1998–2003*

1998–2003 Race/Ethnic Group	Men			Women		
	Incidence*	Mortality*	Ratio	Incidence*	Mortality*	Ratio
American Indian/Alaska Native ^b	275.6	156.4	0.57	231.4	112.5	0.49
Asian or Pacific Islander	377.9	146.3	0.39	297.4	99.1	0.33

*Rates are age-adjusted to the 2000 U.S. standard population and adjusted for delays in reporting with the exception of melanoma.

Figure 61-2. A. Annual age-adjusted cancer death rates* among males for selected cancer, U.S., 1930–2002. B. Annual age-adjusted cancer death rates* among females for selected cancer, U.S., 1930–2002. Rates are per 100,000 and are age-adjusted to the 2000 U.S. standard population. *Rates are age-adjusted to the 2000 U.S. standard population. Note: Due to changes in ICD coding, numerator information has changed over time. Rates for cancer of the lung and bronchus, colon and rectum, uterus (uterine cervix and uterine corpus), ovary, and liver are affected by these changes.

the concept that increasing screening and improved therapies are contributing more to the declining mortality. A report evaluating the reduction of breast cancer mortality in the United States from 1975 to 2000 concluded that both screening mammography and treatment primarily contributed to the reduction.¹⁵ Comparing 1983–1985 with 1995–2001 newly diagnosed cancer patients, 5-year relative survival

rates have increased from 53% to 65% for all races across all cancer sites in the United States.¹⁰

Temporal trends in survival from cancer in children are most encouraging. From 1974 to 2001, five-year survival rates in children under age 15 increased for all sites. From 1995 to 2001, five-year survival rates were 86% for acute lymphocytic leukemia, 52% for acute

myeloid leukemia, 73% for brain and other nervous system, 86% for non-Hodgkin's lymphoma, 95% for Hodgkin's disease, 73% for sarcomas of the bone, 92% for Wilms' tumor, and 79% for all cancer sites combined.^{4,10} There has been little change in the incidence of these neoplasms in children, thus reductions in mortality have resulted in prolonged survival due primarily to improved therapy.

► ETIOLOGY AND PRIMARY PREVENTION

Criteria for Causality

Primary cancer prevention is prevention of the initial development of a neoplasm or its precursor. This can be accomplished only if one or more causes of the neoplasm are known, and it is achieved by reducing or preventing exposure to the causative agent or enhancing exposure to the protective agent. A harmful agent is considered causal if reducing or removing a population's exposure to it results in a decrease in the amount of disease occurring in that population; a protective agent is considered truly beneficial if increasing or expanding a population's exposure to it results in a decrease in the amount of disease occurring in that population.

To determine whether an agent is a cause of a particular disease in humans, information from all relevant studies must be assessed critically. In making such an assessment, evidence for causality is strengthened if the criteria listed in Chap. 2 are met. Additional criteria include evidence that risk is reduced following a reduction in exposure.

Attempts to determine whether an agent is carcinogenic in humans must often be made without information on all of these criteria; yet assessment of whatever evidence is available must frequently be made. Investigators must examine existing evidence to identify additional questions that should be addressed by further studies, physicians must assess available evidence to be able to give their patients adequate advice, and public officials must assess the evidence to determine needs for laws and regulations to limit exposure. Each must weigh the evidence for a causal relationship and consider the consequences of falsely implicating a substance as being carcinogenic when it is not and of failing to identify as carcinogenic a substance that is. All must also be willing to alter their opinions as results of additional investigations become available. Errors of judgment can be minimized by a clear understanding of basic epidemiologic principles and by careful examination of available evidence using the above-referenced criteria for assessing causality.

General Etiological Considerations

At the level of the cell, cancer is a genetic disease. The development of a cancer appears to involve a multistep accumulation of genetic damage, leading eventually to the development of an abnormal clone of cells with a selective advantage over normal cells, and finally to an incipient tumor that acquires the ability to invade surrounding tissue.¹⁶ The molecular epidemiology of cancer involves the use of molecular techniques in epidemiologic studies to provide new insights.¹⁷ For each organ site, a tumor is the end result of multiple genetic aberrations that may be caused by multiple agents, and the same endpoint may be reached via different pathways. As a result, multiple risk factors are observed for all cancers, and only a small proportion of individuals who are exposed to most known carcinogens develop cancer. For example, a factor may increase cancer risk if it contributes directly to DNA damage, alters the ability of the cell to recognize or repair damage, inhibits apoptosis, encourages cell proliferation, enhances vascularization of the incipient tumor, or otherwise confers a selective advantage to that clone of cells. Similarly, agents that inhibit tumor development might act by reducing epithelial absorption of carcinogens, inhibiting the enzymatic activation of procarcinogens, enhancing the metabolic destruction of carcinogenic agents, promoting DNA repair, or causing cell differentiation or

apoptosis and thereby reducing the number of stem and intermediate cells susceptible to the effects of carcinogens.

Most of the genes in which mutations appear to play a mechanistic role in carcinogenesis are categorized as either oncogenes or tumor suppressor genes, or are involved directly in DNA repair. Most identified oncogenes are mutated forms of genes (proto-oncogenes) that code for proteins involved in signal transduction, the regulation of gene expression, or growth-regulating mechanisms such as growth factors or growth factor receptors; overexpression of these genes results in enhanced cell proliferation. Most known tumor suppressor genes function as negative regulators of cell proliferation. The tumor suppressor gene p53, for example, is mutated in a majority of epithelial tumors.

Other contributors to the carcinogenic process probably include genes affecting angiogenesis, metastasis, and other components of the process such as the ability to evade or disable the immune response.

The latent period between exposure to some agent and the development of a neoplasm is dependent in part on the mechanism by which the agent operates. For example, mesothelioma follows exposure to asbestos only decades after exposure; the same is true of breast cancers following radiation to the chest, suggesting that these agents act early in the carcinogenic process. On the other hand, endometrial cancers can occur within two years of exposure to exogenous estrogens, suggesting a late-stage effect of these hormones. Reticulum cell sarcomas have developed within just months of exposure to immunosuppressive drugs in persons with renal transplants. A single exposure may act at one or more points in the progression to neoplasia, and its mechanism of action may vary across cancer sites. For example, epidemiologic evidence suggests that tobacco acts early in the carcinogenesis of esophageal and gastric adenocarcinoma, late in pancreatic tumors, and at both early and late stages in lung tumors.

It must be emphasized, however, that a risk factor can represent a cause in the public health sense, as defined previously, whether or not its precise mode of action is known. For example, we have only incomplete knowledge of the exact mechanisms by which tobacco smoke increases a smoker's risk of lung cancer. For the purpose of primary prevention, however, the mechanisms of action are unimportant. Cessation of smoking will significantly reduce the incidence of lung cancer, and that is what we need to know to take preventive action. Some of the known causes of various cancers are described below.

Tobacco

Tobacco use is the single largest preventable cause of cancer (and other disease) and premature death in the United States.¹⁸ Use of tobacco is responsible for about 21% of all cancer deaths worldwide, which is more than all other known causes of cancer combined.¹⁹ Tobacco increases the risk of cancers of the lung, oral and nasal cavities, esophagus, stomach, liver, pancreas, kidney, bladder, cervix, and myeloid leukemia.¹⁸⁻²¹ Table 61-4 shows the estimated proportion of cases that would be prevented in the absence of tobacco use (the population-attributable risk percent), and the estimated annual number of deaths worldwide and in the United States attributable to tobacco.^{18,19} Population-attributable risks for tobacco are dependent on the proportion of people in the population who use tobacco, the relative risk of the particular cancer in users of tobacco, and the presence of other causes of the cancers of interest in the population. Estimates of population-attributable risks thus vary among populations, and the values for the United States are different from values for other parts of the world. Overall, these estimates outline the importance of cancer prevention through eliminating smoking in populations. Cigarette smoking is responsible for most cancers of the oral cavity, esophagus, and bladder; and it is a cause of kidney, pancreatic, cervical, and stomach cancers along with acute myeloid leukemia.^{22,23} In addition to the major cancer sites mentioned above for which the associations with tobacco are well established, a growing body of evidence implicates cigarette smoking as a contributor to the risk of colon and rectal cancers.²⁴ There is little or no evidence of an association with cutaneous melanoma and conflicting evidence for prostate cancer.

TABLE 61-4. CANCER DEATHS ATTRIBUTABLE TO SMOKING: WORLDWIDE AND U.S. ESTIMATES*

Cancer Site	Smoking Population Attributable Fraction	2001 Deaths Worldwide	Smoking Population Attributable Fraction	2006 Deaths in U.S.†
Lung and bronchus	70	856,000	86	139,716
Oral cavity	42	131,000	71	5,275
Esophagus	42	184,000	71	9,777
Bladder	28	48,000	41	5,355
Pancreas	22	50,000	30	9,690
Liver	14	85,000	29	4,698
Stomach	13	111,000	25	2,858
Leukemia	9	23,000	17	3,788
Cervical, uterus	2	6,000	11	407
All Cancer	21	1,493,000	29	81,963

*Estimated smoking population attributable fraction and worldwide death rates based on Danaei et al., 2005.¹⁹

†Based on 2006 death rates estimated by the American Cancer Society (Jemal et al., 2006).¹⁰

Many of these estimates are based on studies of individuals who smoked cigarettes that were popular decades ago. Risks in comparable smokers of filter and low-tar products may be lower but still appreciable. Furthermore, the number of puffs per cigarette and the number of cigarettes smoked per hour are inversely proportional to the amount of nicotine in the tobacco. Low levels of nicotine therefore result in an increased exposure to carcinogens in tobacco smoke. There is no safe cigarette.

Risks of a variety of neoplasms are also increased in users of other forms of tobacco. Compared to nonsmokers, risk in pipe and cigar smokers is approximately doubled for lung cancer, increased fourfold for cancer of the larynx, and doubled or tripled for neoplasms of the esophagus, oral cavity, pharynx, and bladder. Pipe smoking approximately triples one's risk of lip cancer, and chewing tobacco or using snuff results in a fourfold increase in the risk of oral cancer.²⁵

Secondhand smoke and environmental tobacco smoke also significantly increase the risk of lung cancer.²⁶ Secondhand smoke contains more than 50 carcinogens and there is no risk-free level of exposure. Thus, passive smoking may account for the majority of the lung cancer not due to smoking, residential radon, or industrial exposures. The 2006 Surgeon General's report found that millions of Americans are still exposed to secondhand smoke in their homes and workplaces despite substantial progress in tobacco control.²⁶ Secondhand smoke also causes premature death and disease in children and adults who do not smoke.²⁶ Separating nonsmokers from smokers, ventilating buildings, and cleaning air cannot eliminate exposure to nonsmokers; only eliminating smoking in indoor spaces will do so.

Alcohol

The risk of several human neoplasms is clearly associated with alcohol consumption, especially for cancer of the liver, oral cavity, esophagus, and breast.^{19,27} Risk of hepatocellular carcinomas is increased in heavy drinkers, but the extent to which this is due to the unusually high prevalence of hepatitis B and C in alcoholics is unknown. These tumors tend to develop in alcoholics with macronodular cirrhosis, probably as a result of the rapid regeneration of liver cells in such individuals. If alcohol is a cause of liver cancer, it is an uncommon complication of its use, because these tumors are rare in countries such as the United States where exposure to alcohol is common.

Cancer risk is typically increased only in those tissues that come in direct contact with undigested alcohol. Risk is thus increased for squamous cell carcinomas of the mouth (buccal cavity and pharynx), esophagus, and supraglottic larynx, but not, for example, of the lung or bladder. Esophageal, oral, and laryngeal squamous cell cancers are all also related to smoking, and most studies show the effect of smoking on the risk of these tumors to be greater in drinkers than in nondrinkers. Alcohol thus appears to modify the carcinogenic effect of tobacco smoke. It is not known whether alcohol use increases risk of these neoplasms in the absence of tobacco smoke or other carcinogens.²⁸ The

effect of alcohol on these neoplasms may also be greater in individuals with marginal nutritional status than in better nourished individuals. In the United States, alcohol and tobacco account for about 80% of these cancers.

Adenocarcinomas of the lower esophagus, gastroesophageal junction, and gastric cardia have also been consistently associated with alcohol use, but the relationship is not as strong as for the squamous cell carcinomas of the upper aerodigestive tract. Risks of cancer of the distal stomach, pancreas, colon, and rectum have not been consistently related to alcohol use, but observed associations between beer and rectal cancers and between heavy drinking and pancreatic cancer warrant further study. An association between alcohol intake and breast cancer has been observed in multiple investigations, even after controlling for known risk factors for breast cancer; while this relationship is not well understood, a recent consensus group suggests that 4–9% of breast cancers may be caused by alcohol consumption.¹⁹

Approximately 5% of all cancer deaths worldwide and 4% of cancer deaths in the United States can be attributed to alcohol use.^{18,19} Most alcohol-related neoplasms develop as a result of smoking as well as drinking, and cessation of smoking would have nearly the same impact on the occurrence of these neoplasms as cessation of drinking.

Industrial Exposures

In 1972, the IARC in Lyon, France, initiated a series of monographs on the evaluation of carcinogenic risks to humans. As of 2006, 88 multidisciplinary committees of experts have reviewed the published literature on approximately 900 suspect chemicals, industrial processes, drugs, radiation exposures, and infectious agents and classified them as to their likely carcinogenicity in animals and humans. Of the over 800 chemical and industrial processes evaluated, the available evidence was considered sufficient to clarify 19 agents and groups of agents, 6 mixtures, and 13 industrial processes with exposure circumstances as carcinogenic to humans (Group 1).^{29–39} These, and the neoplasms most strongly and consistently associated with them, are shown in Table 61-5. Over 50 other chemicals, mixtures, and exposure circumstances were judged to be probably carcinogenic to humans (Group 2A); over 200 others were considered possibly carcinogenic to humans (Group 2B). The remaining chemicals, mixtures, and exposure circumstances were considered not classifiable as to their carcinogenicity to humans (Group 3). Estimates of the global burden of occupational cancer are in the 2–4% range.^{40–42}

Environmental Pollution

The evidence that the agents shown in Table 61-5 are carcinogenic in humans comes from studies of relatively high exposure in the workplace. Exposures outside the workplace to most of these agents are sufficiently rare or at such low levels as to be of little importance. However, there are a few exceptions to this that included indoor exposure

TABLE 61-5. OCCUPATIONAL CAUSES OF CANCER

Specific Exposures	Site or Tumor Type
■ Agents and Groups of Agents	
4-Aminobiphenyl	Bladder
Arsenic and arsenic compounds	Lung, skin
Asbestos	Lung, mesothelioma
Benzene	Leukemia
Benzidine	Bladder
Beryllium and beryllium compounds	Lung
Bis (chloromethyl) ether and chloromethyl methyl ether	Lung
Cadmium and cadmium compounds	Lung
Chromium compounds	Lung, sinonasal
Erionite	Mesothelioma
Ethylene oxide	Leukemia, lymphoma
Formaldehyde	Nasopharynx
Mustard gas (sulphur mustard)	Lung, larynx
2-Naphthylamine	Bladder
Nickel and nickel compounds	Sinonasal, lung
Silica, crystalline	Lung
Talc containing asbestiform fibers	Lung
2,3,7,8-Tetrachlorodibenzo- <i>para</i> -dioxin	All-cancer mortality
Vinyl chloride	Liver, lung, brain, leukemia, lymphoma
■ Mixtures	
Coal tar pitches	Skin, lung, bladder
Coal tars	Skin
Mineral oils, untreated and mildly treated	Skin
Shale oils	Skin
Soots	Skin, lung
Wood dust	Sinonasal
■ Industrial Processes with Exposure Circumstances	
Aluminum production	Lung, bladder, lymphosarcomas and reticulosarcomas
Manufacture of auramine	Bladder
Boot and shoe manufacture and repair	Nose, bladder
Coal gasification	Lung, bladder, skin
Coke production	Lung, bladder, skin
Furniture and cabinetmaking	Nose
Hematite mining, underground, with exposure to radon	Lung
Occupational exposure to strong— inorganic—acid mists containing sulfuric acid	Lung, larynx, nasal sinus
Iron and steel founding	Lung
Isopropyl alcohol manufacture, strong acid process	Nasal sinus
Manufacture of magenta	Bladder
Painters	Lung, larynx, esophagus, stomach, bladder, leukemia, lymphoma
Rubber industry	Bladder, leukemia, lymphoma

to vinyl chloride and asbestos, arsenic in air and drinking water, and point sources of arsenic, chromium, and nickel from industrial pollutants.

Numerous efforts have been made to assess the impact of ambient air pollution on lung cancer risk.^{19,43,44} Although rates of lung cancer are higher in urban than in rural areas, smoking is also more prevalent in urban areas. Primarily from large cohort studies in Europe and the United States, there are now results supporting air pollution

as a risk factor for lung cancer. A recent report estimates 5% of lung cancers worldwide are attributable to urban air pollution with this risk rising to 7% in low and middle income countries.¹⁹

Ionizing Radiation

Ionizing radiation can cause a variety of human neoplasms.⁴⁵ Most of the evidence for this comes from studies that followed individuals exposed to moderate or high doses from nuclear explosions, medical treatments, and occupational sources. Exposures have been both external and internal. IARC has identified radionuclides (plutonium-239, radium-224, radium-226, radium-228, radon-222, and thorium-232) and their decay products as well as phosphorus-32, radioiodines, α -particle-emitting radionuclides, and β -particle-emitting radionuclides, in addition to x- and gamma (γ)-radiation, and neutrons, as carcinogenic to humans.^{46,47}

All humans are exposed to natural radiation. Primary sources of natural radiation include inhalation (mainly radon gas), ingestion, cosmic rays, and terrestrial gamma rays.⁴⁸ Approximately half of all ionizing radiation received by individuals in the United States comes from natural background sources. Radium is found in soil where it decays to a radioactive gas, radon-222, which can seep into houses and accumulate under conditions of poor ventilation. Overall, radon gas is the greatest contributor to natural radiation exposure, accounting for about 50% of the total average annual effective dose. Radon-222 progeny, primarily plutonium-218 and plutonium-214, are the likely cause of lung cancer in uranium miners, and with recent data it is felt that residential radon-222 progeny contribute appreciably to the population's lung cancer burden.^{49,50} It has been estimated that 18,600 lung cancer deaths per year are attributable to residential radon progeny in the United States alone.⁵¹ Man-made sources of radiation also exist and include medical uses of radiation, atmospheric nuclear testing, nuclear power production, and occupation activities. In developed countries, medical uses of radiation are the largest source of man-made exposure and, on average, amount to about 50% of the 240 mrem global average level of natural exposure.⁴⁸

Studies of individuals who have received total body radiation from external sources have shown that some organs are more susceptible to the carcinogenic effects of radiation than others. In the atomic bomb survivors in Japan, there were large increases in rates of carcinomas of the anatomically exposed thyroid and mammary glands and of leukemias arising from the highly susceptible cells of the bone marrow; lesser increases in rates of lymphomas and carcinomas of the stomach, esophagus, and bladder were observed; and risks of cancer at other sites were either not altered or the increases were too small to measure with certainty. Risk of leukemia was also increased in early radiologists who took few precautions to reduce their general exposure to radiation and probably also in individuals exposed *in utero* to x-rays from pelvimetry.

Cancer survivorship has been increasing to where cancer survivors now constitute 3.5% of the U.S. population. This is a high-risk group for second cancers, which now account for 16% of all cancer incidence (excluding nonmelanotic skin cancers).⁵² These second cancers represent a serious side effect of treatment with radiation and chemotherapy. Most types of cancer can be caused by exposure to ionizing radiation.⁵³

External sources of radiation directed at specific sites have resulted in a variety of neoplasms. Breast cancer was induced in women treated with x-rays for a variety of benign breast conditions and in women who received multiple fluoroscopies of the chest in conjunction with pneumothorax treatment of tuberculosis. Individuals treated with x-rays for ankylosing spondylitis have had increased rates of leukemia and lung cancer and, like the atomic bomb survivors, lesser increases in rates of lymphomas and cancers of the stomach and esophagus. An increased risk of lung cancer has been observed in women who received radiation following mastectomy for breast cancer and radiotherapy for Hodgkin's disease. A strongly elevated risk for breast cancer has been seen after radiotherapy for Hodgkin's disease. Children treated with x-rays for tinea capitis and enlarged thymus have developed leukemia and neoplasms of the

salivary and thyroid glands. Those treated for an enlarged thymus have also had an increased risk of leukemia, and those with tinea capiti developed more brain tumors than expected.

Internal exposures to radiation have likewise resulted in increased risks of cancer at specific sites. Inhalation of radioactive dusts contributed to the increased rates of lung cancer in the atomic bomb survivors, and inhalation of radon and its decay products resulted in elevated rates of lung cancer in miners of uranium, iron, and fluorspar. Radium inadvertently swallowed by radium-dial watch painters and administered for treatment of ankylosing spondylitis was concentrated in osseous tissues and caused high rates of bone cancers. Individuals exposed to iodine-131 (I-131) in fallout from a hydrogen bomb test and in emissions from the nuclear power plant accident at Chernobyl subsequently had increased rates of thyroid cancer. The radiopaque contrast material thorostrast that was used to x-ray the liver has resulted in hepatic cancers, as well as leukemias and lung carcinomas. Women receiving cervical radium implants and other forms of pelvic radiation for a variety of gynecological conditions have had increased rates of cancers of the rectum, vagina, vulva, ovary, and bladder, as well as leukemia.

The results of most studies show a linear increase in risk of neoplasms with the amount of radiation received over a wide range of observed doses, with a possible decrease in the slope of the dose-response curve at very high levels of exposure (perhaps due to cell killing). These observations are based primarily on studies of individuals who received from tens to hundreds of rads. Doses commonly received today are orders of magnitude lower, and it is uncertain whether the dose-response curve should be linearly extrapolated to these low levels to provide an estimate of the associated risk. There may be a threshold level below which radiation does not induce neoplasms, perhaps because mechanisms of DNA repair are adequate. If so, linear extrapolation would yield estimates of risk to low levels of radiation that are too high. Conversely, chronic exposure to low levels of radiation might be more carcinogenic, rad for rad, than acute exposure at a higher dose. If so, linear extrapolations would underestimate the risk of low doses. Since there is little evidence for the latter possibility, most authorities believe that it is reasonable, as well as prudent, to assume a linear, nonthreshold dose-response relationship. Recent experimental studies have documented that a single alpha particle can provide permanent damage to a cell.⁵¹ This finding supports the biologic plausibility of the linear, nonthreshold relationship.

It is difficult to accurately estimate the number of cancers attributable to radiation from all sources experienced by the general population.⁵⁴ Nevertheless, available knowledge indicates that reducing medical exposures and residential (indoor) radon will have the most impact toward reducing population exposure and radiogenic cancer risk. Political efforts to reduce the likelihood of environmental contamination from nuclear power plants and nuclear weapons will also obviously reduce the risk of radiation-induced neoplasms.

Nonionizing Radiation

Nonionizing radiation, in contrast to ionizing radiation, is electromagnetic radiation that does not have sufficient energy to remove electrons to form an ion (charged particle). Nonionizing radiation includes ultraviolet (UV) radiation, visible light, infrared, and microwave and radio frequencies. Among these the major carcinogen is UV radiation which comes from the sun or artificial sources such as tanning beds or booths.

UV Radiation. Sunlight is definitely a cause of nonmelanoma skin cancers (squamous and basal cell carcinomas), as evidenced by the observations that these tumors tend to occur on exposed parts of the body, risk increases with the amount of sun exposure, and incidence rates are greater in light-skinned than in dark-skinned individuals. However, these skin cancers are rarely deadly, and routine data on nonmelanoma skin cancer are not collected by cancer registries in the United States. The American Cancer Society estimates over one million cases of basal cell and squamous cell skin cancer in the United States in 2006.¹⁸

The relationship of cutaneous malignant melanomas to sunlight is more complicated.^{55,56} Various types of sun exposure have been reported to be associated with melanoma, ranging from severe sunburns, occupational activities, vacation sun exposure, beach activities, other recreational activities, cumulative or chronic sun exposure, and early migration to sunny places. Incidence rates for cutaneous melanoma are highest in individuals with little natural skin pigmentation, often with intermittent sun exposure such as sunburns or sunny vacations.^{55,56} Investigation of migrants to Australia provided evidence that sun exposure at an early age or long-term exposure may be of particular importance.⁵⁵ Early UV exposure is of concern with the expanding popularity of tanning beds and booths. Current evidence suggests an increase in melanoma risk among tanning bed users. Modern tanning bed units have UV levels comparable to tropical sunlight and irradiate almost 100% of the skin, which is assumed to be 2–10 times more skin surface area than sunlight exposure.⁵⁷ Incidence rates may increase as younger populations expose more of their bodies to such units. In the white U.S. population, incidence rates of melanomas of the skin have dramatically increased over the last few decades, due in part to changes in diagnostic criteria and enhanced awareness of the importance of early evaluation of melanotic lesions. Melanoma increases with age (the mean age at diagnosis is about 57). While the relationship between cutaneous melanoma and specific types of sun exposure is complex, the American Cancer Society estimates that nearly all skin cancers are related to UV radiation (even familial cancers that are likely related to genetic and UV radiation).¹⁸ Because nonmelanotic skin cancers are common and largely attributable to sun exposure, sunlight accounts for approximately 40% of all neoplasms.^{10,19} Sunlight accounts for less than 2% of cancer deaths, since these neoplasms are infrequently fatal. Since only cutaneous melanoma is routinely collected and reported by cancer registries, less than 2% of reported cancers appear to be due to UV radiation.¹⁰ All individuals, but particularly those with light skin who burn easily, should be encouraged to avoid excessive direct exposure to intense sunlight and to use sunshades and sunscreens.

Electric and Magnetic Fields. Recent studies have focused public attention on the possible association between exposure to electric and magnetic fields (EMF), particularly from electric power lines and appliances, and risk of cancer. Based on methodological concerns and the lack of experimental evidence, no clear relationships between EMF and chronic disease have been established.^{58,59} However, an association is observed most consistently in studies of childhood leukemia in relation to postnatal exposures above 0.4 microT.^{58,59} Study of EMF is made particularly difficult by our inability to identify and accurately measure the relevant exposure. A number of reviews of the subject have been published.^{58–61}

Sex Hormones and Reproductive Factors

Sex Hormones. Sex steroid hormones have been associated with an increased risk of most reproductive cancers, including breast, endometrium, ovary, cervix, prostate, and testis. This section will evaluate endogenous and exogenous hormonal risks as well as other reproductive factors, many of which also are linked indirectly to potential hormonal alterations.

In evaluating the effects of exogenous female sex hormones on the risk of neoplasms in women, it is important to categorize these substances according to their estrogenic or progestogenic pharmacological effect. At one end of the spectrum are the pure progestational agents, such as depot-medroxyprogesterone acetate (DMPA), which is used as a long-acting injectable contraceptive in many countries and to treat malignant and benign proliferative disorders of the endometrium. Other progestational contraceptives include the “mini-pill” which is an oral contraceptive (OC), the injectable contraceptive, norethindrone, and subcutaneous implants, such as Norplant. At the other end of the spectrum are the pure estrogen preparations. Between the two ends of the estrogen-progestin spectrum are the sequential OCs which contained only estrogen in pills taken for 2 weeks of a cycle followed by a weak progestin of short duration

and which had a net estrogenic effect, and the more commonly used combined OCs with an estrogen and a progestin in each pill, and therefore a net pharmacological effect more progestational than the sequential pills. More recent products differ from these older formulations in dosage and in types of estrogens and progestins contained and are referred to as biphasic and triphasic OCs. These products were developed to reduce side effects of the monophasic OCs that administer the same estrogen/progestin dosage throughout the cycle. Because of the breakthrough bleeding side effect of the biphasic formulations, these are not widely used. Although the findings from studies linking these drugs to reproductive cancers that were conducted through the mid-1990s may not be applicable to the newer contraceptive agents, it would seem prudent to assume that they do until results of additional epidemiologic investigations provide evidence to the contrary. The most common are the conjugated "natural" estrogens (e.g., Premarin), used largely to treat or prevent symptoms and conditions associated with menopause, and the nonsteroidal synthetic estrogen, DES (diethylstilbestrol), to prevent early miscarriage. Those used during peri- and postmenopause to reduce menopausal side effects and osteoporosis include estrogen replacement therapy (ERT) and estrogen/progestin hormone replacement therapy (HRT), the most common of which is Prempro. More recent formulations have been marketed with reduced hormonal formulations yet having similar beneficial effects with fewer adverse side effects.

Although some studies, including a clinical trial, of breast cancer in women given DES for threatened abortion show no evidence of an increased risk of cancer,^{62,63} a larger investigation showed a 40% increase risk with a latency period of 20 years after DES exposure.⁶⁴ The effect of combined OCs on risk of breast cancer has been evaluated in a number of large cohort and case-control studies as well as in meta-analyses⁶⁵ and the risk is increased by about 25% in current users and declines to that of never users about 10 years after cessation of use. The relative risk estimate (RR) in women who ever used OCs was estimated to be 1.1. Tumors tended to be more localized in users than in nonusers, suggesting enhanced surveillance in recent and current users as an explanation for the increased risk. Even if the findings represent a causal phenomenon, use of OCs would result in few additional cases of breast cancer because most current and recent users of OCs are young women with a low background rate of this disease. However, among those who last used OCs less than 10 years ago, for greater than 5 years, the risk is increased approximately 13%.⁶⁵ A combined analysis of two studies of DMPA and breast cancer similarly found an increase in risk in recent and current users of this progestational agent but no increase in risk after 5 years since last use, and an overall RR of 1.1 in women who had ever used this agent.⁶⁶ Studies of breast cancer in relation to ERTs given at menopause have shown an increased risk in women particularly among those who are current users of ERTs for 5 years or longer (RR = 1.2–1.4).⁶⁷ A small increase in risk with years of use beyond 5 years has been observed in most studies, with a decline in risks to that of nonusers from 2 to 5 years after cessation of use.⁶⁸ A collaborative reanalysis of 51 studies⁶⁹ on this issue found that during or shortly after use, there was a RR of 1.02 for each year of use for those with 1–4 years of use, and 1.03 for those with more than five years of use. The addition of a progestin to the regimen increases the risk by an additional 10% over that of ERT users or a 40% greater risk than among never HRT users. Tamoxifen, which has antiestrogenic properties in the breast, and raloxifene, a selective estrogen receptor modulator, have been shown to reduce the risk of breast cancer in the contralateral estrogen receptor positive breast of a woman who receives these adjuvant therapies for primary breast cancer.

In regard to risk of breast cancer associated with endogenous sex steroid hormones, several studies have shown that risk is significantly elevated for women in the top quintile of total estradiol (RR = 1.9), or free estradiol (RR = 2.7) after adjustment for BMI and other risk factors.^{70–73}

The risk of endometrial cancer is increased twofold or more in women who took sequential oral contraceptives and who were not monitored for endometrial hyperplasia.^{67,74,75} In contrast, risk of cancer remains significantly decreased (RR = 0.5) for 20 years or longer in

users of combination OCs⁷⁶ compared to never users. The reduction in risk is even lower among those who used the progesterone-only OCs and in users of DMPA⁷⁷ because of their net progestational effect on the endometrium. Those who received estrogens for menopausal conditions, primarily as ERTs, also are at significantly greater risk of endometrial cancer. Tamoxifen, which is used as an adjuvant therapy for breast cancer, has an estrogenic effect on the uterus and has also been shown to increase the risk of endometrial cancer.⁷⁸ To reduce the risk of endometrial cancer in users of drugs containing estrogens, a progestin is often included, either continuously with the estrogen or cyclically for a specified number of days each month, and this has been shown to markedly reduce the risk of endometrial cancer to that of never users. Several case-control studies have shown an increased total and bioavailable estrogens and decreased plasma levels of sex hormone binding globulin in postmenopausal women who develop endometrial cancer as compared to healthy controls.^{79,80} In premenopausal women, one epidemiologic study showed a decrease in total and bioavailable estradiol.⁸¹ It has further been suggested that in this group of women it is lower progesterone rather than higher estrogen that increases the risk of premenopausal endometrial cancer. Additional evidence of the effects of endogenous hormones on cancer development comes from the increased risk in polycystic ovarian syndrome, a disease that is characterized by low progesterone levels in women who have normal estrogen levels. In both pre- and postmenopausal women, obesity and chronic hyperinsulinemia are associated with changes in total and bioavailable sex steroid levels, especially estrogen. In sum, there are few if any studies that have used a prospective design to directly examine endogenous hormonal levels well in advance of malignancy.

Risk of epithelial ovarian cancer in women who have ever used combined OCs is approximately 50% of that of never users, and the risk decreases with duration of use.⁸² A further reduction in risk is seen in the progesterone-only OCs. The benefit of either type of OC persists 10–20 years after use has been discontinued. The benefit includes women with a family history of ovarian cancer and those with a mutation in the BRCA1 or BRCA2 gene.^{83,84} Furthermore, the reduced risk is similar in parous and nulliparous women without known infertility. A single study has shown no effect of DMPA on risk of ovarian cancer, thus the association is unclear to date. Several large case-control studies have shown an increased risk of ovarian cancer among either ERT (RR = 1.6) or HRT (RR = 1.2) as well as a significant duration effect (RR = 1.3–1.8).⁸⁵ In contrast, the Breast Cancer Detection Demonstration Project cohort follow-up study showed no increased risk with either ever or duration in HRT use of four years or more, whereas risk was elevated in ERT users (RR = 1.8–3.2).⁸⁶ Studies of endogenous hormones associated with ovarian cancer are limited and rely on indirect evidence such as the protective effects of pregnancies and OC use which suppress pituitary gonadotropin secretion and increased risk among women with polycystic ovarian syndrome, who are known to have elevated circulating luteinizing hormones (LH). However, these findings are contradicted by the lack of an increase in risk among those with an early age at menopause and with twin pregnancies, both of which are associated with an increase in gonadotropin levels; in the lack of an increase in ovarian cancer after menopause which is associated with increasing LH and follicle stimulating hormone; and in the increased risk with ERT use and obesity. Research also has shown a lack of association between circulating androgens and ovarian cancer risk in postmenopausal women, but an increased risk is seen with androstenedione and dehydroepiandrosterone in premenopausal women. Despite the link between insulin and insulin-like growth hormones (IGF-I) receptor and activation of intracellular signaling pathways and its effects on metabolism of other hormones, studies to date do not support its involvement with ovarian cancer. Likewise, IGF-I, which has been associated with increased risk of other reproductive cancers, breast and prostate, did not show evidence of an association in the only epidemiologic investigation of risk based on prediagnostic data to date.⁸⁷ In summary, although evidence is accumulating regarding endogenous hormones associated with ovarian cancer, additional investigations particularly among prospective study designs are required.

Studies of cervical cancer and menopausal estrogens have not been conducted. Most studies of OCs and invasive cervical cancer have shown an increased risk with greater than 5 years duration of use in the presence of an oncogenic human papillomavirus (HPV) infection. OCs provide hormonal conditions favorable to the persistence of HPV infection⁸⁸ or transformation of infected cells. Studies of HRTs and risk of cervical cancer are limited but suggest an increased risk in users (RR = 2.3–2.7) and with increasing duration in use.^{89,90}

Combined OCs have clearly been shown to cause benign hepatic cell adenomas and focal nodular hyperplasia. These are highly vascular tumors that can rupture, bleed into the peritoneal cavity, and cause death. Fortunately, they are a rare complication of OC use, occurring at a rate of less than 3 per 100,000 women-years in women under 30 years of age. Case-control studies conducted in developed countries have shown that primary hepatocellular carcinomas are also rare complications of OC use.⁹¹ Some of these studies, plus investigations conducted largely in developing countries, provided evidence that this adverse effect is not mediated by enhancing the influence of other factors such as hepatitis B or C on risk.

DES was prescribed between 1938 and 1971 to treat up to 5 million women in the United States for threatened abortion. Approximately 80% of the female offspring exposed to DES in utero have been found to have glandular epithelium resembling that of the endometrium, and presumably of Müllerian origin, in the vagina or cervix. This is referred to as adenosis. A small portion of women with this condition have developed clear cell adenocarcinomas of the vagina or (less frequently) the cervix in their teens or twenties especially if their mother took DES early in pregnancy.⁹² The risk of clear cell carcinoma is between 1.4/1000 and 1/10,000 among exposed women.⁹³ This represents a high proportion of neoplasms in this age group, including virtually all vaginal cancers. Women exposed in utero to DES with vaginal or cervical adenosis should be followed carefully for the development of clear cell carcinoma. Males exposed in utero to DES are at increased risk of cryptorchidism, which is a significant risk factor for testicular cancer. However, only one study has shown a nonsignificant threefold increased risk of testicular cancer among males with prenatal DES exposure. These neoplasms represent the first documented instances of transplacental carcinogenesis in humans. In some countries, DES has been used as a “morning after” pill to prevent pregnancy or to treat menopausal symptoms. These findings suggest that precautions must be exercised not to give DES to women who may be pregnant.

Colorectal cancer risk has been shown to be protected among OC ever or new users (RR = 0.4–0.7) compared to never users^{94–96} as well as in HRT current or ever users (RR = 0.3–0.5).⁹⁵ Case-control, cohort studies, and a meta-analysis have failed to confirm earlier reports that risk of malignant melanoma is increased by use of OCs.⁷⁶ Compared to never users, those who used OCs for greater than 1 year showed no excess risk (RR = 0.82–1.15), nor for duration, age first used, recency, or latency effects.^{97,98} Isolated reports of associations between OCs and pituitary adenomas, choriocarcinomas, gallbladder carcinomas, and thyroid tumors have also appeared, but these observations have not been convincingly confirmed by epidemiological investigations.⁷⁶

Both prostate and testicular cancers in males have been associated with endogenous sex hormones with the primary hypothesis that androgens are causally related to prostate cancer etiology. Although there have been a number of studies that have investigated the role of androgens, few have had an adequate sample size, serum taken prior to cancer development and diagnosis, or controlled for confounding, especially age-related, known changes in serum hormone levels that may not reflect current cancer risk. In the one prospective study that addressed these issues, the Physicians’ Health Study showed that risk of prostate cancer was greater with increasing testosterone quartile levels (RR = 1.0–2.4), and decreased with increasing sex hormone binding globulin (RR = 1.0–0.4) and estradiol regardless of comparative quartile level (RR = 0.5).⁹⁹ Testicular cancer has been hypothesized to be associated with initial hormonal exposure levels in utero and in the belief that excess estrogen or insufficient androgens lead

to testicular cancer. Maternal exogenous estrogen use during pregnancy has been associated with both cryptorchidism, a significant risk factor for testicular cancer, and subsequent development of testicular cancer in offspring. Also, risk is greater in male offspring of women having their first child as compared to multiparous women, consistent with plasma estrogen levels which are noted to be higher in primiparous women.¹⁰⁰ Although it has been suggested that maternal exposure to DES leads to increased testicular cancer risk, there is insufficient evidence to support this claim.¹⁰¹ Among the testicular cancer risk factors, it appears that late age at puberty is linked to a significant decrease (~50%) in risk of testicular cancer, supporting a hormonal influence in its etiology.^{102,103}

Reproductive Factors. Among women, nulliparity is associated with an increased risk of cancers of the endometrium, ovary, and breast. Risk of ovarian and endometrial cancers decreases with increasing number of pregnancies, whereas pregnancies beyond the first have a lesser protective effect against breast cancer. Risk of breast cancer increases strongly with age at first full-term birth, in contrast to risk of ovarian cancer which actually decreases with increasing age at first birth.^{104–107} Late age at last birth has been associated with a significant reduction in risk independent of parity for endometrial cancer.¹⁰⁸ Earlier age at menarche and late age at menopause are associated with an increased risk of cancers of the breast and endometrium, but not the ovary. Lactation, which suppresses ovarian function, has been inconsistently associated with increasing the risk of breast cancer. The benefit of lactation occurs due to ovulation suppression which is maximal soon after delivery, and short-term lactation appears to have only a small protective effect against ovarian cancer, whereas prolonged lactation seems to confer little additional benefit. Risk of endometrial cancer may be inversely related to duration of lactation, but the effect also is short term, thus there is little or no protection in the postmenopausal years when most endometrial cancers occur. Induced abortion may enhance risk of breast cancer, but studies to date have yielded inconsistent findings. In regard to infertility independent from nulliparity, most studies report an increased risk of epithelial ovarian cancer.⁸² Although the mechanism is not understood, several studies have shown endometriosis to increase the risk of ovarian cancer, and the risk is further increased among those with ovarian endometriosis.^{109,110} Although somewhat less clear, most studies have shown that use of fertility agents is not associated with an increased risk of ovarian cancer.¹¹¹ Tubal ligation confers a 10–80% reduction in ovarian cancer risk regardless of parity and including prospective studies that reduce a potential detection bias of case-control evaluations.^{112–114}

Mechanisms for the associations with parity and lactation are not fully understood, but likely involve endogenous pituitary and ovarian hormones. The development of epithelial ovarian tumors is believed to be promoted by gonadotropin stimulation and reduced by suppression of gonadotropins during pregnancy and lactation. Nulliparous women are on average less fertile than parous women and have more anovulatory menstrual cycles, hence more constant production of estrogens without cyclic progesterone each month. The relative excess of unopposed estrogens is believed to promote endometrial tumor development. Although several mechanisms for the relationship of breast cancer to age at birth of first child have been proposed, none appears adequate. Studies of the endocrinological events associated with childbearing and other endocrinological studies in women at varying risks of cancers of endocrine target organs continue to be conducted to explain the mechanisms by which factors related to childbearing alter risk.

Infectious Agents

Significant knowledge has accumulated over the past several decades about the molecular biology of cell transformation by oncogenic DNA and RNA viruses. The evidence is based on the ability of these viruses to modify gene expression in the host cell leading to a better understanding of how these infectious agents are related to the development of cancers. Among the DNA-related cancers in humans are EBV, hepatitis B and C (HBV and HCV), and HPV.

Among the DNA viruses, EBV, a herpes virus, has been etiologically associated with Burkitt's lymphoma (BL), nasopharyngeal carcinomas (NPC), and Hodgkin's disease.¹¹⁵ The EBV genome established a latent infection in B lymphocytes and is transmitted when these lymphocytes replicate. In healthy individuals, cytotoxic T-cell responses against the latent viral proteins prevent uncontrolled replication of the virus in these B cells. This cancer, which is noted as especially aggressive, has the hallmark chromosomal translocation between 8 and 2, 14, or 22.¹¹⁶ Primary EBV is usually asymptomatic in humans and exists as a latent infection which is seroprevalent in over 90% of the adult population worldwide. Almost all individuals with BL or NPC have antibodies against EBV, compared with lower percentages in unaffected persons, and antibody titers are higher in the diseased cases. A cohort study has clearly shown that EBV infection precedes the development of African BL, where it is referred to as endemic BL. In contrast, isolated cases of non-endemic BL occur throughout the world at a much lower incidence and the association with EBV is much weaker, with only 15–30% of cases outside Africa having evidence of prior EBV infection.¹¹⁷ The EBV genome has been demonstrated in tumor cells from most African BL and virtually all NPCs. However, only a small proportion of individuals infected with EBV develop either of these neoplasms and the worldwide distribution of the two malignancies is different. Thus, it is apparent that other factors are essential in conjunction with EBV for these tumors to develop. Chronic malaria and the subsequent immunosuppression or antigenic stimulation may play a role in African BL although the spread of EBV is through saliva not mosquitoes as originally hypothesized. EBV is associated with the undifferentiated NPC type which is detected primarily in men over age 40 years of age, regardless of geographic location. Although the neoplasm is rare, the incidence is very high in Asian and Alaskan native populations with rates between 25–50/100,000 compared to less than 1/100,000 in Caucasian populations.¹¹⁸ In Singapore, where Chinese, Malays, and Indians live in close proximity and share similar dietary and social habits, the incidence of NPC is 18.5, 3.1, and 0.9 per 100,000 in males, respectively, suggesting that genetic rather than environmental exposures are important to the development of this tumor. Although cofactors for NPC are unknown, they may include human leukocyte antigen (HLA) profiles and environmental risks (e.g., chemical exposures, tobacco smoke, or cooking fumes), and dietary factors such as salted fish. An increased risk of NPC has been identified in Chinese populations for HLA types A2, B14, and B46 whereas a reduced risk is found with HLA A11, B13, and B22.^{118,119} EBV also contributes to the development of Hodgkin's disease. The virus causes infectious mononucleosis, and those with a history of infectious mononucleosis have a two- to threefold increase in risk of Hodgkin's disease but not EBV-negative HL. Compared to nondiseased individuals, cases of Hodgkin's disease have a higher prevalence of antibodies against EBV and higher antibody titers. However, EBV DNA or gene products can be demonstrated in only half of cases, and only 30–40% of cases have anti-EBV antibodies, suggesting either the existence of causal pathways not including EBV or loss of EBV infection after tumor development. In immunodeficient patients such as those receiving transplants or having AIDS, there also is an increased incidence of EBV-associated Hodgkin's disease.¹²⁰

There is strong evidence that hepatitis B and C viruses cause hepatocellular carcinoma (HCC), and an IARC working group has judged that both of these viruses are carcinogenic to humans.¹²¹ HCC has been increasing worldwide and is now the fifth most prevalent cancer with mortality reaching 500,000 people yearly.¹²² Although rare in the United States except among Eskimos, HCC is the most common cancer in parts of Africa and China. This cancer can develop in individuals who are chronic carriers of HBV or HCV. In parts of Africa, Asia, and the Pacific, HBV is endemic with most infections occurring during childhood, and 90% of HCC are infected with HBV. Determinants of the chronic carrier states are not fully understood. Transmission of HBV or HCV is through contact with infected bodily fluids. In high-risk areas, perinatal transmission of HBV from mother to child at or soon after birth, before immune competence is fully developed, results in the child becoming a chronic HBV carrier

and at higher risk of subsequently developing HCC. In areas with lower prevalence of HBV, most infections are acquired horizontally in early adulthood through intravenous drug use or unprotected sex. Less commonly, contaminated surgical instruments and donor organs and medical personnel who are in frequent contact with infected blood products are at highest risk if not vaccinated against HBV. Currently there is no vaccine to protect against HCV. Although blood transfusions were once a significant route of transmission, improved diagnostic tests, greater screening, and vaccination against HBV have dramatically reduced the risk of acquisition of HBV. It is uncertain whether either HBV or HCV directly causes hepatomas or whether they cause chronic hepatitis and liver cirrhosis, which lead to repeated periods of cell death and regeneration, and increase the risk of HCC, perhaps in the presence of other carcinogens such as aflatoxins.

Kaposi's sarcoma is caused by another DNA virus, human herpesviridae (HHV-8). Once very rare, in the early 1980s a more aggressive form of Kaposi's sarcoma associated with immune deficiency began to be seen in AIDS patients and was one of the first indications of the AIDS epidemic. Although the cancer cannot be cured, by treating the immune deficiency, progression of Kaposi's sarcoma can be slowed or halted. As the mortality rate of AIDS dropped in the 1990s, so also did that of Kaposi's sarcoma. Blood tests can detect antibodies against Kaposi's sarcoma and determine whether the individual is at risk of transmitting HHV-8 infection to a sexual partner or whether a donated organ is infected with Kaposi's sarcoma.

It is now well established that oncogenic HPV types are causative in the development of human cancers. HPV is a necessary but not sufficient cause of cervical cancer and also is associated with a high proportion (60–85%) of vulvar, vaginal, penile, and anal sites. Males, most likely due to the characteristics of their genital tissue, have a much lower prevalence of these genital cancers but are the primary source of sexual transmission to the higher-risk females. Recent evidence indicates that 25% of head and neck tumors also are caused by HPV independent of other significant risk factors at these sites, such as tobacco and alcohol. Among the most prevalent and highly oncogenic types are HPV 16 and 18 with a number of other less prevalent oncogenic types that cause genital cancers (HPV 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 73, and 82). Although the majority of cervical cancers are associated with HPV 16, HPV 18 is most frequently associated with aggressive adenocarcinomas of the cervix in younger aged women. HPV is transmitted primarily through sexual contact and invades the tissues by epithelial microtears. Although well over 50% of adults are thought to have been infected in their genitals with HPV during their lifetime, infections usually are cleared or become latent and undetectable. However, in individuals in whom infection persists for a prolonged period of time, intraepithelial lesions are likely to develop, some of which eventually progress to invasive carcinomas. The factors responsible for progression to anogenital malignancies include hormonal factors (e.g., steroid contraceptives), chemical factors (e.g., cigarette smoking), and immunodeficiency (e.g., human immunodeficiency virus [HIV] infection, immunosuppression for renal transplantation). In contrast, HPV is an independent risk factor for head and neck cancer and does not require the other major risk factors for malignancy to develop. HPV types associated with head and neck cancers have been limited primarily to HPV 16, 18, 31, and 33, and both younger age and male gender are more likely to be infected with the virus in the oral tissues. Recently several HPV vaccines have undergone clinical trials and been approved by the United States Food and Drug Administration. Currently, the HPV vaccine is being targeted only to prepubescent and teenage females prior to their sexual debut, but this focus has raised considerable concern as the source of viral infection to the genitals is primarily from male to female. In addition, this strategy fails to address prevention of HPV-associated head and neck cancers which occur predominantly among males.

Among the RNA tumor viruses, the most significant is human immunodeficiency virus (HIV or HTLV-III) which causes acquired immunodeficiency syndrome (AIDS), are at greatly increased risk of Kaposi's sarcoma and of non-Hodgkin's lymphomas.¹²³ As of 2006 an estimated 25 million people have died from AIDS alone.¹²⁴

Transmission is through direct contact of a mucous membrane with a bodily fluid containing HIV (e.g., blood, semen, vaginal fluid, breast milk). In addition to destroying CD4⁺T cells, which are required for functioning of the immune system, and subsequently leading to AIDS, HIV also directly attacks and destroys the kidneys, heart, and brain. Rates of intraepithelial cervical and anal squamous cell carcinomas are also increased in AIDS patients, but increased rates of invasive cancer at these sites have not been observed. Testicular seminomas also occur more frequently in AIDS patients, and there are unconfirmed reports of increased risks of testicular teratocarcinoma, malignant melanoma, leiomyosarcoma, non-small cell lung cancer, multiple myeloma, hepatocellular carcinoma, and Hodgkin's disease.

Another RNA tumor virus, HTLV-I, has been strongly implicated as a cause of adult T-cell leukemias and lymphomas, particularly in some areas of Japan, the South Pacific, the Caribbean, and Africa where the virus is endemic, but this virus is of less significance in the nonendemic United States. The actual population seropositivity level is unclear as most studies have examined selective, high-risk groups. Transmission is believed to occur through cell to cell contact of virus-infected cells during the exchange of bodily fluids (e.g., breast milk, semen, blood transfusions, and contaminated needles of drug users).

Four infectious agents other than viruses have been strongly implicated as causes of human cancers. In 1994, an IARC working group¹²⁵ judged that *Shistosoma haematobium* was a definite cause of bladder cancer (Group 1), that the liver flukes *Opisthorchis viverrini* and *Clonorchis sinensis* were definitely (Group 1) and probably (Group 2) causes of cholangiocarcinomas of the liver, respectively, and that the bacteria *H. pylori* was a carcinogen for the stomach (Group 1). Schistosomiasis affects more than 200 million people and humans are the host for the blood fluke which infects them through the skin exposed to water containing the infective larvae. The eggs elicit granulomas that cause disease in the urogenital system. *O. viverrini* infects humans who eat undercooked fresh-water fish and the adult parasite lives within the intrahepatic bile ducts. The highest incidence of cholangiocarcinoma in the world is in Thailand where the parasite is endemic and the vast majority of these cases are caused by this fluke. The relationship of *H. pylori* to gastric cancer is of potential importance in developed countries. This pathogen has been associated with both intestinal and diffuse histologic types, and most strongly with tumors developing outside the cardia.¹²⁶ It is estimated that *H. pylori* infects the gastric mucosa of about half of the world population and 15% of those infected are associated with the development of gastric cancer, the second leading cause of cancer deaths worldwide. In the United States, blacks, Hispanics, and other minorities are more commonly infected with *H. pylori* and have an incidence and mortality rate 2–3 times that of Caucasians. Over 60% of gastric adenocarcinomas have been attributed to infection with *H. pylori*. The malignancy can be prevented or produce resolution of premalignant lesions by use of antibiotic therapy.

Nutrition and Physical Activity

Reasons for the large international differences in the incidence of most cancers are unknown. Studies of rates in migrants have clearly shown that they are largely due to variation in environmental factors, not in genetic predisposition or susceptibility to carcinogens. Correlational studies have been conducted to identify factors that vary across countries in accordance with variations in the rates of various cancers. These studies have shown a variety of dietary components to be related to a number of different neoplasms. To investigate these associations further, many case-control studies and several large cohort studies have been conducted.^{127,128} A variety of laboratory investigations have been performed to elucidate possible mechanisms for observed epidemiological findings, and randomized trials of dietary supplements or modifications have been conducted or are under way.^{129–132}

Bias in Dietary Studies. Epidemiological studies of diet and cancer are difficult to perform and evaluate for a variety of reasons. One common problem in all epidemiological approaches is that many individual dietary constituents are highly correlated. For example,

diets that are poor in animal protein are also likely to be poor in animal fat and high in carbohydrates and fiber. Additionally, food frequency questionnaires (FFQs) vary in the type of nutrients emphasized through kinds of foods listed, methodology for food selection, definitions of food groups, nutrients in databases, instructions given to responders relative to serving size estimations, format for completing the questionnaire (self-administered or clinician-administered), and methodology for quality control (method of contacting the respondent to resolve items left blank). Under such circumstances, it is difficult to determine which of the interrelated dietary constituents (if any) is responsible for observed variations in risk. Another difficulty is that diet many years prior to the development of a neoplasm may be of the greatest etiological relevance and diets may change over time. Such information is difficult (although not impossible) to obtain in case-control studies. Cohort studies can theoretically overcome this problem, but must include large numbers of subjects and must be continued for decades and hence require large commitments of time and money. Despite these methodological problems, results of recent research strongly suggest that dietary factors contribute to the etiology of a variety of neoplasms. Some of the more likely mechanisms are briefly summarized in the following paragraphs.

Overview of Risk. When reviewing preventable lifestyle and environmental factors related to cancer, a recent consensus group examined major dietary issues and physical activity.¹⁹ They found evidence that low fruit and vegetable intake are associated with cancer of the colon and rectum, stomach, lung, and esophagus. However, low fruit and vegetable consumption is interrelated to dietary fat intake, obesity, and possibly physical inactivity. Being overweight or obese (high body mass index) have been associated with cancer of the corpus uteri, colon and rectum, breast (postmenopausal), gallbladder, and kidney. Obesity is likely also related to physical inactivity which has been associated with breast, colorectal, and prostate cancers.¹⁹ The lack of independence among these factors makes understanding true causal associations difficult.

Carcinogenic Mechanisms. Food items may be contaminated by preformed carcinogens. Aflatoxins produced by fungi that can grow in grains and other crops in warm, moist climates have been linked to liver cancers in some parts of the world. In China, mutagens have been detected in fermented pancakes and vegetable gruels, and these have been related to both esophageal cancer in humans and neoplasms of the gullet in chickens; and nasopharyngeal carcinomas have been related to consumption of salted fish and fermented food during infancy.

Carcinogens may be formed in the body by bacteria. Nitrites may be ingested in small amounts with preserved meats and fish or formed in larger quantities from dietary nitrates, either spontaneously before being eaten or in the presence of bacteria in the body; and carcinogenic *N*-nitroso compounds may then be produced from ingested amines and nitrites by bacteria in the stomach of people with chronic gastritis, in the bladder of individuals with urinary tract infection, or in the normal colon and mouth to produce cancers of the stomach, bladder, colon, and esophagus, respectively.

Smoked and cured foods, charcoal-broiled meats, and some fruits and vegetables from contaminated areas may contain carcinogenic polycyclic aromatic hydrocarbons.

A high-fat diet may increase bile production and produce an environment in the large bowel conducive to the growth of bacteria capable of forming carcinogens, and perhaps steroid hormones, from bile salts. Production of such substances provides one plausible explanation for the observed associations between a high-fat diet and cancers of the colon, breast, and prostate.

Obesity. Overnutrition, leading to obesity, has been associated with endometrial and postmenopausal breast cancers. A possible mechanism is tumor promotion by excess endogenous estrogens. In postmenopausal women, estrogens are derived from androgens produced by the adrenal gland. This reaction takes place in adipose tissue and is enhanced in obese women. Also, early menarche is a risk factor for

breast cancer, late menopause is a risk factor for both breast and endometrial cancers, and both of these factors have been directly or indirectly related to overnutrition.

Physical Activity. Although the epidemiologic evidence is not completely consistent, regular exercise appears to reduce the risk of breast cancer, perhaps because of the effects of physical activity on body weight. There is also evidence that exercise exerts an independent effect on the risk of colon cancer, possibly by decreasing stool transit time and therefore the duration of exposure to carcinogens in the gut.

Protective Dietary Constituents. Dietary constituents may also protect against cancer. Diets high in fresh fruits and raw vegetables have been associated with decreased risks of carcinomas of virtually all sites within the gastrointestinal and respiratory systems, the uterine cervix, and (less consistently) other tissues. Foods rich in retinol (preformed vitamin A) have also been associated with reduced risks of some epithelial cancers. Levels of many of the potentially protective micronutrients are highly correlated in human diets, making it difficult to determine which micronutrients are most strongly associated with reduced risks, and the specific substances in fruits and vegetables responsible for the apparent protective effects have therefore not been conclusively identified. It is likely that different micronutrients or combinations of micronutrients operate at different sites, and a variety of protective mechanisms have been suggested. For example: the reduced risks of stomach and esophageal carcinomas may be due to inhibition by vitamin C of *N*-nitroso compound formation; vegetables of the *Brassicaceae* family have been hypothesized to induce activity of mixed-function oxidases, which may detoxify ingested carcinogens responsible for colon cancer development; and vitamins C, E, and β -carotene quench free radicals that cause oxidative damage to DNA.

Dietary fiber may increase the bulk of the bowel contents, dilute intraluminal carcinogens, and enhance transit time through the gut. These mechanisms would reduce contact of the colonic mucosa with carcinogens and explain the inverse association between dietary fiber and the risk of colon cancer.

Certain plant foods also contain phytoestrogens. These weak estrogens may reduce the risk of hormonally mediated cancers by binding competitively to estrogen receptors and thereby exerting antiestrogenic effects.

Although the evidence that a diet high in fruits and vegetables decreases cancer risk has been used as one rationale for marketing vitamin supplements, there is no evidence that such products are protective against any neoplasm, and some evidence that they may even be harmful. For example, a number of studies have linked high fruit and vegetable intake, as well as high serum β -carotene levels, with a reduced risk of lung cancer, but recent clinical trials of β -carotene supplementation in individuals at high risk of lung cancer found *increased* lung cancer rates among supplemented patients.¹³³ These findings serve as a reminder that our current understanding of the constituents of fruits and vegetables, and their mechanisms of action, is incomplete. Current knowledge suggests that a prudent diet (rather than the average Western diet) should be lower in meats and animal fats and higher in fresh fruits, vegetables, and fiber. Citrus fruits with high levels of vitamin C, vegetables of the *Brassicaceae* family, and vegetables rich in β -carotene might be of particular importance. Smoked, charred, or cured meats would be avoided or used in moderation, as would alcoholic beverages. Caloric intake would be optimized to avoid obesity. This diet would do no harm, probably reduce the risk of cancers, and be compatible with diets advocated to reduce risks of cardiovascular and cerebrovascular diseases. There is little evidence that supplementation of a prudent diet with vitamins would have a beneficial effect on cancer risk.

Genetic Factors

Initial investigations of the role of genetic factors in cancer etiology limited their focus to determining the prevalence and degree of a specific malignancy in family clusters. Such studies suggested that the

risk of a number of cancers, including breast, ovary, colon, kidney, lung, brain, and prostate, was increased in individuals with a history of the disease in a first-degree relative.¹³⁴ Segregation analysis suggested that for many of these cancer sites one or more rare autosomal genes was associated with increased cancer susceptibility.

Recent work has identified a number of these inherited cancers that result from germline mutations (Table 61-6). However, only a small number of cancers are produced by these single gene mutations and it is likely that most of these have been identified by now. The larger proportion of human cancers is due to multiple gene mutations which are much more difficult to identify. Major genetic causes of cancer involve gene-environmental interactions. Inherited mutations in a cancer susceptibility gene predispose the affected individual to develop cancer, usually at an earlier age than occurs in those with nonfamilial causes. Familial retinoblastoma, the prototype of such a condition, arises because an individual inherits a germline mutation in one allele of the Rb gene, which is then followed by a somatic mutation in the other allele.¹³⁵ Somatic mutations at both alleles of the gene are required to cause the more rare sporadic cases of retinoblastoma. In the Li-Fraumeni syndrome involving the other major tumor suppressor gene, p53, there is a germline p53 mutation in 50% of these individuals which is associated with a greater incidence of rhabdomyosarcoma, any childhood tumor or sarcoma, brain tumors, breast cancer, leukemia, or adenocortical carcinomas.¹³⁶

Inherited *BRCA1* and *BRCA2* mutations affect risk of breast and ovarian cancer.¹³⁷ The overall portion of breast cancers in the general population or a random selection is significantly lower (~5%) than in studies that usually focus on high-risk familial populations where rates are as high as 80%.¹³⁸ These genes have received intense public attention because breast cancer is a common disease and because the penetrance of the gene is very high, that is, a large proportion of individuals with the gene mutation will develop cancer. Furthermore, there is significant variability in cancer risk among the *BRCA1/2* mutation carriers which will preferentially predispose to ovarian rather than breast cancer or the converse. Other factors can modify the *BRCA1/2* breast cancer risk including genes at other loci, such as those involved in hormone or carcinogen metabolism, reproductive history, and exogenous exposures such as OCs and smoking. Nonetheless, the prevalence of these germline mutations among women with breast cancer and in the general population is low and accounts for more than a small percent of all breast or ovarian cancers.

TABLE 61-6. GERMLINE MUTATIONS ASSOCIATED WITH FAMILIAL CANCERS

Syndrome	Gene	Cancer
Retinoblastoma	RB	Retinoblastoma, osteosarcoma
Li-Fraumeni	P53	Breast, sarcoma, leukemia, brain
Familial breast, ovary	BRCA1/ BRCA2	Breast, Ovary
Ataxia telangiectasia	ATM	Breast lymphoma, leukemia, others
WAGR	WT2/WT1	Wilms' tumor
Familial adenomatous polyposis/Gardner's syndrome	APC	Colon
Hereditary Nonpolyposis Colorectal Cancer (HNPCC)	hMSH2, hMLH1, hPMS1, hPMS2	Colon
Multiple endocrine neoplasia type 1	MEN1	Carcinoids, pancreas, parathyroid, pituitary
Von Hippel-Lindau	VHL	Renal cell carcinoma, hemangioblastoma

Additional genes also have been implicated in breast cancer: *CHEK2* and *ATM*. The *CHEK2* gene has a moderate penetrance and is independent of the *BRCA1/2* mutations. Those who are carriers of the *ATM* gene have a rare recessive disorder, ataxia-telangiectasia, which greatly increases the risk of breast cancer.¹³⁹

Approximately 6% of colorectal cancers can be attributed to known heritable germline mutations. Familial adenomatous polyposis (APC) is an autosomal dominant syndrome presenting with hundreds to thousands of adenomatous colorectal polyps that are caused by mutations in the APC gene. Adenomas typically develop in the mid-teens in these patients, and colorectal cancer is almost certain if this condition is untreated. Lynch syndrome (hereditary nonpolyposis colorectal cancer [HNPCC]) is an autosomal dominant disorder characterized by early onset of colorectal cancer with microsatellite instability. Mutations in mismatch repair genes lead to a lifetime colon cancer risk of 85% in these individuals, and carcinomas of the endometrium, ovary, and other organs also occur with increased frequency in association with HNPCC.¹⁴⁰

Other familial genes that have been identified are *WT1* and *WT2*, associated with Wilms' tumor, nephroblastoma, in children with approximately 2% of those with Wilms' tumor having a family history and most germline *WT1* mutations are de novo mutations.¹⁴¹ The incidence is approximately three times higher in African Americans and Africans than in Asians with rates in United States and European Caucasians intermediate between Africans and Asians.¹⁴² Those with bilateral tumors have a germline mutation of the gene and tumors arise only if a second event occurs with loss of function of the remaining normal allele. *MEN1* (multiple endocrine neoplasia type 1) syndrome is a hereditary condition characterized by the presence of duodeno-pancreatic endocrine tumors and is an autosomally dominant inherited disorder with a high penetrance. It is characterized by the occurrence of tumors of the parathyroid glands, endocrine pancreas/duodenum, and anterior pituitary gland.¹⁴³ Individuals with Von Hippel Lindau are at risk for the development of tumors of renal carcinoma, as well as cancers of the pancreas, adrenal glands, brain, spine, eye, and ear.¹⁴⁴

Although only a small proportion of cancers appear to be caused by inherited mutations at single loci, it is increasingly clear that genetic factors play an important role in tumors. While some individuals exposed to known carcinogens develop cancer, others with similar exposure do not. These risk modifier genes consist of a number of types. First there are genes involved in the metabolism of environmental carcinogens that can modulate exposure to potentially mutagenic occurrences. One of these groups includes inherited polymorphisms in genes that code for enzymes affecting the ability of the body to metabolize or detoxify carcinogens or potential carcinogens. These include those that code for the glutathione *S*-transferases (GST), cytochrome P-450 enzymes (CYP), and *N*-acetyltransferases (NAT). Some of the presumed high-risk genotypes are highly prevalent and may contribute substantially to the overall cancer risk within populations. Growth regulation effects associated with bioavailable steroid hormones can be modified by several of the CYP inherited genotypes which may affect those with *BRCA1/2* mutations. Among Caucasians, 40–50% have the glutathione *S*-transferase M1 (GSTM1) null genotype, which appears to confer a several-fold increased risk of lung and bladder cancer and other tumors.

► CANCER CONTROL AND PREVENTION

Overview of Known Causes of Cancer

Migrant studies have shown that most unknown causes of cancer are environmental. Such factors are likely related to lifestyle which may include such areas as smoking habits, diet, chemical exposures, and infectious agents.

Among worldwide deaths, nine modifiable risk factors are estimated to be responsible for just over one-third of cancer deaths.¹⁹ The large task of summarizing such data was undertaken by

TABLE 61-7. PERCENTAGE OF 2001 WORLDWIDE AND 2006 U.S. CANCER DEATHS MOST PROBABLY ATTRIBUTABLE TO VARIOUS CAUSES OF CANCER*

Cause	Worldwide Cancer Deaths in 2001	U.S. Cancer Deaths in 2006†
Smoking	21%	32%
Alcohol use	5%	5%
Low fruit and vegetable intake	5%	3%
Human papilloma virus (HPV)	3%	1%
Overweight & obesity	2%	3%
Physical inactivity	2%	2%
Contaminated injections in health-care settings	2%	0.1%
Urban air pollution	1%	1%
Indoor smoke from household use of solid fuels	0.2%	0%
Total joint effect	35%	41%

*Estimated risk factor population attributable fractions and worldwide death rates based on Danaei et al., 2005.¹⁹

†Based on 2006 death rates estimated by the American Cancer Society (Jemal et al., 2006).¹⁰

the Comparative Risk Assessment collaborating groups.¹⁹ They examined cancer deaths attributable to smoking (along with indoor smoke from fuel use and urban air pollution), alcohol use, low fruit and vegetable intake, human papillomavirus, overweight and obesity, physical inactivity, and contaminated injections in health-care settings. Their worldwide data and their estimates for high-income countries as applied to U.S. data are summarized in Table 61-7.^{19,145} The potentially modifiable cancer deaths are largely made up of lung cancer (37%), liver cancer (12%), and esophageal cancer (11%) reflecting cancers with higher proportions of deaths related to potentially modifiable risk factors. While many assumptions were made to create these estimates, the estimates highlight areas in which to focus cancer prevention efforts in order to reduce cancer burden. The largest cancer mortality reduction could be seen if smoking was eliminated.

These data also highlight how little is known about preventative factors for cancer in general. We know more about prevention for specific cancer sites. Smoking is estimated to cause 21% of cancer worldwide and 29% in high-income countries. Based on site-specific cancer rates due to smoking in high-income countries and estimated 2006 U.S. cancer rates, smoking may cause as much as 32% of cancer in the United States. Overall, these estimates outline the importance of cancer prevention through eliminating smoking in populations. An additional 10% of worldwide deaths are estimated to be due to alcohol and low fruit and vegetable intake (5% each). Other items are related to specific cancer sites, including human papillomavirus and cervical cancer, contaminated injections in health-care settings and liver cancer, and lung cancer with urban air pollution and indoor smoke from household use of solid fuels.¹⁹ The American Cancer Society estimates that while a small percentage of all cancer deaths are due to UV exposure, more than one million cases of basal and squamous cell cancers and all 62,190 new cases of melanoma in 2006 are likely due to UV exposure.¹⁸ Use of tanning booths and sunbeds adds to this exposure.

Comprehensive Cancer Control

Comprehensive cancer control is an integrated and coordinated approach to reducing cancer incidence, morbidity and mortality

through prevention, early detection, treatment, rehabilitation, and palliation.¹⁴⁶ Cancer researchers and practitioners in federal agencies, public health departments, research centers, medical practices, advocacy groups, and other settings are engaged in an ongoing effort to develop and implement a comprehensive approach to cancer prevention and control in the United States.¹⁴⁷ This nationwide effort emphasizes the implementation of evidence-based cancer prevention and cancer strategies at the community level. Such an effort is needed to achieve the ambitious national goals to minimize suffering and death from cancer that have been stated by *Healthy People 2010* and the American Cancer Society.

Goals for Cancer Reduction

In 1999, the American Cancer Society set bold cancer-reduction goals for 2015 for the United States as a challenge.¹⁸ The general goals include a 50% reduction in age-adjusted cancer mortality and a 25% reduction in age-adjusted cancer incidence. Their specific objectives include reducing adult tobacco use (to 12%) and youth tobacco use (to 10%), along with increasing consumption of fruits and vegetables (to 75%), physical activity (to 90% of high school students and 60% of adults), school health education, and sun protection (to 75%). The goals also include increasing detection of breast, colorectal, and prostate cancer through screening.¹⁸ The American Cancer Society has focused many goals and prevention efforts on youth related to their belief that starting healthy behaviors in youth is linked to health in adults.

The 10 leading health indicators for *Healthy People 2010* include several related to cancer, including physical activity, obesity, tobacco use, substance abuse, responsible sexual behavior, and access to health care. The goals related to cancer are to reduce the number of new cancer cases as well as the illness, disability, and death caused by cancer. More information can be found on the *Healthy People 2010* website at www.healthypeople.gov.

Strategies for Prevention Efforts

The following is a summary of actions that can be taken to reduce cancer burden:

1. Develop effective smoking cessation programs and continue to urge all users of tobacco to stop using this substance in any form, and encourage all nonusers not to start (especially the young).
2. Advise use of alcohol in moderation, especially by smokers.
3. Suggest a diet higher in fresh fruits and vegetables (and fiber), and lower in fats and meats than the average American diet. Avoid blackened, charred, or smoked foods.
4. Urge obese individuals to lose weight and others not to become overweight.
5. Encourage regular exercise.
6. Emphasize the risks of sexually transmitted infections. More specifically, caution women that multiple sexual partners (of both themselves and their partners) enhances their risk of cervical and other anogenital cancers. Caution men that receptive sexual practices are associated with anal cancer and AIDS, which can lead to Kaposi's sarcoma and other malignancies. Suggest use of barrier contraceptives, especially condoms, to reduce risk of infection.
7. Urge individuals to avoid excess exposure to sunlight and all use of tanning beds or booths, especially if they are light skinned and easily sunburned, and recommend protective clothing and sunscreen use.
8. Support efforts to reduce exposures to known carcinogens in the workplace.
9. Support efforts to identify and reduce exposures outside the workplace to known carcinogens such as arsenic, chromium, nickel, vinyl chloride, and asbestos.

10. Mitigate elevated residential radon levels. Use radiation prudently for medical use.
11. When estrogens are prescribed, use the lowest dose necessary to achieve the therapeutic objective and include a progestin in the regimen.

Screening and Secondary Prevention

Screening is often considered a secondary prevention through prevention of the progression of a disease to a fatal outcome by means of early detection followed by definitive treatment. Screening is one component of early detection, but requires effective treatment. The American Cancer Society believes that early detection can help save lives and reduce suffering from cancers of the breast, colon, rectum, cervix, prostate, testis (testicles), oral cavity (mouth), and skin by use of physical examinations and available screening tests. Physical examinations may find cancer early by examination of the breast, colon and rectum, prostate, testicles, oral cavity, and skin. Laboratory tests or x-rays include mammography (for breast cancer), the Pap test (for cervical cancer), and the prostate specific antigen (PSA) blood test (for prostate cancer). In many cases a combination approach is most effective. For colorectal cancer, a combination of fecal occult blood testing, flexible sigmoidoscopy, double-contrast barium enema, and colonoscopy are recommended by the American Cancer Society (www.cancer.org) beginning at age 50. Secondary prevention against a cancer can be achieved only if there is a stage of that cancer that is amenable to cure, and if there is a means of detecting the cancer at that stage.

Planning a Screening Program

A number of factors must be considered before initiating a screening program:^{148,149}

1. *The sensitivity and specificity of the tests or procedures used for screening:* The number of diseased people that will be missed (false negatives) increases as the sensitivity of the test decreases, and the number of well people that will erroneously be considered possibly diseased (false positives) increases as the specificity of the test decreases.
2. *The target population:* Individuals at highest risk for the disease should be identified, and special efforts should be made to screen such persons.
3. *The prevalence of the disease in the target population:* For any test of given sensitivity and specificity, numbers of false-positive and false-negative tests are functions of the prevalence of the disease in the target population. More false-negative tests occur if the disease is common, and more false-positives if the disease is rare. The latter is of particular importance in screening for cancer.
4. *The predictive value of a positive test:* This is the proportion of individuals with a positive test who actually have the disease. This proportion declines only slightly as test sensitivity decreases, but declines markedly as test specificity declines. In addition, the predictive value of a positive test declines as the prevalence of the disease diminishes. For example, if we have a test of high sensitivity (e.g., 95%) and high specificity (e.g., 98%), and if the prevalence of the cancer in the target population is 1 per 1000, then only 4.6% of the individuals with a positive test will actually be found to have the disease on further evaluation. The rest will have a false-positive test.
5. *The consequences of false-positive tests:* A false-positive test is a false alarm. The consequences of this for the individual, the medical care system, and the screening program must be considered. How much inconvenience or psychological trauma will the individual erroneously screened have to bear? Are there sufficient facilities and personnel to provide the necessary diagnostic tests to determine who actually has the disease? What are the costs of these services and who will pay them? Is morbidity associated with further testing?

(such as biopsies of the breast) acceptable? Do physicians want to have referred to them large numbers of healthy people for diagnostic evaluation? Will possible adverse reactions to the screening program by those falsely screened positive or their physicians have a negative impact on the screening program itself?

6. *Consequences of a false-negative test:* A false-negative test gives the person screened a false sense of security, and the neoplasm may then progress to a noncurable stage and kill the patient. This could have medical-legal implications, particularly if a more sensitive test could have been used. One missed case can result in unfavorable publicity that can have an adverse impact on the screening program.
7. *Applicability of the test:* Can the test be administered to the people in the target population? Are special equipment or special resources needed (e.g., electrical power, water, a mobile van, transportation for the potential screenees)? Can the test be administered rapidly?
8. *Acceptability of the test:* Having made the test available to people in the target population, will the people agree to be screened? What kind of publicity should be given? Are there esthetic or cultural barriers? Is the cost to those being screened acceptably low?
9. *Adverse consequences of the test:* Is there a possibility that the test will do harm? This issue had originally been a great concern in using mammography to screen for breast cancer. The breast is a radiosensitive organ, high doses of ionizing radiation are known to cause breast cancer, and early mammographic techniques resulted in considerable levels of exposure. This controversy had an adverse impact on breast cancer screening programs, with many women fearing mammography. Similar problems should be anticipated with any future radiographic screening techniques.
10. *Life expectancy:* Is the individual's life expectancy longer than the time gained by early screening of asymptomatic individuals? This issue is a concern in screening men over age 75 with PSA for prostate cancer. Older men with no symptoms may die of other causes before a nonsymptomatic prostate cancer grows into a fatal cancer. Thus, it may not be ethical to tell an older man who is more likely to die of other causes that he also has a small prostate cancer.
11. *The evaluability of the program:* Public and private resources are all too often spent on service programs that are never evaluated, and program evaluators are all too often called upon to assist in program evaluation after a project is fully under way or even completed. The time to begin program evaluation is when the program is being planned.

Evaluation of Methods of Screening and Secondary Prevention

The aim of secondary prevention is the prevention of fatal outcome. This implies that a method of secondary prevention of a disease should reduce mortality from that disease, and reduction in mortality should be the measure used to evaluate the method. This is not always done. Two other forms of evaluation have commonly been used, both of which can give misleading results.

One of these is the comparison of cases detected at screening with cases detected by other means, with respect to their stage at diagnosis. It is not surprising that those detected at screening tend to be at a less advanced stage. This does not indicate whether the early detection altered the course of the disease, however. This method of evaluation is based on the assumptions that early lesions have the same natural history as symptomatic lesions and that treatment of early lesions alters the course of the disease. Neither assumption is necessarily correct. For example, not all carcinomas *in situ* of the uterine cervix progress to invasive disease, and individuals with early lung cancer detected at screening with chest x-rays do not have a more favorable prognosis than persons with lung cancer diagnosed later after development of symptoms.

The other misleading method of evaluating secondary prevention is by comparing survival rates, or time to death, in cases detected at screening and cases detected by other means. There are two problems with this method. One is that the time from diagnosis to death may be longer for individuals who have been screened, not because their death is postponed but only because their disease is diagnosed earlier. This is referred to as lead-time bias. The other problem is known as length-bias sampling and results from the fact that neoplasms grow at varying rates: at any point in time (when screening is performed), there will exist more tumors that are progressing slowly than rapidly. Therefore, compared to tumors in symptomatic cases, a higher proportion of tumors detected at screening will be slow growing, so that survival from time of detection will tend to be longer in screened than symptomatic patients, even if early detection does not result in a prolongation of time to death.

Because of the problems of lead-time and length-bias sampling, there is no way of knowing from a comparison of survival rates or survival times whether a secondary prevention program results in a prolonging of life. This can be done only by comparing risks of dying (or risks of advanced disease as a surrogate for mortality) in screened and unscreened individuals.

Individuals who volunteer to be screened may differ from those who do not with respect to factors related to risk of death, and these factors must be taken into consideration when comparing mortality rates in screened and unscreened persons. This can be done in two ways: It is preferable to conduct a randomized trial of the secondary prevention method to be evaluated. The other method is to control statistically for differences between the screened and unscreened during data analysis.

A classic example of a randomized trial of a procedure for secondary prevention is the study of mammography conducted among members of the Health Insurance Plan (HIP) in New York.¹⁵⁰ In 1963, approximately 62,000 women between the ages of 40 and 64 were randomly allocated to one of two groups. Approximately half were offered a series of four annual screenings by mammography and breast palpation (the experimental group). The other half served as a control group and received their usual medical care. Not all women in the experimental group agreed to participate. To eliminate a possible bias due to the remainder being volunteers, the mortality rate due to breast cancer in the entire experimental group was compared to the breast cancer mortality rate in the control group. Inclusion of those not screened in the experimental group gave a conservative estimate of the impact of the program on breast cancer mortality, which represented a combined evaluation of the efficacy and the acceptability of the screening procedures. After 5 years of follow-up, in women in their 50s there was over a 50% reduction in mortality from breast cancer; breast cancer mortality was reduced by one-third in women older than 50. Although there was no beneficial effect on breast cancer mortality in women under 50 after 5 years, follow-up for 18 years showed a small reduction in mortality from breast cancer in these women as well. This observation demonstrates the importance of long-term follow-up in studies of secondary prevention.

Once a screening technique is widely believed to be useful, regardless of whether or not it has been rigorously tested, a randomized trial becomes ethically questionable and operationally impossible. Other less satisfactory methods of evaluation must then be used. This is exemplified by the Pap smear for early detection of cervical cancer. When this technique was first introduced, it was greeted with such enthusiasm that suggestions for a randomized trial were not taken. The need to evaluate this procedure subsequently became evident, but by then it was too late for a randomized trial. As a result, a large number of less satisfactory epidemiological studies have been conducted to attempt to measure the effectiveness of the Pap smear.¹⁵¹ Correlational studies have shown that mortality rates from cervical cancer in many populations have declined following the introduction of screening programs, that the magnitude of the decline is correlated with the amount of screening, and that the decline within some of the populations was greatest in those racial and age groups that received the most screening. Case-control studies of women with

invasive cervical cancer have shown that, compared with normal control subjects, fewer of the cases had prior Pap smears; and a cohort study showed, after controlling for socioeconomic differences between women who enrolled in a screening program and women who did not, that there was a decline in cervical cancer mortality rates in the screened women compared to an increase in rates in those not screened. None of these methods to evaluate the Pap smear are as satisfactory as a randomized trial would have been, although in the aggregate they do provide strong evidence that the procedure reduces mortality.

Current Status of Secondary Prevention of Selected Cancers

Breast Cancer

Mammographic screening in women over age 50 years has clearly been shown in multiple randomized trials to reduce subsequent mortality from breast cancer by 30–40%,¹⁵² and annual mammograms beginning at age 50 are generally recommended. Eight randomized trials of mammography in women 40–49 years of age at entry into the trial have yielded inconsistent results, with none showing a statistically significant reduction in breast cancer mortality after 5–18 years of follow-up. Meta-analyses of data from these trials have yielded different results due to varying lengths of follow-up or methodological concerns about exclusion of some studies. However, meta-analyses with longer follow-up periods show a reduction in risk of dying from breast cancer.¹⁵³ Mammography may be less efficacious in women under age 50 than in older women because breast tissue of women under age 50 is radiographically more dense than that of older women, and early neoplasms are more difficult to visualize on mammographic films. Also, relatively fewer malignancies and more benign lesions occur in younger women, resulting in more false-positive screenings. Despite the lack of consistent scientific evidence,¹⁵⁴ in 1997 NCI recommended mammographic screening for women in their 40s.¹⁵⁵ Nevertheless, there is currently no consensus among experts regarding mammographic screening in women under age 50.

Physical examination of the breast by a medical practitioner has been shown to result in the detection of some malignancies missed by mammography and may therefore be of value as a screening modality in conjunction with mammographic screening. Tumors detected by physical examination or by women practicing breast self-examination have been shown in some studies to be less advanced at diagnosis than symptomatic cancers, but the efficacy of these procedures as primary screening modalities in reducing mortality from breast cancer has not been demonstrated. Randomized trials of breast self-examination have shown no benefit.^{156,157} Indirect evidence suggests clinical examination of the breast is an important means of averting some breast cancer deaths.¹⁵⁶

Cervical Cancer

Cancer of the cervix has also been clearly shown to be amenable to secondary prevention. Results of a critical review of cytologic screening for cervical cancer were published in 1986.^{158,159} By combining data from 10 screening programs in eight countries, it was shown that two negative cytologic smears were more effective than one in reducing mortality from cervical cancer (presumably because of a reduction in false-negative diagnoses) and that the protective effect did not decline until 3 years after a second negative smear. Based on these findings, it is recommended that screening for cervical cancer every 3 years is sufficient after a woman has had two normal smears. Some women, however, do develop invasive disease soon after an apparently normal smear, and studies are needed to determine what proportion of such events are a result of prior false-negative smears and how many represent a rapidly progressing form of the disease. This recommendation also does not take into consideration the benefits of an annual appointment, thus it is suspected that women also will not receive an annual pelvic or breast examine or referral for an annual mammogram or assessment for osteoporosis. Furthermore, this recommendation does not consider that many women utilize gynecologists as their routine physician.

Colorectal Cancer

Fecal occult blood testing (FOBT) and sigmoidoscopy are both used to screen for colorectal cancer. Randomized trials have suggested that use of FOBT leads to a reduction in colon cancer mortality.^{160,161} Screening guidelines for colorectal cancer recommend annual FOBT or sigmoidoscopy for individuals age 50 and older, but suggest that evidence is insufficient to determine which test is more effective or whether the use of both tests together would produce additional reductions in mortality.¹⁶² However, the level of reduction conferred by FOBT is small, and a large proportion of positive tests are false positives, resulting in many unnecessary clinical follow-up evaluations. The cost-benefit ratio of this procedure is therefore low, as is its acceptability, given the aversion that some people have to fecal testing.

Prostate Cancer

PSA has been widely incorporated into medical practice as a screening test for prostate cancer and has resulted in an apparent increase in prostate cancer incidence rates in the early 1990s with a suggestion of a reduction in prostate cancer mortality.¹⁶³ Although PSA testing may prevent deaths by identifying tumors at a treatable stage, there is concern that the test may also identify tumors that would have remained clinically irrelevant during the remainder of a patient's lifetime and thereby may lead men to undergo invasive and potentially unnecessary treatment. The American Cancer Society recommends annual PSA screening in conjunction with digital rectal examination in men ages 50 and over who are expected to live at least 10 more years, but the screening guidelines from the United States Preventive Health Services Task Force recommend against routine screening by PSA.^{162,164} This disagreement will not be resolved without substantial further research.

Other Cancers

A variety of other techniques has been developed for the early detection of cancer. Some have not been rigorously evaluated, and some that have do not show great promise. Studies in industrial settings of urinary cytology for bladder cancer have not yielded encouraging results, and although NCI guidelines recommend oral examination by medical practitioners to screen for oral cancer, the effectiveness of the technique is questionable because of the poor compliance of those individuals at highest risk of the disease.¹⁶⁵

The vagueness of clinical symptoms of gastric (stomach) cancer is the major reason patients do not get diagnosed until the cancer has progressed. Current diagnostic modalities consist of endoscopy, which is the most sensitive and specific method for obtaining a definitive diagnosis. It has replaced barium contrast radiographs due to its ability to biopsy and its ability to directly visualize the lesions. Endoscopy has a sensitivity of 98% versus 14% for barium in the early diagnosis of most types of gastric cancer.^{166,167} Administration of antibiotics against *H. pylori* have also shown a significant reduction in the incidence of gastric cancer.¹⁶⁸ Various screening trials are ongoing in Japan where incidence rates are high.^{169,170} The disease is sufficiently rare in the United States that large-scale screening is not recommended.

Alpha-fetoprotein (AFP) blood levels have been used to screen for primary hepatocellular carcinoma (liver cancer) in individuals serologically positive for hepatitis B surface antigen (HB_sAg) in areas where hepatitis B is endemic and liver cancer highly prevalent. A study from China showed improved survival in asymptomatic persons with small tumors detected by this method, but studies to determine whether it reduces mortality from liver cancer have not been completed. Several methods of screening for chronic liver disease include ultrasound, CT scans (computer tomography), MRI (magnetic resonance imaging), angiography, laparoscopy, biopsy, and AFP. Ultrasound is highly specific but not sufficiently sensitive to detect hepatocellular carcinoma or to support its use in an effective surveillance program when a cut-off value of 20 ng/mL is used to differentiate hepatocellular carcinoma from HCV-infected individuals (80–94% specificity and 41–65% sensitivity).¹⁷¹ Use of CT and MRI as an early diagnostic tool in patients with underlying liver cirrhosis who are at high risk of hepatocellular carcinoma is still unclear. It

appears that both ultrasound and preferentially MRI would provide greater sensitivity as a screening test.¹⁷² Angiography is an x-ray that tends to be uncomfortable, while laparoscopy is a surgical incision of a tube. Thus neither is used for population screening. AFP has limited utility in differentiating hepatocellular carcinoma from benign hepatic disorders because of its high false-positive and false-negative rates. Serum AFP-3 (one of the three glycoforms of AFP) and DCP (des-gamma-carboxyprothrombin) are other widely used tumor markers for hepatocellular carcinoma and appear to be more sensitive than AFP in differentiating hepatocellular carcinoma from nonmalignant hepatology.

Despite considerable interest in the development of ovarian cancer screening using transvaginal ultrasonography or the circulating tumor marker CA-125, neither method is clearly associated with reduced mortality from this disease.¹⁷³

Improved cancer screening must be a part of any long-term strategy to reduce cancer mortality. These efforts must include both the evaluation of new screening methods and research into the most effective ways to implement the techniques that are of demonstrated benefit. The American Cancer Society believes that early detection is warranted for cancers of the breast, colon, rectum, cervix, prostate, testis, oral cavity, and skin. More information on site-specific recommendations can be found at www.cancer.org.

Cancer Survivorship

The National Cancer Institute's SEER program estimates there are 10.5 million invasive cancer survivors in the United States as of 2003.⁴ This number is increasing primarily as a result of earlier diagnoses and more effective therapies. This has created a new challenge in comprehensive cancer control that has been recognized in three recent national reports.¹⁷⁴⁻¹⁷⁶ Concerns of cancer survivors and their families can include long-term physical, psychosocial, and economic effects of treatment as well as rehabilitation and palliation. Care of these survivors and their families can involve the entire spectrum of comprehensive cancer control from prevention to early detection, treatment, rehabilitation, and palliation.¹⁷⁷ To effectively address the needs of this growing population will require a coordinated approach among health-care providers, policymakers, researchers, insurers, advocates, communities, and families.

Heart Disease

Russell V. Luepker

► INTRODUCTION

Cardiovascular diseases (CVDs) are public health concerns around the world, particularly coronary or ischemic heart disease (CHD), hypertensive heart disease, and rheumatic heart disease. CHD remains the leading cause of adult death in industrial societies, although its incidence differs widely and the mortality ascribed to it is changing dramatically (Figs. 62-1 and 62-2). While deaths from CHD are falling in industrialized nations, they are rising dramatically in others particularly in the developing world.¹ The decline of age-adjusted U.S. deaths ascribed to CHD continues for men and women, white and nonwhite (Fig. 62-3). The exact causes of the decline are not established, but much is now known about U.S. trends in out-of-hospital deaths, in-hospital case fatality, and longer-term survival after acute myocardial infarction.² Parallel to the CHD mortality trends are improvements in medical diagnosis and treatment, in population levels of risk factors, and in lifestyle.³ Nevertheless, the critical explanatory data, including incidence trends from representative populations, are few. This deficiency, along with the difficulty of measuring change in diagnostic custom and in severity of CHD, or of its precursor, atherosclerosis, leaves considerable uncertainty about the causes of the mortality trends. Systematic surveillance is now in place in several areas to improve the future detection, prediction, and explanation of trends in CVD rates.²⁻⁵

Deaths ascribed to hypertensive heart disease have diminished over recent decades in many industrialized countries.⁶ In West Africa, Latin America, and the Orient, however, the high prevalence still found in hospitals and clinics indicates the continued worldwide importance of hypertension.

Rheumatic fever and rheumatic valvular heart disease remain public health concerns in many developing countries and are still seen among disadvantaged peoples in affluent nations. On the other hand, syphilitic heart disease, a worldwide scourge until the 1940s, is now rare. Cardiomyopathies, often of unknown or infectious origin, constitute a common cause of heart disease in many regions, particularly Africa and Latin America. Finally, congenital heart disease continues to contribute to the heart disease burden among youth and adults of all countries.

The worldwide potential for primary prevention of most CVD is established by several salient facts: (a) the large population differences in CVD incidence and death rates; CVD is rare in many countries and common in others; (b) dynamic national trends in CVD deaths, both upward and downward; (c) rapid changes in CVD risk among migrant populations; (d) the identification of modifiable risk characteristics for CVD among and within populations; and (e) the positive results of preventive trials.

The following chapter expands on these cardiovascular diseases, their trends and the magnitude of burden on populations. The population-wide factors associated with risk of these diseases are

described. Because the majority of cardiovascular disease is caused by social, cultural, and economic factors, public health approaches are central to prevention and control strategies.

► CORONARY HEART DISEASE

CHD remains the leading cause of adult deaths in many industrial societies. Much about its causes and prevention has been learned from diverse research methods, including clinicopathological observations, laboratory-experimental studies, population studies, and clinical trials. The evidence of causation from all these disciplines is largely congruent. As a result, several ubiquitous cultural characteristics described below are now established as powerful influences on population risk of CHD. These influences and risk factors appear to be safely modifiable for individuals and for entire populations.⁷⁻¹⁰

The sum of evidence suggests that there is widespread human susceptibility to atherosclerosis and, consequently, that CHD is maximally exhibited when the environment is unfavorable. These ubiquitous susceptibilities, exposures, and behaviors lead eventually to the mass precursors of CHD found among so many people in high-incidence societies. The rationale and the potential for preventive practice, as well as for public policy in prevention, are based on several well-established relationships: between risk factor levels and CHD, between health behaviors and risk factor levels, and between culture and mass health behaviors.

Epidemiology of CHD

Summarized here are the salient observations about CHD:

- Population comparisons show large differences in CHD incidence and mortality rates (Fig. 62-2) and in the extent of its underlying vascular disease, atherosclerosis.
- Population differences in the mean levels and distributions of CHD risk characteristics (particular lipid levels) are strongly correlated with population differences in CHD rates.
- Within populations, several risk characteristics (blood cholesterol, blood pressure levels, diabetes and smoking habits) are strongly and continuously related to future individual risk of a CHD event.
- Population differences in average levels of CHD risk characteristics are already apparent in youth. Individual values of children tend to “track” into adult years.
- CHD risk characteristics and incidence in migrants rapidly approach levels of the adopted culture.
- Trends in CHD mortality rates, both upward and downward, occur over relatively short periods of 5–10 years. These trends

Figure 62-1. Age-adjusted death rates for coronary heart disease by country and sex, Ages 35–74, 2002. (Source: National Heart, Lung, and Blood Institute. Morbidity and Mortality Chart Book on Cardiovascular, Lung, and Blood Diseases. Bethesda, Maryland, 2004; NIH Publication.)

Morbidity and Mortality Chart Book on Cardiovascular, Lung, and Blood Diseases. Bethesda, Maryland, 2004; NIH Publication.)

Figure 62-3. Death and age-adjusted death rates for coronary heart disease, U.S., 1979–2002. (Source: National Heart, Lung, and Blood Institute. Morbidity and Mortality Chart Book on Cardiovascular, Lung, and Blood Diseases. Bethesda, MD, 2004; NIH Publication.)

Figure 62-4. Average annual percent change in death rates for coronary heart disease by age, race, and sex, U.S., 1999–2002. (Source: National Heart, Lung, and Blood Institute. Morbidity and Mortality Chart Book on Cardiovascular, Lung, and Blood Diseases. Bethesda, MD, 2004; NIH Publication.)

tend to be associated with changes in medical care and case-fatality rates as well as with trends in incidence and in population distributions of risk characteristics.

- The recent decrease in age-adjusted CHD mortality rates in the United States is shared by men and women, by whites and nonwhites, and by younger and older age groups (Figs. 62-3, 62-4).
- The decrease in age-adjusted CHD mortality rates in the United States is associated with an even greater decrease in death rates from stroke. This leads to increases in lifespan. Moreover, in the last decades there has been a lesser decrease in non-CVD deaths and in deaths from all causes (Fig. 62-5).
- Randomized clinical trials find a direct effect of CHD risk factor lowering on subsequent disease rates. Preventive trials also establish that levels of risk factors, and their associated health behaviors, can be significantly and safely modified.
- The epidemiological evidence is congruent with clinical animal and laboratory findings about the causes and mechanisms of atherosclerosis, the process that underlies the clinical manifestations of CHD.

Role of Diet

Dietary Fats

There is considerable evidence that habitual diet in populations, a culturally determined characteristic, has an important influence on the mean levels and distribution of blood lipoproteins and, therefore, on the *population* risk and potential for prevention of CHD. Several dietary factors influence individual and population levels of low-density lipoproteins (LDL) in the blood, a leading pathogenetic factor in atherosclerosis. These include particular fatty acids and dietary cholesterol, the complex carbohydrates of starches, vegetables, fruits and their fibers, alcohol, and caloric excess. Many investigators consider that the cholesterol-raising properties of some habitual diets are essential to the development of mass atherosclerosis, leading in turn to high rates of CHD. Where average total blood cholesterol level in a population is low (less than 200 mg/dL, or 5.2 mmol/L), CHD is uncommon, irrespective of population levels of smoking and hypertension. From this evidence, there is now a consensus about the leading *population* causes of CHD and general acceptance of policy recommendations that lead toward a gradual, universal change in the

Figure 62-5. Change in age-adjusted death rates since 1950, U.S., 1950–2002. (Source: National Heart, Lung, and Blood Institute. Morbidity and Mortality Chart Book on Cardiovascular, Lung, and Blood Diseases. Bethesda, MD, 2004; NIH Publication.)

habitual diets of populations in which CHD rates are high. Wherever economically feasible, systematic strategies to detect and manage individuals at excess risk are also recommended.

Epidemiological studies comparing stable, rural agricultural societies find a strong relationship between habitual diet, average blood cholesterol levels, and incidence of CHD.¹¹⁻¹³ For example, diets of populations with a high incidence of CHD are characterized by relatively high saturated fatty acid (greater than 15% of daily calories) and cholesterol intake and low carbohydrate intake (under 50%). Diets in populations with a low CHD incidence are characterized mainly by low saturated fatty acid intake (less than 10% of calories) and high carbohydrate intake but widely varying total fat intake (varying mainly in the proportion of monounsaturated fatty acid calories).¹² Most of the difference in mean population levels of serum total (and LDL) cholesterol can be accounted for by measured differences in fatty acid composition of the habitual diet. Moreover, *population* CHD rates can be predicted, with increasing precision over time, by average population blood cholesterol levels.¹⁴ Cross-cultural comparisons of diet versus postmortem findings of atherosclerosis reveal a strong correlation between habitual dietary fat intake of a population and the frequency and extent of advanced atherosclerotic lesions.¹⁵

Studies of migrant populations indicate the predominance of sociocultural influences, including diet, in trends of risk and CHD among migrants. For example, Japanese who migrate to California become taller, heavier, more obese, and more sedentary; their diet changes dramatically; they eat more meat and dairy products, saturated fatty acids and cholesterol, and consume less complex carbohydrate and less alcohol than their counterparts in the Nagasaki-Hiroshima area.¹⁶ They develop higher risk profiles and disease rates within a generation. With few exceptions, migrant Hawaiian Japanese have risk factor values intermediate between mainland and California Japanese, and the CHD rate in migrants generally parallels their mean values for risk factor levels.

The rapid evolving national trends in CHD deaths are another indication of the predominance of culture in the population causes and prevention of CHD, as disease occurrence changes more rapidly than any genetic characteristics. Nevertheless, systematic explanatory studies of trends in CHD mortality are very recent, and current attempts to estimate the relative contribution of cultural versus medical care contributions are quite tentative.^{2-4,17,18} In a number of countries on an upward slope of CHD mortality, smoking and calorie and fat consumption are increasing and physical activity is decreasing, while cardiological practice is probably becoming less effective.¹⁹ In many other industrial countries, including the United States, decreasing CHD mortality rates parallel improved cardiac care and significant reductions in average risk characteristics.^{2,3,17,20} Standardized measurements of risk and disease trends are not generally available for comparisons among countries, but the public health implications of these simultaneous trends in behaviors, risk, disease rates, and medical care are immense.

Another feature of diet, the relative excess of calorie intake over expenditure, influences health through the metabolic maladaptations of hyperlipidemia, hyperinsulinism, and hypertension.²¹ This is sometimes called the metabolic syndrome.²² This caloric imbalance occurs in sedentary cultures and results in mass obesity. With or without mass obesity, however, high salt intake and low potassium intake in populations appear to encourage the wide exhibition of hypertensive phenotypes. Other cations (e.g., magnesium, calcium) may also be significant dietary influences on population levels of blood pressure, while alcohol intake is clearly involved (see below).

Anthropology and paleontology provide insights into the probable effects of rapid cultural change, including modern diets, from the lifestyle to which humans adapted during earlier periods of evolution. Until 500 or so generations ago, all humans were hunter-gatherers. The habitual eating pattern likely involved alternating scarce and abundant calories and a great variety of foods. It surely included lean wild game and usually a predominance of plant over animal calories, a relatively low sodium and high potassium intake, and of course there was universal breast-feeding of infants. Observations of the eating patterns among extant hunter-gatherer tribes confirm the varied nature and the

TABLE 62-1. A MODEL OF INDIVIDUAL DIET-SERUM CHOLESTEROL (TC) RELATIONS WITH INDIVIDUAL EXAMPLES

Genotypic TC Value(mg/dL)	Mean Diet-TC Effect (mg/dL)				
	0	+25	+50	+75	+100
75	75	100	125	150	175
150	150	175	200	225	250

Source: Blackburn H. The concept of risk. In: Pearson TA, Criqui MH, Luepker RV, Oberman A, Winston M, eds. *Primer in Preventive Cardiology*. Dallas: American Heart Association, 1994, pp 25-41; and Keys A, Grande F, Anderson JT. Bias and misrepresentation revisited—"perspective" on saturated fat. *Am J Clin Nutr*. 1974;27:188-212.

It is assumed that an intrinsic lipid regulatory base exists for each individual and is expressed in the first year of life. On this genotype is superimposed the effect of habitual diet, which is either neutral or cholesterol-raising according to properties determined in controlled Minnesota diet experiments, resulting, in this simple additive model, in the adult phenotypes values.

adequacy (or near adequacy) of such an eating pattern for growth and development, as well as for the potential of longevity and the absence of mass phenomena such as atherosclerosis and hypertension.²³⁻²⁵ Although modern humans can scarcely return to such subsistence economies, the anthropological observations suggest that current metabolic maladaptations derived from affluent eating and exercise patterns imposed rapidly on a very different evolutionary legacy result in the mass precursors of cardiovascular diseases found in modern society.²⁴

Despite the generally strong population (ecological) correlations between diet, blood lipid levels, and CHD rates, these correlations are often absent for individuals within high-risk industrial societies.²⁶ This apparent paradox does not negate the causal importance of diet in mass hypercholesterolemia and atherosclerosis. Consider, for example, the simple additive model of Table 62-1, which suggests the powerful influence, in the individual, of inherent lipid regulation. Different individual lipoprotein genotypes may develop widely different adult risk phenotypes and different serum cholesterol levels, while consuming the same U.S.-type diet. Other individuals may have similar blood cholesterol levels while subsisting on very different diets. In contrast, the population model of Table 62-2 makes the assumption that the multiple genes that influence lipid

TABLE 62-2. A MODEL OF POPULATION DIET-SERUM CHOLESTEROL (TC) RELATION WITH POPULATION EXAMPLES

	Mean Diet-TC Effect (mg/dL)				
	Japan 0	Greece +25	Italy +50	United States +75	Finland +100
Population mean TC	75	100	125	150	175
Lower limit (2.5%)	150	175	200	225	250
Upper limit (97.5%)	300	325	350	375	400

Source: Keys A, Grande F, Anderson JT. Bias and misrepresentation revisited—"perspective" on saturated fat. *Am J Clin Nutr*. 1974;27:188-212; and Keys A, ed. Coronary heart disease in seven countries. *Circulation*. 1970;41-42 (Suppl I).

In this oversimplified model, it is assumed that uncommon single gene effects and widespread polygenic determinants of blood cholesterol levels are randomly and usually distributed among large heterogeneous populations, such that a mean population TC value of 150 mg/dL would prevail (SD ± 37.5 mg/dL) in the presence of a habitual average diet having neutral properties in respect to cholesterol. On this mean and population distribution of intrinsic responsiveness is superimposed the average habitual diet effect for a population, which is either neutral or cholesterol-raising according to the country's measured diet composition and properties.

metabolism are randomly and similarly distributed throughout large heterogeneous populations. Under this condition, population means and distributions of blood lipids are seen to be influenced predominantly by the cholesterol-raising or lowering properties of the habitual diet of the population.^{27,28} The range and degree of this dietary influence are estimated from short-term controlled diet experiments.²⁹⁻³¹

Recently, several well-conducted cohort studies have provided evidence of diet-CHD relationships within societies in which CHD risk is high.³²⁻³⁵ With particular care to reduce variability and increase validity of individual dietary intake assessments, all of these studies were able to demonstrate small but significant and often independent prediction of CHD risk based on entry nutrient intake or other dietary characteristics. In our view, this evidence is less persuasive than the powerful synergism of diet, blood lipid levels, and CHD risk so firmly established over 40 years, but it is clearly confirmatory.

With this logic, habitual diet has come to be considered the *necessary* factor in mass hypercholesterolemia and, thus, in the mass atherosclerosis that leads to high rates of CHD. The population data are, however, equally compatible with another idea, that *all three* of the major risk factors (i.e., elevated population averages of blood cholesterol, blood pressure, and smoking) are essential for a high population burden of CHD.

The relationship of habitual diet to population levels of blood lipids and blood pressure, and to CHD rates, is largely congruent with clinical and experimental observations. First, experimental modification of diet has a predictable effect on group blood lipid levels. When calories and weight are held constant in controlled diet experiments and diet composition is varied, the largest dietary contributions to serum total and LDL cholesterol levels are (a) the proportion of calories consumed as saturated fatty and trans fatty acids, (b) dietary cholesterol, both of which raise cholesterol levels, and (c) polyunsaturated fatty acids, which have a cholesterol lowering effect. The role of monounsaturates is debated, with some suggesting a neutral effect while others a cholesterol-lowering effect.^{29-31,36} Although this is debated, these clinical experiments confirm the broader relation found between long-term habitual diet and population mean levels of blood lipids.^{11,12}

Animal experiments are not treated here but are relevant to the human diet-CHD relationship in that lesions resembling the human plaque are produced by dietary manipulations of blood lipoprotein levels; the fatty components of these animal plaques are reversible with dietary manipulations to lower blood lipoprotein levels.^{37,38}

Plasma cholesterol-lowering preventive trials, which tend to complete the overall evidence for causation, indicate the feasibility and safety of changing risk factors and demonstrate the actual lag times between such change and its effect on CHD rates.²² The synthesis of results of *all* these trials and their implications for the public health are central because carrying out the "definitive diet-heart trial" is not considered feasible. Therefore, experimental *proof* of the role of diet in the primary prevention of CHD is not likely to be established.

Lipid-lowering trials demonstrate that substantial lowering of blood lipid levels is feasible, that the progress of arterial lesions is arrested, and that CHD morbidity and mortality are reduced, all in proportion to the cholesterol lowering achieved and its duration. These trials, carried out mainly in middle-aged men with moderately elevated blood lipids, have usually involved cholesterol-lowering medication plus diet. However, because they specifically tested the cholesterol-lowering hypothesis and because their effects are congruent with the observational evidence cited here in support of that hypothesis, these experimental findings have been extrapolated by many authorities to the potential for prevention in the broader population, including older and younger age groups, and those with lower lipid and risk levels.²² Many consider, also, that the results of randomized clinical trials, because of their congruence with the other evidence, may be extrapolated to the larger public health, including the potential for CHD prevention by long-term change in eating patterns of the population as a whole, and, finally, to the prevention of elevated risk in the first place.

Proteins

International vital statistics on deaths correlated with national food-consumption data indicate that, as with fat consumption, strong ecological correlations exist between animal protein intake and death rates from CHD, but there is little evidence that this association is causal. Anitschkow³⁹ found originally that it was dietary lipid rather than protein that resulted in hyperlipidemia and atherosclerosis in his experimental rabbits. Controlled metabolic ward studies in men under isocaloric conditions, with fat intake held constant while protein intake was varied between 5 and 20% of daily calories, found no change in blood cholesterol level (University of Minnesota, unpublished data).

Neither clinical, experimental, nor epidemiological evidence is now sufficient to attribute a *specific* effect of dietary protein on either blood lipid levels or CHD risk. The overall importance of the consumption of meats from domesticated animals and of fatty milk products is therefore thought to rest mainly in their fatty acid content rather than their protein content, at least with respect to CHD risk.

Carbohydrates

There is generally a positive association between population intake of refined sugars and CHD mortality and a negative relationship between complex carbohydrates and CHD mortality. Although these diet components are seriously confounded with other dietary factors that are strongly associated with carbohydrate intake, the effect of certain fibers, including the pectins in fruit, bran fiber, and the guar gum of numerous vegetables and legumes, on blood sugar and on blood lipid regulation has recently attracted greater interest. This is particularly so now that the fatty acid effects are well delineated; yet they fail to explain all of the observed population differences in blood lipid or all the lipid changes seen during experiments involving different nutrient composition.

More important, however, is that plausible mechanisms of atherogenesis are not established for sugars. The broader issue of plant foods (fruits, vegetables, pulses, legumes, and seeds), their complex carbohydrates, protein, other nutrients, and fibers is nevertheless of great public health interest because their consumption may affect the risk of cancers as well as of CVD.

The summary view is that the different amounts of sugars consumed in "natural diets" around the world do not account for the important differences found in population levels of blood lipids and their associated CHD risk. High carbohydrate intake is confounded with low fat intake (since protein intake is relatively comparable), and both are associated with low rates of CHD.

Alcohol

Positive correlations between alcohol consumption and blood pressure levels found for individuals in population studies appear to be dose-related and independent of body weight and smoking habits.^{40,41} Evidence is also consistent with respect to the positive relationship of alcohol consumption to blood high density lipoprotein (HDL) cholesterol level and of change in alcohol consumption to change in HDL cholesterol level. Substitution of alcohol for carbohydrates in a mixed U.S. diet results in a rise in HDL, mainly the HDL₃ subfraction, one that may not be strongly related to CHD risk.⁴²

Experimentally, myocardial metabolism and ventricular function are affected by relatively small doses of alcohol. In addition, neurohormonal links are established between alcohol-stimulated catecholamine excretion and myocardial oxygen requirements. These effects could act as contributory factors to the clinical manifestations of ischemia.

The epidemiological evidence from longitudinal studies about the relation of alcohol to CHD risk is, however, conflicting.⁴³⁻⁴⁵ Inverse relationships of alcohol intake and CHD are found in some studies, whereas a U-shaped, linear, or no relationship is found in others. Positive relationships, when found, are usually independent of tobacco, obesity, and blood pressure levels.⁴⁵

Reasons for these inconsistent findings in the alcohol-coronary disease relationship may involve the poor (self-report) measurement

for alcohol intake as well as misclassification of the cause of death among heavy drinkers who are known to die of sudden, unexplained causes. Moreover, there are many possible confounding factors, including blood pressure levels, cigarette smoking, and diet.

Preventive practice with respect to alcohol is, therefore, based on its social and public health consequences rather than on any possible direct effect, favorable or otherwise, on cardiovascular disease risk. A major concern about regular alcohol use is, however, its enhancement of overeating, underactivity, and smoking, along with its intrinsic caloric density. Given these several relationships, public health recommendations for alcohol are not yet indicated in *any* quantity, as a “protective measure” for heart diseases.

Salt

Salting of food, primarily for preservation, began with civilization and trade. Now salting is based mainly on acquired taste and is likely a “new” phenomenon in an evolutionary sense. Moreover, the mammalian kidney probably evolved in salt-poor regions where the predominantly plant and wild game diet was likely very low in sodium and rich in potassium. Thus survival of humans and other mammals in salt-poor environments may have rested on an evolutionarily acquired and exquisite sodium-retaining mechanism of the kidney. The physiological need for salt under ordinary circumstances is approximately only 1–2 g of sodium chloride per day. It is hypothesized that this mechanism is now overwhelmed by the concentrated salt presented to modern humans in preserved meats and pickled foods, in many processed foods, and in the strong culturally acquired taste for salt.^{24,46}

Clinical, experimental, and epidemiological links between salt intake and hypertension are increasingly well forged.^{46,47} Marked sodium depletion dramatically reduces blood pressure in persons with severe hypertension. Sodium restriction enables high blood pressure to be controlled with lower doses of antihypertensive drugs. In many patients, salt restriction may result in adequate control of mild to moderate hypertension without drugs.⁴⁸ Weight reduction and salt restriction appear to be independently important in lowering high blood pressure.⁴⁸ In summary, a culture with high salt consumption appears to encourage maximal exhibition of an inherent human susceptibility to hypertension. Because potassium tends to reduce the blood pressure-raising effects of sodium, the sodium-potassium ratio of habitual diets also may be important in the public health.⁴⁹

Surveys consistently find strong relationships between average population blood pressure and salt intake.^{47,50,51} High blood pressure is usually prevalent in high-salting cultures, irrespective of the prevalence of obesity. In contrast, hypertension is usually absent in low-salting cultures, despite frequent obesity. Moreover, rapid acculturation to greater salt intake among South Pacific islanders who migrate to industrialized countries is associated with an increased frequency of hypertension and elevated mean blood pressure.⁵² Even within high-salting cultures, when special efforts are made to reduce the measurement error for blood pressure and to characterize individual sodium intake with maximum precision, significant individual salt–blood pressure correlations are usually found.^{52,53}

Despite all this evidence, neither preventive practice nor public health policy on reduction of salting is well advanced. This may be due in part to professional skepticism, based perhaps on the relatively weak individual correlations of salt intake and blood pressure. Admittedly, modification of salt intake by traditional dietary counseling has not been very successful. However, when interventions are attempted in a supportive and systematic way, change in salting behavior is readily achievable.⁵⁴ In the United States, wider education has significantly and widely influenced food processing and marketing of products with lower salt content, and a great deal of voluntary public health action has been taken by food companies.

Current U.S. national dietary goals recommend no more than 4.5–6.0 g of salt daily.⁵⁵ For individuals, this is achievable by not salting foods at the table, by adding no salt in cooking, and by avoidance of salt-rich foods, particularly canned, processed, and pickled foods. Despite the absence of a strong policy, preventive practice and public health approaches to reduced salt consumption are

increasing. Significant public health effects of such population changes might be expected in high-salting societies, in light of recent trends in blood pressure and stroke observed in Japanese populations.⁵⁶

Blood Lipoproteins

Clinical, experimental, and epidemiological evidence of the relationship between certain blood lipoproteins, atherosclerosis, and incidence of CHD is strong, consistent, and congruent. Because much knowledge is available, we present here only a summary of what we regard as the salient facts in this relationship, along with a few key references. The subject was recently reviewed in detail.²²

- Associations are consistently strong between mean population levels of total serum cholesterol and measured CHD incidence.^{11,12}
- Associations are variable between mean population levels of fasting serum triglycerides and coronary disease rates.^{57–58}
- Total serum cholesterol levels at birth have similar means and ranges in many cultures.⁵⁹
- Average levels and distributions of total serum cholesterol differ widely for populations of school-age children.⁵⁹ They tend to parallel the differences found in adult population distributions of blood lipid levels, that is, means and distributions are found to be elevated in youth when they are elevated in adult populations.⁵⁹
- Means and distributions of total serum cholesterol of migrants rapidly approach those of the adopted country, whether higher or lower than the country of origin.¹⁶
- Blood lipids measured in cohorts of healthy adults followed over time show consistently positive relationships, usually with a continuously rising individual risk of CHD according to the entry levels of total serum cholesterol (and LDL), at least until late middle age.^{8,60,61}
- Computation of the population risk attributable to blood cholesterol levels indicates that the majority of excess CHD cases occur in the central segment of the population distribution, that is, 220 to 310 mg/dL, whereas only 10 percent derive from values above 310.^{7,27}
- In healthy cohorts, a strong inverse relationship between individual HDL cholesterol level and its ratio to total cholesterol is found with subsequent CHD risk. It is relatively stronger at older ages and within populations that have a relatively high CHD risk overall.^{36,58,62}
- Large-scale experiments indicate the feasibility and apparent safety of blood cholesterol lowering from moderate changes made in dietary composition, with and without weight loss.^{10,36,63}
- Clinical trials of lipid lowering alone in middle-age, high-risk populations indicates a reduction of CHD risk according to the degree and duration of exposure to the lowered cholesterol level.^{9,10,64–66} Further, clear evidence has emerged that a class of lipid-lowering agents, the “statins” can reduce the risk of further CHD morbidity and mortality when coronary disease is already clinically apparent.^{67,68}
- There has probably been a significant drop, of approximately 10–15%, in the U.S. mean total serum cholesterol level in the last 20 years, which is partly explained by changes in composition of the habitual diet during this period.^{69,70}

Consensus from these facts has resulted in a vigorous population strategy of reduction in blood lipid level in the United States. Major recommendations are now in place for a change in eating patterns among North Americans.³⁶ Moreover, the U.S. National Cholesterol Education Program has apparently increased both public and professional awareness and has improved the medical practice of lowering blood cholesterol.^{22,71–75}

Overweight and Obesity

Whatever the physiological or cosmetic disadvantages of obesity and overweight, their relationship to CVD risk and mortality remains interesting, difficult to dissect, and basically unsettled. From a clinical perspective, extreme obesity is associated with manifest physical limitations and a propensity for many disabilities and illnesses. Beyond this, however, associations with cardiovascular diseases are not consistent throughout most of the distribution of relative weight or skin-fold measurements.⁷⁶

Overweight and weight gain tend to raise risk factor levels, and correction of the many metabolic disorders that accompany obesity is prompt and substantial when weight loss is achieved, with or without an increase in physical activity. When weight loss is carried out primarily through increased physical activity, appetite is generally “self-regulated” and body fat is lost, lean body mass is better maintained, insulin activity is lowered, glucose tolerance is improved, LDL and very low density lipoprotein (VLDL) levels are lowered, HDL level is raised, and cardiovascular efficiency is enhanced. As we shall review here, however, the status of obesity and weight gain and loss as risk factors for CVD is complex.

Obesity is arbitrarily considered to be present when the fat content of the body is greater than 25% of body mass in men and 30% in women. Overweight is equally arbitrarily chosen as greater than 130% relative weight, according to life insurance build and mortality tables, or on a body mass index (kg/m^2) greater than 26. “Ideal weight” criteria are often based on standards associated with the lowest mortality risk in life insurance experience. The prevalence of overweight (and obesity) in U.S. adults is variously estimated from 20 to 50%, depending on the measurement used and the definition chosen, as well as by age, sex, and race classification.

A most salient fact about overweight in the United States is that average weight and relative body weight are increasing, according to national health surveys. Obesity based on a body mass index (wt/ht^2) of $\geq 30 \text{ kg}/\text{m}^2$ in men (20–74 years of age) rose from 10.7% in 1960–1962 to 28.1% in 1999–2002. In women, similar changes have occurred, with the proportion obese in 1960–1962 being 15.7%, rising to 34.0% in the later survey.⁷⁷ (Table 62-3) The prevalence of extreme overweight is increasing at a greater rate than is average weight.⁷⁷ This trend affects all gender and major ethnic groups as shown for overweight.

The causes of *mass obesity* in populations are only partly understood. Widespread abundance, availability, and low cost of calorie-dense foods, along with many environmental cues to appetite, encourage overeating in relation to physiologic need. These environmental “facilitators” act on an apparently widespread genetic susceptibility to obesity. This, in turn, may be an evolutionary legacy from hunter-gatherer lifestyles. Moreover, there are other factors that enhance excess calorie intake relative to need. For example, dietary fat is more efficiently stored as adipose tissue than is carbohydrate under conditions of excess calorie intake.³⁶ Refined sugars have less satiety value than the complex carbohydrates of fruits and vegetables. And alcohol is cheap and available in many societies.

TABLE 62-3. AGE-ADJUSTED PREVALENCE OF OBESITY IN AMERICANS AGES 20–74 BY SEX AND SURVEY

Year	Men	Women
1960–62	10.7	15.7
1971–74	12.2	16.8
1976–80	12.8	17.1
1988–94	20.6	26.0
1999–2002	28.1	34.0

NHES 1960–62; NHANES: 1971–74, 1976–80, 1988–94, and 1999–2002.

Note: Obesity is defined as BMI of 30.0 or higher.
Source: CDC/NCHS. Health, United States, 2004.

One major *cause* of mass obesity in Western populations appears to be the increase of relative sedentariness. Americans are, on average, heavier now than they were earlier in this century when, in fact, they consumed significantly more calories per day.³⁶ The stable, rural, laboring populations that consume (and expend) more energy are, in turn, the leaner populations.¹¹ Unfortunately, however, sedentariness in populations is largely confounded with calorie density and other differences in eating patterns.

Comparisons among and within populations in the Seven Countries Study illustrate the complexity of the relationship of overweight and obesity to CHD and to death from all causes.^{11,12} Among populations, CHD incidence is not correlated with any measure of obesity or overweight. The population distributions of skin-fold obesity are, however, strikingly different. They almost fail to overlap, for example, between the highest skin-fold values found among Serbian farmers and the lowest values among sedentary U.S. rail clerks.¹¹ Obesity is, therefore, a mass phenomenon and is apparently strongly determined by (a) the average energy expenditure of the population and (b) the composition (caloric density) of the diet.

Within populations the picture is highly variable. In East Finns, with high CHD rates, incident CHD cases are evenly distributed across the entry distribution of skin-fold fatness and overweight. In another population with a high CHD incidence—U.S. railroad workers—the relationship between skin-fold obesity and CHD death is weakly positive, in contrast to an insignificant and opposite relationship for relative body weight. In another population with a high CHD incidence, consisting of rural Dutch men, there is a strongly positive linear relationship between CHD incidence and overweight and obesity throughout the wide range of values found there. Among men from the southern Mediterranean regions of Italy, Greece, and Yugoslavia, there is a U-shaped relationship between overweight or obesity and CHD risk, as well as with deaths from all causes. There the thinnest individuals as well as the heaviest and fattest have the higher disease rates; lowest disease risk is found for those with intermediate weight values.^{11,12}

Multivariate analysis in the Seven Countries Study, used to adjust for the many confounding variables related alike to body mass and to CHD, shows no consistent relationship of 10-year CHD incidence with either relative weight or fatness.¹² In most of these populations there is a tendency for CHD incidence to be slightly higher in the upper than in the lower half of the fatness distributions, but this tendency disappears when other variables are simultaneously considered. Similarly, except for men at the extremes of the distribution, within generally high-incidence and overweight U.S. populations, there is little relationship between obesity or overweight and risk of CHD or death in men.

Within populations, several other longitudinal studies, including the Framingham Heart Study,⁷⁸ the Evans County Study,⁷⁹ and the Manitoba Study,⁸⁰ suggest that an independent contribution of relative weight to risk in a society with high CHD incidence may be reflected only in very long-term CHD risk. In Framingham, in addition, weight gain since youth is a risk predictor for CHD.⁷⁸ Finally, in the Evans County Study, initial overweight and weight gain over time are also strongly related to the seven-year incidence of new hypertension.⁷⁹

The ability to distinguish CVD risk according to the body distribution of obesity, usually measured as the ratio of waist to hip circumference (WHR), is relatively recent.⁸¹ WHR is positively related to risk of CHD, premature death, non-insulin-dependent diabetes mellitus, and cancers in women, as well as to established CVD risk factor levels. The finding that several diseases correlate better with fat distribution than with general measures of overweight or obesity has raised major new hypotheses about possible separate metabolic entities and about the pathogenesis, risk, and treatment of obesity.^{82,83}

Results of autopsy studies are inconclusive. The International Atherosclerosis Project concluded that the degree and severity of atherosclerosis were not consistently associated with overweight and obesity.⁸⁴

Finally, a major gap exists in our knowledge of the effect of weight reduction on disease risk in a relatively overweight society

at high risk from combined CHD risk factors. This hugely confounded question, as well as the effects of weight cycling, remains to be clarified.⁸⁵

In summary, obesity and overweight are centrally involved with the many metabolic maladaptations related to diabetes mellitus, hypertension, blood lipids, and probably atherogenesis. It is central to the metabolic syndrome.²² These maladaptations are particularly amenable to correction by weight loss, with or without increased physical activity. The epidemiological evidence indicates, however, that relative body weight and obesity have a different disease-related significance in different populations and cultures. This may be due in part to different composition of the diets by which individuals and populations become obese, as well as to coexisting elevated distributions of other CVD risk characteristics. In most societies with high CHD incidence in which the issue has been systematically studied, the independent relationship between overweight, obesity, and CHD risk is seen mainly at the extremes of relative weight and over the longer term. Inconsistent disease associations and the obvious and dramatic declines in CVD deaths in the United States over the last 40 years, despite the clearly increased average U.S. body mass, indicate the primary importance for population CVD risk of factors other than overweight and obesity.

Physical Inactivity

Two primal human activities are the obtaining and consuming of food. Only since the advent of agriculture, and more recently of urbanization and industrialization, has the sustained subsistence activity of humans changed dramatically. In affluent industrial societies with automated occupations, motorized transport, and sedentary leisure, reduced energy expenditure is one of the more profound changes in human behavior. Aside from its likely importance as a fundamental departure from evolutionary adaptations and its apparently determining effect on mass obesity, the evidence specifically linking physical activity to chronic and CVD disease risk is difficult to obtain and interpret. A definitive, long-term controlled experiment on habitual activity with respect to CVD risk is not considered feasible.⁸⁶ Here is a brief synthesis of the evidence relating habitual activity to CHD risk.

The caliber of the coronary arteries at autopsy is larger in very active people, but limitations of design, method, feasibility, and cost have prevented a satisfactory study of the effect of exercise training on changes in coronary angiograms or functional measures of ischemia. Clinical trials of cardiac rehabilitation after myocardial infarction, including the effects of exercise training, are difficult. Nevertheless, Oldridge and colleagues⁸⁷ carried out a meta-analysis on the “better-designed” studies, noting first that many of the trials demonstrated an effect of exercise on levels of risk factors and exercise tolerance. They used rigorous criteria for inclusion of 10 trials in their statistical summary, which estimated a 24% reduction in deaths from all causes in patients undergoing cardiac rehabilitation and a 25% reduction in CVD mortality. Both estimates were statistically significant and clinically important. The incidence of nonfatal myocardial infarction, however, was 15% higher (not statistically significant) in all the treatment groups combined and 32% higher ($P = 0.058$) in the groups in which cardiac rehabilitation was begun early (i.e., within eight weeks after infarction). Thus, cardiac rehabilitation with exercise apparently had no overall effect on risk of nonfatal infarction and, when initiated early, may even have increased the incidence of nonfatal infarction.

In addition to fatal and morbid outcomes, there is a growing consensus on the benefits of physical activity among patients with clinically significant cardiovascular diseases including myocardial infarction, angina pectoris, peripheral vascular disease, and congestive heart failure. Symptom reduction, improved exercise tolerance and functional capacity, and improvement in psychological well-being and quality of life are among the benefits.⁸⁸ Exercise also improves lipids and blood pressure and helps control obesity.⁸⁹

The major source of information about the role of physical activity in the primary prevention of CHD is indirect, from observational

studies. These usually involve attempts to identify the confounding effects of lifestyle characteristics *other* than physical activity.⁸⁹ A review by Powell and colleagues⁹⁰ concluded that the majority of observational studies meeting their criteria found a significant and graded relationship between physical inactivity and the risk of first CHD event and that studies with a stronger design were more likely to show an effect. These authors calculated a median risk ratio of 1.9, that is, a 90% excess risk of CHD among physically inactive persons.

We analyzed the subset of 16 studies from the review of Powell et al that measured individual levels of physical activity, and we added recent studies from the Multiple Risk Factor Intervention Trial (MRFIT) and U.S. railroad workers.^{89,91,92} All 18 studies showed that habitual physical activity was inversely related to death from CHD or death from all causes. The more recent studies adjusted for confounding risks and this adjustment usually diminished, but did not abolish, the risk associated with physical inactivity. Several studies found that the relation was largely *explained* by the level of physical fitness, in that the gradient of risk with the level of physical activity largely disappeared when measures of fitness were controlled. In a cohort study, fitness measured by a maximal exercise treadmill test predicted all-cause mortality for men and women, independently of other risk characteristics.⁹³

The duration, frequency, and intensity of physical activity that may be *protective* against CHD remain, nevertheless, at issue. Recent studies suggest that an energy expenditure of 150–300 kcal daily, in activity of moderate intensity such as walking and working around the house, is associated with lower risk, as is a moderate amount of vigorous physical activity.^{89,91,92,94} Anthropologic observations suggest that healthy farmers and herdsmen rarely work at a pace that leads to shortness of breath or exhaustion. Systematic observations in the Seven Countries Study indicate that even a substantial amount of regular, vigorous physical activity does not necessarily protect an individual or a population from CVD risk, particularly if other risk factors such as mass hypercholesterolemia are prevalent. In that study, farmers and loggers in eastern Finland were found to be the most physically active of men, and yet they had the highest rates of CHD; there was little less risk among the more physically active within that population.^{11,12}

The interpretation of these many observations is that habitual, current physical activity very likely protects against coronary death.⁸⁹ A basic uncertainty that remains is whether the apparent benefit is due to physical activity itself or to its effect on other risk factors. People tend to exercise if they are able to and if they feel good when they exercise. Fitness, a component strongly determined by constitution, may be a major contributor to an apparently protective effect of physical activity. It is possible that fitness determines both who will be active and who will be protected from CHD.

At least two other pieces of evidence suggest that constitution is *not* the major operant. Any protective effect of having once been a college athlete, and thus presumably genetically superior, disappears with time after graduation, whereas current physical activity is associated with lower risk.⁹⁵ Moreover, it seems that genetic factors are likely to be less important to participation in moderate exercise than to participation in vigorous exercise, but both carry a lower risk of CHD.

Finally, safety should be the foremost consideration both in prescribing exercise for individuals and in making recommendations for the public health. Several studies have found an excess risk of primary cardiac arrest during and shortly after strenuous exercise in all subjects, regardless of their level of habitual physical inactivity, despite a much lower overall risk of sudden coronary death in habitually active subjects.^{96,97} They concluded that the reduced risk of sudden death due to regular physical activity was greater than the excess risk of sudden death during vigorous activity. This view, important for the public health, would be small comfort, however, to the families of those stricken while running. The evidence suggests that brisk walking or other moderately vigorous activity is the more reasonable exercise prescription, at least for sedentary and middle-aged people who have not maintained their fitness from youth.⁸⁹

Diabetes and Hyperglycemia

Since the insulin era began, enabling persons with diabetes to survive, a strong relationship between diabetes and atherosclerosis risk has emerged. Most who die with diabetes succumb to advanced atherosclerosis. In addition, there are important mechanistic interrelations between insulin-glucose regulation, lipoprotein and uric acid metabolism, obesity and hypertension, on the one hand, and atherosclerosis on the other. Unfortunately, the prevalence of diabetes in the U.S. population is rising associated with increasing obesity.⁹⁸ The long-term effects of this trend are unknown.

The association of clinical diabetes mellitus with CHD and atherosclerotic manifestations is documented clinically, pathologically, and epidemiologically.^{99,100} It is thought that hyperinsulinemia, hypoglycemic episodes, or both in treated diabetics, coupled (formerly) with the common prescription of a high-fat, low-carbohydrate low-fiber diet, increases vascular complications. Cross-cultural comparisons suggest that the risk of atherosclerosis and CVD in diabetic patients is indeed related to factors other than the glucose-insulin disorder itself. For example, apparently low rates of atherosclerosis exist in diabetic eastern Jews, Chinese, and Southwest American Indians.^{99,100} The Pima Indians of Arizona are thought to be an example of the theoretical “thrifty genotype,” that is, a population only recently (in evolutionary terms) exposed to calorie abundance, that frequently (50% of adults) develops an obese, diabetic phenotype but nevertheless manifests little CVD.¹⁰¹

In longitudinal studies among cohorts, clinical diabetes mellitus is associated with excess CHD risk and severity of CHD, and many studies confirm the excess of fatal myocardial infarction in women with diabetes.¹⁰² The excess risk among diabetics is not always differentiated by the degree of hyperglycemia or the degree of control. Much of the excess CHD risk in diabetics is, in fact, accounted for by associated risk variables.^{99,100} More severe atherosclerosis, diabetic cardiomyopathy, and a hypercoagulable state are also thought to contribute to the excess risk of diabetes.¹⁰⁰ Finally, in most autopsy studies, coronary artery disease and the frequency and severity of myocardial infarction are greater in diabetics than in control subjects.^{99,100}

Diabetic treatment by the control of blood glucose levels is the mainstay of therapy. However, the role of glucose control in the reduction of cardiovascular and other complications has been controversial. The University Group Diabetes Program (UGDP) reported an increased rate of myocardial infarction with the use of first-generation sulfonyl ureas despite effective blood glucose control.¹⁰³ These effects are not seen with later agents.¹⁰⁴ The Diabetes Control and Complications Trial (DCCT) studied “tight” glucose control in insulin-dependent diabetics. Findings included significant reduction in retinopathy, microalbuminuria, and clinical neuropathy. Elevated LDL cholesterol levels were also reduced with tight control.¹⁰⁵ Cardiovascular and peripheral vascular disease was also reduced, but did not reach significance.¹⁰⁶ Recently, a meta-analysis of clinical trials of the hypoglycemic drug rosiglitazone found increases in myocardial infarction and cardiovascular death.¹⁰⁸ The implications of these observations are still unclear.

In healthy persons glucose intolerance alone is weakly and inconsistently associated with CVD risk.^{100,107} However, high insulin activity was found to be a significant independent predictor of coronary events in cohorts studied in Australia, France, and Finland,¹⁰⁰ and it has also been proposed as a cause of excess atherosclerosis in Asian migrants.¹⁰⁸

In summary, the relationship between diabetes, atherosclerosis, and coronary disease is well established among persons with clinical diabetes living under the conditions of affluent Western culture. Data from other cultures suggest, however, that other factors, such as physical activity, body weight, blood pressure, blood lipid levels, dietary composition, and smoking habits, greatly affect the risk of CHD among diabetics. This, plus evidence that the metabolic disorders of middle-age persons with diabetes can be significantly improved through exercise and modified by diet and weight loss, provide a sound rationale for preventive practice. More study of these complex issues is needed to develop an effective preventive approach to noninsulin-dependent diabetes mellitus itself.

Elevated Blood Pressure: Hypertension

The epidemiology, control, and prevention of hypertension and its complications are summarized here.

It is estimated that hypertension contributes to more than one-half of adult deaths in the United States. It is a strong and independent risk factor for CHD and stroke, and there are plausible mechanisms for its effects on atherosclerosis and vascular disease. Patients with CHD have higher average blood pressure than control subjects. Experimental atherosclerosis induced in animals is directly related to pressure levels within the arterial system. In cohort studies, elevated blood pressure is positively, continuously, and independently related to CHD risk, according to increasing levels of systolic or diastolic blood pressures. The relationship of elevated blood pressure to risk of cerebrovascular hemorrhage and congestive heart failure is even stronger than the relationship to risk of CHD and thrombotic stroke.

The preventive potential for hypertension control is illustrated by drug trials that have demonstrated a significant decrease in rate of stroke and heart failure. The Systolic Hypertension in the Elderly Project (SHEP) demonstrated the importance of systolic blood pressure control in this group.¹⁰⁹ Results of other trials suggest that CHD risk is lowered by control of hypertension, but most have had insufficient power to study this question.¹¹⁰ The recent ALLHAT study treated hypertension with diuretics and more recent antihypertensive drugs with CHD as an endpoint. There was no placebo group. They found thiazide-type diuretics to be superior to more modern agents for combined CVD, stroke and heart failure.¹¹¹

Blood pressure control has greatly improved in the United States in the last 20–25 years, according to surveys showing a substantial decrease in the proportion of hypertensive persons unidentified or not under control.^{55,112,113} These trends have occurred in parallel with downward trends for both CHD and stroke mortality, although a direct relationship cannot be established. In fact, the mortality rate from stroke was diminishing long before safe and effective antihypertensive therapy was widely used. Moreover, stroke death rates in the United States fell during the 1950s and 1960s, when CHD death rates were rising sharply.²

Estimated changes in death rates for CHD and stroke, based on models of hypertension control, suggest a large potential for the prevention of CVD. Primary prevention of hypertension would likely have even more impressive effects on the public health.

Present challenges to preventive practice lie mainly in more effective control of elevated blood pressure in the elderly and in finding the ideal combination of drug and hygienic management for correction of mild or borderline levels of high blood pressure. The larger public health challenge lies in improvement of population wide correlates of hypertension, such as physical inactivity, overweight, and high salt and alcohol intake. Such primary preventive and public health approaches promise to minimize the exhibition of high blood pressure, since human populations are apparently widely susceptible.

Tobacco Smoking

The broader relationship of tobacco to disease and health is detailed in Chap. 54. Much of the clinical evidence of a direct relationship between cigarette smoking and coronary disease was, until recently, anecdotal. Experimentally, ischemic pain, angiographic coronary spasm, and electrocardiographic findings are now demonstrated during smoking in patients with compromised coronary circulation.¹¹⁴

For individuals living within societies with a high CHD incidence, smoking is consistently found to be a strong and independent risk factor for myocardial infarction and sudden death.^{93–95} The risk is continuous from persons who have never smoked, to ex-smokers, to those who smoke even in small amounts and is also related to duration of the habit.^{115,116} Interactions with other risk factors are also important, as indicated by the weak association of smoking with CHD risk in low-risk societies.^{11,12} For example, the observed incidence of CHD in populations that do not have a base of relative mass hypercholesterolemia is much lower than the risk predicted with multiple

regression equations derived from U.S. or northern Europe data.¹¹⁵ The Japanese, for example, with a heavy prevalence of smoking and substantial amounts of hypertension, but without hypercholesterolemia, show much less coronary heart disease than would be predicted.^{11,12}

As is the case with serum cholesterol level, most of the CHD cases attributable to smoking derive from the central part of the distribution, that is, light and moderate smokers; the prevalence of heavy smokers is low. A 17% population-attributable risk fraction for smoking and CHD deaths in the United States was estimated (conservatively) in the Carter Report.¹¹⁷ Smoking is particularly significant in CHD risk among women.¹¹⁸

Smoking cessation is associated with lower CHD rates according to years of cessation.¹¹⁹ While those who have never smoked have the best disease experience, long-term quitters approximate their rates, and even temporary quitters have a better risk experience than persistent smokers.¹²⁰ Improvement in the prognosis of survivors of myocardial infarction who quit smoking also tend to confirm the harmful cardiovascular effects of cigarettes and supports the potential for CHD prevention by reduction of tobacco use.^{116,121}

Synthesis of this evidence, therefore, suggests that cigarette smoking is neither a primary nor a necessary factor in determining population rates of CHD. It is, rather, a strong and independent risk factor for CHD and vascular disease among individuals living in high-incidence populations where there is a significant background of coronary and peripheral atherosclerosis.

Mechanisms presumed to be important in CHD include the physicochemical effects of tobacco, that is, increased heart rate and myocardial contractility and greater myocardial oxygen demand due to raised catecholamine levels, decreased oxygen-carrying capacity of the blood, elevated fibrinogen levels, and platelet-aggregating effects. Other possible mechanisms include elevated fasting blood glucose levels and white blood cell counts and lower HDL levels, all found among smokers.¹¹⁴

A public health policy to foster so-called safer cigarettes, at least with respect to lowering CVD risk, is not supported by the evidence of persistent high exposure to gas-phase toxins in “low-yield” cigarette users.¹¹⁴ Moreover, the promotion and adoption of Western-type cigarettes and smoking patterns in developing countries augurs ill for the future CVD risk in those populations. In contrast, smoking prevalence has decreased substantially in the United States, where large numbers of educated adults in particular have stopped smoking. This is attributed to increased community awareness of the health need to stop smoking, to social pressure and legislation for “clean air” and “smoke-free” environments, and to a greater access to the support and skills needed for quitting. The downward U.S. trend in smoking is not as evident, however, among lower socioeconomic groups and heavy smokers.¹²²

Under “ideal” supportive circumstances, such as that given high-risk participants in the MRFIT, smoking cessation success rates approximate 40% in the first year, with maintenance of this rate for up to four years among volunteer participants. Thus a long-standing medical pessimism about helping patients stop smoking might be replaced by optimism for cessation programs that are systematically applied. Moreover, communitywide educational and legislative efforts are increasingly effective.^{123,124} The results of all these efforts and the population trends downward in smoking frequency provide a rational basis for more public programs and for a more focused national policy to reduce cigarette smoking and tobacco production. It is equally possible that the currently declining rate of cigarette smoking will level off, unless educational programs and wider social support for nonsmoking behavior reach the lower socioeconomic classes, heavy smokers, women, and youth.

Hemostatic Factors

For decades, arguments have existed about the relative predominance of the role of classical risk factors versus thrombosis in the pathogenesis of atherosclerosis and CHD. A more unified theory now joins the effects of diet and blood lipids, physical activity and smoking, and

diabetes and insulin levels to atherosclerosis and to thrombosis. The interaction between chronic arterial wall disease and the blood properties leading to coagulation continues to be a major subject for research as it becomes clear that a critical fixed obstructive lesion is not necessary for myocardial infarction. In fact, thrombi forming on so-called “soft plaques” which rupture account for a significant proportion.¹²⁵ The components of the coagulation system found so far to be of major interest are platelets and fibrin and they aggregate when cell walls are damaged and develop fibrin platelet masses, and platelet aggregation.^{126,127}

Of the several hemostatic variables measured with respect to subsequent CHD risk, fibrinogen has received the most attention. Several investigators conclude that an elevated fibrinogen level is likely to be causally associated with CHD but that its elevation overall may be due primarily to smoking.¹²⁶

As for primary prevention of CHD events with low-level anticoagulation, such as with small doses of aspirin, this appears now to be established for nonfatal myocardial infarction in men.¹²⁸

Physical Environment

It is increasingly apparent that modern industrialized society developed an environment which is not conducive to good health.¹²⁹ Communities are built without parks, playgrounds, libraries, nearby stores, sidewalks, or public transit. The result is dependence on personal automobiles and social isolation. These environments may actually promote chronic diseases such as CHD. There is increasing understanding of the effects of these practices and attempts to promote healthier community designs.

The weather, particularly the influx of cold fronts and rapid falls in barometric pressure, has been correlated with new hospital admissions for coronary events and sudden death.¹³⁰ Reasonable preventive practice includes advice to avoid exposure, in particular the combination of isometric work and cold, and to use light face masks to maintain a favorable personal air temperature and humidity.

Similarly, atmospheric inversions and air pollution are related to hospitalization and death rates from pulmonary and cardiovascular diseases, particularly in the elderly. These observations are increasingly linked to specific environmental pollution agents including nitrogen, sulfur dioxide, ozone, lead, and particulate matter.¹³¹ Most recently fire particles (PM_{2.5}) < 2.5 μm have received attention. The result of combustion, they easily reach the alveoli. Experimental data suggests they may play a role in the etiology and onset of cardiovascular diseases.

Social Support

Several prospective population-based studies have established social support or “social connectedness” as a factor associated with *reduced* risk of death. Two large studies—one from Finland¹³² and one from Sweden¹³³—examined CVD disease risk. The pattern of results suggests a relationship between social support and mortality, at least in men. Whether this is a causal relationship or is attributable to a confounding variable such as baseline health or to personality characteristics such as hostility is unclear, and this line of investigation might well be continued.

Attempts have been made to change psychosocial characteristics experimentally and to measure CHD risk factors and disease changes. Recently, the enhancing recovery in coronary heart disease patients (ENRICH) trial tested cognitive behavioral therapy and antidepressant medications post myocardial infarction to increase social support and decrease depression. The trial showed no difference in the endpoint of recurrent myocardial infarction and death.¹³⁴

Gender and Estrogens

The excess risk of CHD and atherosclerosis in men at earlier ages is documented throughout affluent Western society. The sex differential is much less prominent, however, in nonwhite populations and in

areas where the overall incidence is relatively low.¹³⁵ The particular susceptibility of men is only partly explained by their higher risk factor configurations between the ages of 25 and 60. On the other hand, the relative protection from CHD among premenopausal women is assumed to be related to hormones, although the effect of early oophorectomy, menopause, or estrogen replacement therapy on known risk factor distributions in women fails to completely explain these differences. In countries with a high incidence of CHD, where there is relative mass hyperlipidemia much more of the plasma cholesterol is carried in the HDL fraction in women. Recent experimental evidence concerning mechanisms of LDL and HDL function, related to cell receptors and lipid transport in and out of the arterial wall, confirm this particular biological difference as a likely cause for some of the sex difference in CHD risk.

In contrast, women have a proportionately greater risk of angina pectoris than of myocardial infarction or sudden death. While they have less severe atherosclerosis in the coronary arteries, the sex difference is not as apparent in cerebral, aortic, and peripheral vessels. Survival of women after myocardial infarction is poorer in-hospital, although this is balanced by greater out-of-hospital death for men.

Finally, trends in CHD deaths in the United States indicate that the age-specific decline in mortality is proportionately greater in women than in men.² Similarly, the rise in CHD death rates among women in eastern Europe, where CVD deaths overall are increasing rapidly, is proportionately greater in women and in young women.¹³⁶

The excess risk of thromboembolism, stroke, and myocardial infarction in women taking oral contraceptives (OCs), and the interaction of OCs with age and smoking, are well established. Young women taking OCs have systematically higher serum lipid levels, higher blood pressure, and impaired glucose tolerance compared with control subjects.¹³⁷

Numerous epidemiologic studies evaluated the use of postmenopausal estrogen in the primary prevention of cardiovascular disease.¹³⁸ Meta-analysis suggested a relative risk of 0.50–0.65 for coronary artery disease in estrogen users.¹³⁹ These data exemplify the danger of extrapolating observational studies to therapeutic lesions. When randomized studies of hormone replacement therapy were performed the Heart and Estrogen/Progestin Replacement Study (HERS) and the Women's Health Initiative (WHI) trial, no benefit and potential harm was observed.^{140,141}

In summary, the sex differential for atherosclerosis and cardiovascular disease events and their time trends is not completely explained on the basis of known effects of hormones on the level of risk factors. More study of gender difference is needed.

Genetic Factors

Much current work is opening up the understanding of host-environmental relationships. The relative contribution of genes to disease risk of populations can be exaggerated, however, by studies of gene effects when limited to homogeneous, high-risk cultures where exposure is great and universal. Most of the lack of understanding, and much of the difficulty in identification of susceptible persons, lies in the unavailability of specific genetic markers for CVD and the incapacity of family studies to discriminate intrinsic components without such markers. Recent findings of the gene loci for apolipoprotein regulation hold great promise of an improved understanding of individual differences in blood lipoproteins and their response to diet. There is, for example, evidence of the genetic inheritance of LDL subclasses HDL, apo-B and apo-E.¹⁴² A substantial proportion of the variation in apo-B levels (43%) may be explained by a major locus.¹⁴³ A major gene controlling LDL subclasses may account for much of the familial aggregation of blood lipids and CHD risk.¹⁴⁴

Most intrinsic blood lipoprotein regulation, however, is clearly polygenic and strongly interactive with the environment, especially with composition of the habitual diet. Controlled experiments in metabolically normal people suggest that there is a normal distribution of individual blood lipid responses to a known dietary change.¹⁴⁵

The rare major gene effects that cause extreme manifestations of the hyperlipidemias are increasingly well characterized, but they account for only a small fraction of the mass phenomenon of hypercholesterolemia found in affluent cultures. Thus most atherosclerotic complications and most of the excess CHD events in the general population cannot be attributed to major gene effects. Nevertheless, gene-culture interactions remain important to preventive practice for better detection and individualized therapy of patients who have elevated blood lipid values.

A potentially important aspect of genetically determined diet responses now under investigation is the response of individual lipoprotein fractions to specific dietary factors, mainly fatty acids and cholesterol. A wider issue, however, is the relative magnitude of the contribution of intrinsic regulation to the large population differences found for average blood lipid values and their distributions. For the time being, this contribution remains speculative.

Genetic control of CVD risk factors *other* than blood lipids is even less well-known.¹⁴⁶ For example, not yet identified are genetic traits that might affect individual sensitivity to salt intake, to the atherogenic effect of cigarette smoking, or to the regulation of blood insulin and glucose levels, arterial wall enzymes, or personality type. There has been growing research on the genetics of hypertension. Markers have been discovered in a disease which is most likely polygenic for the proportion heritable.¹⁴⁷

The public health view that a favorable environment assures minimal expression of phenotypic risk provides the rationale for a population approach to prevention. This rationale has not been effectively challenged, but neither has it been universally accepted.

Combined Risk Factors

Clinical, laboratory, and epidemiological studies of CVD risk factors have been oriented mainly toward determining individual causal roles for each factor. Cardiovascular diseases are clearly related, however, in both individuals and communities, to *multiple* factors operating together over time. Multiple-factor risk is firmly established and actually is quantified for both CHD and stroke. Based mainly on Framingham and Pooling Project analysis, a consistent, independent, and at least additive contribution is found for each of the major risk factors: cigarette smoking, arterial blood pressure, and total serum cholesterol level.⁶⁰ The risk ratio between highest and lowest categories for *combined* risk within populations is approximately eight- to tenfold, in contrast to the risk ratio for single risk factors, which is approximately two- to fourfold.

Prediction regressions derived from follow-up experience in European men, with the use of four major risk factors at baseline, when applied to men in the United States, show the multiple-risk concept to be "universal." That is, the regressions define a continuum of CHD risk among individual U.S. men in a society that has quite different CHD rates overall.¹⁴⁸ The slope of the relationship (regression) between the combined risk factors and disease, however, is much steeper in the United States than in the European population. At any given level of multiple risk, U.S. rates are twice those in Europe. This cultural difference in the "force" of risk factors indicates that a sizeable influence on population differences in CHD risk remains unknown, although lifelong exposure to CHD risk is not captured in a single measure. Another indication of the combined force of risk factors comes from studies of low risk groups within industrialized populations. Those with low lipids, normal blood pressure, non-smokers, nonobese, and without diabetes have very low CHD and stroke rates.^{149,150,151} Nevertheless, since these few risk factors operate universally and explain a substantial part of individual and population risk differences, public health action on that part of the difference now explained is both promising and indicated.

Still another interpretation of the evidence of combined risk of CHD is that the synergism between risk characteristics leads to a major potential for preventive effects in the population by achieving relatively small shifts in the means and distributions of the multiple risk factors. This does not exclude the possibility of a population threshold for risk factors, below which population risk is remote. That

is indicated by the relative scarcity of mass atherosclerosis and CHD in societies in which average serum total cholesterol levels are less than 200 mg/dL. Nor does it exclude the concept of *necessary* versus *contributory* causes. In the absence of the presumed necessary factor (i.e., mass hypercholesterolemia), population risk is negligible. It may be that the departures from perfect prediction, found with the use of multiple regression analysis, are due in part to their failure to include the duration of exposure to, or the directionality of, a particular risk level.

► RHEUMATIC HEART DISEASE

Rheumatic fever and rheumatic heart disease remain important public health problems in the world.¹⁵² It is a particular problem where poverty, overcrowding, malnutrition, and inadequate medical care are found.^{153–158} Even in industrialized societies, a relatively high prevalence of rheumatic fever persists in pockets of poverty, and outbreaks have been reported recently in affluent areas.^{159–164} Despite that rheumatic fever is demonstrably preventable and rheumatic heart disease has declined dramatically in most industrialized nations, this condition remains a major public health problem internationally.

For more than 40 years it has been known that group A streptococcus infection underlies initial and recurrent attacks of rheumatic fever (see Chap. 9). The immunologic mechanisms and circumstances by which infection with this organism produces rheumatic fever and rheumatic heart disease and acute and chronic glomerulonephritis are well understood.¹⁶⁵ In some surveys, as many as 3% of patients develop rheumatic fever after known streptococcal infections.¹⁶⁶ As many as 50% of those who have once had rheumatic fever will, if untreated, experience attacks after a subsequent streptococcal infection. This suggests that host factors significantly determine susceptibility. Age is also an obvious factor, for example, infants do not develop rheumatic fever even though they are susceptible to streptococcal infection and glomerulonephritis. Such differences in susceptibility are clearly developmental, such as the variation with age, but others may have a genetic basis. The tendency of rheumatic fever to cluster in families, however, may be explained by shared environment as well as genes.

During the 1960s, the incidence of acute rheumatic fever per 100,000 urban children 2–14 years of age in the United States ranged from 23 to 28 for whites and 27 to 55 for blacks. The incidence was still higher in Puerto Ricans. Currently it is closer to 2 per 100,000 with most cases among the underprivileged.

In other parts of the world, the lowest rates of rheumatic fever have been observed in Scandinavia, with 1.3 cases per 100,000. In underdeveloped nations, the rates are much higher. Prevalence among school-age children in South America ranges from 1 to 10%.¹⁶⁷

Mortality from rheumatic fever and rheumatic heart disease has fallen significantly in the United States in this century. It was 14.8 per 100,000 in 1950, 7.3 in 1970, and 2.7 in 1986, a decline of 82%.

The diagnosis of acute rheumatic fever is made principally from clinical findings with the revised Jones criteria (see Chap. 9).¹⁶⁸ These may be insufficiently sensitive, however, to detect mild cases, particularly in Western countries where clinical patterns have changed so that arthritis is often the only presenting manifestation; chorea, subcutaneous nodules, and erythema marginatum are now rarely seen. Diagnosis may be complicated by the lack of a preceding sore throat or an apparent infection.¹⁶⁹

Current recommendations for the primary prevention of acute rheumatic fever and rheumatic heart disease and prophylaxis for bacterial endocarditis in those with known rheumatic valve disease are found on the American Heart Association website: www.heart.org.

► CONGENITAL HEART DISEASE

Malformations of the cardiovascular system are among the more frequently occurring congenital defects. They result from developmental errors caused by inherent defects in the genetic material of the embryo, environmental factors, or both.^{170–175}

Family studies suggest that the offspring of parents with congenital heart disease have malformation rates ranging from 1.4 to 16.1%.¹⁷⁶ Identical twins are both affected 25–30% of the time. While these and other findings of familial aggregation suggest genetic factors, common environment may also play a role.¹⁷⁵ Chromosomal aberrations or mutations account for less than 10% of all congenital cardiovascular anomalies. In addition, noncardiac disorders also produce cardiovascular defects; these include Marfan's syndrome, Friedreich's ataxia, glycogen storage disease, and Down's and Turner's syndromes.

Maternal viral infections during pregnancy are estimated to cause up to 10% of all congenital cardiac malformations. Rubella in the first 2 months of pregnancy is associated with congenital malformations in about 80% of live births and is thought to account for 2–4% of all congenital heart disease. Subclinical Coxsackievirus infections may be related to congenital heart disease. Acute hypoxia, residence at high altitudes, high carboxyhemoglobin levels, and uterine vascular changes from cigarette smoking are other potential causes.¹⁷⁴ Maternal x-ray exposure results in an increased incidence of Down's syndrome and possibly other congenital defects.¹⁷³ Maternal metabolic defects, such as diabetes mellitus and phenylketonuria, are associated with increased incidence of congenital heart defects.

Animal investigations, which have not been substantiated in humans, indicate that dietary deficiencies in the mother may result in congenital malformations. Obstetric problems are associated with congenital heart disease, including association of advanced maternal age with Down's syndrome and a history of vaginal bleeding (threatened abortion) during the first 11 weeks of gestation with prematurity. The teratogenic potential of drugs, such as thalidomide and folic acid antagonists, is well documented. In addition, dextroamphetamine, anticonvulsants, lithium chloride, alcohol, and progesterone/estrogen are highly suspected teratogens acting in the first trimester of pregnancy, as are certain pesticides and herbicides (see Chap. 33).¹⁷⁷

Data on the true incidence of congenital heart disease are limited. The chief sources of information are birth certificate and hospital birth data.^{171,172} Birth certificate data usually underestimate the true rate as the defect may not be discovered until later. It is estimated that there are 32,000 live-births with congenital heart disease in the U.S. and 1.5 million worldwide annually.^{178,179} A U.S. multicenter collaborative study in 1970 yielded the following incidence rates for congenital heart disease: 8.1 per 1000 total births, 7.6 per 1000 live births, and 16.5 per 1000 twin births.¹⁸⁰ Most are correctable by modern medical and surgical methods, including cardiac transplantation; it is estimated that only one child per 1000 cannot be helped by such approaches.¹⁸¹ As a result, infant mortality from congenital cardiovascular disease has fallen steadily (Fig. 62-6). As with other conditions, mortality among black youth has fallen less than for whites. The correction of congenital defects by surgical and other interventions is an important factor in increasing survival. Patients who have been repaired live into adulthood presenting new challenges in their care.^{178,182}

Although the overall incidence of congenital heart disease has apparently remained stable, the distribution of types of defects may be shifting. This includes unexplained increases in ventricular septal defects and patent ductus arteriosus. A decline in the number of infants born with rubella-caused defects may be explained by vaccination programs.¹⁸⁰

Primary prevention of congenital heart disease includes the following established measures:¹⁷¹

1. Genetic counseling of potential parents and families with congenital heart disease
2. Rubella immunization programs
 - a. Identification of susceptible women of childbearing age by serologic examination
 - b. Immunization of susceptible women
 - c. Avoidance of pregnancy for 2 months after rubella vaccination
3. Avoidance of exposure to viral diseases during pregnancy

Figure 62-6. Infant mortality from congenital malformations of the circulatory system by race, U.S., 1970–2001. (Source: *National Heart, Lung, and Blood Institute. Morbidity and Mortality Chart Book on Cardiovascular, Lung, and Blood Diseases. Bethesda, MD, 2004; NIH Publication.*)

4. Administration of all usual vaccines to all children to eliminate reservoirs of infection
5. Avoidance of radiation during pregnancy
6. Avoidance of exposure to gas fumes, air pollution, cigarettes, alcohol, pesticides, herbicides, and high altitude during the first trimester of pregnancy
7. Avoidance of drugs of any kind during the first trimester of pregnancy, especially drugs of known or suspected teratogenic potential.

► CARDIOMYOPATHIES AND MYOCARDITIS

Cardiomyopathies are a broad group of cardiac diseases that involve the heart muscle. Although less common in industrialized nations, they account for 30% or more of heart disease deaths in some developing countries.¹⁸³ They are of diverse etiology and are usually classified by the functional results of their effects on the myocardium: dilated or congestive, hypertrophic and restrictive. Some recommendations suggest that the term “cardiomyopathy” be reserved for disease of unknown origin involving heart muscle.¹⁸³ However, the common use of the term still associates it with specific causal syndromes when these are known.

Some cardiomyopathies are diagnosed in their acute phase, where inflammation of the myocardium is common (myocarditis). While myocarditis is particularly difficult to categorize, diagnosis has been facilitated by the widespread use of endomyocardial biopsy.¹⁸⁴ These techniques have suggested that an inflammatory reaction is more common than was previously suspected. Identified causes include infectious, metabolic, toxic, allergic, and genetic factors.¹⁸⁵ Myocarditis and cardiomyopathy may be mild and undetected but also can be rapidly fatal with progressive heart failure.

In industrialized nations, cardiomyopathies appear to be increasing in prevalence, although it is unclear whether there is an actual increase or an increase in professional awareness and improved diagnostic techniques.¹⁸⁶ The latter include use of the echocardiogram, Doppler flow studies, and catheter-based endomyocardial biopsy. Surveillance of Olmsted County, Minnesota, found an incidence of idiopathic dilated cardiomyopathy of 6 per 100,000 person years. Overall prevalence was 35.3 per 100,000 population.¹⁸⁷ Mortality from cardiomyopathy in the United States varies by age, race and sex (Table 62-4). Mortality is higher in blacks than whites and greater in men than women. Mortality increases with age, suggesting the pattern of a chronic condition.

Alcohol abuse is an important cause of cardiomyopathy, accounting for approximately 8% of all cases in the United States.^{186,188}

Alcohol causes myocardial damage by several mechanisms.^{189,190} These include (a) a direct toxic effect, (b) effects of thiamine deficiencies, and (c) effects of additives such as cobalt in alcoholic beverages. Abstinence from alcohol may halt or even reverse the cardiomyopathy.¹⁹¹

Another major cause of cardiomyopathy in industrialized countries is viral infection, particularly Coxsackie B virus, echovirus, influenza, and polio,¹⁹² often beginning as a viral myocarditis. Subclinical viral disease is thought to be more common than was previously suspected, with most patients recovering without sequelae. More severe forms, however, result in dilated cardiomyopathy and death due to congestive heart failure or arrhythmias. Recent research has suggested an autoimmune component and indicated that immunosuppressive therapy may be helpful in modifying the disease.¹⁹³ However, early clinical trials have shown no benefit for corticosteroids.¹⁹⁴

Hypertrophic cardiomyopathy (HCM) is another cause of death.¹⁹⁵ Largely undetected until the advent of echocardiographic techniques, it is becoming increasingly clear that this condition can be fatal and be managed with pharmacologic therapy.¹⁹⁵ An Italian registry for HCM found a majority of patients were male (62%) and 89% were New York Heart Association class I–II. Most were in their fourth to sixth decade of life. Cardiovascular mortality was 1% per year, mainly due to heart failure.¹⁹⁶ The genetic origins of this condition are increasingly apparent.¹⁹⁷ In South and Central America, trypanosomiasis (Chagas’ disease) is endemic; an estimated 20 million people are afflicted.¹⁹⁸ Extensive chronic myocarditis with heart failure may be observed years after the initial infection with the trypanosome. An acute infectious phase, characterized by fulminant

TABLE 62-4. DEATH RATES FOR CARDIOMYOPATHY BY AGE, RACE, AND SEX, U.S., 2001

Ages	Deaths/100,000 Population			
	Black Male	White Male	Black Female	White Female
35–44	13.09	3.71	6.14	1.28
45–54	23.75	7.22	11.98	2.82
55–64	43.33	14.95	19.72	6.37
65–74	67.19	35.24	36.27	17.22
75–84	127.71	83.03	69.07	42.41

In 2001, within sex groups, cardiomyopathy mortality was higher in blacks than in whites at each age; within race groups, it was higher in males than in females.

and fatal myocarditis, occurs mainly in children. In most cases, however, an average of 20 years passes before Chagas' cardiomyopathy becomes clinically apparent. An autoimmune process may play some role in the disease.¹⁹⁹ Diagnosis is made by means of serologic study or a xenodiagnostic test. Although antiparasitic agents, such as nitroimidazole derivatives, can alter the acute infestation, there is little evidence that they are effective for the cardiomyopathy.¹⁸³

Schistosomiasis is a major public health problem in the Nile and Yangtze basins where the parasitic infection is endemic, involving 85% of the population in certain areas. Chronic pulmonary embolization leads to pulmonary hypertension and right heart failure, but direct involvement of the myocardium is rare. New antiparasitic agents can limit the infection, but the main preventive strategy is a public health approach to controlling the vectors.

There is increasing awareness of cardiomyopathy in Africa where it is suspected to be higher than reported based on autopsy studies.²⁰⁰ Unfortunately, there are few data on etiology and prevalence.

► SYPHILITIC HEART DISEASE

Although the prevalence and patterns of syphilis worldwide have been altered significantly in the antibiotic era, it remains an important public health problem in many nations. Recent reports indicate a rise in reported cases of primary and secondary syphilis in the United States, and surveys in developing nations indicate continued high incidence and prevalence rates.²⁰¹ An increase in reported cases and a general decline in medical alertness to this condition encourage a continuing reservoir for late complications. Life-threatening tertiary syphilis is found in approximately 25–30% of untreated cases.²⁰² Approximately 10% of those are cardiovascular syphilis, manifest predominantly as uncomplicated syphilitic aortitis, aortic aneurysm, aortic valvulitis with regurgitation, and coronary ostial stenosis.²⁰³ Although a course of antibiotic therapy is indicated when cardiovascular syphilis is diagnosed, there is little evidence that it alters the course of the cardiovascular disease.

Because syphilis remains preventable, detectable, and treatable in the early stages, public health approaches should lead to eradication of the late effects of syphilis, including those in the cardiovascular system.²⁰⁴

► PREVENTIVE STRATEGIES

A population approach to CVD prevention has been formally outlined by the World Health Organization and articulated in the Vancouver Declaration.^{7,205} It embraces both the systematic practice of screening and education for high risk, where national priorities can afford such practices, and broad public health policy and programs in health promotion for communities.

Strategies for preventive practice are now widely available. Community-based strategies, programs, and materials are becoming available. National programs are under way in blood pressure control, diet and blood lipids, and smoking. Finally, health-promotion resource centers are now established for training in the design and dissemination of preventive programs. The student and the health worker are referred to these sources: the Centers for Disease Control and Prevention, Atlanta, GA (www.cdc.gov/heartdisease/prevention/htm); and the Office of Prevention, Education and Control, National Heart Lung and Blood Institute, Bethesda, MD (www.nhlbi.nih.gov/about/opecc/).

Renal and Urinary Tract Disease

Rebecca L. Hegeman

► INTRODUCTION

With over 50 million individuals worldwide having chronic kidney disease (CKD), a well recognized risk factor for cardiovascular disease, CKD is emerging as a worldwide public health problem.¹ As countries develop and industrialize, diseases related to infections, crowding, and poor nutrition recede, and chronic disease associated with affluence, aging, overnutrition, medical interventions, drugs, addictions, and other exposures becomes prominent. While diseases of westernized societies are the main focus of this chapter, globalization has contributed to an increasing rate of noncommunicable chronic disease worldwide. In 2003 it was estimated that 60% of deaths worldwide would be due to noncommunicable diseases, with 16 million deaths resulting from cardiovascular disease and 1 million deaths from diabetes.² Thus, the information in this chapter pertains to an ever widening circle of communities. With ischemic heart disease and cerebrovascular disease now listed as the number one and two causes of death worldwide, it is very probable that renal disease related to vascular disease will become more prevalent. In addition the increase in the prevalence of diabetes virtually assures that chronic kidney disease will continue to be a major cause of morbidity and mortality.

Rates of most renal diseases and of end-stage renal disease (ESRD) in westernized societies rise with age, and increased longevity enhances the expression of both. More males than females are affected by many renal diseases, and more males enter ESRD treatment programs. Some groups recently absorbed into industrialized societies, such as U.S. blacks, North American Indians, Hispanics and Mexican Americans, urban South African blacks, Australian aborigines, Pacific Islanders, and New Zealand Maoris, have especially high rates of renal disease, in part from conditions such as hypertension and diabetes that were rare in their forebears. ESRD treatment programs themselves have produced a whole new set of clinical, economic, and sociological perspectives and concerns.

Renal and urinary tract diseases are frequently asymptomatic for most of their course, and diagnosis is frequently dependent on laboratory and radiologic studies. Clinical renal disease may be manifested by blood, protein, or white blood cells in the urine, often with hypertension. Heavy protein excretion, decreased levels of serum albumin, hyperlipidemia, and edema characterize the “nephrotic syndrome.” Excretory renal function can be normal or impaired and can remain stable or progress to renal failure. Renal impairment generates, and is exacerbated by, hypertension. ESRD defines a situation of chronic irreversible renal failure in which prolonged survival is not possible without dialysis or renal transplantation.

Specific diseases are diagnosed by history and clinical findings, biochemical, serological, imaging, and urodynamic studies, and sometimes by biopsy of the kidneys, bladder, or prostate. Kidney biopsy specimens are examined by light, immunofluorescent, and electron microscopy to aid in diagnosis and prognosis. The serum creatinine

level provides an approximate measure of renal insufficiency, although it varies with muscle mass and diet, underestimates renal insufficiency in the elderly, is relatively insensitive to loss of the first 50% of renal function, and is less sensitive to progressive loss of function in severe renal failure. Glomerular filtration rate (GFR), precisely measured by iothalamate and inulin clearances, can be estimated by creatinine clearance. More recently the MDRD GFR equation has been validated and made readily available. This was developed from data on large numbers of patients screened for a clinical trial in whom iothalamate GFR was measured and takes into account serum creatinine, age, race, and gender.³ Estimating GFR is very important in assessing patients with kidney disease and continues to be a subject of intense interest. The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF K/DOQI) guidelines were first officially put forth in February 2002 and have been largely adopted in research and practice communities. In these guidelines chronic kidney disease has been divided into stages 1 through 5 based on an estimation of GFR with treatment recommendations determined by stage. This classification system was recently endorsed by the Kidney Disease: Improving Global Outcomes (KDIGO) group, an independent group dedicated to the improvement of care of kidney disease patients worldwide.⁴ This classification relies heavily on the level of GFR but is independent of the methods by which GFR is measured thus providing a powerful stimulus to ensure that serum creatinine measurements become uniform across laboratories, more generalizable estimating equations are developed and alternative filtration markers, such as cystatin C, are evaluated more extensively.⁵

Although specific interventions for many diseases are not yet available, progressive renal damage may be slowed by a few standard maneuvers, thereby avoiding or postponing the development of ESRD. Control of coexisting or secondary hypertension, moderate dietary protein restriction, blockade of the renin/angiotensin/aldosterone system in patients with proteinuria and in diabetics, and strict control of blood glucose levels are of proven value.⁶⁻⁸ Other strategies recommended include control of hyperlipidemia, control of obesity, reduction of left ventricular hypertrophy, cessation of tobacco use, and improved nutritional status including a low-sodium diet.⁹

► SPECIFIC RENAL DISEASES

Diabetic Renal Disease

Diabetic nephropathy is the leading cause of ESRD in the United States, accounting for approximately 40% of all patients on dialysis.¹⁰ While the overall incidence of ESRD due to diabetes has leveled off in recent years, over the last decade the number of new patients with diabetes as their primary cause of ESRD has doubled. With the increasing prevalence of diabetes in the general population it is predicted that 58%

of all prevalent ESRD patients in 2030 will have diabetes mellitus as their primary diagnosis. Of the estimated 18.2 million diabetic individuals in the United States, 5–10% have insulin-dependent diabetes mellitus (IDDM) and 90–95% have noninsulin-dependent diabetes mellitus (NIDDM). The lifetime risk of developing nephropathy in IDDM is approximately 30–40%, peaking after approximately 18–20 years. The lifetime risk in NIDDM is less well defined but probably is around 33%. Because most patients with diabetes have NIDDM, the majority of patients in dialysis units have NIDDM. The incidence of ESRD caused by diabetic nephropathy is increased in certain racial and ethnic groups including Hispanics, African-Americans, and Native Americans. Most of the increase in these groups seems to be caused by NIDDM. Familial clustering of diabetic nephropathy has also been noted and may be due to genetic inheritance, shared environment or both.^{11,12} The National Institute of Diabetes, Digestive and Kidney Diseases (NIDDK) has established a multicenter consortium to identify the gene(s) responsible for diabetic nephropathy.¹³ It should also be noted that up to 30% of patients with NIDDM and chronic kidney disease do not have diabetic nephropathy, but some other pathology, most commonly vascular disease.¹⁴

The pathogenesis of diabetic nephropathy is not yet fully understood. Early on the glomerular and tubular basement membranes thicken, and there is accumulation of extracellular matrix in the glomerular mesangium. Over time the glomerular capillary lumina are obliterated and the glomerular filtration rate eventually declines. Functionally, there may be an initial increase in the glomerular filtration rate, but this is followed by the development of proteinuria and systemic hypertension with an eventual decline in renal function. Hyperglycemia is a necessary factor initiating the above events, and tight glucose control reduces the onset of diabetic kidney disease. Current studies are focusing on the role of advanced glycosylation end-products (AGEs), the polyol pathway, transforming growth factor- β , and endothelins (as well as several others) in the accumulation of the extracellular matrix and other histochemical abnormalities which eventually lead to the decline of renal function in diabetics.¹⁵

The most important early clinical marker of diabetic nephropathy is microalbuminuria, or “dipstick-negative” urinary albumin excretion. This corresponds to a urinary albumin excretion rate of 30–300 mg/day or 20–200 mcg/min.¹⁶ Unfortunately it is not as early a marker for diabetic nephropathy as might have been hoped in that irreversible kidney damage may have already occurred by the time it is detected. It is also a risk factor for increased overall mortality. Identification of diabetics with microalbuminuria is important because patients with microalbuminuria progress to develop overt diabetic nephropathy (excretion of > 300 mg. protein per 24 hours) and eventually ESRD, and treatment appears to delay this progression.¹⁷

Several major clinical trials have provided guidance for therapy in diabetics to prevent diabetic nephropathy and the complications associated with it. Treatment of overt diabetic nephropathy with an angiotensin-converting enzyme (ACE) inhibitor in patients with IDDM and NIDDM has been shown to delay (but not totally halt) the rate of deterioration of renal function. This effect is independent of the effect of ACE inhibition on the treatment of blood pressure.¹⁸ This effect has also been shown for angiotensin receptor blockers (ARBs), and there is now evidence that the combination of an ACE inhibitor and an ARB may have additional benefit.¹⁹

The Diabetes Control and Complications Trial (DCCT) has demonstrated the beneficial effects of intensive insulin therapy on the development of type I diabetic nephropathy. Since then several other trials have supported this finding, including the United Kingdom Prospective Diabetic Study which demonstrated the benefit of intensive insulin therapy in type II diabetics.^{20,21} In the DCCT the mean adjusted risk of microalbuminuria (>28 mcg/min) was reduced by 34% in the group of patients on intensive insulin therapy with no baseline retinopathy. Unfortunately intensive insulin therapy did not show a significant benefit in preventing the development of overt diabetic nephropathy in patients who already had microalbuminuria. More recently pancreatic transplantation has been shown to stabilize the progression of diabetic kidney disease at several stages.²²

Hypertension is more common in diabetics with microalbuminuria, especially in patients with NIDDM, and is both a predictor and a consequence of nephropathy in NIDDM. Hypertension has been shown to increase the rate at which diabetic nephropathy progresses and antihypertensive therapy has been shown to slow its course.²³

Although the incidence of diabetic nephropathy among patients who have had IDDM for 25 years or more is falling, the increasing population of elderly patients with NIDDM marks diabetic nephropathy as a continued major cause of morbidity and mortality.²⁴ For this reason annual screening for microalbuminuria is recommended for all diabetics older than 12 years. If microalbuminuria is present and persists, ACE inhibitor or ARB therapy is appropriate in both normotensive and hypertensive patients. Serum potassium and creatinine will need to be monitored, and females of child-bearing age will need to be cautioned about becoming pregnant due to the known adverse effects of ACE inhibition and ARBs on the fetus. Glycemic control should be monitored on a regular basis as well as blood pressure control. In addition, microalbuminuria is frequently associated with elevated levels of cholesterol and triglycerides, so dietary restriction of cholesterol and weight reduction should be emphasized. Cigarette smoking has also been associated with the development and progression of microalbuminuria and should be discouraged.²⁵

While significant advances have been made in the approach to patients with diabetic nephropathy, we await the results of ongoing basic science research studies and clinical trials, which will increase the knowledge and improve the management of diabetic nephropathy, hopefully eliminating or at least significantly reducing the requirement for renal replacement therapy with its attendant comorbidity in this population.

Hypertensive Renal Disease

Hypertension can both produce and complicate renal disease, and its contribution to renal insufficiency is probably underestimated. Hypertensive renal disease accounts for 30% of the prevalent ESRD cases in the United States and is particularly common in African-Americans receiving ESRD treatment.²⁶ While most patients with ESRD have hypertension, the majority of patients with hypertension do not go on to develop ESRD. It seems that elevated blood pressure is permissive to renal disease, especially glomerulosclerosis, in only certain individuals. Among hypertensive patients in the Multiple Risk Factor Intervention Trial (MRFIT), the incidence of all-cause ESRD per 100,000 person-years of hypertension was 16.38 for African-Americans compared with 3.00 for white Americans.^{27,28}

Primary hypertensive renal disease can be of two kinds. The more common, sometimes called “nephrosclerosis,” is a form of chronic renal insufficiency associated with long-standing blood pressure elevation. The second, a form of accelerated renal failure associated with malignant hypertension, is now rare where treatment of hypertension is widespread.

Additional risk factors for nephropathy in hypertensive persons include the degree of systolic hypertension, the presence of diabetes, male sex, increasing age, and high normal serum creatinine levels.

Although widespread treatment of hypertension has reduced other hypertensive morbidities, its effect on hypertensive renal disease is still not clear. Two regional studies in the United States showed that renal damage can progress in some treated hypertensive persons despite *adequate* blood pressure control,^{29,30} and the community-based Hypertension Detection and Follow-up Program (HDFP) confirmed this phenomenon.³¹ More recently the African-American Study of Kidney Disease and Hypertension (AASK) looked at 1094 African-Americans with long-standing hypertension, proteinuria, and unexplained progressive renal disease. Again there was no significant difference in rate of progression of kidney disease between blood pressure groups, although it should be noted that blood pressure was controlled to at least 140/90 or less in both groups. An ACE inhibitor was shown to be more effective in slowing progression of renal disease.³² The inability to show an effect of lower target blood pressures may be related to the length of follow-up in these studies. Long-term follow-up of the participants in the MDRD study suggest that a lower

target blood pressure may slow the progression of nondiabetic kidney disease in patients with moderately to severely decreased kidney function and proteinuria.³³ Regardless of study results, most seasoned practitioners feel that blood pressure control is mitigating much hypertensive renal disease, and the HDFP suggests the superiority of aggressive control over a more relaxed treatment approach.

The definition of *adequate* blood pressure control continues to evolve. Fear of the J-curve phenomenon (increased mortality with lower BPs) in the general hypertensive population has been tempered by the results of several studies including the Hypertension Optimal Treatment (HOT) study where lowering of the diastolic BP to the low 80s in hypertensive individuals was associated with lower cardiovascular morbidity and mortality in diabetics.³⁴ In the context of proteinuric renal disease, lowering blood pressure beyond conventional recommendations has been shown to be beneficial in delaying progression of renal disease, but a more recent study did not support this.^{7,35} It has also become clear that over 50% of hypertensive individuals will require several antihypertensive agents to control blood pressure to the levels obtained in these studies. Retrospective and prospective analyses of large cohorts of hypertensive subjects and comparisons of therapeutic regimens are ongoing and will continue to help clarify some of these issues.

Glomerulonephritis

Glomerulonephritis (GN) encompasses several syndromes with a variety of pathological changes in the renal glomerulus. Injury to the glomeruli is manifest by variable degrees of hematuria and/or proteinuria, red blood cell casts, hypertension, edema, oliguria/anuria, and renal insufficiency. This injury is categorized by morphological or clinical features, precipitating events, or associated conditions. Most forms of GN are probably immunologically mediated, and genetic predispositions to some are suggested by family clusters and by associations with certain HLA types. Associations with specific infections are well established, especially in the developing world, but few precursors or etiologic factors are recognized in the common forms of GN that persist in westernized countries. With the accumulation of series of cases from different parts of the world, there is evidence for geographic, climatic and ethnic differences in the incidence and prevalence of various lesions that may lead to further discoveries about the underlying pathogenesis of various GNs.

GN is a common cause of renal failure and renal death in the developing world, and it is the third most common cause of treated ESRD in the United States, behind diabetes and hypertension.¹⁰ Pathological diagnosis relies on renal biopsy, which does have risks and is done with variable frequency in different parts of the world. Little is known about the distribution or natural history of mild GN or the extent to which subclinical GN might be eroding renal function in the broader community. This could change as more attention is being paid to individuals with GFRs in the 15–60 mL/min range.

Chronic Idiopathic GN. The major morphological categories of idiopathic GN are minimal change disease (MCD), focal segmental glomerular sclerosis (FSGS), mesangial proliferative GN, membranous GN (MGN), and membranoproliferative GN (MPGN). There are probably interfaces among these categories. Each can afflict subjects of all ages, but the distributions are dependent on age. MCD is the most common lesion in children, whereas adults have a broader distribution of all these forms of GN. Idiopathic GN may be associated with infections such as hepatitis B or C or malignancies. MCD has the best prognosis, with remission usual before adulthood. MGN remains the most common cause of idiopathic nephritic syndrome worldwide. It may remit but remains a common cause of renal failure from GN. The incidence of FSGS has increased significantly in the last two decades and is frequently secondary to or associated with other diseases, including infections. It is now the most common primary glomerulopathy underlying ESRD in the United States.³⁶ MPGN, type I, is frequently associated with hepatitis C but other infections and/or tumors may cause a lesion of MPGN. MCD has typically responded

to therapy more reliably than other forms of GN although FSGS with nonnephrotic range proteinuria may have a better prognosis. Immunosuppressive therapy continues to be used for treatment of various forms of idiopathic GN, but ACE inhibition and/or angiotensin receptor blockers to reduce proteinuria are now a mainstay of treatment for all proteinuric renal diseases.^{35,37}

Risk factors for progression of idiopathic MGN, and probably other forms of GN, include elevated serum creatinine, hypertension, male gender, age > 50, renal biopsy evidence of glomerular sclerosis and/or interstitial fibrosis, and the persistence of heavy proteinuria. Progression is rare if protein excretion remains mild or falls toward normal, whether spontaneously or with treatment. With progressive proteinuria, it is highly probable that patients will progress to ESRD.

IgA Nephropathy. IgA nephropathy and thin basement membrane nephropathy continue to be the most common findings underlying a clinical presentation of asymptomatic hematuria and IgA nephropathy is considered to be the most common form of glomerulonephritis in the world.³⁸ It is more common in the western Pacific rim where incidence in older patients is reported to be increasing,³⁹ while in Europe and the United States, lower prevalence rates have been reported. Again local variability in health screening practices and indications for kidney biopsy will influence these statistics. Investigators in Japan found previously unknown IgA mesangial nephropathy in 16% of living kidney donors.⁴⁰ Males predominate by at least 2:1, and, unlike other glomerular diseases, the prevalence is lower in African-Americans. There have been reports of familial clustering.

The pathogenesis of IgA nephropathy remains unknown but it is associated with abnormal deposition of IgA in the glomerular mesangium.³⁹ A number of genetic polymorphisms have been described that may be associated with susceptibility or progression of disease, but it is too early to tell which ones play the largest role. It is thought that multiple viral and bacterial infections can trigger a clinical exacerbation with gross hematuria and sometimes acute renal insufficiency, but again a specific agent has not been clearly identified. The clinical presentation may be quite variable and includes several syndromes. Most patients present with microscopic or macroscopic hematuria. In 30–40% of patients there may be proteinuria usually associated with microscopic hematuria, and in < 10% of patients there is acute renal insufficiency, edema and hypertension on presentation. Skin lesions (Henoch-Schonlein purpura) develop more often in children, and these patients may have skin, joint, and intestinal involvement. Glomerular IgA deposition is associated with several disorders including hepatic cirrhosis, gluten enteropathy, HIV infection, Wegener's granulomatosis, systemic lupus erythematosus, minimal change disease and membranous nephropathy.

IgA nephropathy usually has an indolent course with about 25–30% of patients reaching ESRD within 20–25 years.³⁹ Patients who present with hypertension, heavy proteinuria or an elevated creatinine are at higher risk for progression to ESRD. There is currently no definitive cure for IgA Nephropathy, but there is now more emphasis on treatment with immunosuppressive therapy for those with proteinuria (> 0.5–1.0 g/day) and/or rising serum creatinine despite angiotensin inhibition. Randomized clinical trials have demonstrated the benefit of angiotensin converting enzyme inhibitors and/or angiotensin II receptor antagonists.^{19,41} Efforts should be also be directed at controlling hypertension, goal BP 125/75, and hyperlipidemia if present. A recent multi-centered trial did not demonstrate a benefit of fish oil on progression of disease.⁴² Allograft survival in patients who receive a kidney transplant is good although recurrence of IgAN after renal transplantation is common and becoming a more important cause of graft failure as control of rejection improves.³⁹

Poststreptococcal Glomerulonephritis. The epidemiology and pathogenesis of poststreptococcal glomerulonephritis (PSGN) are well defined.⁴³ It is characterized by the onset of hematuria, proteinuria, hypertension, and sometimes oliguria and renal insufficiency 7–15 days after a streptococcal upper respiratory infection and 21–40 days after a streptococcal skin infection. Although most common in children, it can

occur at all ages. Epidemic disease occurs in crowded and unhygienic living conditions and is common in tropical countries and Third World populations, especially in association with anemia, malnutrition, and intestinal parasites. It may occur in seasonal patterns and sometimes in cycles separated by several years. Epidemic disease is now uncommon in most westernized countries, although sporadic cases continue. Asymptomatic disease is more common than clinical disease in most studies. Males predominate among patients with clinical but not subclinical disease. Only certain strains of streptococci have nephritogenic potential: nontypeable group A streptococci may also have that potential. It has been estimated that an average of 15% of infections with nephritogenic strains result in PSGN, with fully 90% of cases being subclinical, but the proportion varies with site of infection, the epidemic (if any), and the strain. Recurrence is uncommon.

PSGN is due to glomerular immune complex deposition, although the constituent streptococcal antigens are still being identified. A genetic predisposition is evidenced by attack rates in siblings of index cases of up to 37.8% after throat infections and 4.5% after skin infections. A streptococcal origin of acute GN is suggested if cultures or antigen tests have been positive for streptococci, or serum levels of antistreptolysin O (ASO) antibodies are elevated after throat infections (60–80% of cases), or if antihyaluronidase and anti-deoxyribonuclease antibodies are elevated after skin infections. A transient depression of serum complement helps differentiate PSGN from some other forms of GN. Renal biopsy is rarely indicated.

Prevention of PSGN involves improved nutrition, hygiene, and living conditions. Antibiotic treatment of streptococcal infections does not prevent PSGN, although it can confound the diagnosis by reducing ASO antibody production. Treatment does, however, reduce spread of streptococci to contacts and lessen their risk of getting PSGN. Prophylactic treatment for subjects at risk is recommended during epidemics and for siblings or families of patients with PSGN. When active disease is clinically severe, control of volume status and blood pressure is critical.

Urine abnormalities may persist for months after the acute attack. However, with follow-up limited to 10–15 years, studies of broad populations rather than of subjects initially hospitalized show complete recovery for most children, with rapidly progressive acute disease in less than 0.1% and chronic renal failure in less than 1%. More recently an epidemic episode due to group C *Streptococcus zooepidemicus* was described in Brazil.⁴⁴ Of the original group of 134 patients, three patients died in the acute phase and five patients required chronic dialysis. Of 69 patients examined after a mean of two years, 42% had hypertension, 34% had microalbuminuria and 30% had reduced renal function.⁴⁴ Adults have about twice the rate of long-term urine abnormalities as children, and chronic renal failure is more common, although still exceptional. Superimposed hypertension, renal changes with aging, and the hyperperfusion phenomenon might contribute to such a course.

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is the most common genetic renal disorder and the fourth most common single cause of ESRD in the United States.¹⁰ It is characterized by fluid-filled cysts in the kidney, which can compress surrounding tissue leading to renal insufficiency and eventually ESRD. It occurs in every one of 400–2000 live births, and an estimated 500,000 people have the disease in the United States.⁴⁵ Approximately 86% of patients with ADPKD have an abnormality in a gene on chromosome 16 (PKD1 gene locus), and most of the remaining patients have an abnormal gene on chromosome 4 (PKD2 gene locus)⁴⁶ The phenotype associated with PKD2 is usually less severe although penetrance can be variable for both. Approximately 10% of patients have a new mutation with no family history of ADPKD.

Abnormalities in the regulation of cell growth, epithelial fluid secretion and extracellular matrix metabolism contribute to the clinical problems associated with ADPKD. Renal manifestations of ADPKD include hematuria, urinary tract infections, flank pain, nephrolithiasis,

hypertension, and the most serious, renal failure. Approximately 45% of patients will have end-stage renal disease by 60 years of age. Currently there is no curative treatment for ADPKD. Cyst unroofing, dietary protein restriction and inhibition of the renin-angiotensin-aldosterone axis have not been shown to clearly delay progression of disease. Control of hypertension to < 140/90 is beneficial and should be aggressively pursued although it does not change the rate of progression of disease. Urinary tract infections should be treated immediately.

Extrarenal manifestations include hepatic cysts, cardiac valve abnormalities, colonic diverticula, hernias, and intracranial saccular aneurysms. Rupture of the intracranial aneurysms is associated with high morbidity and mortality, and screening is recommended for high-risk patients, such as those with a positive family history of intracerebral bleed, warning symptoms, a previous rupture, or a high-risk occupation where loss of consciousness would place the patient or others at risk.

The diagnosis of ADPKD has traditionally been done by ultrasound or CT evaluation of the kidneys. The sensitivity of these tests is not very high when used in patients under 20–25 years of age although ultrasound has been shown to be fairly sensitive and well standardized for patients > 30 years. Genetic testing can now establish the genotype in approximately 60% of individuals with ADPKD. If a mutation can be identified within a single family member, then testing can be used to determine if relatives carry that mutation and have ADPKD. Genetic counseling is very important for patients with this disorder.⁴⁷

Analgesic Nephropathy

Analgesic nephropathy (AAN) is a slowly progressive renal disease caused by the long-term ingestion of analgesics, classically a combination of agents including aspirin, phenacetin, acetaminophen, caffeine, and/or codeine. It was estimated to be the cause of ESRD in ~ 1–3% of patients in the United States with a higher prevalence in Australia and Europe. While the prevalence of AAN has decreased secondary to the removal of phenacetin from the market, the disease has not been completely eliminated. The prevalence of AAN has been studied more extensively in Australia and Europe where it has been more prevalent.^{48,49}

The pathogenesis of AAN is not well understood.⁵⁰ Examination of the kidneys reveals chronic interstitial inflammation and papillary necrosis. In more advanced cases, cortical scarring occurs, most pronounced over the necrotic papillae, and gross examination of the kidneys reveal them to be small and nodular. Involvement of the medulla and papillae is felt to be secondary to increased concentration of the drugs in these areas with the generation of oxygen radicals and reduction of medullary blood flow due to inhibition of prostaglandins.

AAN is more common in women. Individuals who have chronic pain for which analgesics may be consumed regularly and those with a history of peptic ulcer disease or gastric complaints are more likely to have a history of analgesic consumption. The patients may not be taking the medications at the time of presentation, but it is estimated that at least 1–2 kg of an offending agent need to have been ingested at some time to cause significant renal disease. The urinalysis may be normal or show pyuria, bacteriuria, and proteinuria, which is usually mild. Reduced ability to concentrate urine and renal tubular acidosis may occur, and there may be evidence for papillary necrosis when the kidneys are imaged as well as the reduced size and nodularity previously noted.

In addition to being the sole cause of ESRD in some cases, analgesic use contributes to more minor degrees of renal dysfunction in many other cases, and it is very probable that it contributes to the decline in renal function in patients with other underlying causes of renal insufficiency. The nephrotoxicity of nonsteroidal anti-inflammatory agents (NSAIDs) has been recognized for some time now and is characterized by one of several presentations: acute renal failure secondary to renal vasoconstriction; interstitial nephritis with or without nephrotic syndrome and minimal change disease; hyperkalemia; sodium and water retention; and papillary necrosis. People with underlying volume depletion and/or those with chronic renal insufficiency have a higher risk of developing problems. Most of these conditions

are reversible. NSAIDs are nonselective inhibitors of cyclooxygenase. Of the two related isoforms, COX-2 is constitutively expressed and is the predominant form in the kidneys. Selective COX-2 inhibitors, introduced more recently for their favorable GI side-effect profile, have also been shown, not surprisingly, to cause nephrotoxicity.⁵¹

AAN is preventable, and renal disease has been shown to decrease with decreased availability of agents such as phenacetin. The United States National Kidney Foundation published a position paper regarding analgesic use. It has been recommended that over-the-counter combination analgesics be eliminated and all prescription combination analgesics have a warning on them regarding the risk of renal damage.⁵² Aspirin as a single agent does not appear to impair renal function when used in therapeutic doses, especially the small doses recommended for prevention of cardiovascular events. There is an increased risk of larger doses leading to reversible deterioration of renal function in patients with underlying renal disease, and renal function should be monitored. For patients without liver disease, acetaminophen remains the nonnarcotic analgesic of choice, particularly for patients with underlying renal disease. Habitual consumption should be discouraged as a case-control study done in Maryland, Virginia, West Virginia, and Washington, DC suggests that there may be an increased risk of renal insufficiency in patients who have taken large amounts over a lifetime.⁵³ Prolonged regular use of NSAIDs and COX-2 inhibitors have recently been suspected of having adverse cardiac as well as renal effects and prolonged use should be discouraged.⁵⁴ Renal function should be monitored if regular use is necessary. NSAIDs should be avoided altogether in pregnancy. Use of NSAIDs in combination with other analgesics needs to be prospectively evaluated and should be avoided at this time.

Acute Renal Failure

Acute renal failure (ARF) is characterized by a relatively acute deterioration in renal function. Because defining the exact rate and nature of the deterioration is difficult to do, ARF is not well defined and therefore, it is difficult to compare rates and outcomes. Most cases of community-acquired ARF have a single, treatable cause of renal failure that is either prerenal (secondary to vomiting, poor intake, diarrhea, glycosuria, gastrointestinal bleeding and diuretics) or postrenal (secondary to prostate enlargement from hyperplasia or carcinoma).⁵⁵ It is not very common and the prognosis is usually good.

The incidence of hospital-acquired ARF is increasing with one study showing an incidence of 4.9% in the 1970s and another 7.2% in the mid-1990s.^{56,57} It is more common in patients with underlying chronic kidney disease, 15.7% versus 5.3% in patients with normal renal function.⁵⁷ Greater than 60% of patients with hospital-acquired ARF have had more than one renal insult. It is frequently caused by decreased renal perfusion usually secondary to volume contraction, poor cardiac output or sepsis. In one study postoperative patients accounted for 18% of all ARF, and contrast media and aminoglycosides combined accounted for another 19%. Prognosis appears to correlate with the severity of renal insufficiency and degree of oliguria/anuria.⁵⁶

The frequency of ARF in intensive care units ranges from 6 to 23%. Nearly all of these patients have had multiple renal insults, and it is frequently seen in the context of multiorgan failure. Survival is significantly reduced in these patients, especially in the presence of multiorgan failure.

ARF caused by blood loss and crush injuries is common during war and natural disasters. ARF secondary to general trauma has declined, as has pregnancy-related ARF. Abortion contributed to much of ARF in the past, and now preeclampsia/eclampsia and uterine hemorrhage cause the majority of pregnancy-related ARF. ARF is being seen more commonly now in patients with AIDS, malignancy, and sepsis. The use of NSAIDs and angiotensin converting enzyme inhibitors may also contribute to the development of ARF in patients with underlying renal hypoperfusion. ARF rates secondary to contrast and antibiotics appears to be stable.

Despite increasing awareness of the etiology of ARF and advancing technology, the mortality of ARF has not decreased significantly

over the last several decades. It appears that ARF is not just a marker for severe comorbid conditions, and even mild episodes are associated with increases in morbidity and mortality. A multicenter observational study of 17,126 ICU patients in Austria showed a mortality of 62.8% in patients requiring renal replacement therapy compared to 38.5% in matched controls without ARF.⁵⁸ The exact reason for the above is not clear, and may be related to distant biochemical and histologic effects of renal ischemia on cardiac function and other organ systems yet to be elucidated. While short-term survival is not good for patients with ARF in the ICU, the long-term outcomes in patients who survive to hospital discharge are much better. Of the patients who survived to hospital discharge among 979 critically ill patients with ARF requiring renal replacement therapy (RRT), six month survival was 69% and five year survival 50%.⁵⁹ Preventive options are limited for most causes of ARF and consist of blood pressure support, optimization of cardiac function, treatment of underlying conditions including sepsis and limiting nephrotoxic agents. Volume expansion with normal saline and use of nonionic radiocontrast agents have been shown to reduce the incidence of radiocontrast nephropathy while the role of N-acetylcysteine (NAC) remains less clear. Lack of significant toxicity and low cost have contributed to an increase in its use prior to radiographic procedures which is probably appropriate.⁶⁰

The Program to Improve Care in Acute Renal Disease (PICARD) is an observational registry of critically ill patients with acute renal failure maintained at five geographically diverse academic medical centers in the United States.⁶¹ The PICARD investigators have used their registry to examine the epidemiology of ARF or acute kidney injury (AKI) as it now being called as well as the pathobiology of ARF. Timing and modality of RRT in treatment of ARF remain controversial. There is no clear indication that continuous forms of RRT are superior, but they are frequently used in patients with hemodynamic instability.

Renal Disease and Illicit Drugs

Renal disease related to drug abuse is being recognized more frequently as a cause of renal disease and has great social and economic impact. According to the 2001 National Survey on Drug Abuse, an estimated 15.9 million Americans currently use illicit drugs, and a significant positive and independent association between illicit drug use and risk for mild kidney function decline has been demonstrated.⁶² Several syndromes are recognized.

Focal segmental glomerulosclerosis (FSGS) occurs in intravenous heroin addicts, with heavy proteinuria and progression to renal failure in a few months to years. There is no effective treatment. An immunologic mechanism is postulated, mediated through a response to heroin itself, to adulterants, or to infectious agents. FSGS associated with drug abuse occurs in all ethnic groups, but rates are especially high in young black males, leading to the hypothesis that parental drug abuse unmasks a genetic predisposition to FSGS in blacks similar to that seen for hypertension. It has been suggested that heroin nephropathy is on the decline with an increase in HIV nephropathy.

Renal deposition of amyloid, associated with chronic inflammation and infection, occurs in skin poppers.⁶³ Proteinuria and sometimes renal failure is diagnosed at an average age of 41 years, 10 years older than FSGS patients. In a New York City autopsy series, 5% of addicts and 26% of addicts with suppurative skin infections had unsuspected renal amyloidosis.⁶⁴

Other renal diseases related to drug abuse include immune-complex GN associated with infectious endocarditis or hepatitis B antigenemia, membranoproliferative GN and cryoglobulinemia associated with hepatitis C, necrotizing vasculitis related most strongly to amphetamine abuse, tubular dysfunction and occasionally acute renal failure in solvent sniffers, acute renal failure due to muscle breakdown, and the renal syndromes of human immunodeficiency virus infection.

Treatment of addicts with ESRD is often complicated by non-compliance, communicable diseases like hepatitis B, hepatitis C, and AIDS, and, with continued drug abuse, infection and clotting of vascular access and recurrence of disease in kidney transplants. Because

of the interfaces of drug addiction with crime, some of these subjects are incarcerated. Such problems accentuate dilemmas about responsibility for personal health and allocation of limited resources.

Renal Disease and the Human Immunodeficiency Virus

The understanding of renal disease associated with human immunodeficiency virus (HIV) infection continues to evolve. Renal disease may occur at all stages of HIV illness including the asymptomatic stage, but many complications are associated with acute illness. Patients may develop fluid and electrolyte disorders, acid–base disturbances, and/or acute renal failure secondary to volume depletion, infections, drugs and/or abnormal adrenal steroid synthesis and secretion. There is also a histologically unique nephropathy associated with HIV called HIV nephropathy. Patients with this disorder usually have nephrotic range proteinuria accompanied by renal insufficiency which progresses fairly rapidly to ESRD (within three to six months).⁶⁵ On exam there is frequently no significant peripheral edema or hypertension, and the kidneys are normal to increased in size despite being highly echogenic. This may be contrasted to heroin-associated nephropathy in which hypertension is frequently present, the kidneys are small, and progression to ESRD is a slower process. Although it is not always possible to distinguish HIV-associated disease from other forms of glomerulosclerosis, the following pathological findings are felt to be very suggestive of HIV nephropathy and include focal to global glomerulosclerosis, collapse of the glomerular tuft, severe tubulointerstitial fibrosis with some inflammation, microcyst formation, tubular degeneration, and characteristic tubuloreticular inclusions.⁶⁵

While HIV nephropathy was initially noted to be more prevalent in young black males who were IV drug users; it is now known that it can occur in most risk groups. It has even been reported in children of HIV-infected mothers, where vertical transmission accounts for infection. Development of HIV nephropathy also appears to be more likely in blacks and males.

Patients who are HIV positive and develop acute renal failure due to acute tubular necrosis (ATN) tend to be younger than the non-HIV positive patient with ATN, and frequently the ATN is associated with sepsis. Treatment consists of conservative, supportive care, and hemodialysis may be used until kidney function returns. Much of the ATN associated with HIV disease is preventable if patients receive adequate volume support prior to use of nephrotoxic agents or during episodes of hypovolemia and if attention is paid to medication/antibiotic dosing.⁶⁶

There is no proven cure for HIV nephropathy. There has been a decrease in overall morbidity and mortality due to HIV disease with the introduction of highly active antiretroviral therapy (HAART) in the mid 1990s.⁶⁷ The use of protease inhibitors may be helping to reduce the likelihood of progression of HIV nephropathy to ESRD. Except for a peak in 1998, the number of new ESRD patients with HIV nephropathy has remained stable since 1995; 836 patients were reported in 2002.²⁶ This coincides with the advent of HAART therapy. Symptom-free HIV-positive subjects with chronic renal failure can do quite well on dialysis, but chronic dialysis of subjects with clinical AIDS is complicated by concomitant illness, cachexia, infectious hazards, and prolonged hospitalizations, and survival is usually short.

Hemolytic Uremic Syndrome (HUS)

HUS is one of several clinical syndromes that affect the vasculature of the kidney producing a thrombotic microangiopathy. It is discussed here in relationship to a bacterium, *Escherichia coli* O157:H7, which has emerged as a major cause of diarrhea, particularly bloody diarrhea, in North America. Several studies⁶⁸ have now shown that this *E. coli* is responsible for most cases of HUS in children, which is a major cause of acute renal failure. While it has been isolated in many parts of the world, its prevalence is unknown. Infections are more common in

warmer months, and transmission may occur via undercooked beef, fecally contaminated water, and person-to-person. Infection has also been associated with unpasteurized commercial apple juice.⁶⁹

Patients typically present with abdominal cramping, diarrhea (nonbloody or bloody), nausea, and vomiting. HUS has been reported to occur in about 6% of patients with infection and is diagnosed anywhere from 2 to 14 days after the onset of the diarrhea. It is more likely to affect young children and the elderly. It is characterized by microangiopathic hemolytic anemia, thrombocytopenia and renal failure. Central nervous system manifestations may be present. The renal pathologic lesions include edematous intimal expansion of arteries, fibrinoid necrosis of arterioles, and edematous subendothelial expansion in glomerular capillaries.⁷⁰

There is no specific therapy which has proven to be effective for HUS secondary to *E. coli* infection. Treatment involves supportive therapy with red blood cell transfusions, control of hypertension and dialysis if necessary. Apheresis may be helpful in more severe cases with central nervous system involvement. The prognosis for typical childhood HUS is usually good. Neurological involvement, prolonged oliguria, elevated white blood cell count, age under two years, and atypical presentations have been associated with a poorer prognosis. The mortality rate is 3–5%, and about 5% of patients who survive have severe sequelae, including ESRD.

To prevent *E. coli* infection, patients should be counseled about the risk of eating undercooked ground beef. A thorough history should be taken in suspected cases, and cases should be reported early to prevent spread. Hand washing is essential in institutions such as day-care centers and nursing homes, and children with a known infection should be kept at home. Use of antidiarrheals for acute infectious diarrhea is potentially dangerous.

► URINARY TRACT DISEASES

Urinary Tract Infections

Urinary tract infections (UTIs) are one of the most common types of infection encountered in clinical medicine. They account for more than 7 million physician visits and necessitate or complicate over 1 million hospital admissions annually in the United States.⁷¹ The estimated annual cost of UTIs is \$1.6 billion for evaluation and treatment.^{72,73} Uncomplicated UTIs are most frequent in young, healthy, sexually active women with normal urinary tracts, and it is estimated that 40–50% of women will have a UTI in their lifetime. UTIs are also common in preschool girls, in postmenopausal women, and in elderly men and women, especially those who are institutionalized and those with indwelling urinary catheters. UTIs in older men are often associated with urinary retention due to benign prostatic hypertrophy (BPH), urethral strictures, calculi, and debilitating illness and are thus designated as complicated and more difficult to treat. Boys and men with normal urinary tracts are not often affected, but men can acquire bacterial UTIs through heterosexual or homosexual intercourse, and recurrent UTI is the hallmark of chronic prostatitis. Use of immunosuppressive drugs and recent antibiotic use also place individuals at risk for complicated UTIs.

Most infections are localized to the bladder and urethra, but some involve the kidneys and renal pelvis (pyelonephritis), or the prostate. UTIs rarely lead to renal damage or failure unless they are associated with diabetes, pregnancy, reflux, obstruction, or neurogenic bladder. Diabetic persons with UTIs risk papillary necrosis and sepsis; abortion and other complications can result from UTIs in pregnancy; and morbidity and mortality of UTIs increase greatly in the elderly and in those with complicating conditions, such as spinal cord injury.

Most UTIs in young women are new events, are uncomplicated, and caused by *E. coli* and other bowel organisms that enter the bladder through the short female urethra. Subjects with recurrent UTIs have increased density of bacterial receptors on epithelial cell surfaces in the vagina and bladder. Women with blood groups A and AB who are nonsecretors of blood group substance are at greater risk.

Intercourse, diaphragm use, and failure to void after intercourse all increase risk. Women who have closely spaced recurrent infections with the same organisms or who have pyelonephritis should be evaluated for urinary tract abnormality, as should men with persistent infection. Complicated UTIs are frequently caused by non-*E. coli* pathogens such as *Enterococcus* and *Klebsiella* species.

In the presence of symptoms, white cells and bacteria in a clean-void midstream specimen of urine usually indicate a UTI. The usual bacterial count considered diagnostic on urine culture is $>100,000/\text{mL}$, but many patients have lower counts, including half of those with cystitis and most patients with urethral syndromes. Enterobacteriaceae colony counts as low as $100/\text{mL}$, have a sensitivity and specificity for UTI of 94% and 85%. Subjects with recurrent UTIs can perform an easy and relatively inexpensive dip slide urine culture technique, and self-treatment under medical guidance can be initiated. Many uncomplicated UTIs are treated based on symptoms and pyuria alone.

Screening for bacteriuria in symptom-free persons is not cost-effective and may lead to inappropriate treatment, drug reactions, and selection of resistant organisms. Treatment of asymptomatic bacteriuria is not generally recommended, except in pregnant women, diabetics, and children with vesicoureteral reflux. Symptomatic infections are treated by antimicrobials, and infections associated with sexual intercourse can usually be prevented by single-dose prophylactic therapy. Repeated or prolonged antibiotic treatment can select antibiotic-resistant organisms. Some broad-spectrum antimicrobial agents may not pose this threat and are sometimes used for prophylaxis in subjects with chronic infections.

UTIs are the leading form of nosocomial infection and are especially common in nursing homes. Spread can be reduced by separation of catheterized patients from others who are debilitated or catheterized, and by washing the hands after patient contact. For subjects who require temporary catheterization, risks of infection can be reduced by aseptic insertion, curtailed duration of catheterization, and meticulous care of the patient and the drainage system. However, infection remains very common in persons with chronic indwelling catheters. The bacterial flora in the urine of catheterized subjects is in flux, colonization is often asymptomatic, and repeated courses of treatment are not advised.

Interstitial cystitis is a syndrome of unknown etiology and pathogenesis with symptoms similar to UTIs. It is characterized by nocturia, urgency, and suprapubic pressure and pain with filling of the bladder. It is more common in women and may be the cause of multiple outpatient physician visits. Therapy is frequently not completely effective, and it can occasionally lead to a significant decrease in quality of life.

Urinary Stone Disease

Urinary stone disease has been recognized since antiquity and continues to be a major cause of morbidity. The incidence is increasing not only in the United States, but Sweden and Japan, and is felt to be related to increased dietary animal protein intake.⁷⁴ It is estimated that 10–12% of individuals will have a kidney stone during their lifetime. Risk factors for development of a stone include male sex, Caucasian race, obesity, hypertension, diet high in animal protein and salt but low in calcium and fluid, hot climate or occupation, and family history of kidney stones.⁷⁵ Drugs such as triamterene and indinavir may precipitate as crystals in the urinary tract. The initial stone usually presents in the third to fifth decade and up to 50% will have a recurrent stone within five years. Geographic variations in incidence may be attributable to temperature and sunlight exposure as well as access to beverages. Urinary stone disease is relatively uncommon in underdeveloped countries where bladder stones predominate.

Most kidney stones (75–85%) contain calcium, primarily in the form of calcium oxalate. The remaining stones contain uric acid, struvite, cystine, and/or small amounts of other compounds. The content of the stone may give clues to the underlying physiological problem, especially in the case of stones without calcium. Disorders associated with stone disease include primary hyperparathyroidism, renal tubular

acidosis, enteric hyperoxaluria, sarcoidosis, cystinuria, and urinary tract infection or obstruction. Risk factors associated with calcium stone formation include low urinary volume, hypercalciuria, hyperoxaluria, hypocitraturia, and hyperuricosuria.⁷⁶

Most patients present with flank pain radiating into the groin which is abrupt in onset and frequently severe. Gross or microscopic hematuria, dysuria, frequency, nausea, and vomiting can be present. Occasionally, patients will have an ileus. Diagnosis is confirmed by abdominal plain film, ultrasound, IVP, or CT. Most kidney stones pass spontaneously, and the patient can be supported with analgesics. Urological intervention may be required including endoscopic “basket” removal, extracorporeal shock-wave lithotripsy (ESWL), endoscopic lithotripsy with ultrasonic, electrohydraulic, or laser probes, open pyelolithotomy, and percutaneous nephrolithotomy. These procedures have reduced the costs, morbidity, and hospitalization rates compared with open surgery which is rarely used anymore.

The primary objective of therapy is to prevent the formation of recurrent stones. Patients are asked to strain their urine for stone collection and composition analysis. Conservative management includes analgesics, adequate fluid intake ($\geq 2 \text{ L/day}$), dietary sodium restriction, and moderate calcium intake. Maintaining calcium intake helps prevent absorption of oxalate and outweighs the risk associated with high calcium intake. Oxalate restriction, reduction of animal protein intake, thiazide diuretics, and other agents may also be recommended depending on the patient’s underlying medical condition and the cause of stone formation.

Prostate Cancer

Prostate cancer is a disease of aging men and is an important public health problem in the United States as well as throughout the world. It is the most commonly diagnosed cancer in men except for non-melanoma skin cancer in the United States and is the second leading cause of male cancer deaths.⁷⁷ It is the sixth most common cancer in the world and the most common cancer in men in Europe, North America, and some parts of Africa. It accounts for 15.3% of all cancers in men in developed countries and 4.3% in developing countries.⁷⁸ The incidence, prevalence, and mortality rates from prostate cancer increase with age, particularly after 50 years of age. In the National Cancer Institute’s Surveillance Epidemiology and End Results (SEER) program, the incidence of new cases in white U.S. men in 1995 was approximately 200, 600, and 900 per 100,000 in men aged 50–59, 60–69, and 70 or over.⁷⁹ The incidence of prostate cancer peaked in the early 1990s, in part, but not entirely, related to use of the prostate specific antigen (PSA) as a screening tool. There was a subsequent decline during the mid 1990s perhaps related to the screening effect. The incidence is steadily rising again in almost all countries.⁷⁸ While the presence of histologic cancer appears to be related to age, both genetic and environmental risk factors appear to increase the development of clinical prostate cancer. Asian men have a lower incidence of and mortality due to clinical prostate cancer while Scandinavian men have a higher incidence. Men tend to take on the risk of their host country, but race is also a factor. African-American men have a higher incidence than do black men in Africa or Asia and a higher incidence than white men or Hispanics. African-American men are also diagnosed with later-stage disease, and their survival rates are shorter. In general, socioeconomic status is not felt to explain the incidence differences between African-Americans and whites. There is an increased risk of prostate cancer for men with a family history. While both prostate cancer and BPH appear to be androgen dependent, it has been difficult to determine whether or not BPH is a risk factor for prostate cancer because both are common in men as they age. The risk attributable to prostatitis has similar issues. Associations with venereal disease, sexual activity, and smoking have been proposed but not proven. Studies have been conflicting regarding vasectomy, but more recent studies have not found evidence for an association. Additional possible risk factors include elevated testosterone levels, a high intake of dietary fat, and other dietary habits. Several genetic mutations/deletions and polymorphisms may be associated with an increased risk for prostate cancer but no single prostate cancer gene has been

identified. These findings may support increased attention to screening in certain populations such as African-Americans.

Patients typically present with symptoms of urinary tract obstruction (urgency, nocturia, frequency, and hesitancy) from an enlarged prostate gland causing bladder-neck obstruction. These symptoms are essentially the same as those seen with BPH. Other less common signs and symptoms include back pain from vertebral metastases and new onset of impotence. A few patients have symptoms related to urinary retention caused by bladder-neck obstruction, bilateral hydronephrosis from periaortic lymph node enlargement, or spinal cord compression from epidural extension. Rarely, patients present with an enlarged supraclavicular node or elevation of liver tests. Prior to the increased use of the PSA for screening, diagnosis was made by assessing symptoms, performing a digital rectal exam of the prostate, and transrectal ultrasonography. Today an increasing number of patients present with elevated PSA levels obtained during screening exams. PSA is a glycoprotein produced almost exclusively by prostate epithelial cells. While PSA is elevated in men with prostate cancer and has been shown to correlate with tumor burden in men with established cancer, it is not specific for prostate cancer and may be elevated in cases of prostatitis and BPH. Concerns have been raised about its use as a screening tool leading to increased detection of insignificant cancers with an increase in expense and side effects. Survival studies have yet to show a reduction in mortality because of screening. Currently there is no consensus on the use of the PSA and digital rectal examination for the detection of prostate cancer, but experts do agree that providing education to patients on the risks and benefits of screening is important and some groups recommend annual screening for males > 50 years with a life expectancy of at least 10 years.

Many of the small, well differentiated carcinomas remain confined to the prostate and are only detected at autopsy (latent or autopsy cancers). The majority of tumors never become active, but how to predict which will become so has not been determined. It is estimated that the average lifetime risk of developing prostate cancer in an American male is 17% while the risk of dying from prostate cancer is only 3%.⁷⁷ Management of prostate cancer may include watchful waiting, hormonal therapy, prostatectomy, and radiation therapy depending on the stage of the cancer. Treatment considerations should include age, life expectancy, comorbid conditions, side effects, and costs. Urinary incontinence, impotence, and radiation morbidity comprise the treatment related adverse effects.

The Prostate Cancer Prevention Trial looked at the use of finasteride, a 5-alpha reductase inhibitor which prevents conversion of testosterone to dihydrotestosterone, as a chemo preventive agent. While it prevented or delayed the number of cancers and reduced urinary tract symptoms, it also was associated with an increased risk for high-grade prostate cancer.⁸⁰ Currently there are ongoing trials looking at similar agents as well as chemotherapy for various stages of diagnosed prostate cancer. Multiple clinical trials are currently underway which should help identify the best method of screening, as well as chemo preventive therapies and therapies for the various stages of prostate cancer.

Prostatic Hyperplasia

BPH is extremely common in older men. It has been reported that BPH can be found in 88% of autopsies in men ≥ 80 years of age, and that nearly 50% of men ≥ 50 years of age have symptoms compatible with BPH.⁸¹ Three men in ten may ultimately require surgery. While it frequently causes morbidity, it is rarely responsible for death.

The cause of BPH is not known. Necessary conditions are the presence of androgens and aging. No associations with sociocultural factors, sexual behavior, use of tobacco or alcohol, or other diseases have been consistently demonstrated, and there is no firm evidence that BPH is a precursor of prostate cancer.

In BPH subjects, a period of rapid prostate enlargement occurs, usually after the age of 50, followed by stabilization. Clinical symptoms result from variable compression of the bladder outlet, with difficulties in urinating, and the potential for infection, complete obstruction, and bleeding. Age, urinary flow rate and prostate volume are risk factors for acute urinary retention. Serum PSA is a strong predictor of growth and may be a predictor of risk for urinary retention. The natural history of symptoms can vary greatly. Many subjects have mild symptoms for years, with no change, and many do not require surgical intervention. Evaluation consists of rectal examination, blood chemistry studies, urinalysis and culture, measurement of residual urine volume after voiding, cystourethroscopy, urodynamic evaluation, and imaging or contrast studies of the kidneys and ureters.⁸²

Many patients can be observed while monitoring for progression. Alpha-adrenergic blocking agents and 5-alpha reductase inhibitors have been shown to delay progression of the symptoms and when used in combination may have a greater effect. Alpha reductase inhibitors may reduce the size of the prostate and when used alone or in combination with alpha-adrenergic blocking agents in some studies have been shown to reduce the incidence of acute urinary retention.⁸³ For more severe symptoms, prostatectomy is the standard of care. Indications for surgery vary, need better definition, and should be weighed against the comorbidities, complications, outcomes, and costs. Firm indications are acute urinary retention, hydronephrosis, recurrent urinary infections, severe hematuria, severe outflow obstruction, and urgency incontinence. Persistence of symptoms and impotence can result from surgery in a significant minority of subjects. Newer procedures are being developed including the use of prostatic stents, balloon dilatation of the prostate, laser prostatectomy, and microwave hyperthermia.

▶ END-STAGE RENAL DISEASE (ESRD)

Overall, it is estimated that there are more than 19 million adult Americans affected by chronic kidney disease. ESRD or stage 5, the most advanced stage, affects more than 500,000 people in the United States.²⁶ Although the prevalent ESRD rate has risen each year since 1980, the rate of increase has been falling steadily since the early 1990s. (Fig. 63-1) ESRD can be caused by many renal diseases and by some

Figure 63-1. End-stage renal disease (ESRD). Adjusted prevalence rates and annual percentage change. (Source: USRDS, 2004.)

urinary tract diseases when they are complicated by chronic obstruction or infection. In the United States, diabetic nephropathy is the primary diagnosis in 45% of the prevalent ESRD population, up from 20% of the prevalent population in 1980.²⁶ Hypertension is the primary diagnosis in 30% of the prevalent ESRD population and glomerulonephritis causes < 20 % of ESRD compared with 40% in 1980. There appears to be a slowing of the number of patients whose ESRD is caused by more rare diseases such as Wegener's granulomatosis and lupus, but the number of patients with a primary diagnosis of multiple myeloma/light chain nephropathy continues to increase, perhaps partially related to the aging of the population plus other unknown factors.²⁶

At the end of 2002, approximately 309,000 ESRD patients were being treated in the United States and its territories. Another 122,375 patients had renal transplants. Both the incidence rate and the prevalence rate of ESRD increase with age until 65–74 years at which point the rates decline. The median age of incident ESRD patients has increased 21% from 54 in 1978 to 65 years in 2002. The greatest increase has occurred among Asian patients, from 44 in 1978 to 65 in 2002, a 47% increase. Patients age 45–64 accounted for 35% of the incident population. Only 13% of the incident population is age 20–44, compared to 27% in 1980. Patients age 75 and older now make up > 25% of the population, up from only 8% in 1980. Definite gender and racial differences do exist and they have remained consistent in the United States over the past two decades. While blacks constitute 12–13% of the general population in the United States, they constitute 29–33% of the ESRD population, a rate fourfold higher than that of whites. The ESRD incidence and prevalence rates for Asian/Pacific Islanders and Native Americans are between those of whites and blacks. Prevalent rates of ESRD among males are 1.4 times higher than among females, a rate that has been very consistent over the years.²⁶

The first patient with chronic renal disease was dialyzed in 1960 by Belding Scribner. During the 1960s the development of vascular access, chronic peritoneal dialysis catheters, and improved immunosuppressive therapies allowed patients to choose between some form of hemodialysis, peritoneal dialysis or renal transplantation. With the enactment of the Social Security Amendments of 1972 (effective in July 1973), treatment became available for all patients with ESRD. Currently patients choose one of the above therapeutic modalities based on a combination of medical and social factors. Transplantation is regulated by national and local policies, physician and patient preference, and availability of donor organs.

Relatively recent advances in the treatment of ESRD patients include high flux, bicarbonate hemodialysis using biocompatible membranes, automation of peritoneal dialysis, use of vitamin D derivatives for treatment of renal osteodystrophy, and genetically engineered erythropoietin for treatment of anemia reducing the need for blood transfusions. Continued advancements in the development of immunosuppressive agents have improved the one-year first-time cadaveric transplant survival from 70% in 1984 to > 90% in 2002.

Despite improvements in dialysis technology, mortality remains high. For example, at age 45 the expected remaining lifetime of a white male with ESRD on dialysis is 7.1 years compared with 32.8 years for a white male from the general population. Survival for patients receiving a transplant cannot be directly compared to that for dialysis patients due to selection factors; however, in the example above survival extends to 18.7 years when including all patients with ESRD including those who received a renal transplant. Gross mortality rates of dialysis patients in the United States have been the highest in any surveyed country in the past and continue to be high. An increase in dialysis dose above the currently recommended dose did not improve survival as demonstrated in the HEMO study.⁸⁴ Age, primary diagnosis, acceptance of patients with multiple comorbid conditions, transplantation rates, dose of dialysis delivered, patient compliance, nutrition, and pre-dialysis therapy all may contribute to this phenomenon. The total Medicare payment per patient year (average for all ESRD patients of all ages) is estimated to be \$46,490 for the years 1998–2002. Transplantation costs are less than those for dialysis patients, at \$18,394 per patient year. This does not include the cost of organ procurement for transplantation patients. Annual costs for all ESRD patients rise with

age, primarily due to the decline in transplantation rate for elderly patients. Diabetic patients with ESRD are more costly to treat than nondiabetics.²⁶

Current efforts are being directed at determining if short daily dialysis or prolonged nocturnal dialysis will decrease the mortality rates of ESRD patients. In addition, the Health Care Financing Agency is sponsoring a national study to determine whether more effective and cost efficient ESRD care can be provided using a capitated system. It should be noted that in many low-income countries, such as India, dialysis is currently not available to > 95% of the population.¹

► THE FUTURE

Progress has clearly been made in several areas of renal and urinary tract diseases. In addition to the decrease in the death rate from hypertensive renal disease, renal infections, and renal congenital abnormalities, the incident rate for ESRD caused by diabetes has begun to stabilize, and that for ESRD caused by glomerulonephritis has begun to decline.²⁶ As a specific example, since 1992 the incident rates for white patients with diabetic ESRD have declined 46% in those age 20–29 and 9% in those age 30–39. While rates for blacks remain the highest, the rate of increase appears to be slowing as does the rate of rise for Hispanics. The incident and prevalent rates for Native Americans has slowed but this is due to a change in census methods and will need to be reevaluated.²⁶

While progress has been made, the number of patients age 45–64 reaching ESRD continues to increase in a linear fashion and, with the exception of pediatric patients, waiting times for transplantation continue to increase. Thus, the cost of providing care has not decreased. In 2002, total Medicare costs for the ESRD program were \$17 billion. There also continues to be a discrepancy in incidence of ESRD among racial groups, with the rates among black patients having actually increased 27% for those age 20–29 and 62% for those age 30–39. This may reflect the fact that blacks are more likely to have type II diabetes which is becoming more prevalent as obesity becomes a major public health problem. This, along with the increased incidence of hypertension in blacks, makes it more difficult to treat. While development of strategies such as the Kidney Early Evaluation Program (KEEP) to provide early detection and prevent progression of CKD is clearly important, society will need to address how best to support these programs both in terms of manpower and monetary funds. For westernized societies who have already made a large commitment to life support for subjects with irreversible renal failure, supporting the funding for these programs will continue to be a challenge. For all societies, the challenge remains to better understand the factors that contribute to ESRD. The public health perspectives of many of these diseases remain poorly defined and the distributions and natural histories of many remain obscure. While progress has been made in identifying specific prevention and treatment strategies, many diseases continue to lack specific strategies, and the prevalence of ESRD will continue to increase.

Epidemiological and health services research in renal and urinary tract diseases continues to expand. In the United States the NIDDKD have collated existing data on rates, morbidities, mortalities, resource utilization, and costs. They are supporting studies on diabetic renal disease, hypertension, progressive glomerular sclerosis, progression of renal failure, urinary tract obstruction, prostatic hyperplasia, prostatic cancer screening, and urinary incontinence. They have also established research initiatives in interstitial cystitis, HIV-associated renal disease, the genetic basis of polycystic kidney disease, and renal disease and hypertension in minorities. The CDC's National Health and Nutrition Examination Survey (1988–1994 & 1999–2000) collected information that will yield estimates of rates of kidney stones, UTIs, interstitial cystitis, prostate disease, bladder dysfunction, microalbuminuria, and elevated serum creatinine levels and will give us a better understanding of the risk factors for the various stages of chronic kidney disease. To prevent or delay kidney damage, the National Kidney Foundation has established a free screening program (KEEP) for individuals at increased risk for developing kidney

disease with the goals of raising awareness about kidney disease, providing free testing and encouraging people “at risk” to visit a doctor and follow the recommended treatment plan. Educational information and support is also being provided. The well established United States Renal Data System continues to provide valuable longitudinal data on patients with ESRD. Results of the NIH sponsored Frequent Hemodialysis Nocturnal Trial evaluating the effect of daily and nocturnal dialysis on morbidity and mortality in ESRD patients should be available within the next two to three years.⁸⁴

The results of these initiatives should invigorate the practice of nephrology, guide judicious apportionment of limited resources, support formulation of rational health policy, and improve the overall outcomes for patients with renal and urinary tract disease.

Diabetes

Janice C. Zgibor • Janice S. Dorman • Trevor J. Orchard

► INTRODUCTION

Diabetes is an important chronic disease both in terms of the number of persons affected and the considerable associated morbidity and early mortality. In this review we will focus on the epidemiology and public health implications of diabetes. Diabetes is a chronic disease in which there is a deficiency in the action of the hormone insulin. This may result from a quantitative deficiency of insulin, an abnormal insulin level, resistance to its action, or a combination of deficits. Two major forms of the disease are recognized: type 1 diabetes (formerly referred to as insulin-dependent diabetes) which comprises about 10% of all cases, and type 2 diabetes (formerly referred to as non-insulin-dependent diabetes), which accounts for about 90% of the cases. Type 2 diabetes may occasionally occur as a result of other diseases such as acromegaly and Cushing's syndrome. Metabolic disorders such as hemochromatosis, can also cause the disease. Diabetes can also be drug induced, for example, by steroids and possibly by the thiazide diuretics and oral contraceptives. Finally, diabetes may occur secondary to disease processes directly affecting the pancreas, such as cancer or chronic pancreatitis, which destroy the insulin-producing beta cells in the pancreatic islets (of Langerhans). However, these are relatively rare causes of diabetes.

In addition to these primary and secondary types of diabetes, two further classifications of abnormalities of glucose tolerance are of note. Gestational diabetes occurs during pregnancy but typically remits shortly after delivery. Impaired glucose tolerance (IGT) or impaired fasting glucose (IFG), now termed "prediabetes," are conditions in which blood glucose is elevated but not high enough to be classified as diabetes. Nonetheless these conditions may carry some increased risk of large vessel (e.g., coronary heart) disease.¹ Both gestational diabetes² and prediabetes³ carry an increased risk for the subsequent development of type 2 diabetes. The types of diabetes and clinical stages are outlined in Fig. 64-1.

The other potential precursor to type 2 diabetes is the metabolic syndrome. The metabolic syndrome represents a set of risk factors that predispose individuals to both cardiovascular disease and diabetes. Metabolic syndrome factors include abdominal obesity, atherogenic dyslipidemia (elevated triglyceride levels, smaller LDL particle size, and low HDL cholesterol), raised blood pressure, insulin resistance (with or without glucose intolerance) and prothrombotic and proinflammatory states. The metabolic syndrome is associated with the prediction of both diabetes and cardiovascular disease independent of other factors.⁴ It is hypothesized that clinical improvement in these factors may prevent or delay the onset of diabetes and cardiovascular disease.

► DIAGNOSIS

The diagnosis of type 1 diabetes is fairly straightforward. Type 1 diabetes often, though by no means always, has its onset in childhood. Classically the child will have symptoms of excessive thirst

(polydipsia), excessive urination (polyuria), and weight loss. In a child with high blood sugar, these symptoms almost invariably point to type 1 diabetes. Patients lose virtually all capacity to produce insulin and without treatment they develop severe metabolic disturbances, including ketoacidosis and dehydration, which can lead to death. As death from ketoacidosis is largely preventable, the continuing though small number of deaths from this cause represents a challenge to our preventive health services.^{5,6} In an international study, wide variations in mortality from acute diabetes complications were noted, with high rates in Japan and low rates in Finland.⁷ This variation was thought to reflect disease incidence (low in Japan and high in Finland) and resulting availability of skilled health care.⁷

Type 2 diabetes usually presents in adulthood. In the past, the terms non-insulin-dependent, maturity-onset, and mild diabetes have been used. These terms are somewhat misleading, since type 2 diabetes may present in youth and the complications may be far from mild. Patients with type 2 diabetes, however, produce some insulin, although its secretion is often delayed, and there is usually some resistance to its action in the peripheral tissues. This resistance is often associated with elevated concentrations of insulin, particularly in newly recognized cases. However, concentrations are now recognized to be low in many type 2 diabetes subjects, especially after accounting for obesity and using more specific assays.⁸ In type 2 diabetes, often the diagnosis is not made on the basis of classic symptoms of diabetes but rather on the presentation of one of the complications. Such complications can be macrovascular (accelerated atherosclerosis with coronary artery, peripheral vascular or cerebrovascular manifestations), microvascular (with disease of the small vessels in the kidneys or the eyes), or neuropathic (which may take the form of a variety of neurological syndromes). In addition, the disease may also be recognized as a result of routine screening for elevated blood glucose or by the presence of glucose in the urine. Some cases, however, may be diagnosed because of classic symptoms. (Table 64-1)

Over the years, both the diagnostic criteria and dose of glucose in the standard test for type 2 diabetes (i.e., the oral glucose tolerance test (OGTT)) have varied. Current diagnostic criteria from the American Diabetes Association (ADA) and the World Health Organization (WHO) are presented in Table 64-2. The WHO and ADA criteria differ in that the ADA relies on IFG while the WHO relies on both fasting and post challenge (2 hour) glucose levels. The preference for using a fasting test only, rather than a full OGTT is largely based on the concept that diagnostic testing would be easier and therefore more frequent.

The controversy surrounding these tests is based on the fact that these diagnostic tests may identify somewhat different populations.⁹ Further, data from the Cardiovascular Health Study (CHS) in older Americans suggests that IGT is more predictive of CVD than its fasting corollary IFG.¹⁰ The impact of these different criteria on the prevalence of diabetes has been studied by many investigators.

Stages Types	Normoglycaemia	Hyperglycaemia			
	Normal glucose tolerance	Impaired glucose regulation IGT and/or IFG	Diabetes mellitus		
			Not insulin requiring	Insulin requiring for control	Insulin requiring for survival
Type 1 • Autoimmune • Idiopathic	←				→
Type 2* • Predominantly insulin resistance • Predominantly insulin secretory defects	←			→	→
Other specific types*	←			→	→
Gestational diabetes	←			→	→

Figure 64-1. Disorders of glycemia: etiological types and clinical stages. *In rare instances patients in these categories (e.g., Vacor Toxicity, Type 1 presenting in pregnancy, etc.) may require insulin for survival. (Source: Adapted from the World Health Organization.50)

Because of changes in the criteria for the diagnosis of type 2 diabetes, estimates of the prevalence and temporal trends of type 2 diabetes are difficult, if not impossible, to evaluate. Furthermore, the different criteria for type 2 diabetes used by different research groups and countries make geographical comparisons difficult. As major efforts are made to identify the specific genetic abnormalities in diabetes and to define the disease on the basis of genotypic rather than phenotypic expression, such as hyperglycemia and insulin levels, there may soon be yet another way of classifying diabetes. Furthermore the development of the glycosylated hemoglobin (GHB) test,¹¹ which provides an integrated measure of hyperglycemia over the prior two to three months, represents another dimension that may add to the ability to define diabetes. Currently, clinicians use hemoglobin A1c for this test, although it is not accepted for diagnostic purposes due to methodological variation and other considerations.

Heterogeneity in Primary Diabetes

Although the two different primary types of diabetes have been described, the classification of diabetes into these groups is not simple. For example, children classified with type 1 diabetes may actually have Maturity-Onset Diabetes (MODY),^{12,13} which is characterized by an autosomal dominant pattern of inheritance and a low frequency ketoacidosis. Children in such families, however, are often treated with insulin, although they do not depend on insulin for their survival and actually have type 2 diabetes. Since MODY is uncommon, accounting for <5% of all type 2 diabetes cases, this section will focus on type 1 diabetes and type 2 diabetes. Similarly 5–10% of adults with presumed type 2 diabetes, have evidence of autoantibodies seen in type 1 diabetes, and may have an incomplete form of type 1 diabetes, sometimes called LADA (latent autoimmune diabetes of adulthood).¹⁴

Type 1 Diabetes

Descriptive Epidemiology. Type 1 diabetes is caused by the autoimmune destruction of the beta cells of the pancreas, and represents approximately 10% of all cases with diabetes. At present, lifelong insulin therapy is the only treatment for the disease. Without exogenous insulin injections, individuals with type 1 diabetes will not survive. Although the prevalence of type 1 diabetes is <1% in most populations, the geographic variation in incidence is

enormous, ranging from <1/100,000 per year in China to approximately 40/100,000 per year in Finland (Fig. 64-2).¹⁵ The only chronic childhood disorder more prevalent than type 1 diabetes is asthma. It has been estimated that approximately 20 million people worldwide, mostly children and young adults, have type 1 diabetes.¹⁶

The incidence of type 1 diabetes is increasing worldwide at a rate of about 3% per year.¹⁷ This trend appears to be most dramatic in the youngest age groups, and is completely unrelated to the current increase in type 2 diabetes in children. More children with beta cell autoantibodies, a hallmark of type 1 diabetes, are being diagnosed with the type 1 diabetes around the world each year. Although the peak age at onset is at puberty, type 1 diabetes can also develop in adults. Epidemiologic studies have revealed no significant gender differences in incidence among individuals diagnosed before age 15.¹⁸ However, after age 25, the male-to-female incidence ratio is approximately 1:5. Significant differences have also been reported depending on socioeconomic status, however results have been conflicting.¹⁹ Incidence of type 1 diabetes in Lithuanians aged 0–39 years varies by the urban-rural setting, and the time change differs for men and women during 1991–2000. There is also a notable seasonal variation in the incidence of type 1 diabetes in many countries, with lower rates in the warm summer months, and higher rates during the cold winter.²⁰

Genetic Susceptibility. First degree relatives have a higher risk of developing type 1 diabetes than unrelated individuals from the general population (approximately 6% vs. <1%, respectively).²¹ These data suggest that genetic factors are involved with the development of the disease. At present, there is evidence that more than 20 regions of the genome may be involved in genetic susceptibility to type 1 diabetes. However, none of the candidates identified have a greater influence on type 1 diabetes risk than that conferred by genes in the HLA (Human Leukocyte Antigens) region of chromosome 6. This region contains several hundred genes known to be involved in immune response. Those most strongly associated with the disease are the HLA class II genes (i.e., HLA-DR, DQ, DP). These molecules are involved in the processing of antigens from inside the cell to its surface in order to stimulate an immune response. However, it has become apparent that neither genetic nor environmental risk factors alone contribute to the development of type 1 diabetes. Rather, it is clear that gene-environmental interactions are involved.

TABLE 64-2. CRITERIA FOR THE CLASSIFICATION OF DIABETES

Classification	ADA ¹⁶⁸	WHO
Diabetes*	<p>A. Symptoms (polyurea, polydipsia, unexplained weight loss) of diabetes and casual (anytime of day without regard to meals) plasma glucose ≥ 200mg/dL or</p> <p>B. ^{a,§} Fasting plasma glucose ≥ 126 mg/dL or</p> <p>C. 2 hour plasma glucose ≥ 200 mg/dL during an OGTT[‡]</p>	<p>A. Confirmatory symptoms or</p> <p>B. ^{a,§} Fasting plasma glucose ≥ 126 mg/dL and 2 hour plasma mg/dL glucose ≥ 200 during an OGTT[‡]</p>
Prediabetes [†]	Impaired fasting glucose Fasting glucose 100mg/dL to 125 mg/dL	Impaired glucose tolerance 2 h plasma glucose [§] 140 mg/dL to 199 mg/dL
Gestational diabetes [¶]	Two or more of the following values after a 100-g oral glucose load after an overnight fast (8–14 h) Fasting ≥ 95 mg/dL (plasma) 1 h ≥ 180 mg/dL (plasma) 2 h ≥ 155 mg/dL (plasma) 3 h ≥ 140 mg/dL (plasma)	Women meeting the WHO criteria for diabetes or IGT are classified as having gestational diabetes mellitus

*Diabetes is subclassified as:
 Gestational: Diabetes or impaired glucose tolerance is first recognized during pregnancy. Usually remits postpartum a criteria need to be present on at least two occasions in the absence of unequivocal hyperglycemia.
[†]Prediabetes = impaired fasting glucose or impaired glucose tolerance.
[‡]Following 75 g or oral glucose load.
[§]Fast = no caloric intake for ≥ 8 hours.
[¶]Risk factor assessment should be done at first prenatal visit.

A. IDDM1. The HLA class II genes, also referred to as insulin-dependent diabetes mellitus 1 (IDDM1), contribute approximately 40–50% of the heritable risk for type 1 diabetes.²² When evaluated as haplotypes, DQA1*0501-DQB1*0201 and DQA1*0301-DQB1*0302 are most strongly associated type 1 diabetes in Caucasian populations. They are in linkage disequilibrium with DRB1*03 and DRB1*04, respectively. Specific DRB1*04 alleles also modify the risk associated with the DQA1*0301-DQB1*0302 haplotype. Other reported high risk haplotypes for type 1 diabetes include DRB1*07-DQA1*0301-DQB1*0201 among African-Americans, DRB1*09-DQA1*0301-DQB1*0303 among Japanese, and DRB1*04-DQA1*0401-DQB1*0302 among Chinese. DRB1*15-DQA1*0602-DQB1*0102 is protective and associated with a reduced risk of type 1 diabetes in most populations. Recent reports suggest that other genes in the central, class I, and extended class I regions may also increase type 1 diabetes risk independent of HLA class II genes.^{23,24}

Individuals with two high risk DRB1-DQA1-DQB1 haplotypes have a significantly higher type 1 diabetes risk than individuals with no high risk haplotype. The type 1 diabetes risk among those with only one susceptibility haplotype is also increased, but the effect is more modest. As shown in Table 64-3, relative risk estimates range from 10 to 45 and 3 to 7, respectively, for these groups, depending on race.²¹

TABLE 64-3. SEVERAL TYPE 1 DIABETES SUSCEPTIBILITY GENES

Gene	Locus	Variant	Estimated RR [†]
<i>HLA-DQB1</i>	6p21.3	*0201 & *0302	3–45
<i>INS</i>	11p15.5	Class I	1–2
<i>CTLA4</i>	2q31–35	Thr17Ala	1–2

[†]RR = relative risk

In terms of absolute risk, Caucasian individuals with two susceptibility haplotypes have an approximately 6% chance of developing type 1 diabetes through age 35 years. However, this figure is substantially lower in populations where type 1 diabetes is rare (i.e., < 1% among Asians). In addition to *IDDM1*, two other genes are now known to influence type 1 diabetes risk.²⁵ These include insulin (*INS*) and *cytotoxic T lymphocyte-associated 4* (*CTLA-4*).

- B. *INS*.** The *INS* gene, located on chromosome 11p15.5, has been designated as *IDDM2*. Positive associations have been observed with a nontranscribed variable number of tandem repeat (VNTR) in the 5' flanking region.^{26,27} There are two common variants. The shorter class I variant predisposes to type 1 diabetes (approximate relative increase: 1–2), whereas the longer class III variant appears to be dominantly protective. The biological plausibility of these associations may relate to the expression of insulin mRNA in the thymus. Class III variants appear to generate higher levels of insulin mRNA than class I variants. Such differences could contribute to a better immune tolerance for class III-positive individuals by increasing the likelihood of negative selection for autoreactive T-cell clones. The effect of *INS* appears to vary by ethnicity, with lesser effects in non-Caucasian populations.²⁸
- C. *CTLA-4*.** The *CTLA-4* gene is located on chromosome 2q31–35,²⁵ where multiple type 1 diabetes genes may be located. *CTLA-4* variants have been associated with type 1 diabetes, as well as other autoimmune disease. *CTLA-4* negatively regulates T-cell function. However, impaired activity, which has been associated with the Thr17Ala variant, may increase type 1 diabetes risk. Overall, the relative increase in risk for the *CTLA-4*Ala17 variant has been estimated as approximately 1.5.

Environmental Risk Factors. The epidemiological patterns described above suggest that environmental factors contribute to the etiology of the type 1 diabetes. In particular, the recent temporal increase in type 1 diabetes incidence points to a changing global environment rather than variation in the gene pool, which require the passage of multiple generations. Twin studies also provide evidence for the importance of environmental risk factors for type 1 diabetes. Type 1 diabetes concordance rates for monozygous twins are higher than those for dizygous twins (approximately 30% vs. 10%, respectively).²² However, most monozygous twin pairs remain discordant. Thus, type 1 diabetes cannot be completely genetically determined. Environmental risk factors are thought to act as either “initiators” or “accelerators” of beta cell autoimmunity, or “precipitators” of overt symptoms in individuals who already have evidence of beta cell destruction.²⁹

They also may function by mechanisms that are directly harmful to the pancreas, or by indirect methods that produce an abnormal immune response to proteins normally present in cells. The type 1 diabetes environmental risk factors that have received most attention are viruses, infant nutrition, and hygiene.

- A. *Viruses*.** Enteroviruses, especially Coxsackie virus B (CVB), have been the focus of numerous ecologic and case-control studies.³⁰ CVB infections are frequent during childhood and are known to have systemic effects on the pancreas. Recent

prospective studies are helping to elucidate the role of viruses to the etiology of type 1 diabetes. For example, enteroviral infections occurring as early as *in utero* appear to increase a child's subsequent risk of developing the disease.^{31,32} Other viruses, including mumps,³³ cytomegalovirus,³⁴ rotavirus,³⁵ and rubella,³⁶ have also been associated with the disease.

- B. *Nutrition*.** Another hypothesis that has been the subject of considerable interest relates to early exposure to cow's milk protein and the subsequent development of type 1 diabetes. The first epidemiologic observation of such a relationship was by Borch-Johnsen et al., who found that type 1 diabetes children were breast-fed for shorter periods of time than their non-diabetic siblings or children from the general population.³⁷ The authors postulated that the lack of immunologic protection from insufficient breast-feeding may increase risk for type 1 diabetes later during childhood. It was also postulated that shorter duration of breast-feeding may indirectly reflect early exposure to dietary proteins that stimulate an abnormal immune response in newborns. Most recently it has been hypothesized that the protective effect of breast-feeding may be due, in part, to its role in gut maturation.^{38–40} Breast milk contains growth factors, cytokines, and other substances necessary for the maturation of the intestinal mucosa. Breast-feeding also protects against enteric infections during infancy, and promotes proper colonization of the gut. Interestingly, enteroviral infections can also interfere with gut immunoregulation, which may explain the epidemiologic associations between viral infections and type 1 diabetes.
- C. *Hygiene*.** The role of hygiene in the etiology of type 1 diabetes is also currently being explored.^{41,42} It has been hypothesized that delayed exposure to microorganisms due to improvements in standard of living hinders the development of the immune system, such that it is more likely to respond inappropriately when introduced to such agents at older (compared to younger) ages. This explanation is consistent with recent reports indicating that factors such as day care attendance,⁴¹ sharing a bedroom with a sibling, and contact with pets are protective against type 1 diabetes.⁴² Further studies are needed to determine if improved hygiene can explain the temporal increase in the incidence of type 1 diabetes worldwide.

Treatment and Prevention of Type 1 Diabetes. At the present time, there is no way to prevent type 1 diabetes. Lifelong insulin injections are the only available treatment for the disease. Although a cure for type 1 diabetes is currently unavailable, several large multinational investigations have been designed to evaluate a variety of primary and secondary disease interventions. The tested interventions have included prophylactic nasal insulin (Diabetes Prediction and Prevention Project [DIPP] in Finland),⁴³ oral and injected insulin (Diabetes Prevention Trial-1 [DPT-1] in the U.S.),⁴⁴ as well as high doses of nicotinamide (European Nicotinamide Diabetes Intervention Trial [ENDIT]),⁴⁵ and the avoidance of cow's milk exposure during the first six months of life (trial to reduce in genetically at-risk [TRIGR] in Finland, U.S. and other countries).⁴⁶ These investigations focus on “prediabetic” individuals identified from families with at least one child with type 1 diabetes. DIPP and TRIGR use *HLA-DQB1* screening and recruit only individuals at increased genetic risk. The remaining trials recruit relatives with evidence of beta cell autoimmunity as a pre-clinical marker for disease. To date, none of these interventions have prevented or delayed the onset of type 1 diabetes.^{44–46} However, with the formation of *Type 1 Diabetes TrialNet*⁴⁷ a collaborative network of clinical centers and experts in diabetes and immunology, new intervention strategies are currently being planned. It is ultimately hoped that through genetic testing, individuals at high risk for type 1 diabetes could be identified prior to the onset of the disease—at a time when primary prevention strategies could be safely administered. It is most likely that such predictive genetic testing would be offered to families with an affected individual before it was made available to the general population.

Type 2 diabetes

Epidemiology. Type 2 diabetes is more difficult to define than type 1 diabetes. The rates among and within countries vary dramatically, partially depending on the specific classification criteria used for type 2 diabetes. Worldwide, it is estimated that in 2000, 171 million people had diabetes. The prevalence is expected to increase to 366 million by 2030 according to estimates from the WHO.⁴⁸ Type 2 diabetes occurs in all races, but the prevalence tends to be higher among American Indians, Micronesians, Polynesians, African-Americans, and Mexican Americans.⁴⁹ The prevalence of diabetes is higher in developed countries compared to developing countries, however a considerable increase in prevalence is already being observed in developing nations due to urbanization and westernization.⁵⁰ For example, in communities where there has been rapid economic development, such as in Korea⁵¹ and among the Pima Indians⁵² there appears to be a marked and rapid increase in the incidence and prevalence of type 2 diabetes.⁵¹ In 2005, 14.6 million persons in the United States were estimated to have diagnosed diabetes according to the National Health Interview Survey. This represents an increase from 5.8 million in 1980. It is also estimated that almost one-third as many cases (6.2 million) of type 2 diabetes are undiagnosed. This is made clear by data from the National Health and Examination Survey where the overall prevalence of diagnosed and detected diabetes in the adult U.S. population (> 20 years) is estimated to be about 7% (~20.8 million), with 1.4 million newly diagnosed cases each year.⁵³

Risk Factors. A pattern of increasing mean weight of the population parallels the increasing prevalence of type 2 diabetes.⁵⁴ Similarly, within a population there is a strong correlation between degree of obesity and risk of type 2 diabetes.^{52,55,56} The prevalence of obesity in the United States, defined as a Body Mass Index (BMI) of greater than 30 kg/m², has increased from 12% in 1991 to 19.8% in 2000,⁵⁷ for a total of 44.3 million obese adults. The highest prevalence for obesity was reported in Mississippi at 25.9% in 2001. A corresponding increase is reported in diabetes prevalence from 4.9% in 1990 to 7.3% and 7.9% in 2000 and 2001 respectively.⁵⁷ Interestingly, within a country such as the United States, one generally finds an inverse relationship between obesity and socioeconomic class,⁵⁸ with higher rates of type 2 diabetes in lower socioeconomic groups.⁵⁹ However, a risk factor associated with higher socioeconomic status is decreased physical activity. As socioeconomic status increases, the overall level of physical activity generally declines, especially that related to work. Further, lower rates of physical activity are found in ethnic minorities.⁶⁰ Thus, at the same time that caloric intake is increasing, physical activity is decreasing, most likely leading to an increased prevalence of obesity within the population. Data from the South Pacific suggest that physical activity itself may be an independent risk factor for type 2 diabetes, separate from obesity,⁶¹ while a recent prospective study in the U.S. also suggests reduced physical activity predicts type 2 diabetes.⁶² According to national data from 2003, approximately one-half of U.S. adults age 18–44 achieved recommended levels of physical activity (at least 30 min/day at least 5 days per week).⁶⁰

Nutrition plays a role in both diabetes risk and prevention, while no clear evidence exists supporting a low fat diet for diabetes risk or prevention, the type and quality of fat may be more important than total fat intake. Substituting unsaturated fat for saturated and trans fat are important, however, for prevention strategies. Also, substituting complex carbohydrates such as whole grains for refined grain foods will help individuals achieve a healthy body weight and thus prevention of diabetes and/or cardiovascular disease.⁶³

Genetic Factors. Genetic factors play an extremely important role in the development of type 2 diabetes. In a large study of twins Pyke found that the concordance rates for type 2 diabetes among monozygotic twins was over 90% compared to 50% for type 1 diabetes.⁶⁴ Twin studies, however, do not provide the complete story. In recent years there have been numerous studies of the relationship of genetic markers to the development of type 2 diabetes as well as of type 1 diabetes. Although HLA genes are related primarily to the risk of

developing type 1 diabetes, they may also play a role in type 2 diabetes.⁶⁵ Several candidate genes have been found to contribute to type 2 diabetes susceptibility, including mutations in the insulin gene,⁶⁶ the glucokinase gene,⁶⁷ and mitochondrial gene.⁶⁸ However, it is unlikely that any of these alterations explain the genetic susceptibility to type 2 diabetes on a population basis. Thus family and pedigree studies are still needed to determine the contribution of these genetic markers to the development of type 2 diabetes.

Diabetes Prevention. The development of type 2 diabetes is a two-stage process, with the first stage being resistance to insulin's action (likely exacerbated by obesity and physical inactivity) and the second stage being failure of the pancreas to increase insulin secretion enough to overcome this resistance. This theory receives support from a number of reports including one from the Pima Indians, which showed differing predictive values of fasting and post challenge insulin values for developing type 2 diabetes consistent with a hyperinsulinemic phase followed by eventual insulinopenia.⁶⁹

The interaction between obesity and physical inactivity in relation to the prevention of type 2 diabetes has been studied recently through well-conducted randomized controlled trials. These trials applied sound methods for implementing diabetes prevention strategies, and will be briefly reviewed. The focus of these trials was lifestyle modification including weight loss and increased physical activity. The Da Qing study⁷⁰ followed 577 subjects with IGT from local clinics. Subjects were randomized at the clinic level to diet, exercise, diet and exercise, or a control group and followed for six years. Intervention groups experienced a significantly lower incidence of type 2 diabetes compared to controls (31%, 46%, 42%, and 67.7% respectively). A lower incidence of diabetes was also seen in those with lower BMIs. Similar to the Da Qing trial, the Finnish Diabetes Prevention Study⁷¹ examined whether the onset of type 2 diabetes could be prevented through lifestyle modification in subjects with IGT. Five hundred twenty-two subjects were randomized to an intervention group that received individualized counseling aimed at weight reduction, dietary fat reduction, saturated fat reduction, increased dietary fiber, and increased physical activity. The trial demonstrated that lifestyle changes significantly reduced the risk of diabetes in middle-aged, overweight subjects. After a modest (4.7%) weight loss, those in the intervention group experienced a 58% reduction in incidence of diabetes over a mean follow-up of 3.2 years. Moreover, blood pressure, triglycerides, and high-density lipoprotein cholesterol levels also improved significantly. The study to prevent non-insulin-dependent diabetes mellitus (STOP-NIDDM) trial⁷² randomized 714 (IGT) subjects to acarbose and 715 subjects to a control group. After a mean follow-up of 3.3 years, compared to controls, there was a 25% relative risk reduction in the incidence of diabetes. Finally, in the Diabetes Prevention Program (DPP)⁷³ 3234 subjects with IGT were randomized to placebo, metformin (850 mg twice daily) or intensive lifestyle modification. The lifestyle modification consisted of weekly one-on-one counseling for a 16-week curriculum during the first 24 weeks of the study. Subsequent visits were held about once per month. The goal of the lifestyle arm was 7% weight loss and 150 minutes per week of physical activity. Intensive lifestyle modification reduced the incidence of type 2 diabetes in persons at high risk by 58% in comparison to the metformin study group in which incidence was reduced by 31%. The DPP has also shown that these interventions reduce the incidence of new metabolic syndrome by 41% (lifestyle) and 17% (metformin) compared with placebo.⁷⁴

Screening

The recent emphasis on diabetes prevention has prompted a growing number of blood glucose screenings. The purpose of screening is to identify asymptomatic individuals who may have diabetes, however, screening is not the same as diagnosis, as diagnostic tests are performed in individuals with signs and symptoms of the disease.⁷⁵ Further, the effectiveness of diagnosing an asymptomatic individual is still speculative.⁷⁶ Screening in the community setting outside a health care setting may not be completely effective because of the

possibility of inadequate follow-up after a positive test, or repeat testing in those who are negative. Therefore this type of screening is currently not recommended.⁷⁵ Screening by a health care professional or within the health care setting for pre-diabetes and diabetes should be considered in those ≥ 45 years of age, particularly in those with a BMI ≥ 25 kg/m². In those < 45 years of age, screening should be considered if they have another risk factor for diabetes (e.g., physically inactive, first-degree relative with diabetes, member of a high-risk ethnic population, delivered a baby weighing > 9 pounds or diagnosed with gestational diabetes, are hypertensive ($\geq 140/90$ mmHg), high-density lipoprotein cholesterol (HDLc) level < 35 mg/dL and/or a triglyceride level > 250 mg/dL, have polycystic ovarian syndrome (PCOS), previously tested and had IGT or IFG, other clinical conditions associated with insulin resistance, or a history of vascular disease).⁷⁵ Any screening should be followed by education about results and risk for future disease. A policy ensuring adequate follow-up should also be in place.

► MORBIDITY AND COMPLICATIONS OF DIABETES

Prior to the introduction of insulin in 1922 by Banting and Best, life expectancy of patients with type 1 diabetes was about 1–2 years. After the development and widespread use of insulin, there was a dramatic increase in life expectancy for patients with type 1 diabetes. Suddenly those with type 1 diabetes could lead relatively normal lives. However, 20–30 years later the long-term sequelae of type 1 diabetes began to become evident.

Both type 1 diabetes and type 2 diabetes patients are at risk for these long-term complications. Complications come mainly from disorders of the circulation, either macrovascular, including accelerated atherosclerosis resulting in stroke, heart and peripheral vascular disease, or microvascular disorders of the kidney and retina, as well as neuropathy. The complications appear to be similar for both type 1 diabetes and type 2 diabetes, although the prevalence may be somewhat higher in type 1 diabetes mainly due to longer diabetes duration in those with type 1. The relationships with age and duration also vary between the two types of diabetes, partly because of the younger age of onset of type 1 diabetes (which leads to complications at a younger age) and the difficulty of determining the onset of type 2 diabetes (which means complications are often present at the onset of known disease). However, careful analysis controlling for these time-dependent variables suggests that the incidence of the microvascular complications is remarkably similar by true duration.⁷⁷ The following discussion will mainly focus on type 1 diabetes, since these data are more complete.

Mortality

Mortality rates for people with diabetes are two- to threefold higher than those without diabetes, with cardiovascular disease as the leading cause of death.⁷⁸ In an international study, Diabetes Epidemiology Research International (DERI), mortality in young cohorts of type 1 diabetes cases from four different countries (the United States, Israel, Japan, and Finland) was investigated. The study showed tremendous variation in diabetes-related mortality. In addition to the high mortality from acute complications, the Japanese cohort also had a high mortality from renal disease (276/100,000/y) compared to Finland (16/100,000/y, $p < 0.05$).⁷⁹ Data from the Children's Hospital of Pittsburgh diabetes registry as of 1982, demonstrated a sevenfold increased risk of death overall, and a 20-fold increased risk in those over the age of 20 compared to the general population.⁸⁰ While over half of the deaths were due to renal disease, there was an 11-fold increased risk of death from CVD compared to the general population of the same age. These findings were particularly significant in the 30+ age group. The Steno group further demonstrated the strong effect of renal disease with those developing proteinuria, having an eightfold greater risk of coronary heart disease (CHD) than a matched group who did not develop proteinuria.⁸¹ These results were supported by Krolewski et al.,⁸² where in type 1 diabetes subjects seen at

the Joslin Clinic,⁸¹ CHD deaths occurred early after the third decade of age, and over the next 25 years. One-half died of or had CHD. The Allegheny County registry has more recently shown an improvement in 20-year survival by diagnosis cohort (1965–69, 1970–74, 1975–79).⁸³ When cause-specific mortality was examined, the County cohort combined with mortality from the Epidemiology of Diabetes Complications Study cohort, a significant decline in renal⁸⁴ and acute complications⁸⁵ was noted. There were, however, differential results by race where African-Americans experienced a fivefold excess mortality due to acute complications.⁸⁵ This decline in mortality may be explained by only a decline in acute complications, but microvascular complications as well. Data from the Steno Clinic in Denmark showed declining trends in microvascular complications by diagnosis cohort at 20 year duration.⁸⁶ Similar results were also shown in the EDC cohort in those who had reached 20 years of diabetes duration; however there was not a corresponding decline in CHD,⁸⁷ although the number of events was relatively small. Longer follow-up is necessary to determine any definitive trends in macrovascular disease.

Diabetic Retinopathy

Epidemiology. The prevalence of diabetic retinopathy is highly related to diabetes duration for both type 1 and type 2 diabetes.⁷⁵ After 20 years of type 1 diabetes, virtually 100% of patients show some evidence of damage to the retina called background retinopathy. Similar prevalence rates are seen in type 2 diabetes for patients treated with insulin, although rates are lower (around 55%) for those not on insulin.⁸⁸ In addition, as many as 70% of patients who have type 1 diabetes⁸⁹ and 30% of patients who have type 2 diabetes⁸⁸ on insulin may develop proliferative changes in the eyes that may lead to blindness.

In 2002, three million adults age 18 or greater reported some type of visual disturbance. In the 20–74 age group, diabetes is the leading cause of blindness in the United States, and is responsible for approximately 12,000–24,000 new cases of blindness year. The crude prevalence of retinopathy in people over the age of 40 is 40.3% in people with diabetes compared to 3.4% in the general population.⁹⁰

Prevention. Retinopathy was the primary outcome of a major U.S. study called Diabetes Control and Complications Trial (DCCT).⁹¹ This landmark study clearly demonstrated the value of intensive therapy (with normal blood sugars as a goal) for type 1 diabetes subjects in preventing or delaying the microvascular complications. Progression of retinopathy was reduced by 54% in the intensive therapy group compared to conventional therapy over a mean follow-up period of 6.5 years.⁹² In type 2 diabetes, the United Kingdom Prospective Diabetes Study (UKPDS) demonstrated that achieving near normal glycemic control, reduced the risk of two-step progression of diabetic retinopathy by 21%,⁹³ while reducing blood pressures resulted in a 34% risk reduction for deterioration of retinopathy by two or more steps over 7.2 years of follow-up.⁹⁴

As diabetic retinopathy can be detected before it threatens vision, blindness due to diabetic retinopathy can be prevented in many cases. Detecting and treating diabetic eye disease can reduce vision loss by 50–60%.⁹⁴ The Diabetic Retinopathy Study has demonstrated that individuals with severe diabetic retinopathy can be treated successfully and their vision preserved with laser photocoagulation therapy.⁹⁵ It is thus important that patients and physicians be educated about the need for frequent eye examinations and that adequate clinical treatment for diabetic retinopathy be available in the community.

Renal Disease

Epidemiology. Diabetic renal disease is a major cause of morbidity and mortality among those with diabetes.^{5,79,96,97} Diabetes is currently the leading cause of treatment for end stage renal disease (ESRD), accounting for 44% of the 42,813 new ESRD cases during 2001. According to the 2001 data, 142,963 people with diabetes have ESRD and are living on chronic dialysis or with a kidney transplant. Diabetes increases the risk of renal failure 17- to 20-fold. Approximately 40% of people with type 1 diabetes^{97,98} eventually develop significant

clinical proteinuria and renal disease. Studies from Pittsburgh⁸⁹ suggest that around 70% of type 1 diabetes subjects will eventually have some degree of renal damage (i.e., including those with microalbuminuria—a more modest degree of abnormal urinary albumin excretion that is predictive of more advanced disease). The relative risk of mortality from renal disease for persons with diabetes compared to the general population is highest for those in the 15- to 44-year age group, consistent with a higher prevalence and severity in type 1 diabetes.⁹⁶

Prevalence rates are somewhat lower in type 2 diabetes overall, partly because the later age of onset means many patients may have died from heart disease before there has been sufficient duration to develop renal disease. Despite recent advances in the diagnosis and treatment of renal failure in diabetes, the problem has not been resolved.

Prevention. The presence of microalbuminuria appears to predict the subsequent development of diabetic nephropathy and end stage renal failure.⁹⁹ Of particular note is the value of ACE inhibitors and angiotensin receptor blockers (ARB) in slowing the progression of renal disease.⁷⁵ The effect of ACE inhibitors appears to be independent of any blood pressure lowering effect. Hypertension, which may be primary or secondary to the renal disease, accelerates the development of renal failure. Lipid disturbances may also predict the development of microalbuminuria.¹⁰⁰ The major predictor, however, of the development of early diabetic renal disease is poor glycemic control.¹⁰¹ The value of an intensive therapy regimen was also clearly demonstrated in the DCCT (54% reduction).⁹¹ Interestingly, in type 1 diabetes, insulin resistance is emerging as a powerful predictor of nephropathy¹⁰² as well as coronary artery disease (CAD), which may explain their association. Further, much attention is being paid to the genetic susceptibility to nephropathy, as there is clearly a major genetic component.¹⁰³

Neuropathy

Epidemiology. Another major complication of diabetes is neuropathy. Clinically significant neurological disability usually does not occur until at least five years after the diagnosis of diabetes. The major consequences of diabetic neuropathy are pain, weakness, and loss of sensation. Parallel disorders of the autonomic nervous system may lead to problems of sexual function and urinary and gastrointestinal abnormalities. Research has focused on the metabolic causes of the nerve damage and the specific biochemical lesions that lead to neurological changes.¹⁰⁴ One recent epidemiological study has demonstrated both a high prevalence of distal symmetrical neuropathy in type 1 diabetes, 70% after 30 years,⁸⁹ and a strong relationship with cardiovascular risk factors, for example, lipid disturbances, cigarette smoking and especially hypertension.¹⁰⁵ A major problem in diabetic neuropathy is how to measure it. Multiple techniques are currently advocated.¹⁰⁵⁻¹⁰⁷ However, this further complicates determining the actual prevalence of this complication.

Prevention. It has long been recognized that strict control of blood sugar may improve neural function, for example, peripheral nerve conduction.¹⁰⁸ The DCCT and UKPDS results also confirm the value of lower blood sugar levels in preventing/delaying clinical neuropathy.^{91,93} The above findings concerning blood pressure and lipids suggest that studies to evaluate the benefits of controlling these factors may also be worthwhile. Another area that has been investigated recently is the role of a new group of drugs called aldose reductase inhibitors. Although the results have been variable, most trials to date have involved late-stage neuropathy.¹⁰⁹ A greater benefit might be seen if these metabolically active drugs were used earlier.

Macrovascular Disease and Atherosclerosis

The most convincing epidemiological evidence for increased cardiovascular disease in diabetes comes from large-scale prospective studies, many of which were primarily designed to study cardiovascular disease in the general population. Studies like Framingham¹¹⁰ have demonstrated that the diabetic individual (uniquely defined in Framingham as “glucose intolerant”) has a greatly enhanced risk and that

cardiovascular disease is the leading cause of death in those with diabetes.^{111,112} Diabetes leads to a greater than normal risk for all manifestations of atherosclerosis, including coronary, cerebrovascular, and peripheral vascular disease.^{110,113} The latter is so common in diabetes that half of all lower extremity amputations in the United States occur in persons with diabetes.⁵⁹ In the general population women have a lower risk of CHD than men, but this advantage is lost in women with diabetes, who have rates approaching those of men.^{78,114-117} A meta-analysis suggests that a reduction in the gender differential for CHD in diabetes is true for CHD mortality but not for morbidity.¹¹⁸ The survival of diabetic patients, especially women, after a cardiac event also appears to be less than that seen in the general population.^{119,120}

Although when it occurs, atherosclerosis is often more extensive in diabetic^{121,122} than in nondiabetic subjects, although not all studies show a clear relationship between blood sugar and CVD. For example in the UKPDS, HbA1c was a borderline predictor of myocardial infarction (MI) and intensive therapy had only a borderline ($p = 0.052$) 16% reduction in CHD events.⁹³ Divergent opinions also are apparent in terms of the role of blood sugar in the nondiabetic range. Some studies have shown the group with IGT to have a greater than normal risk of CVD.^{1,123} Early studies failed to show a relationship between blood glucose levels in the nondiabetic range and CVD,¹²⁴ however recent meta regression analysis and pooled analyses show a relationship in the normal glucose range.^{125,126} Recently, investigators from the Epidemiology of Diabetes Interventions and Complications Study (follow-up of the DCCT) reported on the long-term benefit of early intensive glycemic control on the incidence of CVD. Among 1375 patients, the number of incident CVD events in those intensively treated during the DCCT compared to those on conventional therapy (46 compared to 98 events).¹²⁷

The IGT stage is often characterized by hyperinsulinemia and insulin resistance. In the Paris study, in multivariate analyses, insulin concentration rather than diabetic IGT status was the stronger predictor of CHD.¹²⁸ A further factor linked with hyperinsulinemia is central adiposity, which was discussed earlier as a risk factor for the development of diabetes.^{129,130} Central adiposity is also a risk factor for CVD independent of obesity,¹³¹ a finding most clearly shown in women. Consequently a male type of fat deposition (if found in women) may be associated with hyperinsulinemia¹³² and thus may provide a marker for a metabolic derangement predisposing to both diabetes and CVD generally, and the relatively poorer cardiovascular prognosis of diabetic women. This association of central adiposity with insulin resistance and the metabolic syndrome is thought to be the prime basis of the excess CVD in type 2 diabetes and glucose intolerance and also has been proposed as a leading feature of CVD in type 1 diabetes.^{133,134}

As lipoproteins are altered in diabetes, it is tempting to hypothesize that these changes account for the increased CVD risk seen in diabetes. Many studies,^{110,111,116,129,130} have shown that serum cholesterol levels relate to CVD risk in those with diabetes in a way similar to that seen in the general population. However, total and LDL cholesterol levels are not greatly elevated in many diabetics, so the role of cholesterol in explaining the *increased* risk in diabetes is limited.¹³⁵ Data from the Multiple Risk Factor Intervention Study (MRFIT),¹³⁶ which screened over 360,000 men for CVD risk factors and subsequently followed them for mortality, suggests diabetic men had rates three times higher than nondiabetics all along the cholesterol curve. The MRFIT data is exclusively type 2 diabetes. In type 1 diabetes, as indicated earlier, it appears that the major determinant of CVD risk is proteinuria⁹⁸ although recent data suggest that hypertension, white blood cell count, HDLc, non-HDLc, diabetes duration and smoking are associated with incident CAD events.¹³⁴

If cholesterol concentration has a limited role, other lipid measures may be of greater importance to diabetes. Reports suggest that triglyceride level is an independent risk factor for CVD in diabetes.^{137,138} Furthermore, alterations in HDL concentration and lipoprotein composition occur in diabetes, which may further increase cardiovascular risk.¹³⁹ Insulin itself, beyond its effect on the lipids, can have direct effects on the arterial wall that promote

atherogenicity.^{140–142} Hyperinsulinemia has also been related to blood pressure elevation.^{143–146} The importance of insulin is also shown by its demonstration as an independent risk factor for CVD in some,^{147–150} but not all,^{151–153} prospective studies of men in the general population, however distinguishing insulin effects per se from hyperinsulinemia representing insulin resistance is difficult.

Many studies have demonstrated altered hemostatic factors including platelets and fibrinogen which may provide yet another mechanism for the enhanced CVD risk in diabetes.^{154,155} Thus it is abundantly clear that those with diabetes have severe handicaps to face in terms of cardiovascular risk above and beyond the lipoprotein disturbances.

► SUMMARY AND FUTURE

The DCCT and UKPDS have put beyond question the value of intensive therapy to lower blood sugar levels in terms of the so called triopathy of type 1 and type 2 diabetes complications (retinopathy, nephropathy, and neuropathy).¹⁵⁶ As intensive therapy with insulin also increases the risk of severe hypoglycemia⁹¹ and is difficult to translate into general practice, it would seem prudent to also focus on other CVD risk factors (e.g., hypertension and hyperlipidemia) to prevent these complications in type 2 diabetes. Studies examining cardiovascular events among people with type 2 diabetes demonstrate that controlling these risk factors can directly impact the occurrence of both new^{157–161} and repeat events.^{162–164} Two major trials^{165,166} are underway testing the value of intensive glycemic therapy in terms of CHD prevention and another trial (BARI2D) addresses the best means of treating patients with diabetes and heart disease.

While the evidence for the prevention of diabetes and its complications is clear, translation into the community of diabetes care providers and patients is difficult. The goal of prevention is to improve short and long term outcomes as well as the economic consequences of a disease. Models of chronic illness care that focus on a multilevel approach to primary and secondary prevention are necessary in order to prevent the morbidity and mortality associated with diabetes.

Respiratory Disease Prevention

David B. Coultas • Jonathan M. Samet

Diseases of the respiratory system are an important public health problem in all countries. The respiratory system, which includes the lungs and the upper airway that joins the trachea to the larynx, is exposed to a wide range of potentially injurious agents (Table 65-1). On average, an adult inhales about 5 L of air per minute; with exercise, the amount may increase 20-fold or more. With 10,000–20,000 L of air inhaled daily, agents present even in low concentrations may be toxic. The respiratory system is equipped with a remarkably effective system of defense mechanisms against inhaled particles and gases. Disease may result, however, if an acute exposure overwhelms the defenses (e.g., toxic gas inhalation), if an agent is particularly toxic even at low concentrations (e.g., toluene diisocyanate), if exposure is sustained (e.g., cigarette smoking), or if the exposed person is particularly susceptible (e.g., asthmatics).

Respiratory diseases are major causes of disability and death worldwide,^{1,2} with over 11 million deaths or about 20% of all deaths due to perinatal respiratory conditions, lower respiratory tract infections, chronic respiratory diseases, and lung cancer (Table 65-2). The distributions of causes-of-death from respiratory diseases varies between countries and regions with lower respiratory tract infections predominating in the developing countries of Africa, Eastern Mediterranean, and Southeast Asia; and chronic respiratory diseases such as chronic obstructive pulmonary disease (COPD) and asthma, and lung cancer deaths occurring more frequently in more developed regions including the Americas, Europe, and Western Pacific. Among children under 5 years of age, about 21% of all deaths, or 2.27 million deaths in 2000, were due to pneumonia;³ and about 90% of these deaths were among children from 42 developing countries. The markedly higher childhood mortality from acute respiratory tract infections in developing countries as compared with those in developed countries probably reflects poorer nutrition and immunization practices and more frequent low birth weight, crowding, and indoor and outdoor air pollution.⁴ Emerging infections (e.g., SARS) and increasing international travel are a growing public health concern for children and adults.⁵

Chronic diseases of the respiratory system and respiratory tract cancer are major causes of morbidity and mortality among adults. Internationally, the rates of occurrence of respiratory tract cancer and of nonmalignant chronic diseases of the respiratory system can be directly related to patterns of cigarette smoking.⁶ However, inconsistencies in the association between mortality from COPD and patterns of cigarette smoking have been found.⁷ These inconsistencies may be partly explained by differences among countries in reporting of COPD mortality and smoking prevalence. Despite the limitations of available data, mortality from all tobacco-related diseases is estimated to increase dramatically over the next two decades. For example, in 1990, approximately 3 million total deaths were attributed to tobacco and the number is estimated to grow to 8.4 million in 2020, with the largest increases of tobacco-related deaths coming in India, China, and other parts of Asia.¹ Other environmental

and occupational respiratory exposures cause potentially preventable chronic respiratory diseases. Indoor air pollution from domestic wood burning for cooking has been associated with an increased risk of chronic bronchitis and chronic airflow obstruction.⁸ In many countries, environmental and occupational agents that cause disease have become subject to regulation to ensure that workplaces are healthful and that neither outdoor nor indoor air causes adverse effects. Such regulations are not in place throughout the world, however, and where they do exist, enforcement and compliance are variable.

► PEDIATRIC RESPIRATORY DISEASES

Respiratory Distress Syndrome

Respiratory distress syndrome (RDS) in the newborn results primarily from surfactant deficiency associated with lung immaturity.⁹ Because of surfactant deficiency, the lung does not effectively exchange oxygen and carbon dioxide after birth, and positive pressure ventilation is frequently required to maintain life. Bronchopulmonary dysplasia or chronic lung disease of infancy is a frequent sequela of RDS and is characterized by persistent pulmonary dysfunction usually defined as need for ventilatory support or supplemental oxygen at 36 weeks after conception.⁹ The prognosis of BPD is variable and it may be a risk factor for chronic lung disease in childhood and adulthood.¹⁰

In the late 1980s, between 60 and 70 thousand cases of RDS were reported annually in the United States and about 5000 children died per year from RDS, accounting for 20% of all neonatal deaths.¹¹ With changes in obstetric and neonatal care mortality of very low birth weight infants (501–1500 g)¹² RDS-related mortality has declined.¹³ However, among black infants RDS-related mortality declined less rapidly compared to white infants.¹³ Of infants who survive RDS, estimates of the proportion in whom BPD develops vary from 10 to 45%.¹⁴

Several risk factors have been established for RDS, including prematurity, male sex, white race, cesarean section, and perinatal asphyxia.¹⁵ The incidence of RDS is inversely related to gestational age and birth weight, both measures of fetal prematurity. Among infants less than 28 weeks gestation, the incidence of RDS is approximately 80%, declining to about 60% after 29 weeks gestation, and is less than 1% 39 weeks gestation.¹⁵ Overall, about 70% of very low birth weight infants develop RDS.¹²

Prevention of premature birth represents the most effective method for reducing morbidity and mortality associated with RDS.¹⁶ However, because prematurity is frequently a result of poor socioeconomic conditions, and therefore not directly amenable to medical intervention, prematurity and RDS will remain public health problems until underlying causes can be remedied. Medical interventions discussed below offer the best available methods for lessening morbidity and mortality from RDS.

TABLE 65-1. MECHANISMS OF LUNG INJURY AND EXAMPLES OF INJURIOUS AGENTS AND ASSOCIATED DISEASES

<i>Mechanism of Injury</i>	<i>Example</i>	
	<i>Agent</i>	<i>Disease</i>
Infection	Respiratory syncytial virus <i>Streptococcus pneumoniae</i>	Bronchiolitis Pneumonia
Carcinogenesis	Cigarette smoke Asbestos	Lung cancer Mesothelioma
Immunologic Inflammation	Thermophilic actinomycetes Cigarette smoke Oxides of nitrogen	Hypersensitive pneumonitis COPD Silo-fillers' lung
Fibrogenesis	Asbestos Coal dust	Asbestosis Coal workers' pneumoconiosis
Other	Plicatic acid Cotton dust	Western red cedar workers' asthma Byssinosis

Prenatal identification of fetuses at high risk for RDS can be accomplished by analysis of amniotic fluid phospholipids.¹⁵ As the fetus matures, amniotic fluid lecithin concentration increases while sphingomyelin concentration remains constant. Ratios of lecithin to sphingomyelin (L/S) of 2:1 or greater are associated with low risk for RDS. The probability of RDS is 40% with a L/S ratio less than 1.5, 33% with a ratio of 1.5:2, and 10% with a ratio of 2 or greater.¹⁵ However, the L/S ratio may not predict lung maturity in diabetic mothers.¹⁵

Medical interventions including antenatal corticosteroids and surfactant replacement provide partial solutions for the prevention of RDS and its complications.⁹ The administration of corticosteroids to the mother within seven days of delivery has been shown to decrease the frequency of RDS and mortality among infants delivered before 32–34 weeks gestation, but there is insufficient evidence that repeated doses beyond seven days are beneficial and may in fact be harmful.⁹ Moreover, while post-natal corticosteroids have been used to treat BPD, the available evidence suggests that the long-term complications outweigh the short-term benefits.¹⁷

Surfactant replacement with either natural extracts or synthetic forms has proven effective for decreasing complications associated with RDS with an overall 40% reduction in mortality.⁹ Prophylactic treatment is most effective when delivered at the time of delivery compared to waiting until the development of symptoms in infants at risk for RDS, and natural extracts are more effective than synthetic forms.⁹

► CYSTIC FIBROSIS

In the United States, cystic fibrosis is the most common lethal genetic disease in whites of Northern European descent, estimated to occur in about 1 in 3500 live births in 1990.¹⁸ The disease occurs less frequently in other racial and ethnic groups in the United States with estimates of 1 in 14,000 black births; 1 in 11,500 Hispanic births; 1 in 10,500 American Indian and Alaska Native births; and 1 in 25,500 Asian births.¹⁸ Cystic fibrosis is transmitted as an autosomal recessive trait, and the heterozygote frequency in persons of Northern European descent is about 1 in 25.¹⁹

More than 1000 mutations of the cystic fibrosis transmembrane conductance regulator (CFTR) gene on chromosome 7 have been characterized since the gene was identified in 1989, and one mutation (delta F508) accounts for about two-thirds of all CF alleles worldwide.²⁰ The CFTR gene mutations result in an inability of epithelial cells to secrete chloride ions and the production of an abnormally thick mucus, and impaired binding and killing of bacteria.²¹ This defect affects the lungs, intestines, and exocrine glands and may result in diverse clinical manifestations, but patients invariably develop chronic obstructive pulmonary disease from repeated infections that destroy lung tissue.²¹ Pulmonary involvement has been reported in over 90% of all patients with cystic fibrosis and accounts for the majority of hospital admissions and deaths.²²

The prognosis for patients with cystic fibrosis has improved markedly over the last 35 years. Based on data from the National

TABLE 65-2. WORLDWIDE AND REGIONAL NUMBERS OF DEATHS (>1000) FROM RESPIRATORY DISEASES, 2002

<i>Condition</i>	<i>Americas</i>	<i>Europe</i>	<i>Western Pacific</i>	<i>Eastern Mediterranean</i>	<i>Africa</i>	<i>SE Asia</i>	<i>Total</i>

Source: www.who.int/whr/2004/annex/en/ (Annex Table 2)

Cystic Fibrosis Patient Registry, the median survival in the United States has increased from 14 years in 1969 to 33 years in 2001.²⁰ The improving prognosis of cystic fibrosis probably reflects the beneficial effects of early recognition, nutritional support, and antibiotic therapy.^{20,22}

While associated with ethical and logistical challenges, screening for cystic fibrosis during the pre- and postnatal periods has received growing attention as a method for prevention of cystic fibrosis.²⁰ However, because there are over 1000 mutations that may cause cystic fibrosis it is not feasible to conduct population-wide screening of all parents for these mutations. Therefore, prenatal screening programs have often focused on affected families and screening for the most common mutations. Since 80% of children with the disease are born into families without a history of cystic fibrosis,²³ using this method of prenatal screening will have little impact on the incidence of the disease. Moreover, the sensitivity for detecting the 25 most common genetic mutations among affected couples varies widely between ethnic groups, and the predictive value for detecting affected fetuses is low.²⁴

Because of the limitations of prenatal screening, most screening programs for cystic fibrosis have focused on early detection through screening of newborns. In 2003, the Centers for Disease Control and the Cystic Fibrosis Foundation conducted a workshop to review benefits and risks of newborn screening for cystic fibrosis,²⁰ and concluded that “the magnitude of the health benefits from screening for cystic fibrosis is sufficient that states should consider including routine newborn screening for cystic fibrosis in conjunction with systems to ensure access to high-quality care.” An estimated 800,000 newborns will be screened in the United States by the end of 2004 through 11 statewide programs.²⁰

The improving survival among persons with cystic fibrosis has been attributed to better medical care through comprehensive centers that provide a multidisciplinary approach to management.²⁵ However, the relative contributions of the various components of care to the improvement cannot be readily established. The details of management of cystic fibrosis are beyond the scope of this review and have been discussed extensively elsewhere.²⁵

Respiratory Tract Infection

Respiratory tract infections are the main cause of morbidity and mortality among children living in developing countries and, although a much less frequent cause of death, the predominant source of morbidity including hospitalizations among children living in developed countries.^{4,26–28} Respiratory viruses are responsible for most childhood respiratory tract infections, although bacteria, *Mycoplasma* and *Chlamydia* cause some infections at particular ages. Respiratory tract infections in childhood may plausibly have long-term sequelae, including loss of lung function after severe episodes of lower respiratory tract infection, the development of asthma, the development of bronchiectasis, and an increased risk of developing COPD in adulthood.^{29–31}

In developed countries the predominant clinical syndromes associated with childhood respiratory tract infection include colds (infections of the upper respiratory tract), epiglottitis (infection of the epiglottis), croup or laryngotracheobronchitis (infection of the larynx and large airways), bronchiolitis (infection of the small airways), and pneumonia (infection of the lung tissues). Rhinoviruses are most closely associated with colds, parainfluenza viruses with croup, respiratory syncytial virus with bronchiolitis, and various viruses, including respiratory syncytial virus and the parainfluenza viruses with pneumonia.^{32,33} Bacteria cause epiglottitis. Epiglottitis, croup, bronchiolitis, and pneumonia may be severe and cause death through respiratory failure. In less developed countries, measles and whooping cough may be important causes of severe respiratory tract infection.³⁴

Childhood respiratory tract infections are extremely common. Surveillance data for general population samples worldwide show that children experience five to nine respiratory illnesses during the first year of life;⁴ by the teenage years children still have about two or three respiratory illnesses annually.³⁵ Mortality from childhood

respiratory tract infections is low in the United States and other more developed countries, about 0.1 deaths annually per 1000 children from birth through the age of five years. However, mortality rates for this same age group vary widely between developed and developing countries and are more than 1000 times greater in some developing countries.²⁷ Moreover, under-five mortality rates within developing countries vary substantially.²⁷

Many risk factors for respiratory tract infection have been identified. In developing countries, overcrowded dwellings, poor nutrition, low birth weight, and possibly intense smoke pollution underlie the high rates.^{4,36,37} Studies in developed countries have shown that males have higher rates of infection, as do younger siblings of school-age children who introduce infections into households. Children from homes of lower socioeconomic status also tend to have more respiratory infections. Maternal cigarette smoking has also been causally linked to increased occurrence of respiratory tract infections during the first years of life.³⁸ Attendance at day care centers also increases the occurrence of respiratory tract infections among preschool children.⁴ Some studies indicate that breast-feeding decreases risk and that use of a gas-fueled stove increases risk, but the evidence on these associations is conflicting.^{39–41}

Present understanding of risk factors for respiratory tract infection in childhood indicates several approaches for primary prevention. In developing countries, improved living conditions, better nutrition, breast feeding, and reduction of smoke pollution indoors should reduce the burden of morbidity and mortality associated with respiratory tract infections.^{42,43} In developed countries, mothers should be encouraged to stop smoking or to avoid smoking in the presence of their children. Effective vaccines are available for a limited number of bacteria (e.g., *Streptococcus pneumoniae*, *Haemophilus influenzae*)⁴⁴ and viruses (e.g., influenza)⁴⁵ that cause respiratory tract infections. However, the use of these vaccines as a public health intervention remains an active area of investigation and recommendations of expert groups are evolving. For example, the Advisory Committee on Immunization Practices now recommends influenza vaccination for children 6–23 months of age.⁴⁵

Asthma

Asthma is a chronic condition characterized by airway inflammation and hyperresponsiveness; reversible airflow obstruction; and episodic wheezing, cough, and dyspnea.⁴⁶ Asthma results from a number of genetic variations and environmental exposures in early childhood, and the phenotypic expression of the disorder is heterogeneous.⁴⁷ Various methods are used to measure the occurrence of asthma making comparisons between studies difficult.⁴⁸

Numerous investigations of the occurrence of asthma in children have been conducted worldwide, and data from cross-sectional and longitudinal investigations indicate a wide range in the prevalence and incidence of childhood asthma.^{46,49,50} The International Study of Asthma and Allergies in Childhood (ISAAC) used standardized questionnaires to determine the prevalence of asthma-related symptoms among children 6–7, and 13–14 years of age from 156 centers in 56 countries.⁵¹ More than 750,000 children were surveyed and the prevalence of self-reported wheezing in the previous 12 months ranged from 1.6 to 36.7%.⁴⁹ In the United States, data from nationwide samples and survey populations using different measures of asthma (“during the past 12 months, have you had asthma?” or “episode of asthma or asthma attack during the preceding 12 months”) compared to the ISAAC study also indicates that asthma is a common disease in children and has increased over the period from 1980 through 1995 (Fig. 65-1).⁵² While explanations for these wide variations in the occurrence of asthma between countries and over time remain an active area of investigation, the lower prevalence of asthma in developing countries and variation in prevalence within populations with similar genetic backgrounds suggest a major role for environmental factors in the variation in the occurrence of asthma.

In cross-sectional and prospective investigations many personal, lifestyle, and environmental risk factors have been identified for asthma (Table 65-3).^{47,50} Among the personal factors, genetic

Figure 65-1. Estimated annual prevalence of self-reported asthma by age group in the United States, 1980–1995. (Source: Adapted from Mannino et al. 2002.⁵²)

susceptibility likely plays a major role determined by a number of genetic variations, which control multiple biological mechanisms involved in asthma including allergic sensitization, inflammation, and bronchial hyperreactivity.⁴⁷ Studies of familial aggregation of asthma and twins show a strong familial influence on the prevalence and incidence of asthma,⁵⁰ but these studies do not separate genetic from common environmental effects.⁴⁷

While genetic susceptibility has a major role in the development of asthma and is an active area of investigation, many other personal characteristics have been associated with asthma (Table 65-3). Data from Tucson, Arizona,⁵³ and Rochester, Minnesota,⁵⁴ show a sharp decline in the incidence of asthma from early childhood to adolescence (Fig. 65-2) with a corresponding shift from a higher occurrence in males during early childhood to a higher occurrence in females in adolescence and young adulthood,⁵⁰ which may be explained by differences in airway geometry.⁵⁵ The occurrence may vary widely between racial and ethnic groups⁵⁶ and is higher in blacks compared with whites.⁵² Atopy, defined by positive skin tests to common aeroallergens, predicts increased risk of asthma if present in the parents or child.⁵⁰ Similarly, in prospective investigations of persons without asthma at baseline, bronchial hyperresponsiveness is associated with development of recurrent wheezing or asthma.⁵⁰

TABLE 65-3. RISK FACTORS FOR CHILDHOOD ASTHMA

■ **Personal and Genetic Factors**

- Age
- Male gender
- Race/ethnicity
- Family history
- Atopy
- Obesity
- Bronchial hyperreactivity

■ **Environmental and Lifestyle Factors**

- Maternal smoking
- Environmental tobacco smoke
- Personal smoking
- Respiratory tract infections
- Allergen exposures
- Breastfeeding
- Ambient air pollution

Figure 65-2. Annual incidence rates per 100,000 person-years by sex and age for definite and probable asthma cases among Rochester residents, 1964 through 1983. Hatched bars = females; shaded bars = males. (Source: Yunginger JW, Reed CE, O’Connell EJ, et al. A community-based study of the epidemiology of asthma. Incidence rates, 1964–1983. *Am Rev Respir Dis.* 1992;146:888–94.)

In addition to personal characteristics a number of pre- and post-natal factors have been associated with the development of asthma (Table 65-3).^{47,50} Prenatal factors associated with an increased risk of asthma include younger maternal age (e.g., < 26 years) and maternal smoking during pregnancy.⁵⁷ While the fetus may be sensitized to allergens *in utero* the risk of allergen exposures during pregnancy is uncertain.⁴⁷ Low birth weight (< 2500 g) is associated with an increased risk of asthma. The role of breastfeeding as a risk factor for asthma is controversial; the mixed findings may be explained by methodological differences between studies.⁴⁷ In several cohort studies, breastfeeding through the first four months of life is associated with a decreased risk of incident asthma.⁵⁰ Childhood obesity has consistently been associated with an increased risk for development of asthma.⁵⁰

A wide range of environmental risk factors for asthma has been investigated including viral lower respiratory tract infections, and indoor and outdoor exposures.⁵⁰ More severe episodes of lower respiratory tract infection are associated with subsequent asthma and increased airway reactivity.⁵⁰ Involuntary exposure to tobacco smoke, particularly maternal smoking, is independently associated with asthma.^{58–60} Exposure to aeroallergens such as house dust mite, cockroach, and fungi during infancy is associated with a marked excess risk of asthma.^{50,61} While a number of infectious and environmental agents have been linked to the development of asthma, patterns of exposure to other infectious agents (e.g., bacteria) and bacterial components (e.g., endotoxin) during infancy may partly explain the rising occurrence of asthma in developed countries with decreased exposure and the lower occurrence in developing countries where exposures are higher. This potential explanation for variations in the occurrence of asthma has been termed the “hygiene hypothesis.”⁶²

Few investigations of the primary prevention of asthma through control of modifiable risk factors have been conducted.^{63,64} At least four randomized primary prevention trials are in progress, and results from one randomized trial in Canada of high risk infants enrolled before birth (n = 545) compared a multifaceted intervention (i.e., avoidance of house dust mite, pets, environmental tobacco smoke, day care until after the first year of life; delay of solid foods; and encouragement of breast feeding) to a control group has demonstrated a lower occurrence of asthma in the intervention group (16.3%) compared to the control group (23.0%) at two-years of age (odds ratio 0.60 [95 confidence interval 0.37–0.95]).⁶⁴ In a similar study of 251 infants from the UK, investigators found a lower risk of asthma-related symptoms at three years of age, but the difference was not statistically significant.⁶⁵ Moreover, there was no difference in the prevalence of physician-diagnosed asthma.

The natural history of wheezing illnesses and childhood asthma have been described in a number of longitudinal studies in developed countries.⁶⁶ Asthma symptoms usually begin in infancy and early childhood, and remit over time. In a longitudinal study of 826 newborns, Martinez et al.⁶⁷ found that about 30% of children develop a wheezing illness during the first 3 years of life, and of these children about 60 percent are symptom-free at age six and overall only about 15% develop persistent wheeze and asthma.⁶⁶ In a study of more than 11,000 children from the UK, only 50% of children who had a diagnosis of asthma at age five years continued to have the diagnosis at age 10 years.⁶⁸ Involuntary exposure to tobacco smoke, ambient air pollution, and infections have been shown to exacerbate asthma.^{38,69,70}

Most preventive strategies for asthma have been directed at secondary prevention with pharmacologic and other interventions to lessen morbidity.⁶⁶ The use of bronchodilators, corticosteroids, and disodium cromoglycate greatly reduces morbidity from asthma. Many nonpharmacological interventions have been examined, including environmental control, prevention of sensitization in infancy and childhood, immunizations, allergen immunotherapy, physical training, chest physiotherapy, and education.^{71–73} In the United States⁷⁴ and internationally,⁴⁶ strategies for asthma education have been developed to prevent morbidity and mortality from asthma.

Death from childhood asthma, although infrequent, is well documented and potentially preventable. Childhood mortality rates from asthma vary from country to country and by age, sex, and race in the United States. In the United States, annual mortality rates for asthma among children 5–14 years of age increased 89% during the period 1980 through 1999, from 1.9 per million to 3.6 per million, respectively.⁵² There was little change in the mortality rate from asthma for children four years of age and less. During this period the mortality rates were consistently higher among blacks compared with whites.

Findings from retrospective studies suggest that clinical severity of asthma predicts risk of death.⁷⁵ Factors that are suspected to affect mortality include failure on the part of patients and physicians to recognize severity, behavioral patterns, underuse of inhaled or oral corticosteroids, overuse and overdependence on nebulizers, and additive toxicity from combined use of theophylline and beta-agonists. For individual children, however, the predictive value of these factors is limited.

▶ ADULT RESPIRATORY TRACT DISEASES

Asthma

As in children, the occurrence of asthma varies widely worldwide and regionally.^{76,77} In the early 1990s, a standardized cross-sectional survey, the European Community Respiratory Health Survey, was conducted at 48 centers in 22 countries and 137,619 adults 20–44 years of age were enrolled.⁷⁶ Overall, the median prevalence of reported current asthma was 4.5% with a range of 2.0–11.9%. This variation in the prevalence of asthma was further supported by measurement of bronchial hyperresponsiveness with overall prevalence of 13.0% and range of 3.4–27.8%. In the United States, the overall prevalence of self-reported current, health-professional-diagnosed asthma among adults 18 years of age and older was 7.5% in 2002, and ranged from 4.7% in the U.S. Virgin Islands to 11.5% in Puerto Rico. Moreover, during the period 1980 through 1996, the prevalence of asthma in the United States increased with the greatest increase (124%) among persons 15–34 years of age.⁵²

In addition to childhood asthma extending into adulthood, other risk factors for asthma in adults include personal characteristics, lifestyle, and environmental exposures. Among adolescents and adults, asthma is more common among females compared to children, where asthma is more common among males. This difference may be explained by differences in airway geometry and increased bronchial hyperresponsiveness among adult females compared to males.⁷⁶ However, the higher incidence in older women may partly be explained by physician bias in labeling obstructive lung disease in women as asthma rather than COPD.⁵³

A number of lifestyle characteristics and environmental exposures have been investigated as potential factors contributing to the rising occurrence of asthma in adults including nutritional factors,^{78–80} smoking,⁸¹ and occupational exposures.^{82–84} Overall, results from longitudinal studies and randomized trials of dietary intake of various nutrients have been inconsistent.⁷⁸ In contrast, a consistent finding in children and adults has been the association between increasing weight and increased risk for asthma. Among 135,000 Norwegians, 14–60 years of age, Nystad et al.⁷⁹ found that among men and women, overweight and obesity were associated with an increased risk for asthma. For obesity (BMI ≥ 30 kg/m²) the relative risks (95% CI) for asthma among men and women were 1.78 (1.35–2.34) and 1.99 (1.67–2.37), respectively, adjusted for smoking, education, and physical activity. Evidence on the association between active smoking and development of asthma has been inconsistent,^{81,85} and the inconsistency may be partly attributed to methodological differences between studies. Longitudinal studies provide the strongest evidence for making causal inferences. In a recent prospective case-control study of incident asthma in Finland,⁸⁶ the adjusted risk of asthma was increased among current (OR = 1.3, 95% CI = 1.0–1.8) and former smokers (OR = 1.5, 95% CI = 1.1–2.0) compared to never-smokers. Occupational asthma is of special concern, with approximately 250 causative agents identified.⁸² The population attributable risk for occupational exposures has ranged from 5 to 30% depending on the methods used to define asthma and exposure.^{83,84}

The economic impact of asthma is greatest among persons 18 years of age and older.⁸⁷ In 1985, the overall costs for asthma in the United States were estimated at \$4.5 billion with approximately 66% of the costs associated with persons 18 years of age and older. Emergency room use, hospitalizations, and death accounted for 43% of the total economic impact of asthma, suggesting that asthma costs could be reduced by interventions targeting these three areas.

Overall, strategies for asthma management and prevention in adults differ little from those in children and incorporate pharmacological and other interventions. However, many asthmatics do not receive optimal medical management.^{88,89} Control of exposure to house dust mite allergen has not been effective in adult asthmatics.⁹⁰ Early recognition of the relationship between an occupational exposure and asthma is important since prompt removal from exposure correlates best with full resolution of asthma.⁸² Certain occupations may be associated with an increased risk of death from asthma.⁹¹

While death from asthma is uncommon, the majority of asthma deaths occur in adults and asthma mortality rates among adults have increased worldwide;^{92,93} however, since 1996 mortality rates among adults in the United States have started to decline.⁵² Mortality rates are highest among females and blacks.⁵² Among asthmatics fewer than 5% die from asthma.^{92–95} Population-based investigations have provided conflicting results on survival among adults with asthma that may be partly explained by methodological differences.^{92–95} Impaired lung function is associated with increased mortality.⁹⁵

Chronic Obstructive Pulmonary Disease

COPD is a clinically applied term for persistent and generally symptomatic obstruction to airflow within the lungs. The lungs of most persons with COPD display a mixture of emphysema, enlargement and destruction of the air spaces, and inflammation and narrowing of the smaller airways, although in some persons emphysema or airway abnormalities may predominate.^{96,97} Emphysema reduces the driving pressure for airflow, and the airway abnormalities increase the resistance to airflow.

A small number of cases of COPD, distinguished by severe emphysema, occur in smokers and nonsmokers with deficiency of alpha-1-antitrypsin, a substance that defends against injury by proteolytic enzymes,⁹⁷ however, most cases result from cigarette smoking.⁸⁵ Occupational agents can also contribute to the development of COPD.⁹⁸ Other postulated risk factors for COPD include childhood respiratory tract infection^{29,30} and hyperresponsiveness of the airways of the lung.^{99,100}

The natural history of COPD generally follows a slow but progressive course that offers a lengthy time window for intervention. The results of epidemiological studies suggest that impaired lung growth from smoking during childhood and adolescence¹⁰¹ and sustained loss of ventilatory function beyond that expected from aging alone causes clinically evident COPD (Fig. 65-3).^{85,96} The rate of decline in smokers tends to increase with the amount smoked, and smoking cessation results in a slower rate of decline compared with that in smokers unable to quit.⁸⁵ Among smokers with mild airflow obstruction, moderate to marked airways hyperreactivity is more common in women (48%) compared with men (25%)¹⁰² and is associated with accelerated decline in lung function.¹⁰⁰

Clinicians make the diagnosis of COPD in patients with sufficient chronic airflow obstruction to result in shortness of breath and limitation of exercise capacity. In epidemiological studies COPD is considered to be present if lung function tests demonstrate a specified degree of impairment or if a physician's diagnosis is reported. Although prevalence can be readily assessed with the use of these criteria, a physician's diagnosis may result in substantial diagnostic misclassification.¹⁰³ Moreover, incidence cannot be described over short periods because of the slow evolution of impairment in persons developing COPD.

Epidemiological data from throughout the world show that COPD is common among adults, with wide variation in prevalence estimates.^{96,104,105} While differences in the definition of COPD partly contribute to the variation in prevalence, population differences in the distribution of risk factors also explain differences in prevalence.¹⁰⁴ The prevalence is greater among men than among women, and increases with age and the extent of smoking.¹⁰⁶

Mortality rates for COPD, although subject to well-described limitations,¹⁰⁷ provide another measure of occurrence.¹⁰⁴ Unfortunately, procedures and codes for classifying COPD as the underlying cause of death have not been consistent across this century. Consequently, mortality trends must be interpreted cautiously. Moreover, attribution of a death to COPD ordinarily requires contact

with a clinician and diagnosis of the disease. In spite of the limitations of death certificates in investigating COPD, mortality data for the United States document a dramatic increase in deaths from COPD.¹⁰⁴ In 1980, 52,193 deaths were attributed to categories related to COPD; by 2000 the number of deaths from COPD was 119,054.¹⁰⁴ Mortality rates have been consistently higher among whites compared to blacks, and while men have had higher mortality rates than women, during the period from 1980 through 2000, women experienced a greater increase in mortality rates and in 2000, the number of deaths from COPD was higher among women (n = 59,636) compared to men (n = 59,118).¹⁰⁴ Worldwide, mortality rates among countries are highly variable, but overall, mortality from COPD has been increasing. In 1990 COPD was ranked as the sixth leading cause of death in the world and by 2020 it is estimated to be the third leading cause of death.¹

The 1984 Report of the Surgeon General concluded that 80–90% of COPD in the United States is attributable to cigarette smoking.⁹⁶ The slow evolution of COPD provides an opportunity to identify and to target for intervention the smokers in whom the disease is developing. With sustained smoking, lung function in smokers, declining at a more rapid rate (Fig. 65-3), tends to drop below normal levels. Lung function testing of chronic smokers can identify individuals whose function has dropped below the range of normal values but not yet reached the degree of impairment associated with frank COPD.¹⁰⁸ These at-risk persons could then be targeted for intensive smoking cessation interventions.¹⁰⁹

Acute Respiratory Distress Syndrome

The clinical syndrome of acute respiratory distress syndrome (ARDS) was originally described in the late 1960s; it represents a diffuse response of the lung to a wide variety of causative factors including pneumonia, aspiration and other inhalational injuries, sepsis, trauma, pancreatitis, multiple transfusions, and drug overdose.¹¹⁰ The clinical picture comprises pulmonary edema that does not have a cardiac basis and respiratory failure.

Figure 65-3. Decline of FEV₁ at normal rate (solid line) and at an accelerated rate (dashed line). **A**, Person who has attained a "normal" maximal FEV₁ during lung growth and development; **B**, Person whose maximal FEV₁ has been reduced by childhood respiratory infection, CAO = chronic airflow obstruction (Source: From U.S. Department of Health and Human Services: The Health Consequences of Smoking. Chronic Obstructive Pulmonary Disease. DHHS Publication No. (PHS) 84-50205, Rockville, MD: Office on Smoking and Health, 1984.)

Because of the multiple causes of ARDS and the lack of a consistent definition, the incidence of ARDS has been difficult to determine.^{110,111} Estimates of the incidence of ARDS in the United States from an ARDS research network range from 17.3 to 64.2 per 100,000 inhabitants per year.¹¹² Overall, about 25% of patients with any one of the risk factors will develop ARDS, ranging from 13% among patients with drug overdose to 43% among patients with sepsis.¹¹³ Increasing age and active smoking have been associated with increased risk for development of ARDS.^{113,114} Mortality from ARDS is high, with 40–60% of patients dying from complications including sepsis and multi-organ failure.¹¹⁰

In summary, acute respiratory distress syndrome occurs as a consequence of severe lung injury by diverse and distinct agents. Preventive strategies must be directed toward the causative factors (e.g., pneumonia, sepsis, and motor vehicle accidents).

Pulmonary Thromboembolism

The diagnosis of pulmonary thromboembolism presents a number of diagnostic challenges and thus frequently goes undetected. Therefore, available estimates of incidence, which range from 1.2 to 1.8 per 1000 persons/year underestimate the true occurrence of the condition.¹¹⁵ While pulmonary thromboembolism is associated with high mortality, differences between study populations and follow-up contribute to wide variations in reported case fatality (2.3–28%).¹¹⁵ Overall, mortality rates for pulmonary thromboembolism in the United States have declined during the period 1979 through 1998, from 191 per million to 94 per million, respectively.¹¹⁶ A number of patient characteristics have been associated with increased mortality including increasing age, being male and black, and associated comorbid conditions (e.g., trauma, cancer).¹¹⁶

Identification of risk factors for pulmonary thromboembolism (Table 65-4)¹¹⁵ is key for making a correct diagnosis. Several recent reports have highlighted the importance of long-distance air travel as a cause of thromboembolic disease.^{117,118} However, about 50% of patients with pulmonary embolism do not have clinically evident risk factors (i.e., trauma, surgery, marked immobility, or active cancer).¹¹⁹ Therefore, a high index of suspicion is necessary for making the diagnosis of pulmonary thromboembolism.

TABLE 65-4. RISK FACTORS FOR VENOUS THROMBOEMBOLISM

■ Personal and Genetic Factors

Increasing age
Obesity
Inherited thrombophilias (e.g., Factor V Leiden mutation)

■ Lifestyle and Environmental

Cigarette smoking
Long-haul air travel
Immobility

■ Women's Health

Pregnancy
Oral contraceptives
Hormone replacement therapy

■ Medical Illness

Previous venous thromboembolism
Cancer
Hypertension
Congestive heart failure
Stroke

■ Surgical

Trauma
Orthopedic surgery
Other major surgeries, especially for cancer

Source: Data from Goldhaber SZ. Pulmonary embolism. *Lancet*. 2004;363:1295–1305.

Because of the high frequency of pulmonary thromboembolism and the difficulties of diagnosis, prevention has been a major area of investigation, and the evidence and recommendations for prevention have been extensively reviewed elsewhere.¹²⁰ Both pharmacological and mechanical methods are available for prevention of thromboembolism, and the selection of specific preventive interventions is determined based on the patient's risk for thromboembolism and for bleeding complications from the pharmacological agents used for prevention.

Diffuse Parenchymal Lung Diseases

The diffuse parenchymal lung diseases, also referred to as interstitial lung diseases, are a heterogeneous group of disorders comprising more than 200 entities, many of which are rare with no known cause, and result from injury to the pulmonary interstitium (Table 65-5).¹²¹ However, in the general population only five major diagnostic categories of these diseases are usually seen, including occupational and environmental, drug- and radiation-induced, connective tissue diseases, idiopathic interstitial pneumonias, and granulomatous disorders.¹²²

In a population-based investigation of the occurrence of interstitial lung diseases the overall prevalence was higher in men compared with that in women, 81 per 100,000 and 67 per 100,000, respectively.¹²² The overall incidence was 32 per 100,000/year among men and 26 per 100,000/year among women.¹²² Idiopathic pulmonary fibrosis is the single-largest category, accounting for 51% of all incident cases. Interstitial lung diseases of known cause (e.g., asbestosis, coal workers' pneumoconiosis, silicosis, hypersensitivity pneumonitis, drug induced) compose only about 15% of incident cases in the general population.

While few etiological studies have been conducted, both endogenous and environmental factors have been proposed as determinants of interstitial lung diseases of unknown causes. With regard to endogenous factors, rare familial forms of diffuse parenchymal lung diseases provide evidence for genetic factors in the development

TABLE 65-5. DIFFUSE PARENCHYMAL LUNG DISEASES

■ Known Causes

Inhaled agents
 Inorganic dusts, gases or fumes
 Organic dusts
Drugs
Poisons
Radiation
Infectious agents
Medical Conditions
 Chronic pulmonary edema
 Chronic uremia
 Hepatitis, cirrhosis
 Transplantation rejection
 Metastatic cancer

■ Unknown Causes

Idiopathic Interstitial Pneumonias (IPF, NSIP, DIP, RBILD, COP, AIP)*
Sarcoidosis
Collagen-vascular disorders
Angiitis and granulomatosis
Eosinophilic pneumonias
Histiocytosis X
Hereditary and familial disorders (e.g., tuberous sclerosis)
Storage disorders (e.g., amyloidosis, alveolar proteinosis)

*IPF = idiopathic pulmonary fibrosis, NSIP = nonspecific interstitial pneumonia, DIP = desquamative interstitial pneumonia, RBILD = respiratory bronchiolitis interstitial lung disease, COP = cryptogenic organizing pneumonia, AIP = acute interstitial pneumonia.

Source: Adapted from Demedts M, Wells AU, Anto JM, et al. Interstitial lung diseases: an epidemiological overview. *Eur Respir J*. 2001;18(Suppl 32):2S–16S.

of these disorders, however, the genetic determinants of these diseases remain an active area of investigation.^{123,124}

Inhalation of environmental agents and exposure to drugs account for most interstitial lung diseases of known cause, and a growing number of recent investigations have found associations between environmental exposures and idiopathic pulmonary fibrosis.^{123–131} Examples of environmental factors that have been associated with idiopathic pulmonary fibrosis include cigarette smoking, working with livestock, wood dust, and metal dust. Infectious agents, viruses,¹²⁷ and *Mycoplasma*¹³² have been implicated as causes of pulmonary fibrosis, indistinguishable from idiopathic pulmonary fibrosis, but the importance of these agents as causes of interstitial lung disease in the general population is not known. The risk of sarcoidosis is increased with agricultural employment and work environments with mold/mildew exposure.¹³¹ Exposure to environmental agents may also alter risk of development of interstitial lung diseases of known or unknown cause; cigarette smoking decreases the risk of sarcoidosis¹³¹ and hypersensitivity pneumonitis,¹³³ and increases the risk of other interstitial lung diseases.¹³⁴

Because most interstitial lung diseases are of unknown cause, little can be offered for prevention now. However, growing evidence suggests that exposure to environmental agents is associated with idiopathic pulmonary fibrosis, the most common interstitial lung disease. As evidence accumulates to fulfill the criteria for causation for specific exposures and determinants of individual susceptibility are identified, specific recommendations for prevention may be possible.

Sleep Apnea

The sleep apnea syndrome is characterized by excessive daytime sleepiness, snoring, and many episodes of cessation of breathing during sleep.¹³⁵ In the majority of cases, the syndrome results from recurrent collapse of the pharynx with blockage of the passage of air.¹³⁵ Because of recurrent apneas, significant lack of oxygen may develop and cause fragmented sleep and secondary complications. The excessive daytime sleepiness may result in a number of psychosocial problems and substantially increases the risk of automobile accidents.¹³⁶ If untreated, moderate to severe sleep apnea syndrome results in excess mortality.¹³⁶

Based on a number of surveys that have been conducted worldwide, the prevalence of the sleep apnea syndrome in the general population is estimated to be less than 5%.¹³⁶ The prevalence is higher among men, habitual snoring, and obese persons and increases with age. Because of the increasing occurrence of obesity and high prevalence of the syndrome in the general population, with the associated morbidity and mortality, the sleep apnea syndrome presents a major public health problem.

Little information is available on the prevention of morbidity and mortality from the sleep apnea syndrome, and the long-term benefits of treatment remain to be established.¹³⁵ For moderate to severe sleep apnea, continuous positive airway pressure through a nasal mask is the main treatment modality. Because obesity is often associated with the syndrome, weight reduction is frequently recommended but offers limited improvement unless body weight is substantially reduced. Alcohol avoidance is recommended because it can cause sleep apnea in persons who simply snore and can worsen the severity of apnea among patients with the sleep apnea syndrome.

► CONCLUSIONS

Respiratory diseases are common causes of morbidity and mortality worldwide, and many of these diseases can be prevented. Because the occurrence of the various respiratory diseases may vary widely in different geographic locations, epidemiological data are important for development of prevention strategies. Of particular public health concern is tobacco smoking, a major cause of avoidable respiratory disease from the prenatal period through adulthood.

Musculoskeletal Disorders

Jennifer L. Kelsey • MaryFran Sowers

Musculoskeletal disorders are common, affect all age groups, and are associated with a great deal of disability, impairment, and handicap. More than 12 million people in the United States have their activity limited by musculoskeletal disorders, a figure greater than for any other disease category (Fig. 66-1).¹ Musculoskeletal impairments affect about 14% of the population, with the spine most commonly involved, followed by the lower extremity or hip and the upper extremity or shoulder (Table 66-1).² Each year about 11% of the population in the United States experience a musculoskeletal injury severe enough that medical care is sought or activity is restricted for at least half a day.² The total economic cost to the United States of musculoskeletal conditions was estimated to be \$284 billion in 2000,³ second only to diseases of the circulatory system. Indirect costs from lost earnings and services represent a particularly high proportion of this cost, since many people are affected during their most productive years.

► DISORDERS PRIMARILY OF ADULTS

Low Back and Neck Pain

From 75 to 85% of people experience low back pain at some time during their lives.⁴ Most episodes of low back pain improve within a few weeks, but recurrences are common, and low back pain often becomes a chronic problem with intermittent, usually mild, exacerbations.⁵ In a study of English patients seen by general practitioners for low back pain, after one year only 25% had no pain or disability, even though the majority were no longer seeking care from their practitioner for their problem.⁶ In a small proportion of cases the pain becomes constant and severe, and such cases account for a high proportion of the cost; one study found that 25% of the cases accounted for 90% of the costs.⁷

The specific lesion responsible for low back pain usually is not known. It is likely that the different conditions comprising the category “low back pain” (e.g., sprains and strains, disc herniations, spinal stenosis, spondylosis and spondylolisthesis, facet abnormalities) have in part different etiologies. However, until these specific conditions are identified and differentiated in epidemiologic investigations, the category “low back pain” as a whole must generally be considered as a single category. Techniques such as magnetic resonance imaging and computerized tomography are not particularly helpful in most instances because of the low correlation between symptomatology and the abnormalities seen on imaging.⁵

Low back pain is more common in people who do heavy manual work than in those whose work is sedentary. Jobs that involve heavy lifting (e.g., of objects weighing 25 lb or more) are associated with an increase in risk for back pain. Components of lifting that appear to increase the risk for both herniated disc and low back pain in general include frequent lifting of heavy objects while bending and

twisting the body, holding heavy objects away from the body while lifting, and failing to bend the knees while lifting.^{8–10} Several studies have found a modest association between cigarette smoking and low back pain and between smoking and herniated disc, probably because of the pressure exerted by frequent coughing or the decreased diffusion of nutrients into the intervertebral disc.¹¹ Motor vehicle driving and exposure to other forms of whole body vibration are detrimental to the spine.^{9,12–15} Some evidence suggests that tallness is a risk factor for low back pain, that heavy body weight has little or no effect, and that a narrow spinal canal increases the risk, at least for lumbar disc herniation.^{16,17} Although psychological factors are often said to play a role in the etiology of low back pain, there is little firm evidence to support or refute this belief. Among possible psychological risk factors, the strongest evidence is for low social support in the workplace and low job satisfaction.¹⁸

One useful approach to the prevention of low back pain is modification of factors in the work place.⁷ Although low back x-rays and medical examinations have not proved useful as routine screening tests for selection of workers, selection on the basis of strength testing for jobs involving heavy manual work appears to reduce the likelihood of back injury. Training workers to bend the knees while lifting does not seem to have reduced the number of back injuries, partly because of poor compliance. Educational programs implemented among postal workers¹⁹ and nurses²⁰ have also not reduced the frequency of low back problems. Rather, redesigning jobs to minimize bending and twisting motions and to reduce the amount of weight lifted may be more likely to decrease the number of back injuries and also may allow an injured worker to return to work sooner. Wearing lumbar supports in some high-risk occupations is sometimes used for primary prevention, but the limited available evidence suggests that it is probably not effective.²¹

Exercises to strengthen back and abdominal muscles and to improve overall fitness can somewhat decrease the incidence and duration of low back pain.²² Other possible methods of primary prevention include cessation of smoking, moving around from time to time in situations requiring prolonged exposure to one position, and vibration dampening. Use of motor vehicles with adjustable seat positioning and good lumbar support, reducing the amount of time professional drivers must drive, and improving the ergonomic properties of their driving situation may also be beneficial.^{15,23}

Most back pain improves without any specific therapy. Predictors of disability from low back pain include long duration of the pain; a history of previous low back pain, disability, and hospitalizations; low educational level and employment grade; psychosocial factors such as dissatisfaction with the job and low social support on the job; heavy physical demands on the job; heavy smoking; whether insurance payments are being received; the perception of fault; and whether a lawyer has been retained.^{24–26} Of considerable importance in tertiary prevention for many people with acute low back pain is a continuation of normal activities to the extent tolerated and a prompt

Figure 66-1. Estimated number of persons in the United States in 1984 with limitation of activity attributable to specific disease categories. (Source: Holbrook TL, Grazier L, Kelsey JL, Stauffer RN. The Frequency, Occurrence, Impact, and Cost of Musculoskeletal Conditions in the United States. Chicago: American Academy of Othopaedic Surgeons; 1984.)

return to work (Table 66-2).^{26,27} On first returning to work, however, the worker should avoid lifting heavy objects, bending, twisting, sitting in a low chair, and remaining in the same position for long periods of time. Ergonomic redesign of physically demanding jobs may facilitate return to work.²⁸ Because surgical treatment is often unsatisfactory, conservative approaches such as strengthening exercises, physical therapy, and back schools are frequently used for tertiary prevention. Evidence from randomized trials indicates that exercises that include aerobic conditioning and strengthening of the back and legs can reduce the likelihood of recurrences.²² Although back schools have different emphases, most (a) teach patients enough about spinal mechanics so that they can use their backs effectively

and avoid pain and damage, (b) try to effect attitude changes through psychological approaches, and (c) offer exercise and physical fitness programs.²⁹ There have been no definitive evaluations of the efficacy of back schools, and their effectiveness remains controversial.³⁰

The percentage of the population having neck pain at some time during their lives is around 60–70%.³¹ As with low back pain, neck pain can be caused by a variety of different lesions, and recurrences are

TABLE 66-1. PREVALENCE OF MUSCULOSKELETAL IMPAIRMENTS IN THE UNITED STATES IN 1995

Type of Impairment	Estimated No. of Affected Individuals	% of Population
All musculoskeletal impairments	36,438,000	13.7
Back or spine	18,454,000	7.0
Lower extremity or hip	13,421,000	5.1
Upper extremity or shoulder	4,563,000	1.7

common. The number of people with neck pain appears to have been increasing. This increase is thought to be attributable to the lower percentage of the work force participating in heavy manual work and the greater number of people sitting for long periods in front of video display terminals.

Knowledge of risk factors for neck pain is scanty. Previous neck pain and low back pain are strong predictors.^{32,33} Prolonged exposure to awkward postures, especially in poorly designed workspaces, appears to be associated with mild neck pain. For instance, frequent use of video display terminal with a fixed keyboard height that requires a bent neck can cause neck pain.^{34,35} Some evidence indicates that heavy lifting, cigarette smoking, frequent aquatic diving from a board, motor vehicle driving, and exposure to other sources of whole-body vibration increase the risk for neck pain in general or prolapsed cervical intervertebral disc in particular.^{36–38} There have been a few reports that repetitive motions, forceful exertions, prolonged neck flexion, handling tasks that involve reaching, pushing, and pulling, constrained positions, arm force, arm posture, and twisting and bending of the trunk may also be related to risk for neck or neck/shoulder pain.^{32,35,39} Several psychological factors have been associated with the development of neck pain, but results are inconclusive as to which are most important.^{35,40,41}

Little research has been undertaken on the primary prevention of neck pain or on ways to reduce the likelihood of disability among those with neck pain. However, it would be expected that reductions in the amount of heavy lifting, reaching, pushing, and pulling, cigarette smoking, prolonged time spent in awkward positions such as a video display terminals, motor vehicle driving, and exposure to other forms of whole-body vibration would result in decreased risks. Encouraging workers using video display terminals to take frequent breaks appears to enhance recovery from neck and upper-limb disorders,⁴² and might reduce the likelihood of developing neck pain in the first place.⁴³

Osteoporosis

Osteoporosis is characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increased risk of fracture.⁴⁴ Fractures of the hip, vertebrae, and distal radius are particularly common. Although osteoporosis may occur secondarily to such conditions as hormonal defects, connective tissue disorders, or certain drug therapies, most cases are idiopathic.

Males have higher bone mass than females, and American Blacks have higher bone mass than non-Hispanic whites, Hispanic whites, and Asian-Americans.⁴⁵ After about age 40–50 years, bone mass is lost in both men and women of all racial and ethnic groups, but a particularly rapid decrease occurs in women in the years around and following menopause. Most research on osteoporosis has been undertaken in women, and unless specifically indicated, the material presented in this section pertains mainly to women. It has been estimated that a white woman of age 50 has a 17% chance of fracturing a hip, a 16% chance of fracturing a distal forearm, and a 16% chance of having a clinically diagnosed vertebral fracture during the remainder of her lifetime.⁴⁶

Bone mass in later adulthood, when osteoporotic fractures are most common, depends on bone mass in young adulthood, when bone mass is at its peak, and on the extent of bone loss after the peak is reached. Heredity is an important determinant of bone mass in childhood, adolescence, and early adulthood, but the role of genetics on rates of bone loss with aging or in association with menopause is less clear. Most osteoporosis is considered to be polygenic, resulting from the interaction of common polymorphic alleles with multiple environmental factors.⁴⁷ Although evidence is not definitive, it appears that weight, physical activity, calcium intake, and possibly other nutrients also affect bone mass in childhood, adolescence, and early adulthood, but to a lesser extent than heredity.^{48,49} In some adolescents and young adults, disruptions of the reproductive hormone axis from anorexia, intense athletic activity, and use of progestin-only injectable contraceptives can lead to lower than normal bone mass.⁵⁰

The relatively rapid rate of bone loss in middle-aged and older women has been related to a decrease in estrogen production. Women

who have had an oophorectomy have earlier loss of bone mass than other women. On the average, the lower the endogenous estrogen concentration around the time of menopause, the higher the rate of bone loss.⁵¹ Thin women are at higher risk than obese women, partly because of their lower estrogen production, their lower concentration of circulating estrogens, and the decreased mechanical stress on their bone.

In the adult years a low level of dietary calcium consumption is modestly associated with lower bone mass, and calcium supplementation affords some protection against loss of bone mass.^{52,53} The role of other dietary constituents is less clear. It is known that prolonged immobilization may result in loss of bone mass. The effect of light physical activities like walking is uncertain, but more vigorous impact and nonimpact exercise programs have been shown to have a modest protective effect against loss of bone mass in the lumbar spine and probably the hip as well.⁵⁴ Whether exercise reduces the risk for fractures is unclear.⁵⁵ Cigarette smoking after menopause increases the risk for osteoporosis and hip fracture.⁵⁶ Heavy, but not moderate, alcohol consumption⁵⁷ and corticosteroid use⁵⁸ are associated with lower bone mass and an increased risk for fracture at all ages, while use of thiazide diuretics is associated with increased bone mass and decreased risk of hip fracture.⁵¹

Recommended prevention strategies start with measures that will promote adequate bone mass at an early age, such as a diet adequate in calcium accompanied by adequate vitamin D acquired through diet or sunlight exposure, sufficient physical activity, and not smoking. In adulthood, randomized trials indicate that supplemental calcium affords a small amount of protection against loss of bone mass.⁵² Vitamin D formulations have a positive effect on bone mass, and probably reduce the frequency of vertebral fractures, but whether they also reduce the incidence of nonvertebral fractures is less certain.⁵⁹ Randomized trials have shown that exercise programs involving aerobic activity, weight bearing activity, resistance exercises, and endurance and strength training result in less loss of bone mass.^{54,60,61} Additional research is needed to determine the intensity and types of exercise that are most beneficial.⁵⁴

Because dietary calcium, calcium supplements, vitamin D and physical activity have only modest beneficial effects on the preservation of bone mass in perimenopausal and postmenopausal women, pharmaceutical agents may be recommended to prevent or retard loss of bone mass. Although menopausal hormone therapy with estrogen alone or estrogen with progestin protects against loss of bone mass and the occurrence of fractures while it is taken, it is no longer recommended for prevention because of the conclusion by the Women's Health Initiative⁶² that its long-term risks outweigh its long-term benefits. Bisphosphonates such as alendronate (Fosamax) prevent or retard loss of bone mass, but alendronate has been shown to protect against fractures only in women who already have very low bone mass.⁶³ Trials with newer bisphosphonates, including etidronate and risedronate, show similar results.⁶⁴ Some users experience gastrointestinal side effects, and, in addition, the long-term effects of the bisphosphonates are not known. The selective estrogen receptor modulator raloxifene (Evista) has been shown to retard loss of bone mass and to reduce the occurrence of vertebral fractures, but not to reduce the risk for nonvertebral fractures, including hip fracture.⁶⁵ Calcitonin in both intranasal and injectable forms has been shown to reduce somewhat the likelihood of new vertebral fractures, and is sometimes recommended for women who cannot take the other agents.⁶⁶ Teriparatide, a recombinant human parathyroid hormone that acts through increasing bone formation, reduces the risk for both vertebral and nonvertebral fractures. Its long-term effects are not known, however, and it is approved for use for a maximum of two years in patients at high risk for fracture.⁶⁶ In summary, the usefulness of pharmaceutical agents in the prevention of osteoporosis and osteoporotic fractures in women without very low bone mass has not been clearly demonstrated, as each of these drugs has limitations.

In recent years, screening apparently healthy perimenopausal and postmenopausal women for high fracture risk by measuring their bone mineral density has been undertaken, most commonly by dual energy x-ray absorptiometry. However, many questions remain about the

appropriateness of screening, such as who should be screened, what skeletal sites should be screened, whether multiple measurements over time are needed, what other information on risk should be obtained along with the measurement of bone mass, and what therapy should be recommended for those with various degrees of low bone mass.⁶⁷ Because of the uncertainties associated with available therapies, it is not clear what should be done as a result of findings on screening, unless bone mass is found to be very low. Ultrasonography, which is usually applied to the heel bone and which may provide information about the architecture and elasticity of bone as well as about bone mineral density, has been found to predict hip fracture.⁶⁸ Since ultrasound is less expensive, faster, and radiation-free compared to other methods commonly used to measure bone density, it may be increasingly used as a screening tool. Because ultrasound and bone densitometry predict fractures, in part independently, it has been suggested that using both measures would likely predict fracture occurrence better than either one alone.⁶⁹ However, questions remain about the utility of screening by any means.

Reducing the likelihood of falls among both women and men with osteoporosis may be an important way to prevent fractures. Risk factors for falls include increasing age, female sex, functional limitations (including problems with balance and gait and poor muscle strength), arthritis, symptoms of depression, orthostatic hypotension, cognitive impairment, visual impairment, various other chronic illnesses, and use of multiple prescription medications.^{70,71} The greater the number of these risk factors, the higher the risk of falling. Table 66-3 shows strategies demonstrated in randomized controlled trials to reduce the likelihood of falling among elderly women and men living in the community. Nonspecific advice about modification of home hazards has not proved effective,^{70,72} but standardized assessment by an occupational therapist coupled with specific recommendations and follow-up after hospital discharge has been associated with a 20% reduction in risk of falls both inside and outside the home among persons who have a history of falling in the previous year.⁷²

Whether a fracture results from a fall and the site of the fracture will depend on such factors as the orientation of the fall, a person's ability to initiate protective responses, the presence of shock absorbers such as a person's fat, and bone strength.^{71,73,74} Falling sideways or straight down greatly increases the risk for a hip fracture, while breaking the fall with an outstretched hand decreases the risk of fractures of several sites including the hip, but increases the risk for distal forearm fracture.⁷⁴ Falls from heights or on to hard surfaces increase the risk for fractures.⁷⁴ A history of falls, a recent increase in the number of falls, and previous fractures are predictive of hip fracture.⁷⁵ Architectural and geometrical properties of bone also affect the likelihood of a fracture.^{76,77} Randomized trials in nursing homes and in certain other populations at high risk for hip fracture have shown that institutions with programs in which hip protectors are provided have reduced risks for hip fracture, although compliance is a problem.⁷⁸

Osteoarthritis

Osteoarthritis, a heterogeneous condition of poorly understood etiology, is characterized by focal loss of articular cartilage with proliferation and remodeling of subchondral bone. Manifestations include pain

and stiffness accompanied by loss of function. The presence and severity of osteoarthritis in most population studies has been classified using radiographic criteria defined in the Atlas of Standard Radiographs of Arthritis.⁷⁹ These criteria include osteophytes, bony spurs, joint space narrowing, subchondral cysts, and bony remodeling. Newer imaging technologies characterize other important attributes of the disease processes, including bone marrow edema and irregularities of articular cartilage.^{80,81}

Idiopathic osteoarthritis may affect single joint groups (most commonly the knees, hands, feet, hips, and spine) or may present as generalized osteoarthritis, characterized by involvement of three or more joint groups and typically affecting perimenopausal and postmenopausal women.⁸² Secondary osteoarthritis follows the occurrence of traumatic, congenital, developmental, or systemic disorders involving the joints.

The etiology of osteoarthritis is multifactorial and associated with systemic factors, including obesity, aging, gender, and heritability. Obesity is known to increase the risk for osteoarthritis of several joints.^{83,84} Even in middle-age, obesity is associated with more than a twofold increase in knee osteoarthritis.⁸⁵ The prevalence of osteoarthritis and the proportion of cases that are moderate or severe increase with age.⁸⁶ Under age 45, the age-specific prevalence is higher in men than women, while over age 55, the age specific prevalence is greater in women than men. Women have a greater number of joints involved and more frequently report morning stiffness, joint swelling, and nocturnal pain.⁸⁷ The more common occurrence of Heberden's nodes in women is believed to be related to a single autosomal gene that is dominant in women and recessive in men.⁸⁸ Heritability estimates from twin studies range from 0.39 to 0.65, and are independent of known risk factors including obesity.⁸⁹ Studies using techniques of recombinant DNA analysis have demonstrated linkage of a polymorphism of the type II collagen gene (Col2A1) with generalized osteoarthritis.⁹⁰

Repetitive joint trauma associated with occupational activity predisposes to osteoarthritis. For instance, high prevalence is found in the elbows and knees of miners,⁹¹ in the fingers of cotton pickers,⁹² in the hips of farmers,⁹³ and in the fingers, elbows, and knees of dock workers.⁹⁴ Jobs requiring a great deal of knee bending, squatting, kneeling, stair climbing, heavy lifting, and mechanical loading increase the risk for knee osteoarthritis.⁹⁵

The knee is among the commonly affected joints. Radiographic evidence of knee osteoarthritis, defined as grade two or greater, is estimated to be present in about 30% of people over the age of 65 years, and of those with radiographic evidence, one-third are symptomatic.⁹⁶ The frequency of radiographic knee osteoarthritis is rarely evaluated in persons younger than age 55, but one study reported that in women aged 40–55, the prevalence is 15%.⁹⁷ Disabling symptoms in the knee occur in about 10% of persons older than age 55, and of these, about one quarter are severely disabled.⁹⁸ On a population basis, the magnitude of the disability from knee osteoarthritis is considered to be as great as the disability associated with heart disease, and is greater than the disability from any other medical condition among the elderly.⁹⁹ A World Health Organization report predicts that in the next 15 years knee osteoarthritis will become the fourth most important global cause of disability in women and eighth most important cause in men.⁹⁶ Studies in persons with radiologic evidence of knee osteoarthritis have identified the following factors to be predictive of knee pain: severity of radiographic changes, presence of morning stiffness, crepitus on passive range of motion, and a feeling of low spirits.¹⁰⁰

In addition to obesity, other nonoccupational risk factors for osteoarthritis of the knee include knee injury, meniscectomy, and also the presence of Heberden's nodes.¹⁰¹ Several studies have noted an inverse association between osteoporosis and osteoarthritis of the knee and hip.¹⁰² A history of unilateral knee injury has been strongly associated with ipsilateral but not contralateral osteoarthritis of the knee.⁹⁵ Recreational, low-impact physical activity, including running, does not appear to be associated with knee osteoarthritis in most people, but elite athletes and recreational runners who already have abnormal or injured joints are at increased risk for osteoarthritis.¹⁰³

Osteoarthritis of the hip is more weakly associated than the knee with obesity, hip injury, and Heberden's nodes, but is rather strongly associated with developmental disorders that may affect the shape of the hip joint, including developmental dislocation of the hip and slipped capital femoral epiphysis.¹⁰²

Osteoarthritis of the knee is associated with decreased survival in persons aged 55 and older.¹⁰⁴ Likely explanations for this observation include the association of obesity with both osteoarthritis and mortality and possibly the adverse effects of treatment with nonsteroidal anti-inflammatory drugs (NSAIDs). One study noted excess proportionate mortality from gastrointestinal diseases in persons with osteoarthritis,¹⁰⁴ while another demonstrated an increased incidence of gastroduodenal ulcers in subjects with osteoarthritis and knee pain.¹⁰⁵ Finally, osteoarthritis of the knee, especially with concomitant pain, often results in long-term activity and mobility limitation.¹⁰⁵

Regarding primary prevention, several potentially modifiable risk factors have been identified, including obesity and repetitive joint usage and trauma. Weight loss can lower risk for the development of osteoarthritis and probably also slows disease progression.¹⁰⁶ Reduction in the number of injuries and reduction of exposure to repetitive mechanical stress on the joints in the work place should be beneficial. While early treatment of conditions such as developmental dislocation of the hip, slipped epiphysis, and various other developmental and acquired bone and joint disorders may curtail the development of, or limit the extent of, osteoarthritis, studies suggest the importance of prevention of these disorders in the first place rather than relying on treatment alone. For example, Pinczewski and colleagues¹⁰⁷ reported that 70% of persons with anterior cruciate ligament injuries treated surgically with a patellar tendon graft developed radiological evidence of osteoarthritis within seven years.

Screening tests for osteoarthritis are not presently available. However, two biomarkers may emerge as candidates for screening. Elevated levels of cartilage oligomeric matrix protein (COMP), a glycoprotein found in cartilage as well as in ligaments, tendons, menisci, and synovial tissue, have been identified in persons with knee osteoarthritis compared with those unaffected, as well as persons with osteoarthritis-related collagen gene mutations, synovitis, and inflammatory arthropathy due to rheumatoid arthritis.^{108,109} Sowers and colleagues¹¹⁰ reported that baseline hsC-reactive protein (hsC-RP)

concentrations increased in a progressive manner with each interval of the Kellgren-Lawrence scale for prevalent knee osteoarthritis or incident osteoarthritis and in women with bilateral knee osteoarthritis compared with unilateral osteoarthritis of the knee. Unfortunately, neither COMP nor hsC-RP is specific for osteoarthritis.

Intervention strategies aimed at controlling the symptoms of pain, stiffness, and the functional limitations associated with knee osteoarthritis have been organized into a set of clinical recommendations (Table 66-4).¹¹¹ The first recommendation indicates that optimal management incorporates a combination of nonpharmacological and pharmacological modality. Recommended nonpharmacological modalities include exercise programs and physical therapy, weight loss, and wedged insoles, frequently accompanied by a pharmacological intervention. Educational activities include learning appropriate methods of lifting and bending to maintain and improve muscle strength, flexibility, and range of motion.¹¹²⁻¹¹⁵ Whether acupuncture is effective as a treatment for osteoarthritis remains an open question.¹¹⁶

If medication is used, acetaminophen (paracetamol) is generally the first choice rather than NSAIDs because of its better overall gastrointestinal system safety profile.¹¹⁷ Recently, the use of therapeutic agents for osteoarthritis has become more complex in regard to weighing the benefits from relief of pain and disability versus the possibility of adverse events. There is support for the use of NSAIDs, although the addition of a gastroprotective agent, such as a histamine-2 receptor antagonist, may be required to reduce the risk of duodenal and gastric ulcers.¹¹¹ Until recently, alternative recommendations to NSAIDs would have included COX 2 selective inhibitors,¹¹⁸ but recent reports of adverse cardiovascular events have led to a worldwide withdrawal of some products.¹¹⁹ Slow-acting agents for osteoarthritis, including glucosamine sulfate, chondroitin sulfate, diacerein, and hyaluronic acid, have been evaluated largely in terms of their effect on pain rather than structure.^{120,121} This has led to the conclusion that these agents have efficacy in the treatment of pain, but at this time there is minimal knowledge of their effect on structure.¹¹¹ Joint replacement has become the intervention of choice for individuals with severe pain and disability refractory to nonsurgical treatment.^{111,122} The success of total hip replacement has been recognized for many years, while more recently it has been concluded that total knee replacement is also safe and effective in reducing pain and improving function and quality of life.¹²²

TABLE 66-4. RECOMMENDATIONS FOR MANAGEMENT OF OSTEOARTHRITIS OF THE KNEE BASED ON BOTH EVIDENCE AND EXPERT OPINION

- 1 Optimal management of knee osteoarthritis requires a combination of nonpharmacological and pharmacological treatment modalities.
- 2 The treatment of knee osteoarthritis should be individually tailored, taking into account:
 - (a) Knee risk factors (obesity, adverse mechanical factors, physical activity)
 - (b) General risk factors (age, comorbidity, polypharmacy)
 - (c) Level of pain intensity and disability
 - (d) Signs of inflammation
 - (e) Location and degree of structural damage.
- 3 Nonpharmacological treatment of knee osteoarthritis may include education, exercise, appliances (sticks, insoles, knee bracing), and weight reduction
- 4 Paracetamol is the oral analgesic to try first and, if successful, the preferred long-term oral analgesic.
- 5 Topical applications (NSAID, capsaicin) have clinical efficacy and are safe.
- 6 NSAIDs should be considered in patients unresponsive to paracetamol. In patients with an increased gastrointestinal risk, nonselective NSAIDs and effective gastroprotective agents should be considered.
- 7 Opioid analgesics, with or without paracetamol, are useful alternatives in patients in whom NSAIDs, are contraindicated, ineffective, and/or poorly tolerated.
- 8 Symptomatic slow-acting drugs (glucosamine sulfate, chondroitin sulfate, avocado-soybean-unsaponifiable [ASU], diacerein, and hyaluronic acid) reduce symptoms and may modify structure.
- 9 Intra-articular injection of long acting corticosteroid is indicated for flare of knee pain, especially if accompanied by effusion.

Source: Data from Jordan KM, Arden NK, Doherty M, et al. EULAR Recommendations 2003: an evidence based approach to the management of knee osteoarthritis: Report of a Task Force of the Standing Committee for International Clinical Studies Including Therapeutic Trials (ESCSIT). *Ann Rheum Dis*. 2003;62:1145-55.

Rheumatoid Arthritis

Rheumatoid arthritis is a chronic inflammatory disease thought to be of autoimmune etiology, characterized by proliferative synovitis that results in bony erosion and destruction of articular cartilage; these processes give rise to typical articular deformities. The clinical symptoms include stiffness, pain, and swelling of multiple joints, most commonly the small joints of the hands and wrists. Rheumatoid arthritis usually develops over time in a symmetric fashion. It also may be associated with a variety of extra-articular manifestations that incorporate many characteristics of a systemic disease including vascular, renal, and eye disease complications. The clinical course is highly variable. Persistent rheumatoid arthritis is associated with progressive disability^{123,124} and earlier mortality.¹²⁵ Although some studies suggest that, overall, the disease course may be more benign than previously thought,¹²⁶ other studies indicate that the impact of inflammation on the vasculature is substantial, and that the use of treatments to control inflammation may improve quality of life and functioning but not vascular integrity.¹²⁵

The lifetime incidence of rheumatoid arthritis is between 0.5% and 1.0%, with an annual incidence of 25–50/100,000.¹²⁷ Prevalence and incidence estimates of rheumatoid arthritis have been limited by the absence of a gold standard against which classification systems can be evaluated. Current classification systems have evolved over time from the 1958 American Rheumatism Association (ARA) criteria¹²⁸ and the New York criteria¹²⁹ to the current 1987 criteria of the American College of Rheumatology (ACR).¹³⁰ A recent study used data from the Third National Health and Nutrition Examination Study (NHANES III) to compare rheumatoid arthritis prevalence estimates in persons over the age of 60 using three different rheumatoid arthritis classifications.¹³¹ The prevalence was about 2% using each set of criteria.

In NHANES III, the prevalence of rheumatoid arthritis was approximately 1.5 times greater in older women than older men.¹³¹ Prevalence increased with age, with 1.6–1.9% affected in the 60–70 year age range compared to 2.5–2.8% in persons 70–80, suggesting there is more rheumatoid arthritis in older birth cohorts.¹²⁷ In the Olmsted County, Minnesota, catchment area, the incidence of severe extra-articular manifestations was 1 per 100 person-years of follow-up; approximately 15% of rheumatoid arthritis patients had these manifestations at any given time.¹³²

Several American Indian tribes have particularly high prevalences of rheumatoid arthritis, including the Yakima of central Washington State and the Mille-Lac Band of Chippewa in Minnesota. Asians, including Japanese and Chinese, appear to have lower prevalences than Whites.¹³³

Genetic factors have an important etiologic role in rheumatoid arthritis.¹³⁴ The disease exhibits familial aggregation and a higher concordance rate in monozygotic than in dizygotic twins. Studies have demonstrated a strong association between the class II major histocompatibility antigen HLA-DR4 and rheumatoid arthritis; in whites, the relative risk for this association exceeds 4.0.^{135,136} This association occurs across race/ethnic groups, with the exceptions of the Yakima Indians of Washington State, Asian Indians, Greeks, and Israeli Jews. Further, the HLA-DR4 subtype has been associated with the extra-articular manifestations.¹³⁴ In those who lack HLA-DR4, there is frequently an association between rheumatoid arthritis and HLA-DR1. HLA-DR10 and HLA-DR14 may also be associated with rheumatoid arthritis.¹³⁷ Other genetic markers of immunologic status are being investigated.¹³⁴ The role of infectious agents as etiologic factors in rheumatoid arthritis has been extensively explored, but no specific agent has been implicated.¹³⁸

Declining incidence among women, but not men, was noted between the periods 1960 through 2000; these findings were consistent with a protective effect of oral contraceptives first reported by the Royal College of General Practitioners Oral Contraceptive Study.¹³⁹ A meta-analysis confirmed a protective effect of oral contraceptive use on the development of rheumatoid arthritis, with a pooled relative risk of 0.70.¹⁴⁰ It is thought that oral contraceptives, and possibly non-contraceptive hormone replacement therapy, modifies the course of rheumatoid arthritis by preventing the progression of mild to severe disease, rather than preventing the development of disease.

Rheumatoid arthritis is associated with excess mortality, with a standardized mortality ratio of about 170.^{133,141} Causes of death that

are more frequent in persons with rheumatoid arthritis include respiratory and infectious diseases and gastrointestinal disorders. It is likely that some of the excess mortality is related to complications of therapy. Persistent synovitis, the presence of rheumatoid factor, extra-articular involvement, functional losses, low levels of education, and the HLA-DR4 epitope have been associated with increased mortality and excess disability.^{142,143}

Disability is a major concern among persons with persistent rheumatoid arthritis. A meta-analysis found that physical demands of the job, older age, low functional capacity, and lower educational attainment are factors that predict work disability. There was little evidence that biomedical factors, personal factors (i.e., coping strategies) and adaptive programs at work are important in contributing to or ameliorating work disability.¹⁴⁴

Methods of primary prevention or screening for rheumatoid arthritis are not currently available. First-line medical therapy incorporates salicylates or NSAIDs. These drugs are anti-inflammatory, analgesic, and antipyretic, and lead to improvement in pain and swelling. However, there is no evidence that they affect the underlying disease process. It is now recommended that second-line therapies that may modify the course of the disease be initiated early in persons with persistent synovitis.¹⁴⁵ Such therapies include anti-malarial drugs, sulfasalazine, methotrexate, intramuscular gold, D-penicillamine, azathioprine, and cyclosporin A. Oral corticosteroids probably have a role in management of the rheumatoid arthritis patient as an adjunct to remittive therapy.¹⁴⁵

Foot Disorders in Older Adults

About three-fourths of fully active older adults complain of painful feet.^{146,147} Among institutionalized adults, foot problems are one-fifth as common, indicating an important etiologic role for stress on the feet from ordinary physical activity. In a survey in which feet were professionally examined in a sample of community-dwelling older adults in Massachusetts,¹⁴⁸ the prevalence of foot disorders was higher still, including 75% for toenail disorders, 60% for lesser toe deformities, 58% for corns and calluses, 37% for bunions, and 36% for signs of fungal infection, cracks/fissures, or maceration between toes. Toenail conditions, fungal symptoms, and ulcers or lacerations were more common in men, while bunions and corns and calluses were more frequent in women.

Foot pain, especially if chronic and severe, can be a significant cause of disability.^{149,150} In addition, even slight deformities of the foot can lead to impaired proprioception, skeletal problems, changes in gait and balance, and pain, resulting in increased risks for falls¹⁵¹ and foot fracture.¹⁵² The prevalence and severity of foot conditions increase with age, as the aging process can result in neuropathy, ischemia, and atrophy of the planter fat pad.¹⁵³ With age, the skin of the foot may become dry, scaly, thin, and less elastic, the dermis may atrophy, and the nail plate tends to become thin. These changes predispose to a variety of conditions, such as callus formation, plantar keratosis, heel pain, susceptibility to infection, and other skin and nail problems. Chronic conditions such as diabetes, peripheral vascular disease, and arthritis often involve the feet,¹⁵³ and obesity has been reported to be a risk factor for foot pain.¹⁵⁰ A variety of static and functional deformities of the feet, such as hallus valgus, digiti flexus, and trophic changes, are related to degenerative disease. The majority of painful conditions of the foot seen by orthopedists originate in soft tissues such as muscles, ligaments, tendons, nerves, and blood vessels. Articular and skeletal disorders of the feet may result from congenital abnormalities, infections, neoplasms, and trauma,¹⁵⁴ as well as from osteoarthritis, rheumatoid arthritis, and, less commonly, gout. Improperly fitting shoes and other stresses on the foot can lead to bunions, hammer toes, and claw toes.

Prevention at all levels includes appropriate treatment of diseases that can involve the feet, the wearing of proper shoes, wearing socks or stockings, bathing the feet frequently, avoidance of obesity, protection against infection and trauma to the feet, and proper care of toenails.¹⁵⁵ Once foot problems occur, soft, well-padded shoes should

be worn to relieve pressure in sore areas. Pads, moleskin, lamb's wool, and hammer-toe pads applied to localized areas of soreness may be helpful. In most instances, these simple methods can reduce much of the discomfort associated with foot problems. In some cases, rest, application of heat and cold, specific exercises, and use of special corrective shoes may be needed.¹⁵⁴ Almost half of all people with foot disorders are not receiving care for the problem.¹⁵⁵

Paraplegia and Quadriplegia

The most common cause of paraplegia and quadriplegia in Western countries is vertebral fractures and dislocation from trauma. Complete transection of the spinal cord results in paralysis of all muscles supplied by motor neurons below the level of the lesion and in the loss of skin sensation in all areas supplied by sensory neurons below the lesion. Because neurons in the central nervous system do not regenerate, both motor and sensory paralysis is permanent.

The effect on the patient, family, and friends is immediate and enormous. Most affected individuals were previously independent and must learn to cope with partial or complete paralysis, loss of sensation in major parts of the body, and loss of voluntary control over body functions, frequently including bowel and bladder dysfunction and loss of sexual function. The patient's work, marriage, family, and social relationships are likely to be substantially altered.¹⁵⁶

In the United States, nearly 200,000 people are disabled with spinal cord injuries, with 11,000 new cases occurring each year.¹⁵⁷ Spinal cord injuries occur most frequently in persons ages 15–40 years, are 3–4 times more common in males than females, and are more frequent in blacks than whites.^{157–159} In developed countries, motor vehicle accidents, especially those involving motorcycles, are by far the leading cause of these injuries. One study in the United States¹⁶⁰ found that among those whose spinal cord injury occurred as a result of being in a motor vehicle, 70% were involved in a vehicle rollover, and 39% were ejected from the vehicle. Only 25% reported using seatbelts. In another study¹⁶¹ drugs and alcohol had been used before the injury in at least 25% of cases. Other major causes are falls (especially in the elderly); sports and recreational activities such as diving in shallow water, injuries sustained during gymnastics and hard contact sports; violence-related injuries; and self-inflicted injuries.^{158,159,161,162} In developed countries the proportion of spinal cord injuries attributable to sports and recreational activities has increased in recent years, while the proportion of work-related accidents has decreased in many countries as safer work practices have been implemented. In developing countries, other common causes include falling from trees, carts, and bicycles, and carrying heavy loads on the head; violence has become a more common cause in recent years.¹⁵⁸

The most important primary prevention measures in developed countries are those that reduce the likelihood of motor vehicle accidents and lessen the risk of injury if accidents do occur. These measures include not driving after drinking alcoholic beverages; reduced speed limits; use of seat belts, headrests and airbags; and wearing of helmets by motorcyclists. Prevention of falls in the elderly and safety measures in occupational and recreational settings are also important. For instance, in high school and collegiate football, rules banning "spearing" or initial contact with the top of the helmet when making a tackle have markedly reduced the frequency of permanent cervical quadriplegia resulting from participation in that sport.¹⁶³ In Canada, a decline in the number of major spinal cord injuries has been noted in ice hockey following the implementation of educational programs and rules changes; injuries from being checked or pushed from behind into boards were especially affected.¹⁶⁴ In developing countries, education on safe tree climbing and on carrying heavy objects is needed.¹⁵⁸

The number of survivors with paraplegia and quadriplegia has greatly increased because of medical and surgical advances. Since most of those injured are in their late teens and early adult years, enormous costs and very long-term severe disability ensue. Lifetime costs per patient generally range from about \$500,000 to over \$2 million.¹⁶² In addition to psychological problems, the greatest difficulties are in self-care, locomotion, obtaining employment, and medical

complications. Common medical complications include urinary tract infections, pressure sores, cardiac and vascular problems, and autonomic dysreflexia.¹⁶⁵ Patient education and good nursing care can reduce the likelihood of many of these complications, especially pressure sores and urinary tract infections.¹⁵⁸

The main object of tertiary prevention is to return the affected person to maximum physical and social functioning. Both physical and psychological adjustments are needed. Accordingly, in addition to specialists in orthopedic and neurological surgery, other specialists that should be involved in therapy of these patients include occupational and physical therapists, psychiatrists, orthotics specialists, urologists, and vocational counselors. Long leg braces, crutches, and gait training may help highly motivated paraplegics with low-level lesions return to walking and may even enable them to become self-supporting. Because many paraplegics drive cars, wheelchair accessibility of public buildings is becoming increasingly important.¹⁶⁶ Sexual counseling also may be helpful for many.

► DISORDERS PRIMARILY OF CHILDREN

Scoliosis

Scoliosis, or abnormal lateral curvature of the spine associated with rotation of the vertebrae, is the most common cause of spinal deformity in North American children.¹⁶⁷ Of the various forms of scoliosis, the most common and serious is adolescent idiopathic scoliosis. About 2–3% of children develop curves of 10° or more before growth ceases, and about 2–3 per 1000 children develop curves of 30° or more.^{168,169} Persons left with significant curvature frequently develop spinal osteoarthritis in adulthood; lung and heart complications may occur. Also, further curve progression sometimes takes place in adults.

Scoliosis is most frequently diagnosed around the ages of 11–14 years in girls and 14–16 years in boys. The ratio of female to male cases seen at surgery is as high as 5–1, but mild curves of less than 15° are found with almost equal frequency in both sexes. Once girls have reached menarche, their risk for developing scoliosis is reduced.¹⁷⁰ Although surgical series have indicated that scoliotic curves are most common at the thoracic level, screening programs identifying children who do not necessarily seek medical care have found that the peak frequency is at the thoracolumbar level.¹⁷¹

The risk for scoliosis in first-degree relatives of cases is about 3–4 times higher than in other children.¹⁷² Twin studies indicate a genetic etiology for both the development and progression of scoliosis,¹⁷³ but the mode of inheritance is uncertain. Little is known of other risk factors for development of the disease. Some evidence suggests that prepubertal standing height, sitting height, recent increase in sitting height, and early age at gain in sitting height are predictive,¹⁷⁴ and that children who are skeletally more mature, taller, and leaner at the onset but not at the end of puberty are most likely to be affected.^{170,176} These observations suggest that the scoliotic spine grows faster and earlier than the normal spine.^{170,176,177} Impaired visual and vestibular functioning, defects in proprioceptive postural control, asymmetric muscle activity, unequal leg length, high concentrations of calcium in paraspinous muscles, collagen disorders, and defects of the elastic fiber system may be etiologically involved, but evidence is not conclusive.^{176,178,179}

Most curves do not progress. The main risk factors for progression of existing curves are double curves as opposed to single curves, thoracic curves as opposed to curves at lower levels, curves of greater magnitude, absence of a sacral tilt, limb length inequality, early chronological age, skeletal immaturity, and female sex.^{180,181}

Because so little is known of the etiology of adolescent idiopathic scoliosis, primary prevention is not feasible. However, detection of early disease by screening is being undertaken in many places and screening for scoliosis is required by law in some states in the United States. It is assumed that with early detection, affected children can be treated by conservative means and thereby avoid surgery. The traditional screening test for scoliosis has been the forward-bend test, in which the child's back is examined while he

or she bends forward from the waist. The rotation that accompanies the lateral curvature in scoliosis results in posterior prominence of the ribs on the concave side of the curvature, so that a “rib hump” is often apparent on forward bending. The forward-bend test has good specificity but fairly low sensitivity. Moiré topography, in which a photograph of the back is used to measure the degree of topographic asymmetry, and the humpometer, which measures back contour and shape, are not recommended as screening procedures; despite their high sensitivity, their relatively low specificity results in excessive numbers of false positives.^{177,182} The inclinometer (scoliometer), which measures trunk asymmetry as an indicator of trunk rotation, has been reported to have high sensitivity and fairly good specificity, but it has not been used much and only limited evaluation has been undertaken.^{183,184} Most school screening programs use the forward-bend test.

In the United States, school screening programs are identifying large numbers of children with possible spinal curvatures. Positive screening tests are followed up with x-ray examination for more definitive diagnosis. Curves of over 5° are monitored by further x-ray examination every few months. Should a curve progress to 20°–25°, treatment is generally indicated to try to prevent further progression. Braces are most commonly used for curves of 25°–40°, while surgery to correct at least part of the deformity and to halt further progression is often indicated for curves of 40° or greater, particularly in children who are likely to continue growing.

Many questions have arisen about the desirability of widespread screening for scoliosis.^{185–187} First, it is uncertain that school screening programs have brought about a reduction in the prevalence of severe deformities and thereby the number of operations needed. In particular, the efficacy of conservative treatment in preventing progression is uncertain. Also, many children screened as positive are not subsequently seen for definitive diagnosis. On the other hand, many false positives occur, resulting in referral for far too many x-ray examinations as well as a great deal of medical expense and anxiety. Better training and evaluation of the staff who do the screening may be needed.^{169,185} The optimal ages for screening and whether males should be screened at all have not been determined. Because of these uncertainties about the effectiveness of screening for scoliosis, the U.S. Preventive Services Task Force was unable to recommend for or against routine screening of adolescents for scoliosis.¹⁸⁸

Slipped Capital Femoral Epiphysis

Slipped epiphysis of the head of the femur, in which epiphysis of the head of the femur is displaced backward and downward off the diaphysis, is primarily a disease of adolescents. It is closely related to the adolescent growth spurt and does not occur once the epiphysis is fused to the shaft of the femur. In the northeastern United States about 1 in 800 males and 1 in 2000 females will be diagnosed as having a slipped epiphysis before they reach 25 years of age.¹⁸⁹ The magnitude of the male excess varies from one geographical area to another and appears to have decreased over time. The median age at diagnosis is 13 years for males and 11–12 years for females; the earlier age in females corresponding to their earlier onset of puberty. Blacks are affected more frequently than whites. In most studies in northern latitudes, symptoms begin more frequently in spring and summer than in fall and winter.^{190,191}

A large proportion of children with slipped epiphysis are markedly overweight;^{192,193} about half are at or above the 95th percentile for their age (Fig. 66-2). Children with slipped epiphysis tend to have undergone slower-than-average skeletal maturation and to be tall for their age at the time of diagnosis.¹⁹⁴ Familial aggregation of cases has been reported,¹⁹⁵ but it is not clear whether this aggregation is primarily attributable to inherited characteristics or to common environmental factors.

Many of these risk factors are related either to a weakening of the epiphyseal plate, such as occurs during periods of rapid growth, or to increased shearing stress on the plate.¹⁹⁶ Animal experiments indicate that a deficit of sex hormones relative to growth hormone brings about a widening of the epiphyseal plate and a reduction in the shearing force necessary to displace the epiphysis.¹⁹⁷ Higher body weight increases the shearing stress on the epiphyseal plate, and also

Figure 66-2. Percentage of children with slipped epiphysis with weights at or above 95th percentile for their age. (Source: Adapted from Kelsey JL, Acheson RM, Keggi KJ. *The body builds of patients with slipped capital femoral epiphysis.* Am J Dis Child. 1972;124:276–81.)

is associated with an increased tilting backwards of the femur, further increasing the shearing stress.¹⁹⁸ Children with the unusual combination of being overweight and undergoing slow maturation would appear to be at high risk, and these children should be carefully watched for slipped epiphysis.

The only known means of primary prevention is avoidance of obesity in adolescents. No screening tests for slipped epiphysis exist, but the diagnosis should be suspected in adolescents who have a limp and hip or knee discomfort, especially if there is restriction of internal rotation of the hip. X-ray examination should be performed immediately to confirm the diagnosis. The condition is bilateral in 20–25% of cases. Decision analysis has indicated that prophylactic pinning of the asymptomatic contralateral hip should be considered in children with a slipped epiphysis in one hip.¹⁹⁹ At a minimum, the contralateral hip should be carefully monitored, especially for those whose first slipped epiphysis occurred at an early age.^{193,200} Slippage that is stable, meaning that weight bearing is possible with or without crutches, and slight degrees of slippage that are treated early by hip pinning have a favorable prognosis, whereas cases diagnosed late and that involve severe displacement are more likely to result in early onset of osteoarthritis of the hip and permanent disability despite treatment.

Fractures in Children

Each year about 1 in 20–25 children fracture or dislocate a bone.^{201,202} One-third of children fracture at least one bone before 17 years of age.²⁰³ In childhood, fracture incidence rates increase until about ages 11 years in females and 14 years in males,²⁰³ with males at higher risk throughout childhood and adolescence.^{203–205} In one series²⁰⁴ over one-half of childhood fractures occurred while the child was at play, participating in a sport, or in a traffic accident. In another series,²⁰⁵ 36% of childhood fractures occurred during sports and leisure-time activities, and 3.5% were the result of assaults. The U.S. Health Interview Survey indicates that the bones most frequently fractured in children are the hand, radius and ulna, carpals, skull and face, clavicle, foot and ankle, and humerus.¹

Fractures of the phalanges of the hands often occur during contact sports, skating, playing and fighting, while fractures of the distal forearm tend to result from a fall on an outstretched hand, particularly during ball games, and bicycle, playground, and skateboard accidents. Carpal and metacarpal fractures most often result from fighting, falls, bicycle accidents, ball games, skiing, and skating. Fractures of the clavicle frequently occur during falls, ball games, and contact sports. Ankle fractures most often result from the foot being caught in a bicycle wheel and from falls, and also from ball games, skateboards, roller skates, mopeds, motorcycles, skiing, skating, cycling, and playing.²⁰⁴ Tall and heavy children as well as those who smoke may be at elevated risk for childhood fractures.²⁰⁶

The primary prevention of fractures in children depends mainly upon reducing the number of sports and recreational injuries, automobile and bicycle accidents, falls, child-battering injuries, and other traumas. The use of impact absorbing surfaces in playgrounds could reduce the frequency of fractures at many sites, and wearing wrist guards during certain sports could reduce the risk of fractures of the radius and ulna.²⁰⁵

Fractures usually heal rapidly in children; the younger the age, the more rapid the healing. However, if the growth plate is involved in the fracture, growth in that bone may be adversely affected, particularly if a crushing injury has occurred. Other complications are rare but may include infection, delayed union, nonunion, avascular necrosis, and malunion. Prevention of these complications involves thorough cleansing and removal of all dead and contaminated tissue from an open (compound) fracture and competent initial treatment of the fracture.

Developmental Dysplasia/Dislocation of the Hip

In developmental dysplasia/dislocation of the hip the head of the femur is displaced completely or partially out of the acetabulum. Partial displacement is sometimes referred to as subluxation of the hip. Because many dislocations tend to occur immediately after birth or occasionally later during the first year of life, the term “developmental dislocation/dysplasia of the hip” is now frequently used instead of the older term “congenital dislocation of the hip.”²⁰⁷ In about 80% of cases the diagnosis is made shortly after birth, and in the remaining cases the diagnosis is made later, especially when the child starts to walk. Although it is possible that some of these late-diagnosed cases represent dislocations missed around the time of birth, there is good evidence that some dislocations do develop after birth.²⁰⁷

Developmental dislocation/dysplasia of the hip includes the following categories: (a) dislocated hips, which are hips dislocated in a resting position, with the dislocation present at birth; (b) located but unstable or dislocatable hips, which are hips that rest in a located position but are unstable or dislocatable on clinical examination and provocative maneuvers; (c) dysplastic hips, in which the acetabulum is shallow or dysplastic.²⁰⁷

The prevalence of developmental dysplasia/dislocation of the hip varies considerably from one geographic area to another. Frequencies ranging from 1 per 1000 to 10 per 1000 births have been reported in most North American and Western European populations and in Israel, Australia, and New Zealand. Higher rates of from 10 per 1000 to 100 per 1000 have been observed in the Navajo, Apache, and Cree-Ojibwa Indians of North America, in the Lapps, and in the populations of Hungary, northern Italy, Brittany, and the Faroe Islands. Developmental dysplasia/dislocation of the hip is rare among blacks in South Africa, the West Indies, and Uganda, as well as among Chinese living in Hong Kong.¹⁷⁶ Although the frequency of developmental dysplasia/dislocation of the hip has been reported to be rising in certain areas, much of the apparent rise may be attributable to more extensive screening after birth and to increased awareness by physicians.

In North America, girls are affected more frequently than boys in the ratio of about 6 to 1. Rates are also higher in whites than blacks. In most areas, a greater than expected number of cases are encountered in children born in late fall and winter than in summer.²⁰⁸ Familial aggregation of cases occurs; both hereditary and environmental factors contribute to the familial excess.^{209,210} On the average, infants with developmental dysplasia/dislocation of the hip have had longer gestation periods than other infants and are considerably more likely to have been born by breech delivery than other infants.^{208,210} Position in utero may be involved in the etiology, since breech position in utero elongates the ligament of the hip joint capsule by persistent upward pressure of the greater trochanter.²¹¹ Ligamentous and capsular laxity are also probably predisposing factors.²¹²

No feasible methods of primary prevention are known. In regard to secondary prevention, it is now routine to examine newborn infants for developmental dysplasia/dislocation of the hip. Without prompt treatment the affected leg may be shorter, the child may limp, gait abnormalities may develop, surgery may be required, and osteoarthritis of the hip is likely to occur in young adulthood. Two screening tests

have generally been used: the Ortolani and the Barlow. The Ortolani test involves placing the hip in flexion and gently adducting and then abducting the hip. The test is considered positive if a palpable jerk and audible clunk are heard as the head of the femur returns to the acetabulum. Some practitioners also consider an audible click to constitute a positive test. In the Barlow test, gentle downward pressure is exerted over the lesser trochanter with the hip in flexion and adduction; the unstable hip shifts from the acetabulum, and a sensation similar to the Ortolani sign is produced. When the leg is allowed to abduct, the hip is reduced.

About half of the hips noted to be unstable or dislocatable immediately after birth become stable within a few days;²¹³ thus, these tests are often repeated at around three weeks. Infants showing positive results then are treated with braces, splints, or harnesses for 2–4 months. X-ray examination of the hip is of limited value in the newborn, but is an important diagnostic tool in children past the age of 3 months. Routine checks on hips of these infants should be done until they are walking well. If the disease is diagnosed after the neonatal period, surgery is generally required, and the prognosis is poorer.²¹⁴

Despite the routine use in many locales of screening tests for developmental dysplasia/dislocation of the hip, many questions have arisen regarding the effectiveness of screening by the Ortolani and Barlow tests.^{215–217} For instance, it appears that incidence rates of developmental dysplasia/dislocation of the hip requiring prolonged treatment are no lower now than they were before screening became widespread. Both the sensitivity and specificity of the screening tests are poor. In one study,²¹⁵ only one-third of genuine cases were detected, and the ratio of false positives to true positives was 10 to 1. Thus, for every one infant who benefits from splinting as a result of a positive test, 10 infants undergo unnecessary splinting. Furthermore, there is no consensus on indications for treatment, the timing of treatment, and the type of splint to be used. The question has arisen as to whether the screening procedures may themselves induce hip dislocation. Although these screening tests require experienced examiners for proper performance and interpretation, inexperienced examiners are often used, thus increasing both false-positive and false-negative rates. Better knowledge of which hips will spontaneously stabilize would allow better decisions about the cases who should receive immediate treatment. Disagreement exists about the significance of a soft audible or palpable click without evidence of abnormal movement between the femoral head and acetabulum.²¹⁸ More data are needed to resolve these issues, but in the meantime, routine screening with these tests is recommended by most professional groups.^{219,220}

In recent years, ultrasound, which provides a defined image of the bony and cartilaginous neonatal hip, has become widely available for screening for developmental dysplasia/dislocation of the hip. Although it was initially believed that it might alleviate some of the problems with the Barlow and Ortolani tests,^{221,222} its use as a routine screening test in all infants has not been found to be cost-effective. Even its use as a screening test in high-risk infants is controversial. Among its limitations are its high cost, the large proportion of hips testing positive on screening that develop normally, and the tendency of some cases to occur after the neonatal period.^{219,220,223,224} In addition, while adequate inter-observer agreement in reading ultrasound scans may be obtained with proper training, producing the scans is subject to even more variability. Thorough training and more attention to detail are needed to improve this situation.²²⁵ Although ultrasound may be of some value in following up infants who show instability on the Ortolani or Barlow test,^{217,226} professional groups do not recommend routine screening with ultrasound for either all infants or those at high risk.^{219,220}

► CONCLUSION

The extent to which musculoskeletal disorders may be prevented varies considerably from one disorder to another. Some methods of primary prevention are possible for back disorders, osteoporosis,

osteoarthritis, foot disorders, paraplegia and quadriplegia, slipped epiphysis, and fractures. However, these preventive measures frequently involve changes in individual behavior that are difficult to achieve. Screening tests for scoliosis, congenital dislocation of the hip, and osteoporosis are available. Although the tests for scoliosis and congenital dislocation of the hip are widely used at present, many questions regarding their efficacy remain unresolved.

Secondary and tertiary prevention are the levels more frequently used for the major musculoskeletal disorders of adults. However, with the exception of reconstructive joint surgery, secondary and tertiary prevention for such common problems as back pain and the arthritic disorders often have met with only limited success. Because of the chronicity of most of the common musculoskeletal conditions and the frequent reliance on only partially successful secondary and tertiary prevention measures, it is not surprising that musculoskeletal disorders have such a major effect on the quality of life and are associated with such high individual and societal costs. Improving the quality of life of affected individuals and further development and evaluation of screening tests will remain important in the management of musculoskeletal disorders, but it is also hoped that more emphasis will be placed on identification of feasible ways of preventing these disorders from occurring in the first place. Since the elderly are most frequently affected by musculoskeletal disorders and since the numbers of elderly will be increasing greatly over the next several decades, development of better methods of prevention at all levels is an urgent public health concern.

Neurological Disorders

James C. Torner • Robert B. Wallace

► INTRODUCTION

Neurological disorders include many diseases and conditions of acute and chronic development. The etiology of these disorders can be infectious, toxic, genetic, traumatic, and ischemic, and related to other chronic pathophysiologies. The occurrence may be at birth, which may confer a lifelong disability, or may occur in middle or late life, which may result in progressive disability and death. Neurological disorders may have an insidious onset or have symptoms that are nonspecific, making classification difficult. Early stages of some disorders are characterized by a variable presentation or by subtle signs and symptoms that are difficult to detect or that go unrecognized. Individuals often ignore symptoms until function is impaired. Some disorders in children may be developmental and may go undetected until the children reach the age at which deficits could be assessed. Hence, recognition, diagnosis, and progression of neurological symptoms may affect the true magnitude and onset of neurological disorders.

Diagnoses of neurological disorders requires not only recognition of symptoms but confirmation with a neurological examination. The neurological examination may be specific to symptoms and to onset. Diagnostic tests have changed with advances in imaging and electrophysiological testing. The use of computerized tomography (CT) scanning, magnetic resonance imaging (MRI), cerebral blood flow measurement and positron emission tomography (PET) have increased the certainty of diagnoses. Additional cognitive tests developed by neuropsychologists have aided in the diagnosis of cognitive decline. Hence the evaluation of incidence and prevalence over time is difficult due to changing diagnostic criteria and the likelihood of changing classifications and inclusion of milder or early-onset disease.

The burden of neurological disease is increasingly important as a determinant of health policy in costs and services. The Global Burden of Disease Study utilized the Disability Adjusted Life Years (DALYs) as an estimate of magnitude or burden of diseases.¹⁻³ Brain diseases encompass a broad spectrum including neurological, neurosurgical, and psychiatric conditions. Thirty-three percent of the years lived with disability and 13% of the DALYs are from neurological and psychiatric disorders. The major impact of the aging related disorders of Parkinson's disease, Alzheimer's disease, and other dementias and cerebrovascular disease on the global burden is evident world-wide and also in North America (Table 67-1).

► U.S. MORTALITY, INCIDENCE AND PREVALENCE OF NEUROLOGICAL DISORDERS

The International Classification of Diseases Version 10 was implemented in 1999. Comparability of the classification depends on the condition.⁴ Table 67-2 includes mortality data for the United States for 2002 for neurological conditions identified by the new ICD10

classification. Since 1999, crude mortality rates of neurological disorders have been increasing mainly due to the increasing number of older persons. Most are low with exception of cerebrovascular conditions, dementia and Alzheimer's disease and Parkinson's disease. Cerebrovascular disease remains a major cause of death with a rate of 56.4 per 100,000 persons. The mortality rate for cerebrovascular disease has been declining across both genders and all races groups. Rates of death from progressive neurological disorders such as Parkinson's disease and Alzheimer's disease have increased as the population becomes older.

Using discharge diagnoses as measures of the magnitude of neurological disorders on the health care system; from the National Hospital Discharge Survey of 2004 shows that discharge rates for epileptic seizures, migraine, multiple sclerosis (MS) and malignant brain neoplasms were highest when the first-listed diagnoses were used⁵ (Table 67-3) (Fig. 67-1).

Increases in admissions from 1990 were observed in 2004 in HIV, brain neoplasm, Alzheimer's disease, Parkinson's disease, carpal tunnel syndrome, and cerebrovascular disease. These reflect the increasing incidence with aging and an increase in prevalence due to the chronic nature and successful treatment of some of these conditions. The use of CT and MRI has improved diagnosis and changes in classification are reflective of this.

The last national assessment of clinic use was the National Ambulatory Medical Care Survey (NAMCS) of 1991-1992. The NAMCS examined the 7,253,000 visits to neurologists that were reported by respondents.⁶ The rate of visits was 2.9 per 100 persons per year. Only 6% of the visits were referred, and 15.5% were new patients. Most of the visits (81%) were due to symptoms with 43% of those from nervous system problems and 23% from musculoskeletal complaints. The main reasons for the visits were headaches (18%), seizures (9%), and sensory disturbances (5.5%). Only 36% of the visits resulted in a diagnosis of nervous system disorders; 21% were symptoms and signs, 15% were musculoskeletal conditions, 8% were mental disorders, and 7% were injuries or poisonings. In the NAMCS of 1993, visits to neurologists increased to 8,393,000 (1.2% of total visits) but there were 22,556,000 (3.1%) total visits for symptoms from the nervous system, and 77,737,000 (10.8%) visits with a principal diagnosis of nervous system or sense organ disorders. Headaches accounted for 10,736,000 visits (1.5%).⁷

The 2004 National Health Interview Survey asked respondents about conditions causing the highest percentage of limitation of activity.⁸ Stroke was reported in 2.6%. Prevalence varied by gender, age, race, education, and income. Pain disorders reported were migraine headaches, 15.3% of adults in the last three months. Low back pain was prevalent in 27.1% and neck pain in 14.6%. Migraine was more common in younger women. Back and neck pain were also more in women.

The magnitude of neurological disorders worldwide and in the United States is wide ranging in incidence, prevalence, and mortality

TABLE 67-1. GLOBAL ESTIMATES OF DEATHS AND DALYS FROM GLOBAL BURDEN OF DISEASE STUDY, 2000

Cause	Global				U.S., Canada		U.S., Canada

as well as across ages and etiologies. The remainder of the chapter describes several neurological disorders that are an increasing public health problem and with some the etiology is yet to be identified.

► CEREBRAL PALSY

Cerebral palsy (CP) is a group of nonprogressive motor impairment syndromes that arise during brain development and is recognized early in life as the child develops.⁹ CP is classified based on the extremities involved and the neurological dysfunction (spastic, athetotic, hypotonic, dystonic, or combined). The most common form is spastic CP which is present in about 80% of prevalent cases. The presence of other neurological disabilities, such as mental

retardation, seizure disorders, and sensory problems, are more common in persons with CP. The Metropolitan Atlanta Developmental Disabilities Surveillance Program in 1991 found that 48% of 599 CP children in their study had vision impairment, 8% had hearing impairment, and 17% had mental retardation.¹⁰

CP occurs between 1.5–3.0 of every 1000 live births. However this rate depends on definition and inclusion based on impairment.^{9–11} Because CP is developmental, it may present in a variety of forms and severities and may disappear with growth. Case ascertainment may require surveillance using multiple sources. The Disabilities Education Act allows surveillance through special education programs in school systems. In Atlanta over 90% of children with developmental disabilities could be identified through education sources.¹² Prevalence then may be a better measure than incidence. CP has been identified by early school age in 1.4–5.1 per 1000 children. In Atlanta the prevalence rate was 2.4 per 1000 in ages 3–10 years and the rate was lowest in the younger ages (2.0/1000) for both disabling and nondisabling CP. There is a slight excess of males and blacks among affected persons in Atlanta. Ethnicity is not consistently related, however to CP.

Prematurity is the most important risk factor with weight at birth the surrogate measure. Nearly one-fourth of children with CP are less than 1500 grams at birth and one-half are less than 2500 grams.

Innate genetic factors may play role in CP occurrence. Several studies have reported positive familial history and genetic risk in CP children. Twins are at higher risk but they share a common pregnancy and birthing process.¹³

Other risk factors include maternal factors prior to pregnancy such as long menstrual cycles and a history of spontaneous abortions and stillbirths. Low socioeconomic status increases the risk of CP. During pregnancy, factors that may increase risk include hyperthyroidism, thyroid hormone drugs, and exogenous estrogen. There is an association with occurrence of other congenital malformations which has also been observed.^{9,10,15} At birth, low birth weight and immaturity are among the most consistent risk factors for CP. Several factors may contribute to early delivery or low birth weight. These include intrauterine infection and congenital malformations. A number of markers of maternal infection have been linked to CP, including chorioamnionitis, maternal fever, antibiotic use, uterine tenderness, and neonatal sepsis.^{18,19} Intracranial hemorrhage in premature infants is associated with CP. The increase in survival of infants with very low birth weight, has increased the causal distribution of CP. A study by Pharoah et al showed that low birth weight infants account for nearly 50% of cases of CP.¹⁴

Physical injury during the perinatal and postnatal periods such as intrauterine exposure to heavy metals, neonatal hyperbilirubinemia, and exposure to benzyl alcohol may be related to CP occurrence.²⁰ Severe asphyxia at birth may account for about 10% of all CP.^{21–23} Difficult birth is associated with increased risk of CP only among children who have neurological symptoms in the neonatal period. Postnatal causes of CP include neonatal encephalopathy, trauma, or occlusion of a cerebral artery or vein. These may account for 12–21% of cases.

TABLE 67-2. NUMBER OF DEATHS AND DEATH RATE IN U.S. POPULATION OF NEUROLOGICAL DISORDERS, 2002

ICD10	Disorder	Number	Rate per 100,000
G00–G03	Meningitis	700	0.24
G04–05	Encephalitis	365	0.13

854	Intracranial injury of other and unspecified nature	5

Source: Centers for Disease Control and Prevention <http://www.cdc.gov/nchs/about/major/hdasd/nhds.htm#Publications>

Most of the risk factors for CP are in the prenatal period. The decreased use of isoimmunization for Rh factors has been associated with a decrease of CP of the athetoid type. Improvements in obstetric and neonatal care and an increasing frequency of obstetric interventions have not been associated with a decrease in incidence of CP.^{8,24,25} Abnormalities of coagulation such as factor V Leiden and antiphospholipid antibodies have been associated with CP in full-term infants.^{26,27}

Studies have shown a possible protective effect of administration preceding delivery of magnesium sulfate for protection from cerebral hemorrhage and development of CP.²⁸ The paucity of information about and the variety of causal factors for the majority of CP that is not attributable to birth events severely limits the development of strategies for prevention.

► HIV INFECTION

Since 1981 when the human immunodeficiency virus (HIV) type 1 and the acquired immunodeficiency syndrome (AIDS) first appeared in the United States the epidemic has increased to nearly a half million people.²⁹ Almost half have died from this devastating infection. HIV has manifestations in neurological disorders also. Neurological manifestations include HIV dementia, myelopathies, neuromuscular disorders, and CNS infections of cryptococcal meningitis, toxoplasmosis, progressive multifocal leukoencephalopathy, cytomegalovirus, mycobacterium tuberculosis, neurosyphilis, and primary CNS lymphoma. Meningitis, neuropathy, and myopathy can occur before the AIDS-related complex is present. Dementia, myelopathies, and opportunistic infections are present as the disease progresses into AIDS.^{30,31}

Estimates of incidence and prevalence of the neurological manifestation of HIV are problematic. Many of the studies are retrospective based on autopsy or clinical populations.³⁰ The estimates vary widely depending on the population and the definition used. Most often the diagnosis is based on clinical findings without verification. Some estimates are based on HIV-AIDS cohorts but generalizations between locations and severity of illness is problematic. With the introduction of highly active antiretroviral therapy (HAART) in the 1990s, there has been a significant decline in opportunistic infections. HAART has increased survival for individuals with HIV/AIDS.^{32,33} HIV-associated dementia (HIV-D) has decreased by 40–50%.³⁴ The prevalence of sensory neuropathies however is in excess of 20%.³⁵ Prolonged HAART may further increase this rate. HIV-D and HIV-related sensory neuropathies (HIV-SN) have a combined prevalence of between 30–50% in advanced HIV disease, suggesting that HAART does not provide complete protection against neurological damage.³⁶

HIV dementia is characterized by cognitive and memory impairment. It is associated with the onset of AIDS and it is estimated that approximately 3% of AIDS patients present with dementia as their first symptom. The prevalence varies by type of study from 7 to 66%.^{37–39} An estimate derived from CDC data is that 2.8% of AIDS cases have dementia.³⁷ The Multicenter AIDS Cohort Study found a 3.3% figure. They also found that after AIDS has developed there was a 7% incidence per year of dementia.³⁸ Factors associated with HIV dementia include lower CD4⁺ cell counts, anemia, low body mass index, older age, and other systemic AIDS symptoms.³⁸ The proportion of AIDS cases with dementia has not changed but there is some indication of improvement with zivovudine treatment.^{40,41}

Inflammatory demyelinating polyneuropathies may occur either in acute or chronic form. The estimates are from 0.5 to 3.0% of patients have these conditions.^{30,42} Other neuropathies may occur. Sensory neuropathy occurs in the later stages of HIV infection.⁴³ Toxic neuropathy associated with antiretroviral agents also occurs.^{44,45} The manifestation of these disorders is severe pain and impaired walking ability. It is estimated from a clinical population that 13% of the patients may be affected.^{46,47}

Opportunistic infections are a hallmark of AIDS progression. Infections can affect the central nervous system. Cryptococcal meningitis is present in about 10% of AIDS cases and is associated

Figure 67-1. United States Hospital Discharge Rates 1990 versus 2002 for selected neurological diseases; first diagnosis.

with a drop in CD4⁺ count below 200 cells/mm³.^{48,49} A common cause of mass lesion abscesses is toxoplasmosis. The prevalence varies between locations. CNS infection is a result of latent reactivation and may be inhibited by prophylactic treatment of pneumonia. CMV infection can lead to retinitis and encephalitis in patients with HIV.^{50,51,55} CMV retinitis is common in patients with CMV infection causing visual loss or blindness in 15–28% of AIDS patients. Encephalitis presents with confusion, disorientation, and memory loss and may occur in approximately 2% of AIDS patients. Primary CNS lymphoma is rare but has been increasing due to immunosuppression frequency.⁵³ Up to 3% of AIDS patients develop CNS lymphoma. Many of these patients are diagnosed at autopsy. Prior AIDS-related illness and low CD4⁺ counts are linked to lymphoma occurrence.⁵⁴

The public health burden of HIV and AIDS remains a challenge. With increasing survival, the prevalence of HIV or AIDS neurological conditions will increase. HIV-associated dementia (HIV-D) remains a common problem of dementia worldwide and with the magnitude of HIV in Africa, the rates of dementia may be a pending epidemic. HIV-related sensory neuropathies (HIV-SN) represent the most common neurological disorders associated with AIDS and may also increase.

► **CREUTZFELDT-JAKOB DISEASE**

Creutzfeldt-Jakob disease (CJD) is a rare, degenerative, invariably fatal brain disorder. There are three major types of CJD: sporadic CJD, hereditary CJD, and acquired CJD. In the United States the incidence is from 250 to 300 new cases per year.^{55,56}

There is no treatment that can cure or control CJD. Current treatment is aimed at alleviating symptoms and making the patient as comfortable as possible. About 90% of patients die within one year. Patients progress through failing memory, behavioral changes, lack of coordination and visual disturbances toward mental deterioration, involuntary movements, blindness, weakness of extremities, and coma.

The cause of CJD is a type of protein called a prion. Prions exist as harmless proteins but can take the infectious form which has a different folded shape than the normal protein.

In the mid 1980s bovine spongiform encephalopathy (BSE) emerged in the United Kingdom in cattle. Infected animals may have consumed contaminated cattle feed, perhaps with scrapie leading to the silent spread of the BSE epidemic. Acquired CJD called variant (vCJD) has been identified in young people.^{57,58} This form of CJD is different than sporadic CJD in age of onset and symptomatology. The clinical manifestations in vCJD patients include psychiatric symptoms such as anxiety, depression, and withdrawal. The development of neurological signs, such as myoclonus and extrapyramidal dysfunction, is often delayed for several months after illness onset. The most striking early neurological sign in some vCJD patients is persistent dysesthesia or paresthesia.

vCJD has been linked to ingestion of beef tainted with BSE; most cases have occurred in the United Kingdom and Europe. Cases may still occur because of the long latency of the abnormal prion in the manifestation of symptoms. An interesting finding is the susceptibility for vCJD. All vCJD patients to date have been homozygous for methionine at the polymorphic codon 129 of the human prion protein gene.^{57,58} Although the scientific basis is unknown, researchers have suggested that methionine homozygosity may be associated

with a shorter incubation period, younger age distribution, and specific clinicopathologic profile. The possibility exists that vCJD could potentially occur in persons who are heterozygous or homozygous for valine at codon 129 after a longer incubation period.

While the possibility of vCJD exists in the United States, only one human case has been reported in a person who spent time in the United Kingdom. The United States Department of Agriculture (USDA) has conducted a large, nationwide survey of cattle for slaughter and there is a very low probability of bovine or human CJD in the United States.

The bloodborne transmission of vCJD has long been possible.⁵⁹ A probable bloodborne, person-to-person transmission of vCJD was reported in the United Kingdom in a 69-year-old man who had vCJD onset in late 2002. Both the donor and recipient died of pathologically confirmed vCJD. The patient was the first ever with methionine and valine heterozygosity at the polymorphic codon 129 of the prion protein gene, which indicates that persons who are not homozygous for methionine can be susceptible to infection by the BSE agent. The FDA has recommended a blood donor deferral policy to exclude donors who have spent specific periods of time in the United Kingdom and other European countries.⁵⁹ This policy was implemented in 1999.

Further surveillance for vCJD in Europe is warranted due to the long incubation period and the possibility of a delay in codon 129 heterozygote persons. In the United States little risk is estimated from cattle due to the limited number of infected cattle.

► WEST NILE VIRUS

West Nile Virus (WNV) was first discovered in the West Nile District of Uganda in 1937. WNV spread across areas of Africa, Eastern Europe, West Asia, and the Middle East. It eventually began appearing in the Eastern United States in 1999. In 2005, WNV spread into areas of the western United States. Over 2700 human cases were observed, representing 19% of the counties of the United States. However the largest number of cases occurred in California. Cases occurred from June to November with the peak period in August and September.⁶⁰⁻⁶²

WNV is transmitted by a mosquito vector and can result in encephalitis in infected humans and equine. WNV can also result in wild and domestic bird mortality. Certain birds (e.g., corvids, common grackles, house finches, and house sparrows) develop high-titer WNV viremia, making them highly infectious to feeding mosquitoes. Many of these species also have high (>40%) mortality from WNV infection.^{1,6} The *Culex* species of mosquito is the most prevalent in case pools.⁶³

Neurological symptoms of meningitis, encephalitis, or acute flaccid paralysis occurred in 42.5% of the symptomatic cases. West Nile fever was present in 52.2% of the cases and 5.3% had unspecified illnesses. It is estimated that 80% of cases are asymptomatic.^{61,64} The severe symptoms can include high fever, headache, neck stiffness, stupor, disorientation, coma, tremors, convulsions, muscle weakness, vision loss, numbness, and paralysis. These symptoms may last several weeks, and neurological effects may be permanent.

Ongoing WNV surveillance monitors the spread of the virus and helps target prevention and control strategies. Increased arboviral diagnosis, testing, and reporting, through the ArboNET surveillance system detects increased transmission of all endemic and foreign arboviruses.⁶⁵ No effective vaccine exists for humans; hence prevention of WNV disease is dependant upon community mosquito control and personal protection against mosquito bites by use of repellents and minimization of outdoor exposure.

► SEIZURE DISORDERS

Seizures are alterations in consciousness associated with an above-normal discharge of neurons of the brain. Seizures can be classified based on etiology as acute symptomatic (provoked) seizures and unprovoked seizures. Unprovoked, recurrent seizures are considered epilepsy. Seizures are classified by onset as simple or complex partial

seizures, or generalized major motor, absence, or myoclonic seizures. EEGs are used to verify the diagnosis and to determine the electrical activity pattern.⁶⁶⁻⁶⁸

Epilepsy occurs mostly in the young and the old. The overall incidence in the Rochester, Minnesota population studies for 50 years was 44 per 100,000 persons.⁶⁹ All convulsive disorders had an incidence of 130 per 100,000 persons. The incidence of partial seizures cases was observed to be 25 per 100,000 and generalized onset to be 19 per 100,000. Generalized seizures are highest during the first year of life, decrease throughout childhood and increase again in the elderly. Partial seizures have a relatively constant rate up to age 65 and then increase sharply. For generalized seizures with onset in early life, females are at higher risk, and for later life seizures, males are at higher risk. For partial seizures, the rates are similar until age 65 when men are at higher risk. There has been a slight decrease in incidence of epilepsy over time, but an increase in incidence in the elderly. The prevalence of epilepsy varies widely among populations, from 27 to 40 per 1000. In Rochester, the prevalence in 1980 was 6.8 per 1000. Sixty percent were partial seizures and 75% were of unknown etiology. The prevalence in several studies is higher in blacks in the 20–66 year age range.⁷⁰

A number of factors have been associated with epilepsy and are related to development of definable brain lesions. These include severe head injury, stroke, CNS infection, brain tumors, and CNS degenerative diseases.^{71,72} Factors that have a causal pathway are associated at birth with brain development, such as mental retardation and cerebral palsy. Febrile seizures are related to increased seizure risk. These may occur in 2.3–4.7% of children. Other factors that have shown a relationship, but without a direct causal pathway, are drug abuse—for example, heroin—and medical conditions such as asthma, hypertension, and depression. Suggested but unproven risk factors include pre- or perinatal adverse events and immunizations. Positive family history has also been associated with development of epilepsy. Familial aggregation is strongest for febrile seizures.⁷³ Twin studies have shown a higher concordance for monozygotic compared to dizygotic twins.⁷⁴ The role of genetics in partial epilepsy is being explored but will require further studies of gene-environment interaction.

Seizure control can be obtained in a majority of patients. Recurrence rates show that 25% will suffer a recurrence in the two years following the first seizure but this rate varies by the presence of risk factors.

► HEADACHES

Headache is the most common neurological disorder. Based on a telephone interview in a population-based study, 90% of men and 95% of women reported a headache in the last year. From 65 to 71% of women and 48–50% of men report one headache per month. Headache is one of the most common symptoms prompting people to seek medical care.^{75,76} It is estimated that 5.5 million days of activity restriction can be attributed to headache each year by adults in the United States.^{77,78} From the National Health Interview Survey in 2003, 15.1% of adults reported a severe headache or migraine in the previous three months.

Headaches may be primary or secondary to another disorder such as brain tumor, stroke, or vasculitis. Primary headaches can be classified into tension-type, migraine, and cluster. Diagnosis is based on clinical presentation. Classification criteria were established by the International Headache Society.^{79,80} Distinguishing aspects of migraine include unilateral onset with associated anorexia and sometimes nausea and vomiting. The presence of a warning (aura) has also been described as a prodromal change in mood and is used as part of the diagnosis.

The incidence of migraine depends on gender, age and type. The lifetime prevalence of migraine has been estimated to be 8% with women having a prevalence of 25%. A one year prevalence is 6% for men and 15% for women. In general, women have more migraines than men do, particularly with auras occurring most frequently in young adult life. The incidence of migraines from the Rochester, Minnesota population was 294 per 100,000 for women and 137 per 100,000 for men using data from 1979 to 1981. Between age five and puberty the incidence probably approximates 10% per year.⁸¹

The incidence increases in females with the onset of menses. The peak age for women is between 20 and 24 years of age. The incidence returns to the male level at about the age of 40. In both women and men, incidence appears to decrease, beginning in the early 40s.

Prevalence of migraine headache may vary in populations and may be increasing. This could be due to varying definitions. Using the International Headache Society criteria, the prevalence of migraine in four population-based studies was from 13 to 15% in women and 4–6% in men.⁸² Data from Rochester, Minnesota showed an increased from 25.8 per 1000 to 41 per 1000 from 1981 to 1989 in both sexes combined.

While migraine was thought to occur more often in high socioeconomic groups, data from the American Migraine Society shows the opposite. Data from the National Health Interview Survey also showed the low socioeconomic and middle economic groups may have similar rates. Rates of clinically diagnosed migraine may be higher due to higher rates of physician diagnoses in the high socioeconomic population.^{78,83}

The risk of migraine may be familial but may be overestimated due to biases in ascertainment.⁸⁴ The strongest evidence of a genetic association is from the higher concordance in monozygotic than in dizygotic twins. If genetic factors contribute to a person's propensity for migraine, then other factors, usually exogenous, are likely to play an important role in determining the occurrence and frequency. Risk factors for headache onset in women are related to menstrual flow or the use of oral contraceptives. Other factors include ingestion of some foods (those with tyramine, including chocolate and aged cheeses) or alcoholic beverages (red wines, particularly). Psychosocial characteristics also appear to be associated with headache occurrence. These include characteristics of perfectionism, inflexibility, and hypochondriasis, as well as propensity to anxiety and depression. Stress and psychosocial events may be important. The consequences of migraine are not viewed as life-threatening but migraine may be associated with hypertension, atherosclerotic heart disease, and stroke.⁸⁵

In contrast to migraine are cluster headaches which occur in groups most often in the spring and fall. These occur more in men than women. Onset is also in midlife but later than migraine. The incidence is 15.6 per 100,000 for men and 4.0 per 100,000 for women.⁸⁶ Smoking may be associated with cluster headaches but personality characteristics may also play a role. Cluster headache occurrence appears to be related to peptic ulcer occurrence as well as cancer-related deaths.

The cost of headaches is enormous. The restricted activity and disability, the use of medications, and the number of physician visits for diagnosis and treatment is large. Annual productivity lost due to migraine alone is estimated at \$1 billion per year.⁸⁷

► NEUROTOXIC DISORDERS

Classic heavy metal exposures and solvents have led to neurological disorders. Occupational exposures have also been reported for acute neurological disease following exposure to industrial chemicals.^{88,89} Neurotoxic effects of organophosphorus insecticides include paralysis.⁹⁰

Implications of chemicals for chronic diseases are being evaluated. For Parkinson's disease the relationship of 1-methyl-4-phenyl tetrahydropyridine (MPTP) to parkinsonism symptoms demonstrated the influence of acute ingestion. Similar compounds such as paraquat and rotenone have caused parkinsonism in animals. Pesticides have been observed in several human studies to be related to neurological symptoms. A meta-analysis found a combined odds ratio of 1.94 (CI = 1.49–2.53).⁹¹ Chemicals in herbicides, insecticides, alkylated phosphates, organochlorines, and wood preservatives have also demonstrated increased risk.^{92–95}

Alzheimer's disease has been speculated to be potentially of neurotoxic origin but studies have not been conclusive. Chemicals implicated include aluminum, and solvents and electromagnetic fields. Further research is needed to provide evidence.

Amyotrophic lateral sclerosis (ALS) has been investigated particularly in the geographical cluster of the Western Pacific. Considerable research into the role of cycad derivatives and ALS has been done. Other studies have examined the association of heavy metals and ALS. Occupations with heavy metal exposure may be of higher risk. The role of agricultural chemicals has also been postulated because of a higher risk observed in farmers. Recently Persian Gulf War veterans were observed to have a higher rate of ALS. The source of the exposure is unknown.⁹⁶

► MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is one of the demyelinating diseases and is characterized by white matter lesions.⁹⁷ Classification of MS is dependent on clinical criteria that feature multiple lesions in the CNS separated in multiple locations and symptomatic attacks. Clinical presentation occurs in midlife and is highly variable. The spectrum of MS ranges from benign disease to rapidly fatal cerebral demyelination. Symptoms include sensory, visual, and motor dysfunction. The disease is generally progressive and is characterized by clinical remissions and exacerbations.⁹⁸ Diagnosis of MS has been aided by the use of MRI which may detect early lesions.⁹⁹

Onset of MS occurs between ages 15 and 65 years. The median ages at onset for cases identified in Rochester, Minnesota were 34 years for men and 32 years for women.¹⁰⁰ Women had an incidence of 7.7 per 100,000, and 3.4 per 100,000 for men. MS shows a north-south geographical distribution. Another disease, which had a differential geographic pattern, was poliomyelitis. However with MS the northern hemisphere has distinct high risk zones. Prevalence increases as latitude increases. This has been observed in the United States and Europe. High-risk areas have prevalence rates of MS of greater than 50 per 100,000; low-risk areas have less than 5 per 100,000.

Studies among migrants suggest that persons who move from an area of high prevalence to one of low prevalence take on the risk level of their new environment. The country (latitude) and the age of migration appear to be an important determinant in MS risk.^{101,102} Migration before early adolescence (before age of 15) shifts the risk to the new country. With migration after 15 years, the individual has the risk of the former country. Kurtzke in studies of the Faroe Islands, felt that a minimum exposure time of two years was necessary to confer susceptibility.^{103–105}

After 50 years of studying MS the causes are still unknown. The hypothesis is that gene and environmental factors are necessary for MS occurrence. Ethnic background may play a role since the highest rates are in areas populated by those with a northern European/Scandinavian background. Clusters and epidemics of MS have been reported. Clusters have been reported in Canada, Norway, and Florida. Epidemics have occurred in the Faroe Islands and in Iceland.^{103–105} No cases of MS were apparent before 1945. Since then cases have been reported with peaks in 1945, 1955, and 1965.

Infectious agents have been studied extensively, but no single agent has yet been identified. Measles virus and canine distemper virus has received the most attention. Case-control studies have demonstrated a relationship with dog ownership. Infection may also be related to immunologic changes to increase susceptibility. Ecological studies have shown associations with low temperature, plants, soil, industrialization, meat consumption, type of meats, and dairy foods. Other factors that have been investigated with conflicting results include trauma, and exposure to trace elements and heavy metals, such as zinc and lead. Cigarette smoking may exacerbate the MS symptoms. Studies have demonstrated an increased risk in long-term smokers.¹⁰⁶

A possible role for genetic factors in the etiology of MS has also been investigated. Caucasians of European descent are at highest risk. There has been familial aggregation of MS reported in several studies.¹⁰⁷ Familial aggregation may be due to shared environment or genetic susceptibility. Twin studies have generally found a greater concordance for MS among monozygotic twins than among dizygotic twins. The risk to family members is low with 4% for siblings and

2–4% for children depending on gender. Since northern Europeans have a higher frequency of HLA-DR2, haplotype studies of HLA in MS have been the most consistent.¹⁰⁸ Further candidate genes are peptide transporter genes and genes encoding tumor necrosis factor.

The incidence of MS may be increasing as reported in Rochester, Minnesota.¹⁰⁰ Changes in diagnostic studies may lead to improved ascertainment but few longitudinal, population-based databases exist.

Survival is longer for women than men. Approximately 75% of MS patients will survive 25 years or more.¹⁰⁹ The rate of progression and disability is variable. Many patients, even with progression, remain ambulatory for many years. There is currently no definitive therapy for MS that affects the ultimate course of the disease but steroid or ACTH therapy is used for acute exacerbations. Beta-interferon and azathioprine may be helpful in preventing relapses but data on rate of progression are inconclusive.

► STROKE

Stroke is as the third leading cause of death and a major cause of long-term disability in the United States. It is estimated from population studies that strokes occur in 500,000 new cases and 200,000 recurrent cases each year.¹¹⁰ The total prevalence of stroke is estimated to be 4.7 million people in the United States. Stroke costs approximately \$51.2 billion every year for acute care and long-term consequences. Stroke has declined over the past 30 years and has slowed in the most recent decade. Blood pressure control has been responsible for most of the major decline. Hence, stroke incidence and mortality reduction still remain as one of the health targets for the U.S. population.

There has been a major recognition of stroke subtypes in classification, epidemiology and treatment. In the International Classification of Diseases, etiology, and pathology divides stroke into nine major groupings. Hemorrhagic stroke includes subarachnoid and intracerebral hemorrhage and well as other or unspecified intracranial hemorrhage. Ischemic stroke classification is based upon the location and duration of the occlusion. In addition, nonspecific categories of acute but ill-defined, and late effects of cerebrovascular disease are also used. New codes in ICD-10 were developed but the classification is similar.⁴ The comparability of ICD-9 and ICD-10 for cerebrovascular disease showed an increase by 6% for ICD-10 due to the inclusion of deaths from pneumonia secondary to stroke.⁴

The further classification is based upon stroke etiology, that is, occlusive disease and embolic origin. Large vessel occlusive disease and small vessel disease have differential causation and prognosis. Nearly one-third of strokes are of embolic origin, small-vessel thrombotic comprise 20%, and large vessel at 31%. Hemorrhagic stroke accounts for the remainder at 17%.^{110,111}

Stroke mortality differentially affects individuals by race and gender. The highest risk group is black males. In 2000, the rate for black males was 87.1, for black females it was 78.1, with white males at 58.6 and white females at 57.6. Hispanics and Asian/Pacific Islanders and American Indian/Alaskan Native groups have lower rates of stroke mortality. From 1990 to 2000, the stroke mortality rate fell 12.3%. However, the actual number of strokes rose by 9.9%. With the increasing number of persons 65 years and older, the number of stroke deaths will continue to increase.

There is a geographic variation in stroke. Mortality rates for stroke are higher in the southeast part of the United States.¹¹² This is known as the *stroke belt*. Lowest rates are found in the mountain states. Differences may be due to risk factors such as hypertension and diabetes and suggested differences in access and type of care for stroke.¹¹³

Stroke risk factors can be classified in terms of nonmodifiable risk factors and modifiable risk factors. Those not modifiable include age, gender, race, and family history. Nonmodifiable risk factors alert us to those populations that we can target for modifiable risk factors. Those modifiable risk factors include hypertension, smoking, diabetes, cardiac disease, hyperlipidemia, physical activity, obesity, nutrition, drug abuse, hormone therapy, inflammatory disease, and biomarkers of risk.

High blood pressure remains as the major modifiable risk factor for heart disease and stroke.^{114,115} The Multiple Risk Factor Intervention Trial (MRFIT) examined 350,000 men from 1973 to 1975 and followed for major fatal outcomes. An eightfold increased risk across systolic blood pressure (SBP) deciles and a fourfold risk for diastolic blood pressure (DBP) were observed. A comprehensive analysis of risk by blood pressure by MacMahon et al, showed that the associations of DBP with stroke demonstrated a “positive, continuous, and apparently independent association” which was consistent across all studies.¹¹⁶ Within the range of DBP (70–110 mm Hg), there was no evidence of any *threshold*. Approximately 50 million adults in the United States have high blood pressure. There has been an increase in the awareness of high blood pressure. The National High Blood Pressure Education Program began in 1972 and it has increased awareness of the importance of detection and control of blood pressure which has resulted in not only more hypertension control but also in the reduction of heart disease and stroke.¹¹⁷

Stroke risk increases with cigarette smoking independent of hypertension or age.¹¹⁸ The general increase is nearly 40% for men and 60% for women. The risk for smokers of two packs per day is approximately twice that of smokers who smoke less than half a pack per day.³¹ Evidence suggests that smokers decrease their risk when they quit and is back at the risk of nonsmokers 5 years after quitting.¹¹⁹

The risk for stroke is greater with the presence of diabetes. Studies have demonstrated a 1.5- to 3.0-fold increase in risk. Diabetes has been shown to be a consistent factor for atherothrombotic stroke. For hemorrhagic stroke the risk is reversed. Diabetics have age-adjusted stroke mortality and morbidity rates higher than nondiabetics.¹²⁰

As evidence of the progression of atherosclerosis and increased risk for stroke, carotid stenosis is an important indicator. The risk of carotid disease was clearly demonstrated in the prospective follow-up of the North American Symptomatic Carotid Endarterectomy Trial (NASCET).¹²¹ The follow-up of patients with 70–99% stenosis demonstrated the risk of any ipsilateral stroke at three years was 28.3% for medically randomized arm and the combined disabling or fatal ipsilateral stroke risk was 14.0%. Over 80% of the first strokes were of large-artery origin. Clearly, the debate is what the magic cut-off for risk is and should patients be screened.

Cardiac disease and abnormalities including coronary artery disease, congestive heart failure, left ventricular hypertrophy, valvular heart disease, atrial fibrillation, and cardiac thrombosis increase the risk of stroke. In Rochester, Minnesota the relative risk estimate for stroke was 2.2 and in Framingham the magnitude was similar with 1.9 for men and 2.2 for women.¹²²

Atrial fibrillation affects close to 2 million individuals in the United States. Fifteen percent of the strokes occur in patients with atrial fibrillation. Data from Rochester, Minnesota indicated that atrial fibrillation has been increasing as a cause of ischemic stroke for both men and women and is independent of age.⁴⁰

Cerebral infarction from sickle cell disease may be preventable according to a randomized clinical trial (stroke prevention in sickle cell anemia) to evaluate the prevention of a first stroke in children with sickle cell disease.¹²³ Regular red cell transfusions sufficient to reduce the percentage of Hb S gene product from over 90 to less than 30 of total hemoglobin was associated with a marked reduction in stroke.

High plasma levels of lipids are an important modifiable risk factor for coronary heart disease.¹²⁴ In the Atherosclerosis Risk in Communities (ARIC) study cohort in 305 subjects with clinical ischemic stroke, the analyses demonstrated weak and inconsistent associations with each of the five lipid factors.¹²⁵ Only among women was high HDL cholesterol associated with decreased risk of stroke.

Overweight adults are a major epidemic and these adults are at an increased risk of developing numerous chronic diseases. In the women of the Nurses’ Health Study, and the men in the Health Professionals Follow-up Study, the risk of developing stroke increased with levels of overweight among both women and men.¹²⁶

In a study of stroke subtype, the incidence of ischemic stroke, hemorrhagic stroke (subarachnoid or intraparenchymal hemorrhage), and total stroke was examined in the Nurses Health Study.¹²⁷ During

16 years of follow-up, 866 total strokes (including 403 ischemic strokes and 269 hemorrhagic strokes) occurred. Women with increased BMI ($> = 27 \text{ kg/m}^2$) had significantly increased risk of ischemic stroke, with relative risks of 1.75, for BMI of 27–28.9 kg/m^2 ; 1.90 for BMI of 29–31.9 kg/m^2 ; and 2.37 for BMI of 32 kg/m^2 or more. For hemorrhagic stroke there was a nonsignificant inverse relation between obesity and hemorrhagic stroke. Weight gain from age 18 years until 1976 was associated with an RR for ischemic stroke of 1.69 for a gain of 11–19.9 kg and 2.52 for a gain of 20 kg or more. Also weight change was not related to risk of hemorrhagic stroke.

Physical inactivity has been demonstrated to increase the risk of stroke two- to threefold. Recently, in a cohort study in Finland of 2011 men the risk of low cardiorespiratory fitness was evaluated with the maximum oxygen consumption. The relative risk was 3.2 for all strokes and 3.5 for ischemic stroke.¹²⁸

Another controversial risk factor has been the use of exogenous estrogens. Use of oral contraceptives has increased, and there is uncertainty about the stroke risk associated with their use. In case-control study techniques of women with ischemic stroke from four Melbourne hospitals, the current use of the oral contraceptives, in doses of $< = 50 \mu\text{g}$ estrogen, was not associated with an increased risk of ischemic stroke.¹²⁹

In female members of the California Kaiser Permanente Medical Care Program, the odds ratio for ischemic stroke among current users of oral contraceptives, as compared with former users and women who had never used such drugs, was 1.18.¹³⁰ The adjusted odds ratio for hemorrhagic stroke was 1.14. However with respect to the risk of hemorrhagic stroke, there was a positive interaction between the current use of oral contraceptives and smoking.

For postmenopausal estrogens the observational studies warranted prospective trials. The Women's Health Initiative (WHI) trial of estrogen plus progestin was stopped early because of adverse effects, including an increased risk of stroke in the estrogen plus progestin group.¹³¹ For combined ischemic and hemorrhagic strokes, the intention-to-treat hazard ratio (HR) for estrogen plus progestin versus placebo was 1.31. The HR for ischemic strokes was 1.44 and for hemorrhagic stroke, 0.82. Excess risk of all stroke was apparent in all age groups, in all categories of baseline stroke risk, and in women with and without hypertension, prior history of cardiovascular disease (CVD), use of hormones, statins, or aspirin. Another randomized, double-blind, placebo-controlled trial of estrogen therapy was done in postmenopausal women who had recently had an ischemic stroke or transient ischemic attack.¹³² With a mean follow-up period of 2.8 years, the women in the estrogen group compared to placebo group showed no benefit (relative risk in the estradiol group, 1.1). The women who were randomly assigned to receive estrogen therapy had a higher risk of fatal stroke (relative risk, 2.9). This therapy was shown not to be effective for the primary or secondary prevention of cerebrovascular disease.

Epidemiologic evidence, animal studies, angiographic and ultrasound studies in humans, and a limited number of clinical trials suggest that vitamins C and E may be protective and that folate, B6 and B12, by lowering homocysteine levels, may reduce stroke incidences. Few population-based studies have examined the relationship between dietary intake of folate and risk of stroke. In the National Health and Nutrition Examination Survey I Epidemiologic Follow-up Study (NHEFS), dietary intake of folate was assessed at baseline using a 24-hour dietary recall.¹³³ Incidence data for stroke over an average of 19 years of follow-up showed a relative risk of 0.79.

Although hypercoagulable states are most often associated with venous thrombosis, arterial thromboses are reported in protein S, protein C, and antithrombin III deficiencies, factor V Leiden and prothrombin gene mutations, hyperhomocysteinemia, dysfibrinogenemia, plasminogen deficiency, sickle cell disease, and antiphospholipid antibody syndrome. Antiphospholipid antibodies have been associated with increased stroke risk. In the Stroke Prevention in Young Women Study, a positive anticardiolipin antibody and/or lupus anticoagulant was found in a greater proportion of cases. The findings support the importance of more research to determine the

role of antiphospholipid antibodies as an independent risk factor for stroke.¹³⁴

The role of C-reactive protein (CRP) in stroke was observed in several studies to predict incident stroke independent of LDL cholesterol. Statins have also been shown to reduce CRP independent of lipid changes. In the Physicians' Health Study of healthy middle-aged men and in the Women's Health Study of healthy postmenopausal women, total cholesterol and CRP both predict incident myocardial infarction and only CRP predicts incident stroke.^{135,136} Similar findings have been found in the National Health and Nutrition Examination Survey (NHANES), the Leiden 85-Plus Study and the Framingham Heart Study. In the Framingham Heart Study, CRP was found to be a strong predictor of stroke even after adjustment for other risk factors. The plaque stabilization concept through anti-inflammatory mechanisms provides a working hypothesis as to why statins might reduce cerebrovascular risk.^{137–139}

Primary prevention includes modifying risk factors of lifestyle and behavior such as not smoking; diet such as fish, fruits, and vegetables; adequate physical exercise; limiting alcohol; and adhering to physician recommendations for screening, monitoring, and treating blood pressure, cholesterol, and diabetes (blood glucose). Secondary prevention requires intervention by the health care provider, which includes hypertension treatment, cholesterol treatment, for example, statins, TIA treatment, antiplatelets, anticoagulation for atrial fibrillation and other cardiac sources, ACS treatment, and carotid endarterectomy.

Recently the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) completed double-blind, active-controlled trials. The study enrolled 42,448 patients, >55 years old, with hypertension (systolic BP $>140 \text{ mmHg}$ and/or diastolic BP $>90 \text{ mmHg}$) and at least one other coronary heart disease (CHD) risk factor. Treatment comparison was with the diuretic chlorthalidone and three other agents.^{140–142} The doxazosin treatment arm of the blood pressure-lowering component of the trial had a higher incidence of major CVD events compared to chlorthalidone. The doxazosin arm, compared with the chlorthalidone arm, had a higher risk of stroke (RR, 1.19). For lisinopril versus chlorthalidone, lisinopril had higher six-year rates of combined stroke (6.3% vs. 5.6%; RR, 1.15). Thiazide-type diuretics were found to be superior.

In a meta-analysis the odd ratios for differences in systolic pressure between group in 62,605 hypertensive patients.¹⁴³ Compared with old drugs (diuretics and beta-blockers), calcium-channel blockers and angiotensin converting-enzyme inhibitors offered similar overall cardiovascular protection, but calcium-channel blockers provided more reduction in the risk of stroke (13.5%). All of the antihypertensive drugs had similar long-term efficacy and safety but calcium-channel blockers were more effective in stroke prevention.

The Scandinavian Simvastatin Survival Study demonstrated with 5.4 years of follow-up a significant change in stroke risk by lowering cholesterol of 3.4% versus 4.6% ($p = 0.03$).¹⁴⁴ The study showed that a 28% risk reduction in stroke and TIA could be achieved. It was noted in the study that 55% of the subjects also were on aspirin. Another study, the Long-term Intervention with Pravastatin in Ischemic Disease (LIPID), demonstrated a similar result of 3.4% compared to 4.4%; a p -value of 0.02.¹⁴⁵ The risk reduction of 24% was found in nonhemorrhagic strokes; 84% of the patients were also on aspirin. A meta-analysis of 12 trials comprising 182 strokes in the statin group and 248 in the placebo group demonstrated that stroke was reduced in all trials or secondary prevention trials. However, subgroup analysis indicated that no difference in primary prevention was evident.

Aspirin has been studied in a number of trials with differing dosages. A meta-analysis of 16 trials with a dosage ranging from 75 to 1500 mg/day was done.¹⁴⁶ The hemorrhagic stroke rate was .26% or an increased risk of 12% was found. However the ischemic stroke rate of 1.7% was associated with a 39% risk reduction. Hence there was greater benefit than risk with aspirin use.

Anticoagulants have been evaluated in stroke prevention. For patients with atrial fibrillation, Warfarin reduces stroke by 68%. The

annual stroke rate reduced from 4.5 to 1.4% per year. However, there is a tendency for cardioembolic stroke to undergo hemorrhagic transformation. Also, patients under 60 years old with lone atrial fibrillation without other stroke risk factor were observed to not need warfarin.¹⁴⁸

Surgical prevention of stroke was shown to be efficacious through the North American Symptomatic Carotid Endarterectomy Trial (NASCET).^{149,150} Patients less than 80 years old with a recent hemispheric TIA or nondisabling stroke and atherosclerotic lesion were included in the trial. Patients with a stroke from a cardioembolic source or uncontrollable hypertension or diabetes were not included. The average age was 66 years (range 35–80 years) and one-third of the subjects were women. Thirty-two percent had a prior stroke. Most risk for surgery was early with a 5.8% incidence of stroke or death. However, at two years the risk of ipsilateral stroke was reduced by 65% in patients with a >70% carotid stenosis. The European Carotid Surgery Trial (ECST), and the VA Cooperative Study (VACS) also demonstrated that carotid endarterectomy decreases stroke in symptomatic patients with high-grade extracranial carotid artery stenosis.¹⁵⁰ The combined risk ratio estimate was 0.67 and found a similar benefit for men and women.

Carotid endarterectomy to reduce the incidence of cerebral infarction in patients with asymptomatic carotid artery stenosis was studied in a prospective, randomized, multicenter trial. Patients with asymptomatic carotid artery stenosis of 60% or greater reduction in diameter were randomized—and after a median follow-up of 2.7 years the aggregate risk over five years for ipsilateral stroke and any perioperative stroke or death was estimated to be 5.1% for surgical patients and 11.0% for patients treated medically.

Stroke prevention requires then a combination or continuum risk factor assessment, modification and interventions. Modifiable risk factors such as blood pressure, cholesterol, blood sugar, body mass index, homocysteine, and smoking habits can be routinely done. Prescription and adherence of blood pressure medications, statins, and antiplatelet agents have been shown to be effective as secondary prevention methods. Surgical prevention by carotid endarterectomy has also proven to be effective but should be reserved for those with high-grade stenosis. The role of angioplasty in secondary or tertiary prevention of ischemic strokes still needs evidential proof. With increasing age of the population there will be an increase in the number of strokes. Prevention is the key in the next decade to provide a decrease in disability and death.

► PARKINSON'S DISEASE

Parkinson's disease is a progressive neurologic disorder with bradykinesia, resting tremor, rigidity, and postural reflex. The disorder is due to progressive loss of pigmented neurons associated with loss of dopamine. The onset is insidious, progression tends to be gradual, and the course of the disease is usually prolonged. Diagnosis is based on clinical criteria which have changed over time due to changes in clinical practice. Misdiagnosis with depression and multiple system involvement leads to variable case determinations. Parkinson's disease may occur with dementia in 10–25 % of cases.¹⁵¹

Incidence rates for Parkinson's disease are varied and reported to range from 4 to 20 per 100,000. In Rochester, Minnesota the incidence was 20.5 per 100,000 and in a study in northern Manhattan the rate was 13 per 100,000.^{152,153} The incidence rates increase with age with the highest rates in 70 to 79-year-olds. Prevalence of Parkinson's disease has varied widely with the range from 31.4 to 347 per 100,000.¹⁵⁴ Differences in case ascertainment using clinical, drug usage, and survey data may account for this variation. There has been little change in the age-adjusted incidence in Parkinson's disease over time but with increasing age and survival the number of affected individuals is likely to increase.

Parkinsonism may be a direct result from exposure to toxins (e.g., carbon monoxide or manganese), drugs (e.g., phenothiazides), traumatic or vascular lesions of the brain, or tumors.¹⁵⁵

Arteriosclerosis, when present, is most likely a concurrent disease rather than a subtype of parkinsonism. Postencephalitic parkinsonism is well recognized but accounts for a relatively small and decreasing proportion of all prevalent cases. However, the cause of most cases of Parkinson's disease remains obscure. Age is a known risk factor because the occurrence is dependent upon the loss of neurons, which indicates a chronic onset. Whether or not men or women are at greater risk is difficult to establish. Population studies have suggested men are at higher risk but the prevalence may be higher in women due to their longer survival.

The debate of genetic predisposition versus environmental exposure is unresolved. Several studies of familial aggregation suggest that a positive family history of Parkinson's disease is present in 16 to 41% of idiopathic cases. Pure genetic forms may account for only 10–15% cases. Twin studies do not show a relationship with clinical Parkinson's disease or f-dopa uptake analysis.¹⁵⁶

Environmental exposures are suggested through variations in the geographic distribution of the disease and by associations from analytical studies.¹⁵⁵ Parkinson's disease incidence is higher in Europe and North America.¹⁵⁵ With population studies, the rates are higher for whites and Hispanics than blacks; however, the door-to-door survey in Copiah County, Mississippi found no difference in rates.¹⁵⁵ A difference in clinical diagnosis of Parkinson's disease may play a role in this relationship.

Etiological studies using a variety of case ascertainment methods have suggested that rural residence, farming, well-water drinking, and herbicide/pesticide exposure are related to Parkinson's disease.¹⁵⁵ Infectious agents have been evaluated, particularly focusing on the epidemic of 1918. However no agents or relationships have been found. Coronavirus titers have been found to be elevated in Parkinson's patients which may indicate an animal exposure. Other factors that have been suggested but unproven include head trauma and emotional stress.^{157,158} Recent studies suggest that diet may be important. Animal fat and protein intake may increase risk. Antioxidants have demonstrated inconsistent results as a protective factor.^{159,160} Numerous studies have reported a lower risk of Parkinson's disease among cigarette smokers. Various explanations for this observation have been proposed, but whether the inverse association between cigarette smoking and risk of Parkinson's disease has biological significance or behavioral relationship remains controversial.^{155,161} Caffeine consumption may also be protective.¹⁶² The observation that drug abusers exposed to the meperidine derivative MPTP sometimes have a syndrome clinically indistinguishable from advanced Parkinson's disease, as well as subsequent studies using animal models of MPTP toxicity, support the hypothesis that environmental exposures may be important in causing Parkinson's disease.^{163–165}

Parkinson's disease remains an increasing problem with the advancing age of the population. The disease leads to progressive disability. Agents have demonstrated efficacy in limiting the symptoms and disability. The etiology has yet to be determined.

► DEMENTIAS

Dementia is a relatively heterogeneous clinical syndrome characterized by a decline in intellectual functioning such as memory, reasoning, judgment, calculation, abstraction, and language. In addition to the decline in cognitive abilities, there are clear decrements in everyday functioning such as activities of daily living and social activities. The diagnosis of dementia requires that there be no coexisting disturbances of consciousness¹⁶⁶ or any other acute conditions or situations that preclude clinical or psychological evaluation of cognitive performance. There is no universal agreement on the criteria for the dementia syndrome, but several useful published criteria exist in the International Classification of Diseases and elsewhere.^{166–168} The dementia syndrome has many known causes, including a variety of concurrent nonneurologic diseases, medications, and toxic environmental exposures;¹⁶⁶ some dementia patients with defined environmental or anatomic causes may have their syndromes at least partially

reversible. However, it is generally felt that over half of clinical dementia cases are due to Alzheimer's disease (AD), with the next most common causes being related to cerebrovascular disease and Parkinson's disease.¹⁶⁹ Human immunodeficiency virus is neurotropic, and an AIDS-related dementia syndrome has been identified as the most common neurologic complication of this disease. However, AIDS is associated with increased risk of other important central nervous system conditions, some of which may have dementia-like clinical features, and the differential diagnostic possibilities must be kept in mind.¹⁷⁰

The epidemiology of the dementias and AD suggests that they are an important and growing public health problem, particularly among older persons. While community surveys of the prevalence and incidence of dementia and AD can be methodologically challenging, it appears that the prevalence of dementia in persons 85 years and older and residing in the community may be as high as 40–50%.^{171,172} The prevalence of dementia has been found to double every five years of age from age 3–70.¹⁷³ Accurate geographically-based prevalence and incidence of dementia are sometimes hampered by several factors, including frequent supervening of substantial clinical morbidity, the refusal or inability of demented patients to participate in surveys and the increased likelihood that dementia patients will be institutionalized. However, there is considerable geographic variation with low incidence rates reported in developing countries.^{174–176}

Because it is the most common form of dementia, AD has received substantial attention in terms of etiology, pathogenesis, and prevention. As dementia in general, AD increases in incidence with increasing age among older persons.^{177,178} The geographical variation may be due to variation in diet, education, life expectancy, social-cultural factors and environmental factors. Several putative risk factors for AD have been identified, such as prior head trauma and aluminum exposure, but few have received consensual agreement as to being true causes, and no known risk factors as yet form a specific prevention strategy.^{179–181} Possible preventive effects of exogenous estrogen use are still unproven.¹⁸¹ Other possible protective factors include education, gene APO E2, antioxidant consumption, and use of some anti-inflammatory medications. The discovery of genetic factors with three genes (APP, PS1, and PS2) in familial and APO E4 in nonfamilial AD is an important advance but not yet confirmed in large studies.^{173,182,184}

Interventions are still focused on the caregivers and behavioral management.^{185,186} Focusing on risk factors for cardiovascular and cerebrovascular disease may lessen the risk for multi-infarct dementia.

► CONCLUSION

The changing incidence of neurological conditions is in part changing diagnosis and classification. The increasing prevalence of chronic neurological conditions is due to the aging of the population, effective treatments, and longer survival. New problems such as the spread of WNV or the zoonotic spread of CJD have increased the need for surveillance, prevention, and health care. This has profound impacts on the magnitude of disability and impairment in the population and will have more as the number of people with chronic conditions increase. There are still many neurological conditions that public health screening or prevention await further research. The exciting findings of genetic predisposition aided with environment interaction studies are important for future research in determining causation and risk. The need for public health and clinical services will continue to grow as the neurological disease burden increases.

Disabling Visual Disorders

Dawn M. Oh • Kean T. Oh

Although the prevalence of blindness worldwide is not precisely known, new global estimates from 2002 World Health Organization (WHO) show at least 37 million people are blind and another 124 million people have low vision. This figure is based on the standard international definition of blindness: a visual acuity (VA) of less than 3/60 or corresponding visual field loss in the better eye with best possible correction, and a VA of <math><6/18</math> (but greater than 3/60 or a field loss of less than 20%) constituting “low vision.” Because of the essential nature of vision for most endeavors, the frequency of blindness also reflects a global loss in disability-adjusted life years, and is considered by WHO to be a key barrier to development worldwide. The causes of blindness and visual loss, most preventable through primary intervention or secondary therapy, include a small core of major diseases including: cataract (47.8%), glaucoma (12.3%), diabetic retinopathy (4.8%), macular degeneration (8.7%), trachoma (3.6%), onchocerciasis (0.8%), and corneal opacities (5.1%) (Fig. 68-1). However the fraction of the blindness burden for each disease differs substantially from region to region (Fig. 68-2).

The total disease burden of blindness varies along a variety of demographic factors. First, blindness rates vary geographically (Fig. 68-3) with the largest impact occurring in regions least able to afford the loss in human resources or address economic costs of treatment. More than 90% of the world’s visually impaired are found in developing countries. Furthermore, WHO estimates that some 75% of all worldwide blindness is avoidable through prevention or treatment. Age also remains the primary risk factor associated with most blinding disorders, regardless of etiology (Fig. 68-3) with more than 82% of all blindness occurring in the 50+ age group (though they constitute only 19% of the world population). This age-related distribution has been further deepened by an aging world where populations over 50 years of age increased by 30% (versus an overall population increase of 18.5%) from the last global blindness estimates of 1990. Indeed, that the blindness rate remained stable despite the aging effect over this time (38 million estimated blind in 1990) signifies a lower than projected blindness rate (With age increases the projection was 52 million blind in 2002.). This decrease has been attributed to a variety of factors, including increase in public awareness and accessibility of services, to successful elimination efforts for blindness in Gambia, India, Morocco, Nepal, Sri Lanka, Thailand, and other nations with previously high endemic blindness rates. Finally, blindness and visual impairment are unequally distributed between men and women, with females having a significantly higher risk of visual impairment (a female:male ratio ranging from 1.5 to 2.2 worldwide).¹

Some visual disorders, while not major causes of blindness worldwide, represent significant medical cost, and, without treatment, significant loss of daily life functions, as in the case of uncorrected refractive error. Another area of public health interest among the less-blinding disorders is international emphasis on screening children for amblyopia, treatable only in childhood. Minor visual complications

may also characterize populations at increased risk for developing blinding visual diseases; for example, myopics are at increased risk for retinal detachments and glaucoma.

Major recent research has provided new insights into causes, risk factors, and treatments of most visual disorders. This research reinforces the need for multidisciplinary, and often development-oriented, consideration and intervention in the area of visual health. The need for sufficient and appropriate data to make such policy decisions has generated new methodologies for measurement, such as WHO programs that use a standardized method of low-cost, small-scale field surveys to provide more reliable blindness data than were previously available. These new research approaches are even more crucial as more diseases are found to have multifactorial causes, and the traditional areas of public health interest, such as health behavior patterns (smoking and cataracts or age-related macular degeneration [AMD]), nutrition (vitamin A and xerophthalmia, antioxidants and AMD), and education (trachoma and public health education), are drawn into the circle of causation for blinding disorders.

This chapter emphasizes and reviews the major causes of blindness worldwide as well as other important visual disorders, notes risk factors where information is available, and suggests the most important clinical and public health interventions to control these conditions.

► CATARACT

Unoperated cataract is the main cause of visual loss globally, with 20 million people currently estimated to have severely reduced vision (3/60 or worse) as a result of cataracts. With current global aging rates, and the prevalence of cataract doubling with each decade of age after 40 years, this number is expected to reach 40 million by 2020. Primarily a disease of aging, cataract describes the opacification of the lens of the eye. This gradually blinding process is associated in its most common form (“senile cataracts”) with an increase in the weight and thickness of the lens and a decrease in accommodation as new layers of cortical fibers are laid down, hardening the lens nucleus. While not subject to primary prevention in most cases, effective surgery for the removal of the lens and its replacement have been developed and dramatically refined. The most desirable treatment is now phacoemulsification, removal of cataract tissue, of the lens. The international lack of access to trained ophthalmologists and issues of surgical cost, however, leave the statistics of blindness from cataract high, despite this effective treatment. Issues of education and cultural acceptance have complicated efforts to increase access to care, with studies in Nepal and Kenya reporting that even with free surgery and transport use rates from 70% to below 60% occurred.² In wealthier nations, with greater access to both surgery and information, the demand for cataract surgery has now extended to portions of the population who would not even be considered visually reduced elsewhere.

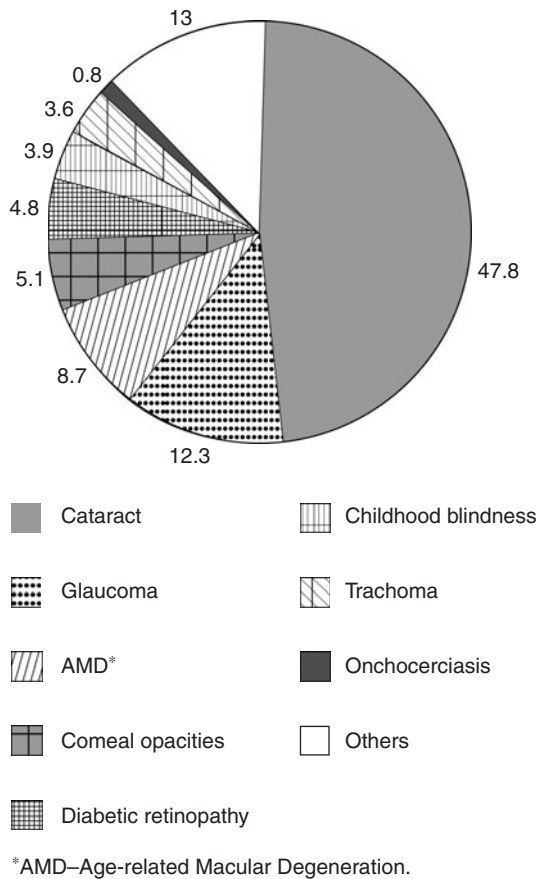

Figure 68-1. Causes of blindness. (Source: Resnikoff S, Pascolini D, Etya'ale D, et al. *Global data on visual impairment in the year 2002*. Bull World Health Organization; November 2004;82 (11).)

Although cataract development is predominantly associated with age, in developing nations it often occurs earlier in life: India reports average age of development for visually significant cataracts to occur some 14 years earlier than in the United States with 82% of Indians ages 75–83 with visually significant cataract or aphakia versus 46% in the United States at the same age. Outside of the primary risk factor of age, some environmental, physical, and nutritional risks have also been associated with earlier onset or progression of cataracts. These include exposure to UV-B light, diabetes, high blood pressure, corticosteroid therapy, smoking, alcohol, protein energy malnutrition, and dehydration.³ These last two risk factors may indicate an antioxidant relationship with cataracts and suggest that studies in antioxidants may implicate dietary protective factors, but

studies have not found a definitive relationship. While studies of vitamin therapy are not yet complete, the main preventive measures remain decreasing UV-B exposure and smoking cessation.

Current international focus is on the development of low-cost intraocular lenses, sutures, and other equipment used in cataract surgery, as well as the training of human resources for surgery in many of the world's least developed countries, which carry high disease burdens. The importance of this human resource increase is exemplified in Africa where there is only about 1 ophthalmologist per 1 million people. Regular ophthalmologic examinations are necessary for proper identification of cataracts and eventual surgery.

▶ GLAUCOMA

While glaucoma is considered with some certainty to be the second leading cause of blindness worldwide behind cataracts, the estimated disease burden of 6.7 million cases expected worldwide by 2000 proved an underestimate, and current estimates are subject to controversy. This is due in no small part to the persistent lack of an accessible inexpensive consistent screening test and system. Demography-based models however, suggest a rate of around 9.3 million people having some type of bilateral glaucoma blindness. Eighty-five percent of patients affected by glaucoma are in the developing world.⁴ The total numbers affected by glaucoma are split between primary angle closure glaucoma (PACG) and primary open angle glaucoma (POAG). The overwhelming majority of cases of PACG are in Asia and Asian-descent populations, while POAG is distributed throughout the world, with high rates in populations of African-descent. The rate of occult glaucoma is roughly equal to that of detected disease even in developed nations, making it a further public health challenge.

Like cataract and AMD, glaucoma is predominantly a disease of aging, with prevalence rates increasing dramatically over the age of 65, making it another of the visual disorders being affected by the graying of the world's population. Although in the past elevated intraocular pressure (IOP) was considered the cause and part of the definitive diagnosis of the disease, it is now accepted that elevated IOP may be associated with as little as 10% of POAG. The characteristic visual field loss that describes glaucoma has remained constant, however, for over a century, with progressive damage of optic nerve fibers causing a loss of vision from peripheral to central vision in a spiraling pattern. This damage is related to changes in vascular perfusion of the optic nerve head and is worsened by elevated IOP. Progression of the disease can be prevented in many cases by trabeculectomy or topical drug treatments, which lower IOP. However, patients often, especially in the developing world, do not present for treatment until substantial permanent visual loss has already occurred. Clearly glaucoma is a prime target for early intervention measures; unfortunately, making an early diagnosis is problematic, especially when characteristic field loss, often not noticeable until 80% or more of the optic nerve is permanently damaged, is now

Global estimate of visual impairment, by WHO region (millions), 2002:

	African region	Region of the Americas	Eastern Mediterranean region	European region	South-East Asia region	Western Pacific region	Total
Population	672.2	852.6	502.8	877.9	1590.8	1717.5	6213.9
# of blind people	6.8	2.4	4	2.7	11.6	9.3	36.9
% of total blind	18%	7%	11%	7%	32%	25%	100%
# with low vision	20	13.1	12.4	12.8	33.5	32.5	124.3
# with visual impairment	26.8	15.5	16.5	15.5	45.1	41.8	161.2

Figure 68-2. Visual impairment by region. (Source: WHO Fact Sheet N°282, November 2004.)

Figure 68-3. Geography of blindness (Source: Available at http://www.who.int/blindness/data_maps/blindness.jpg. WHO maps and information website.)

considered the definitive diagnostic tool. Other measurements of optic nerve head signs, such as cup-to-disc ratios, cup asymmetry, and splinter hemorrhages, although useful supplemental information, lack both sensitivity and specificity. These complications in addressing glaucoma have led to it being left off of the systematic goals for the VISION 2020 plans of WHO for the time being.

While epidemiologic studies of POAG are limited by their differing disease definitions, small sample sizes, and questionable sampling methods, they suggest a number of risk factors for the development of POAG, with or without elevated IOP (sometimes called “normal or low-tension glaucoma”). Age is the most constant risk factor, with the incidence over 60 years being seven times that of the under 40 age group. Race is another factor, with the risk for blacks shown to be four times greater than that for whites in both the United States and United Kingdom, and with most glaucoma in blacks occurring at a younger age. Family history of glaucoma is also a risk factor, with approximately 13–26% of cases having a genetic component. Other putative risk factors include diabetes (via increased IOP); myopia; hypertension; inconsistent associations with modifiable risk factors including smoking and an atherosclerotic diet; and protective effects from vitamin B₁₂, ω-3 fatty acid, magnesium, and exercise.⁵ Glaucoma is a serious public health challenge, as efforts center on identifying causes that may help prevent the disease as well as developing more useful screening techniques, especially for international field work.

► MACULAR DEGENERATIONS AND DYSTROPHIES

A wide spectrum of macular disease contributes significantly to blindness in the United States and worldwide, encompassing known hereditary dystrophies and multifactorial degenerations such as age related macular degeneration. Without accurate understanding of the disease process, primary intervention may be misguided and ineffective.

Recent progress in molecular genetics has allowed many hereditary macular dystrophies to be mapped, and in many instances, the specific gene causing the disease has been defined. While no definitive treatments for macular dystrophies exist, identification of the underlying gene and its function has provided insight into specific disease processes. For instance, Stargardt macular dystrophy is the

most common macular dystrophy with a prevalence of about 1 in 10,000, and known to be caused by the ABCA4 gene. Animal models raise the possibility of deleterious effects of high dose vitamin A supplements and the potential role of excess sunlight exposure.⁶ Thus, while no clinical trials yet exist, patient counseling includes avoidance of ubiquitous “eye health” supplements with vitamin A, and recommendation of good UV light eye protection. Then, patients with all forms of macular dystrophies respond well to low vision rehabilitation. Most individuals have small, well-defined central scotomas with healthy paracentral and peripheral vision facilitating their rehabilitation with low vision devices. Finally, genetic counseling for families with inherited retinal diseases is necessary to educate them regarding the risk of disease in further children.

Age-Related Macular Degeneration

AMD is the leading cause of blindness for people older than 65 years in the United States, Western Europe, and Australia (representing roughly 50% of all blindness by cause in these regions). AMD is defined by diffuse morphologic changes at the level of the retinal pigment epithelium (RPE).⁷ Patients experience central vision loss through atrophy of the RPE and retina or due to the development of choroidal neovascularization (CNV). Although no incidence rates are available for AMD, studies in the U.S. population have reported prevalences ranging from 6.4 to 16% in the elderly and rates of nearly 20% in the most old.^{7,8} It is believed that the number of advanced AMD cases in the United States will be 7.5 million by the year 2030, up from 2.7 million in 1973.⁸ The Age Related Eye Disease Study (AREDS) estimated that there are 8 million people at risk for progressing to advanced AMD.⁹

The pathophysiology of macular degeneration is poorly understood and likely multifactorial. Proposed mechanisms have included oxidant stress and atherosclerosis^{10,11} with reported risk factors including age, sex, family history, iris color, cardiovascular disease, body mass index,¹² smoking, light exposure, and nutritional deficiency in antioxidants and zinc.¹³ Many of these risk factors are defined by population-based studies and, depending on the study, have variable validity. For instance, sun exposure and iris color were not found to be risk factors by the genetics factors in AMD study group.¹⁴

However, other factors, specifically smoking, continue to be validated by follow-up studies. Thornton et al. reviewed the smoking association and found that 17 studies of various designs showed a strong association while five studies found no correlation. Subsequent to that study, the Genetics Factors in AMD study showed an increasing risk with rising pack years of smoking so that by 40-pack years, risk for both geographic atrophy and CNV formation was significantly increased. Cessation of smoking reduced risk of AMD and required more than 20 years to approximate the risk of nonsmokers.^{15–17} Cardiovascular risk factors such as C-reactive protein, IL-6 and homocysteine also continue to be validated by multiple centers.^{18–20} Recent advances have also implicated inflammation and the immune system in the pathogenesis of AMD. A single polymorphism in the complement factor H gene, Tyr402His has been associated with as much as 43–50% AMD cases. This single nucleotide polymorphism may confer susceptibility to AMD both for geographic atrophy and CNV development. Patients homozygous for this polymorphism were found to be 6.3 times more at risk than patients with the “wild type” sequence and the risk was highest for homozygous smokers.^{21–23}

The AREDS demonstrated clear preventative benefit to the use of antioxidants and zinc in AMD. This study showed a 19% reduction in progression of patients with intermediate AMD to advanced AMD that was defined by clear vision affecting changes.²⁴

While previous studies examining the role of micronutrient supplementation were equivocal, the AREDS shifted patient counseling to actively promoting vitamin supplementation to patients at risk.²⁵ When considering the population at risk of 8 million Americans, over 300,000 people taking these antioxidants would be prevented from progressing to advanced AMD and associated vision loss in the next five years. The economic public health effect is illustrated by a similar model demonstrating a savings of 5.6 billion Canadian dollars when considering just photodynamic therapy as a treatment, let alone the current and future pharmacologic agents such as pegaptanib and ranibizumab. The authors suggest that these savings could be magnified tenfold in the United States due to currency and population.²⁶ Lutein supplementation has also been suggested as a means of slowing the progression of geographic atrophy as well.²⁷ Other dietary risk factors associated with atherosclerosis and high body mass index, such as dietary fat, also appear to carry increased risk for AMD. Thus, dietary modification is a strategy for primary prevention of AMD.²⁸ Finally, smoking cessation is strongly recommended from the standpoint of AMD risk reduction as well.

Treatment of AMD currently focuses on neovascularization associated with AMD. Initially, treatment only involved thermal photocoagulation of CNV. The efficacy of laser was demonstrated to prevent further vision loss through the multicenter macular photocoagulation studies (MPS). Photodynamic therapy (PDT) and intravitreal pharmacologic agents such as pegaptanib (Macugen) now also are used to treat CNV from AMD.²⁹ The pharmacologic agents target vascular endothelial growth factor (VEGF) and its role in AMD. At best, however, current treatment strategies tend only to stabilize vision with only a small fraction of patients experiencing substantial improvement in their central vision. Future medications include the use of ranibizumab (Lucentis) and bevacizumab (Avastin). Early case series as well as a double blinded multicenter trial raise the possibility of vision, improvement for patients with choroidal neovascularization.^{30,31} The comparison of ranibizumab and bevacizumab raises economic and ethical issues given the initial use of bevacizumab for AMD as an “off label” approach and the significant difference in cost between it and both ranibizumab and pegaptanib. Currently, however, low vision management plays a key role in the care of patients with AMD. It will likely continue to maintain its place in the care of AMD patients despite recent pharmacologic advances.

Other Macular Conditions associated with Central Vision Loss

Other conditions known to be associated with CNV in the macular include presumed ocular histoplasmosis, pathologic myopia, angioid

streaks, and idiopathic causes. AREDS recommended supplementation has not been examined regarding risk reduction in these conditions. Treatment of CNV in these conditions tends to parallel AMD and includes thermal ablation, once again evaluated in the MPS series of studies, PDT, anti-VEGF medications and thermal photocoagulation. Another clinical trial known as the subfoveal surgical trials (SST), also evaluated the efficacy of subfoveal surgery for conditions with CNV. The SST showed no benefit comparing surgical removal of CNV due to histoplasmosis or idiopathic causes to observation. There was a marginal benefit shown evaluating quality of life factors between surgical patients and those randomized to observation.^{32,33}

► RETINAL VASCULAR DISEASE

Diabetic retinopathy is the leading cause of blindness in the United States among individuals 20–64 years old, accounting for 12% of all new cases of blindness each year. This retinal vascular disease causes visual morbidity through the proliferation of neovascular fronds and the development of macular edema. There are roughly 700,000 Americans with proliferative retinopathy and more than 500,000 with macular edema.³⁴

Primary prevention of diabetic retinopathy is based on good diabetic and hypertensive control. The Diabetes Control and Complication Trial (DCCT) demonstrated a 60% reduction in the risk of retinopathy with intensive control (versus standard treatment) of insulin-dependent diabetes mellitus (IDDM). After 3.5 years, the risk of progression was more than 5 times lower with intensive control.³⁵ The results of the DCCT indicate that careful control of blood sugars in all diabetics will retard the onset of diabetic retinopathy. The UKPDS, further demonstrated that lowering the glycosylated hemoglobin just one point resulted in a significant reduction of intervention. Screening for the presence of diabetic retinopathy is a very important first step to secondary management, and guidelines have been established for both IDDM and non-insulin-dependent diabetes mellitus (NIDDM) patients. One study showed that only 40–45% patients with diabetes mellitus were appropriately screened and of those patients, 11% required treatment for diabetic retinopathy.

Treatment of diabetic retinopathy has been guided by a series of well-designed multicenter trials. Initial studies demonstrated that panretinal photocoagulation reduced the risk of severe visual loss by greater than 50% over no treatment.³⁶ Later multicenter trials established firm definitions and guidelines for the treatment of clinically significant diabetic macular edema. Focal photocoagulation reduced visual loss from diabetic macular edema by about 50% as well.³⁷

The second most common retinal vascular disease involves *retinal vein occlusion*. Risk factors for retinal vein occlusion include hypertension, cardiovascular disease, diabetes mellitus, increasing age, and glaucoma.³⁸ Patients with a 677 C-T mutation in the methylenetetrahydrofolate reductase gene (MTHFR) were thought to have an increased risk of thromboembolic events. However, more recent studies show that this relationship is more related to total serum homocysteine and low folate levels. Regardless, patients with multiple thromboembolic events, including BRVOs and CRVOs should be screened for low folate levels and high serum homocysteine.³⁹ Folate supplementation in these instances may reduce the risk for further events.

Branch retinal vein occlusion (BRVO) causes decreased vision primarily by cystoid macular edema, neovascularization, and ischemia. Focal photocoagulation for macular edema resulted in 65% gains in visual acuity among treated patients. Scatter laser photocoagulation was found to lower the risk of vitreous hemorrhage following the development of neovascularization.^{40,41} Central retinal vein occlusion, however, did not demonstrate benefit for macular edema following focal photocoagulation, though panretinal photocoagulation was an effective means of treatment for iris and angle neovascularization following an ischemic CRVO. Treatment at this stage prevents further progression to neovascular glaucoma and potentially, the loss of the eye.⁴²

Retinal vascular disease is a common cause of visual morbidity in the United States and worldwide. Because risk factors involve systemic

disease, prevention of major retinal vascular disease involves control of these systemic diseases. Large multicenter trials have studied and established the management of these diseases following their development.

► TRACHOMA

Responsible for 5.9–8 million cases blindness worldwide, trachoma, unlike the above visual disorders, is an infectious disease, concentrated in poor and rural areas of the world, with the highest burden among women and children.⁴³ While no longer a leading cause of blindness worldwide (Trachoma represented some 15% of global blindness as recently as 1990), it remains the leading infectious cause. Its cost, given its early effects in children, is estimated at US\$ 2.9 billion a year in productivity loss.⁴⁴

Chlamydia trachomatis, the causative microorganism, and eye-seeking flies, the vector of transmission, are endemic in Central America, Brazil, Africa, the Eastern Mediterranean, and several Asian nations. *C. trachomatis* causes an inflammation in the eye, resulting in the formation of follicles in the conjunctiva which scar the eyelid until it turns inwards with the lashes rubbing the eye, gradually leading to blindness. This process can be halted at the primary level by the improvement of living standards and hygiene in endemic areas, as proper face-washing with clean water is protective. This control may be supplemented by the new availability of the long-acting azithromycin as an effective but extremely expensive treatment and by surgery on underturned lids to prevent progression to blindness. This combination of strategies has been labeled “SAFE” (surgery, antibiotics, face-washing, and environmental improvement) and implementation of control efforts in the last decade have reduced rates in such counties as Morocco by 90%, giving encouragement to other regions in the possibilities for eradication of a disease which is considered one of the world’s oldest known infectious diseases, having been described by the ancient Egyptians.⁴⁵ Nevertheless, 50 years of global public health efforts to eradicate trachoma has emphasized that, without improvement in the sanitation, water, population densities, economies, and attention to literacy and cultural appropriateness in public education programs, secondary interventions will not be successful in completely controlling the disease.

► ONCHOCERCIASIS

In endemic regions of Africa, the Arabian Peninsula, and the Americas, onchocerciasis, or “river blindness,” is the second leading infectious cause of blindness. Of those currently infected, approximately 99% are in Africa. While the dermatologic effects of onchocerciasis are more common among the infected (6 million people), the blindness is nevertheless an important issue in visual health.¹ The disease, caused by the parasite *Onchocerca volvulus*, is spread by the black fly population in endemic areas, and the intensity of infection is the best indicator of risk for developing blindness. Unfortunately, onchocerciasis is a public health example where development projects have assisted in the proliferation of the disease by increasing vector breeding sites (near fast-flowing rivers or streams). Current international efforts at eradication are focused on both controlling the vector and the use of a recently developed suppressive drug, ivermectin, which is being distributed with WHO efforts. Based on past experience with problems of access, understanding of the disease, and cultural appropriateness of development projects, these efforts are now targeted at developing local initiatives and community-based prevention plans.

► XEROPHTHALMIA

The leading cause of blindness in children worldwide is now cornea scarring primarily from blinding malnutrition, also known as xerophthalmia, resulting from vitamin A deficiency. A difficulty in estimating

consistent rates and impact comes from a high rate of mortality from malnutrition and measles within this category of children.⁴⁶ Other children show primarily signs of clinical xerophthalmia, from eye dryness to ulceration. In this case, the micronutrient deficiency leads to irreversible blindness in the young. Current recommendations include exclusive breast-feeding for the first 4–6 months of life and complementing diets with food items high in vitamin A. Preventive interventions include programs to distribute high doses of vitamin A to infants and children in areas with high rates of micronutrient deficiency. In the case of xerophthalmia, the nutritional deficiency leading to blindness also represents an increased risk for other childhood illnesses and mortality.

► AIDS AND THE EYE

AIDS is an increasing world health problem, and more than 200,000 individuals are affected by it in the United States. Because of its overall increasing prevalence, it has also become a significant cause of visual morbidity. Between 40 and 70% of all AIDS patients exhibit ocular disease, and postmortem examinations have found evidence of ocular disease in greater than 95% of cases.^{47,48} AIDS may involve the eye directly by causing a microangiopathy, characterized by the presence of cotton wool spots, or by opportunistic infection, or neoplastic and neuro-ophthalmologic manifestations. Anterior segment manifestations include common diseases, such as molluscum contagiosum, as well as rare diseases, such as microsporidial keratitis and Kaposi’s sarcoma. The most common posterior segment opportunistic infection is cytomegalovirus (CMV) retinitis. It affects between 5 and 40% of AIDS patients. CMV rarely causes retinal disease unless the CD4 count falls below 50 cells/mm³. CMV viral load also has been found to play a key role in predicting CMV retinitis. Initially, CMV retinitis may be asymptomatic or present with trivial symptoms. Hence, screening this population is important to identify patients requiring initiation of therapy. Antivirals for CMV have been shown in the studies for ocular complications of AIDS (SOCA) to prolong the life of AIDS patients. Finally, CMV retinitis predisposes patients to retinal detachments, even as the retinitis itself goes into remission. The incidence of CMV retinitis—associated retinal detachment is 24% at one year. Highly active antiretroviral therapy (HAART) strategies have allowed recovery of patients CD4 counts. For patients with CMV retinitis in remission, maintenance therapy is continued to prevent reactivation of CMV retinitis. Once the CD4 count of a patient recovers, however, maintenance therapy can safely be discontinued. However, the HAART strategy has introduced a new condition to these patients as their immune system recovers known as immune recovery uveitis.⁴⁹

In the era of HAART, CMV viral load has become more predictive of mortality and quality of life.⁶⁰ Thus, shifting efficacy in therapy for AIDS patients has resulted in improved mortality and new conditions related to immune system recovery.

► RETINOPATHY OF PREMATURITY

Retinopathy of prematurity (ROP) is a multifactorial disorder of premature infants that affects 1300 children each year.^{50,51} Between 85 and 90% of low-birth weight children exposed to oxygen will demonstrate some evidence of ROP, though relatively few infants suffer severe visual impairment.⁵² It is estimated that only 6% of infants reach a stage of ROP requiring treatment.⁵³ Time of oxygen exposure and to a lesser degree oxygen concentration, low birth weight, and short gestation are key risk factors for the development of ROP. Exposure to high concentrations of oxygen interferes with the process of retinal vascularization in premature infants. Consequently, neovascularization, vitreous hemorrhage, and tractional retinal detachment by fibrovascular proliferation results in visual morbidity.^{54,55} It was previously felt that careful management of arterial oxygen could prevent the onset of ROP, but increased ability of neonatologists to keep

smaller, more premature infants alive has resulted in a resurgence of ROP in spite of careful oxygen control. It is now evident that ROP is driven by multiple factors in addition to oxygen exposure.⁵⁶

Because of the high incidence of ROP in low birth-weight infants, careful screening is an important step in the management of this disease. Current recommendations call for infants below 1500 g birth weight to be carefully screened at specific intervals. Cryotherapy for patients who reach a well-described threshold stage has reduced the risk for retinal detachment in these infants by 50%. Laser photocoagulation has recently supplanted cryotherapy as the primary means of treatment of threshold ROP.⁵⁷ The Early Treatment for ROP (ETROP) study has addressed guidelines for earlier treatment of ROP than threshold level using laser photocoagulation to improve outcomes.⁵⁸ For patients who develop subtotal retinal detachments, scleral buckling surgery has a high rate of success. Without this surgery, 85% of patients will progress slowly. Once total retinal detachments develop, they are often complicated and require extensive surgical intervention.

Thus, advances in neonatology have resulted in an increased incidence of ROP in spite of careful oxygen management. Primary prevention of ROP must address means of reducing premature and low-birth weight infants. Studies have examined vitamin E as a prevention strategy for ROP, but this supplementation has been shown to only possibly reduce the severity of disease. Once ROP is identified, however, management guidelines allow prevention of visual morbidity in the majority of infants. Long term risk for adults with ROP includes high myopia, macular dragging and retinal detachment. The final report from the cryotherapy for ROP study showed the rate of retinal detachment after 10 years was still 4.4% in treated patients.⁵⁹ These patients will need lifetime ophthalmologic monitoring and care.

► OTHER VISUAL PROBLEMS

Although we have considered the most common blinding disorders, the most common ocular complaint is loss of sight due to refractive error. In the case of myopia, this means that distant objects are focused anterior to the retina because of a longer eye and cannot be seen clearly. In, hyperopia there is a shorter eye where the focus falls behind the retina, making closer objects difficult to view. Finally, with presbyopia there is a loss of accommodative functioning, where the eye cannot adjust to bring near objects into focus; this accommodative loss is primarily associated with aging. The majority of cases of refractive error can be corrected through glasses; however, severely myopic patients are also at increased risk (regardless of refractive correction) for retinal detachments and glaucoma, both potentially blinding.

Another common visual disorder that has been subject to extensive public health intervention at the screening level is amblyopia. Amblyopia describes the preferential use of one eye. This imbalance in use occurs from different refractive errors or muscle balance in each eye during the first six years of life. The most effective treatment remains early patching of the dominant eye, with cases being identified as early as possible. To reach these cases, vision-screening is recommended worldwide at the preschool and elementary levels.

Visual disorders span a large range of effects, from the inconvenience of refractive error, to infectious diseases, to blinding degenerative disorders. In each case, however, appropriate screening identification and intervention remains the international challenge of the public health community.

Psychiatric Disorders

Evelyn J. Bromet

Psychiatric disorders occur in every socioeconomic, racial, and cultural group in the world and are among the top 10 contributors to the global burden of disease.¹ In the United States, 8–18% of children and adolescents and 26% of adults recently experienced a psychiatric or substance use disorder.^{2,3} Alzheimer's disease is found in 8–15% of people over age 65.⁴ In the last several decades, a great deal has been learned about the distribution of psychiatric and substance use disorders in the population, their familial, biologic, social, and psychologic risk factors, illness course and prognosis, and the socioeconomic costs of these disorders.

Psychiatric disorders account for a large proportion of all chronic health problems. Moreover, an individual's mental state greatly influences general health status and ability to access needed health care services. Four issues underscore the importance of mental health issues for public health and preventive medicine: (a) quality of life is largely determined by a person's mental state; (b) a large proportion of people in primary care have undetected psychiatric or substance disorders; (c) many physical disorders have an important mental component; and (d) as the risk of premature death recedes, the risk of chronic impairment rises. Given the significance of mental health problems, the search for causes is urgent.⁵ As modifiable risk factors are identified, primary prevention becomes increasingly appropriate and cost-beneficial.

Progress in our understanding of the public health significance of mental disorders follows on the heels of the advances in classification and diagnosis. Current concepts of mental illness are rooted in the diagnostic characterizations of Kraepelin and Bleuler.⁶ The current classification system used in the United States is the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, now in its fourth edition (DSM-IV).⁷ This document reflects a consensus about the types of mental disorders present throughout the life cycle and the constellation of signs and symptoms characterizing each disorder. In making a diagnosis, a clinician depends mainly on the results of a comprehensive mental examination, which focuses on the patient's (a) cognition; (b) current state of consciousness, confusion, or contact; (c) mood or affect; (d) connectedness of thought patterns, hallucinations, delusions, or distortion of thoughts and ideas; (e) personality (e.g., passivity, aggression, helplessness, rebelliousness); (f) behavior patterns, and (g) the complaint bringing the patient into treatment. In epidemiologic research, these domains are systematically evaluated using structured or semistructured diagnostic instruments.

Epidemiologic research designed to estimate the incidence and prevalence of mental disorders evolved over the past 100 years. Three generations can be identified: (a) the period before World War II, in which information about mental illness typically was provided by key informants and agency records (the median prevalence rate in these reports was 3.6%); (b) World War II to the 1970s, in which representative samples of the population were interviewed with

extensive psychological and psychosomatic symptom inventories from which psychiatrists made ratings of levels of impairment (the median rate was 20%); and (c) 1970s to the present, in which representative population samples are interviewed with structured diagnostic interview schedules.⁸ The lifetime prevalence of psychiatric disorders ranges from 30% in the Epidemiologic Catchment Area (ECA) studies⁹ conducted in the early 1980s to almost 50% in the National Comorbidity Survey Replication (NCS-R)¹⁰ conducted in 2001–2003.

This chapter focuses on findings from recent epidemiologic studies, although important earlier results and classic studies are also described. For a more detailed historical account of the epidemiology of mental disorders, see recent reviews.^{5,8,11} To ground the research reviewed in this chapter, it is important first to describe the basic tools that are used for case ascertainment in psychiatric research. One set of tools was developed for clinical research in patient populations. The need for these was first articulated in the early 1960s, when it was recognized that hospital admissions in England were more often diagnosed with depression while similar patients in the United States were given the diagnosis of schizophrenia.¹² This observation led to the first international study of diagnosis (the U.S.-U.K. project) which trained psychiatrists in both countries to use systematic interviewing techniques and explicit diagnostic criteria. Under these conditions, the diagnostic distributions in England and the United States proved to be remarkably similar.¹³ The WHO program of research on schizophrenia also demonstrated the value of using uniform, structured assessment with patients within and outside the formal treatment network.^{14,15} In the United States, the need to define homogeneous patient populations for clinical drug trials and multicenter collaborative research propelled the development of pivotal semistructured assessment procedures for use by psychiatrists.¹⁶ One of the most influential measures came about as an offshoot of the multisite NIMH Collaborative Program on the Psychobiology of Depression. In order to insure that patients from different centers would be reliably classified, the investigators developed the Schedule for Affective Disorders and Schizophrenia¹⁷ (SADS), a semistructured diagnostic interview schedule designed for experienced clinicians, and the Research Diagnostic Criteria¹⁸ (RDC), which provided operational criteria for the classifying the most prevalent disorders found in patient populations. The Structured Clinical Interview for Diagnosis (SCID) was subsequently created for clinically experienced raters to match the DSM-III-R and DSM-IV criteria.¹⁹

As important as these tools are for classifying patients, a tool was also needed to reliably diagnose respondents in large-scale population-based research. For such studies, nonclinical, or lay, interviewers are more cost-effective than clinicians. In the late 1970s, the National Institute of Mental Health (NIMH) developed the Diagnostic Interview Schedule (DIS),²⁰ a fully structured instrument designed specifically for lay interviewers. The ECA was the first large-scale

study to administer the DIS. Nearly 20,000 individuals from catchment areas in New Haven, St. Louis, Baltimore, Los Angeles, and Durham, North Carolina were interviewed.²¹ The DIS has been translated into many languages. A subsequent instrument, the Composite International Diagnostic Interview (CIDI), was developed by the WHO to permit diagnoses to be coded according to the DSM and the ICD systems. An expanded version of CIDI was recently administered to more than 10,000 respondents in the National Comorbidity Survey Replication^{3,10} and has been translated for use in countries in Asia, South America, Africa, and Europe.

This chapter is organized around Morris' framework on the uses of epidemiology.²³ In providing an overview of public health psychiatry, this chapter reviews information on the epidemiology, treatment, and prevention of mental disorders.

► COMMUNITY DIAGNOSIS

General Prevalence Studies

The first U.S. prevalence study of mental illness (or insanity as it was then called) was conducted in Massachusetts in 1854 by a physician, Edward Jarvis, who undertook a census of the "insane" by gathering information from general practitioners, other key informants such as clergymen, and records of mental hospitals and other official agencies.²⁴ Jarvis identified 2632 *lunatics* and 1087 *idiots* needing "the care and protection of their friends or of the public for their support, restoration, or custody." This method of using key informants to identify cases of mental illness was the method of choice for psychiatric epidemiology until after World War II.

After World War II, several studies of mental health in the general population were conducted using symptom inventories to determine rates of psychological impairment. The most well known was the Midtown Manhattan study.²⁵ Symptom data were collected by social workers, and psychiatrists then used this information to rate the level of impairment. More than 20% of the population was judged as being severely impaired. The first national morbidity study was conducted in the 1950s by investigators at the University of Michigan.²⁶ Consistent with the Midtown Manhattan finding, 20% of the population said yes when asked whether they ever felt that they were going to have a nervous breakdown. National studies have also been conducted on drinking patterns and alcohol-related problems, and about 12% of respondents were classified as "heavy drinkers."²⁷

The high rates of impairment from these symptom-based studies were regarded with skepticism. Surely the rate of diagnosable disorders would be lower than 20%. In fact, the findings from subsequent studies of diagnosis also produced unexpectedly high rates of psychopathology. The first large-scale study was the ECA which was designed as a longitudinal study.²⁸ Specifically, the DSM-III version of the DIS was administered in face-to-face interviews conducted initially and at one-year follow-up. The resulting incidence,²⁹ 6-month,³⁰ and lifetime³¹ prevalence rates are presented in Table 69-1. Overall, 25% of the population had a lifetime disorder, and 12% had a disorder in the past year. The most common disorders were alcohol abuse/dependence, phobias, major depression, and drug abuse. The least common disorders were schizophrenia, mania, and somatization. Three important observations resulted from this study. First, most disorders had their onset in adolescence or young adulthood. Second, only a minority of respondents with a diagnosable mental disorder received care, and most of that was obtained from general practitioners, not mental health specialists. Third, the rate of comorbidity was high. For example, almost one-third of respondents with a mental disorder had a comorbid substance use disorder.

The ECA findings on the prevalence of schizophrenia merits separate comment. The differential diagnosis of schizophrenia versus other psychotic conditions is difficult to formulate even for experienced psychiatrists. Thus the reliability of this diagnosis in the ECA was low, and prevalence estimates are better determined from more reliable sources of information, such as case registries and psychiatrist

TABLE 69-1. AVERAGE RATES OF PSYCHIATRIC DISORDER IN THE EPIDEMIOLOGIC CATCHMENT AREA STUDY (N = 18,571), CONDUCTED IN SELECTED CATCHMENT AREAS OF NEW HAVEN, CT; DURHAM NC; ST. LOUIS, MO; BALTIMORE, MD; AND LOS ANGELES, CA

Disorder	Lifetime Prevalence	6-mo. Prevalence	1-yr. Incidence
Alcohol abuse/dependence	13.3	4.7	1.8
Phobia	12.5	7.7	4.0
Drug abuse/dependence	5.9	2.0	1.1
Major depressive episode	5.8	3.0	1.6
Obsessive-compulsive	2.5	1.5	0.7
Antisocial personality	2.5	0.8	—
Panic	1.6	0.8	0.6
Cognitive impairment	1.3	1.3	1.2
Schizophrenia	1.3	0.8	—
Mania	0.8	0.5	—
Somatization	0.1	0.1	—

Prevalence rates adapted from Kessler RC, Chiu WT, Demler O, et al. Prevalence, severity, and comorbidity of 12-month DSM-IV disorders in the National Comorbidity Survey Replication. *Arch Gen Psychiatry*. 2005;62:617–27; and incidence rates from Eaton WW Jr, Kramer M, Anthony JC, et al. The incidence of specific DIS/DSM-III mental disorders: Data from the NIMH Epidemiologic Catchment Area Program. *Acta Psychiatr Scand*. 1989;79:163–78. Incidence rates do not include data from the New Haven site. Rates of cognitive impairment reflect current impairment at the time of interview only. Clinical data are based on the Diagnostic Interview Schedule and DSM III. Rates are expressed as percentages.

interviews. A recent review of such studies found that the median point prevalence of schizophrenia is 4.5 per 1000.³³

Ten years after the ECA was conducted, Kessler and colleagues undertook the first national probability sample study of the distribution of DSM-III-R disorders.³³ In this study, known as the National Comorbidity Survey (NCS), a modified version of the CIDI was administered from 1990 to 1992 to 8098 individuals aged 15–54 from the 48 contiguous states. Special efforts were made to recruit initial nonrespondents, and the final response rate was 82.6%. To assess psychotic disorder, respondents endorsing psychotic symptoms were reinterviewed by telephone by a psychiatrist with the SCID. Overall, almost 50% of the sample met criteria for a psychiatric or substance use disorder in their lifetime, and about one-quarter had a diagnosable condition in the year prior to interview. Consistent with the ECA results, the most prevalent conditions were depression, anxiety, and substance use disorders. Among respondents with a disorder in the prior 12 months, 17.4% had a single disorder, 23.1% had two disorders, and 58.9% had three or more disorders. Consistent with the ECA, the age of onset of most disorders was adolescence or young adulthood.

A replication of the NCS was conducted from 2001 to 2003 with close to 10,000 individuals selected from throughout the United States.^{3,10} Table 69-2 provides the lifetime and 12-month prevalence rates from this recent survey. The overall rates of disorder were similar to those found a decade earlier. The most prevalent disorders were major depression, alcohol abuse, social phobia, and specific phobia. One-quarter of respondents met criteria for two or more disorders in their lifetime, and the age of onset continued to be adolescence and young adulthood.

Comparative Studies

Research comparing the rates of mental illness across geographic areas dates back to the pioneering work of Faris and Dunham,³⁴ who showed that hospitalization rates for schizophrenia in Illinois state institutions decreased progressively with distance away from the center of

TABLE 69-2. LIFETIME AND 12-MONTH PREVALENCE RATES OF DSM-IV PSYCHIATRIC DISORDERS IN THE NATIONAL COMORBIDITY SURVEY REPLICATION (N = 8098) CONDUCTED IN 2001–2003

<i>DSM-III-R Disorder</i>	<i>Lifetime (%)</i>	<i>12-month (%)</i>
Mood disorders		
Major depressive disorder	16.6	6.7
Dysthymia	2.5	1.5
Bipolar disorders	3.9	2.6
Anxiety disorders		
Panic disorder	4.7	2.7

Social phobia	12.1	6.8
Specific phobia	12.5	8.7
Generalized anxiety disorder	5.7	3.1
Post-traumatic stress disorder	6.8	3.5
Substance use disorders		
Alcohol abuse	13.2	3.1
Alcohol abuse with dependence	5.4	1.3
Drug abuse	7.9	1.4
Drug abuse with dependence	3.0	0.4
Any disorder	46.4	26.2
2+ disorders	27.7	5.8
3+ disorder	17.3	6.0

Chicago. Forty-six percent of the cases were from the inner city area compared with 13% from the outermost districts. Faris and Dunham hypothesized that the inner city environment elicited mental illness, rejecting the alternative explanation that social selection or drift was responsible for these higher rates (see later on). Since then, studies conducted in other urban areas have consistently shown the same pattern.

Urban-rural differences in rates of treated mental illness have been studied extensively. Dohrenwend and Dohrenwend's classic review³⁵ concluded that neuroses and personality disorder were more prevalent in urban areas, but schizophrenia rates did not differ according to urbanicity. While some subsequent evidence has supported their conclusions for adults^{36–38} and children,^{39–40} recent findings are somewhat at odds with these conclusions. For example, Van Os and colleagues⁴¹ found that the prevalence of psychosis in a community sample increased progressively with level of urbanization. A population-based study in France found no significant urban-rural differences in general psychopathology.⁴² Urban-rural differences in the prevalence of dementia have also been evaluated, with three Scandinavian studies reporting significantly lower rates in rural compared to urban areas.⁴³ Such studies are important both for understanding underlying risk factors and for determining where to locate mental health intervention programs.

International variations in rates of mental disorders and substance use disorders have also been the focus of research.⁴⁴ Using an expanded version of the CIDI, a recent international study, the World Mental Health Survey Consortium, found that the prevalence of recent episodes of DSM-IV disorders ranged from 4.3% in Shanghai to 26.4% in the US (interquartile range = 9.1–16.9%).²² In studies based on the DIS, the rates of alcoholism in 10 regions around the world ranged from 5% in Taiwan to 22% in Korea.⁴⁵ In spite of differences in prevalence, the clinical profiles were similar, with the mean age of onset in the early 20s, the mean number of symptoms about four, and males having significantly higher rates than females. International studies that use the same protocol are criticized for lacking cultural sensitivity regarding how psychiatric and substance disorders are manifested. On the other hand, studies that use unique tools provide prevalence estimates that cannot be compared. Thus in the absence of biological markers of disease, the value of current

systematic efforts, such as the World Mental Health Survey Consortium, appears to outweigh the limitations.

► INDIVIDUAL RISKS AND CHANCES

Several individual risk factors are associated with the occurrence of psychiatric disorders, including gender, age, social class, marital status, ethnicity, physical health, family history of mental disorder, and season of birth.

Gender

Gender differences in rates of substance abuse, anxiety disorders, and depression have been confirmed in community samples, primary care patients, and treatment samples in psychiatric and substance abuse clinics. The male:female ratios are approximately 6:1 for alcoholism, 1:2 for depression, and 1:2 to 1:3 for phobias. Many social and biological factors have been hypothesized to underlie these differences, including recurrence risk,⁴⁶ drinking habits, expressing emotion, social roles, role performance and role-related strains, as well as professional biases in diagnosis.⁴⁷ In contrast, there is no overall gender difference in the prevalence of schizophrenia although the age at first hospitalization occurs earlier in males (late teen to early 20s) than females (late 20s).

Psychopathology is twice as common in prepubertal boys than girls, but the sex ratio reverses itself during adolescence. At the other end of the life spectrum, a recent study found that the eight-year incidence rate of dementia was somewhat lower in men (14.4 per 1000) than women (19.0 per 1000).⁴⁸

Age

Some psychiatric disorders, such as attention deficit-hyperactivity disorder, first appear in childhood. As noted earlier, other diagnoses, such as mood and anxiety disorders, also have their onset early in life and decrease progressively with age.^{10,33} For alcohol-related problems, the peak period of heavy drinking is early 20s,⁴⁹ but the rate of diagnosable alcohol abuse/dependence who appear for treatment peaks in the early 40s. Finally, dementia is rare in people under age 60, but after that, the rate doubles every five years.⁴³

Social Class

Numerous studies have been undertaken to understand the relationship between social class and mental illness, also encompassed by the term, health disparities. As noted above, the ecological studies, starting with that of Faris and Dunham, emphasized the importance of social class in relation to schizophrenia and argued that features of the physical or social environment of poor neighborhoods caused the higher than expected numbers of patients from those areas. Other nonecological studies also support an environmental explanation. For example, in their classic study, Hollingshead and Redlich found that among psychiatric patients, schizophrenia was associated with being born and raised in lower social class neighborhoods.⁵⁰ Their findings suggest that downward social mobility does not explain the social class pattern. More recent studies, however, indicate that social selection is the more plausible explanation for schizophrenia. In a classic study of occupational attainment, patients with schizophrenia had jobs with lower status than those of their fathers and than what had been predicted by their school careers.⁵¹ Currently in schizophrenia research, the potential genetics findings have tipped the balance in favor of the social selection rather than the social causation hypothesis.⁵²

Lower social class status is also associated with higher rates of depressive symptoms, alcohol abuse or dependence, drug abuse or dependence, and antisocial personality disorder.^{10,52} In addition, lower social class status is a risk factor for many psychiatric disorders of both childhood⁵³ and old age.⁵⁴ Social causation, rather than social

selection, is the primary explanation for the social class findings for these conditions.

Ethnicity

The NCS³³ found no differences in rates of anxiety disorders according to ethnicity. However, compared to blacks, whites had higher rates of mood and substance use disorders and lifetime comorbidity. Except for enuresis, Costello and colleagues also found similar rates of psychopathology in black and white children.⁵³

Consistent with the NCS finding for mood disorder, research on suicide has consistently found that whites have significantly higher rates of suicide than nonwhites, particularly white males. Later in this chapter we discuss the temporal changes in the suicide rate of young white males. Here it is important to note that the age-adjusted suicide rates for Native Americans and Chinese-Americans are substantially higher than those for whites. In fact, the rate for native American youth is more than double that of same-age peers.⁵⁵

Research on psychosis has shown that some ethnic groups have higher than expected rates of schizophrenia, especially indigenous populations of certain regions of Croatia^{56,57} and western Ireland.⁵⁸ In older studies of psychiatric patients in the United States, African-American patients were disproportionately diagnosed with schizophrenia and were hospitalized at a younger age and for longer periods of time than whites. However, these findings are generally attributed to clinical bias and racism. Indeed the NCS found no race differences in the rates of clinician-derived diagnoses of psychosis.⁵⁹

Marital Status

Being single and being separated or divorced are associated with an increased risk of several psychiatric disorders, although whether this reflects cause or consequence is unknown. Community studies have also found that married men are less depressed than unmarried men, but married women are more distressed than unmarried women.²⁵ This suggests that being married is a protective factor for men but not for women.

In schizophrenia, several studies have found that being single at the time of first hospitalization confers a poorer prognosis. However, this finding may be an artifact of gender, age, and/or poor premorbid functioning.

Physical Health Status

Several sources of evidence point to strong links between physical and mental health.⁵ First, psychiatrically ill populations have higher than expected mortality than their nonpsychiatrically ill counterparts. In one study, the adjusted mortality rate of psychiatric patients was elevated two- to threefold.⁶⁰ Another study reported that 6% of patients reporting to a psychiatric emergency service died within two years of the visit, whereas the expected rate was 1.6%.⁶¹ In a community sample aged 55 and older, the odds of dying over a 15-month period was four times higher for people with a mood disorder than for persons who did not have a mood disorder.⁶²

A second source of evidence is that hospitalized patients have an elevated rate of psychiatric disorders compared to nonhospitalized controls. It has long been known that infectious diseases can produce serious mental disorders.⁵ In addition, high rates of major depression and depressive symptoms are found in patients hospitalized with chronic conditions, such as multiple sclerosis, cancer, diabetes mellitus, cardiovascular disease, thyroid disease, and chronic pain.⁶³ One study reported that 61% of severely ill hospital patients were depressed compared with 21% of less ill patients.⁶⁴ Whether depression and related disorders are a risk factor for disease onset or disease severity, a consequence of disease, or a consequence of hospital-induced disability is difficult to determine.

Third, outpatient primary care patients have high rates of psychiatric symptoms.⁶³ In the ECA, 22% of respondents who recently attended a medical care facility met criteria for a DSM-III disorder compared with 17% of nonattenders.⁶⁵ A review of British studies of psychiatric morbidity in general practice patients concluded that 20–25% suffered from psychiatric disturbances, primarily mood disorders.⁶⁶ In a large international study of ambulatory patients, the WHO assessed more than 5000 patients in 15 primary care centers around the globe and found that 24% were diagnosed with a psychiatric or substance use disorder.⁶⁷ Despite the high prevalence of psychiatric disorders, especially depression, psychiatric problems in primary care patients are often undetected or are misdiagnosed, in part because both physicians and patients focus on somatic symptoms and possible physical diagnoses.

Familial Aggregation

Considerable research on familial aggregation of psychopathology has been conducted. In schizophrenia, monozygotic twins have a concordance rate for schizophrenia between 33% and 78% compared with 8–28% for dizygotic twins. The risk for developing schizophrenia, given the presence of an affected first-degree relative, is approximately 10% (compared with an overall prevalence of less than 1%).⁶⁸ Weissman⁶⁹ reviewed findings from family studies of depression and reported a two- to threefold increase in major depression in adult first-degree relatives of patients with depression. Weissman's study of the offspring of depressed parents also found a threefold increase in risk for psychiatric disorder (24% compared with 8% among controls).⁷⁰ The preponderance of evidence regarding alcoholism deriving from family, twin, and adoption studies also points to a genetic vulnerability for developing this disease.⁷¹ Modern studies of genetic causes of mental disorders, and the interaction of genetic and environmental factors, hold great promise for clarifying these familial associations observed over the past 50 years.⁵

Season of Birth

Seasonal variation in rates of stillbirths, neonatal deaths, and congenital rubella is amply documented, although the impact of seasonal variation appears to have diminished over time.⁷² In England, Scandinavia, and the United States, patients with schizophrenia are disproportionately likely to be born during the winter or spring months. Possible explanations for this phenomenon include nutritional factors during pregnancy, genetic factors, and exposure to infectious or viral agents.⁷³

► CAUSES

New understandings of the origins and course of mental disorder emerge when clinical research, laboratory studies, sociological inquiries, and epidemiology interact. A dramatic illustration occurred early in the twentieth century, when pellagra psychosis accounted for almost 10% of the admissions to mental hospitals. In South Carolina during the early 1920s, Goldberger et al.⁷⁴ showed that pellagra was associated with a nutritional deficiency, although the specific items missing from the diet were only later identified. As a result of dietary changes, pellagra psychosis became rare in the United States, although it remains endemic in parts of Africa and India.

This section is limited to a discussion of social and physical environmental causes of mental disorders. Because psychiatric disorders often develop insidiously, it is often difficult to separate risk from consequence. Thus here we use the terms risk factor and correlate interchangeably. Genetic causes, and gene-environment interactions, have also been found for rare conditions, such as early-onset Alzheimer's disease, and candidate genes are being studied for other psychiatric disorders. To date, the findings are regarded as very preliminary and thus are not included below.

Social Environment

Stress in the social environment has been linked to a variety of common mental disorders. As mentioned earlier, ecological studies hypothesized that environmental stress was a cause of mental disorders. Here we conceptualize stress as a set of disruptive environmental presses or stimuli and review findings on personal rather than ecologically determined stressors.

Communitywide Traumas. Communitywide stressors expose large numbers of people to uncontrollable events and thus provide a unique opportunity to understand both short-term and long-term psychological sequelae. Recent examples include the nuclear power plant accidents at Three Mile Island (TMI) in 1979 and at Chernobyl in 1986, the terrorist attack on 9/11, and the 2005 tsunami. Like many disasters, the TMI and Chernobyl accidents were not acute, time-limited events but involved a sequence of interrelated stressful occurrences that unfolded over a long period of time, including the initial crisis, intermittent radiation leaks, difficulties surrounding the clean-up operations, and in the case of Chernobyl, permanent evacuation and elevated rates of thyroid cancer in children. The 9/11 and tsunami catastrophes occurred abruptly, but they too created a number of other crises in their wake. These events have all been shown to elevate the rate of psychopathology. For example, the TMI study of mothers of preschool children living within 10 miles of the plant found that the rate of depression and anxiety doubled during the year after the accident⁷⁵ and remained high over the subsequent 10 years.⁷⁶ Similarly, populations residing near Chernobyl had significantly poorer mental health than controls 6–11 years after the disaster.⁷⁷ Research on 9/11 victims and the tsunami survivors also demonstrate the psychological toll of these kinds of events.

In general, the psychiatric sequelae of human-made and natural disasters have consistently found that in the short term, survivors experience anxiety and mood problems. The greater the magnitude of the disaster, the greater and the longer is the effect. The disorder that has mostly frequently been studied after disasters is posttraumatic stress disorder (PTSD). This disorder is defined as a response to an unusual stressor in which an individual reexperiences the traumatic event through recurrent thoughts or dreams, experiences psychic numbing, and has symptoms such as sleep disturbance, survivor guilt, difficulty concentrating, hyperarousal, avoidance of activities associated with the event, and an intensification of symptoms if reexposed to a similar event. PTSD is often comorbid with mood, anxiety, and substance disorders. Thus, in disaster studies, the most consistent risk factors for PTSD are similar to those for other adverse mental health outcomes. These include being female, having a prior history of psychiatric disturbance, and having greater involvement in the disaster in terms of loss of life or property or fear of adverse health consequences.⁷⁸

Studies of combat veterans show that such trauma is a particularly potent trigger of short-term and long-term adverse mental health consequences. Since the Vietnam war, there has been considerable interest in the emotional well-being of combat veterans, especially the onset and persistence of PTSD. A national study of Vietnam veterans conducted in the late 1980s reported a point prevalence rate of 15.2% and a lifetime rate of 31% among combat veterans.⁷⁹ These high rates led the Department of Veterans Affairs to increase research and treatment programs for this vulnerable group. Recent studies of Gulf War veterans also show elevated rates of mood and anxiety disorders, especially PTSD.⁸⁰

Personal Adversities and Strains. Another common method for studying stress is to administer a checklist of positive and negative life events. Studies employing these checklists typically find that these events play a relatively minor and transient role in evoking psychiatric symptoms in general population samples. In vulnerable populations, these events sometimes have more important consequences. For example, in schizophrenia, life events were shown to trigger psychotic episodes, particularly in patients having inadequate social support.⁸¹ Personal vulnerability factors can also increase the impact of life events,

especially in depressed populations.⁸² For example, a seminal study by Brown and colleagues found that working class women were at particular risk when they lacked a confiding relationship with their husbands, were not employed outside the home, had three or more children under the age of six years, or endured the loss of their own parents in childhood.⁸³

Two specific events, unemployment⁸⁴ and bereavement⁸⁵ have been studied extensively. Both were shown to produce short-term deleterious effects in more than 50% of exposed individuals. The vulnerability factors that magnified the impact of these stressors included inadequate social support, poor physical health, and preexisting financial difficulties.

Chronic strains at work or at home are also associated with impairments in mental health. With regard to the work environment, employees in jobs characterized by high levels of demand, little autonomy over decision making, conflicting requirements, and task-related ambiguity experience higher levels of psychological symptoms and alcohol abuse than employees with less occupational strain.⁸⁶ The combination of high demands and low decision latitude is particularly stressful.^{87,88} Marital stress is associated with depression and substance abuse; moreover stress in the family environment is a well-documented risk factor for behavioral problems in children. Indeed, children reared in families with high levels of conflict, abuse, or neglect are at risk for a range of health problems, including depression, sleep disorders, developmental delay, generalized anxiety, school behavior problems, phobias, and antisocial behavior.⁸⁹

Physical Environment

Three aspects of the physical environment are described in this section: toxic exposures in the work place, lead exposure among children, and homelessness.

Occupational Exposures. Exposure to lead, mercury, carbon monoxide, carbon disulfide, and the like may cause serious central nervous system (CNS) disturbances. In *Alice in Wonderland*, Lewis Carroll immortalized the well-known hallucinations, delusions, and mania produced by high-level mercury exposure in the character of the Mad Hatter. Since the nineteenth century, dramatic case reports have described cognitive and neurasthenic symptoms and even suicide in workers exposed to a variety of solvents.

An issue of ongoing public health concern is the potential health effects of low-level neurotoxic exposures. Lead and solvents are two such exposures that have been investigated extensively. Recent epidemiologic studies suggest that even at accepted levels, occupational lead exposure can have an adverse effect on neurocognitive functioning.⁹⁰ Several Scandinavian studies of male workers chronically exposed at threshold or subthreshold levels to solvents reported significantly more CNS symptoms (headaches, fatigue, depression dizziness, memory disturbances), nonspecific somatic complaints (nausea, abdominal pain, skin problems, and aches and pains), and impaired performance on cognitive tasks compared with unexposed controls.^{91–94} A study of female workers also found that low-level solvent exposure was significantly associated with increased depression, CNS disturbance, and an array of nonspecific somatic complaints.⁹⁵ However, these studies contain some serious methodological flaws,⁹⁶ and further confirmation from epidemiologic research is needed. One difficulty with occupational studies of this sort is sample bias because workers who are sensitive to the exposure find employment elsewhere, and the sample is then subject to the “healthy worker” effect.

It has also been hypothesized that the combination of low-level exposure and high occupational stress is especially deleterious, but empirical findings have so far been mixed.^{97–99} In this regard, it is interesting to note that mass psychogenic illness has been found in workplaces containing both high stress and low-level solvent exposures.¹⁰⁰

Lead Exposure in Children. Environmental exposure to lead was shown to have a significant effect on the cognitive performance of children. In their classic study, Needleman et al. took tooth samples from elementary school children and showed that lead exposure was

significantly related to lower intelligence test scores, even after adjusting for 39 risk factors, including social class and parental IQ.¹⁰¹ In an 11-year follow-up study of these children, higher dentin lead levels continued to be predictive of both school performance and school dropout.¹⁰² Although this study was the object of considerable controversy, the central findings have been confirmed in many subsequent studies.

Homelessness. Rates of mental illness among homeless adults and children are alarmingly high. In one study, more than one-quarter of homeless individuals were found to have a major chronic mental illness, such as schizophrenia or substance abuse.¹⁰³ Compared with socioeconomically matched controls, homeless children have more overt health problems and more psychiatric risk factors, such as abuse, neglect, and elevated blood lead levels.¹⁰⁴ In some cities, deinstitutionalization of the mentally ill from state mental hospitals contributed significantly to the problem of homelessness. The risk of homelessness among discharged state hospital patients was as high as 28% in New York City.¹⁰⁵ New interventions have been designed to address the mental health and substance abuse problems in homeless populations, but this is particularly difficult population to engage and maintain. For a review of this research, see reference.¹⁰⁶

► HISTORICAL TRENDS

Although in psychiatry, historical trends are difficult to study because the diagnostic nomenclature and availability of services have shifted over time, important research has been conducted on the temporal stability of psychosis, depression, adolescent suicide, and suicidal behavior.

Psychosis

A major debate centers on whether the prevalence of schizophrenia increased as a function of industrialization. A pioneering analysis by Goldhamer and Marshall focused on mental hospital admission rates for psychosis from 1840 to 1940.¹⁰⁷ They concluded that a progressive increase in hospital admissions occurred among the elderly, but the rates of psychosis (primarily schizophrenia) among young and middle-aged groups changed very little. Eaton, however, extended the time period to 1970 and reported that the prevalence of psychosis did indeed increase.¹⁰⁸ Potential explanatory factors include changes in environmental exposures, infant mortality and longevity, lifestyle changes associated with industrialization, and/or artifactual variables such as who enters the treatment system and availability of services.¹⁰⁹ As intriguing as these hypotheses are, however, a subsequent study found no temporal changes, and the issue remains unsettled.¹¹⁰

Depression

Evidence has also accumulated regarding an increase in depression since World War II. In Lundby, Sweden, a longitudinal study was initiated in 1947¹¹¹ in which direct interviews by psychiatrists, information from key informants, and medical records were used to determine psychiatric diagnoses of the entire population. Based on follow-up interviews by psychiatrists in 1957 and 1972 with 97% of the original cohort, a significant increase in the incidence of nonpsychotic depression was detected.

Although the Lundby study remains the only direct source of evidence regarding an increase in depression, other indirect sources of evidence, such as the suicide patterns discussed below, also suggest that depression has increased.¹¹² As with psychosis, temporal changes, if present, could be due to either environmental factors or artifactual variables, such as differential mortality, changes in diagnostic criteria, reporting biases, and changing attitudes about depression in society.

Suicide in Adolescents and Young Adults

Between 1955 and 1980, the rate of suicide in people 15–24 years of age tripled, increasing from 2.6 per 100,000 population to 8.5 per

100,000 population, making suicide the second leading cause of death in this age group.¹¹³ The group at highest risk was white males. In addition to sex, the chief risk factors were prior suicide attempts, substance abuse, mental illness, and family history of mood disorder and suicide. The presence of firearms in the home is perhaps the most important risk factor.¹¹⁴ Thus public health programs aimed at reducing adolescent suicide must focus not just on personal risk factors but also on lethal agents in the home environment.

Suicide Behaviors

Suicide ideation and attempts are precursors to completed suicide. A recent report by the NCS investigators compared the rates of suicide behaviors (i.e., ideation, plans, gestures, and attempts) in the 1990–1992 NCS cohort with those of the 2001–2003 NCS-R cohort.¹¹⁵ Overall, the rates proved to be remarkably stable. For example, 2.8% of the earlier and 3.3% of the more recent cohort reported suicidal ideation (having serious thoughts of suicide). The one important difference, however, was the extent to which respondents with ideation and attempts received treatment. In the 1990–1992 cohort, 40% of ideators who made a suicide gesture and 50% who made a serious attempt received treatment. However, in the later cohort, the proportions receiving treatment doubled.

► COMPLETING THE CLINICAL PICTURE

Since the majority of individuals with common mental disorders do not receive treatment from mental health specialists, community studies are needed to improve our understanding of their clinical signs and prognosis. Thus, recent studies applying formal diagnostic criteria to community populations have helped complete the clinical picture by pointing out that the syndromes of depression and alcoholism, for example, may be different in treated and untreated groups. A study of white collar employees found that 10% of managers and professions met lifetime criteria for alcoholism, but the vast majority of these cases became social drinkers with no serious legal, social, occupational, or clinical consequences.¹¹⁶ Thus unlike impressions from clinical samples, or individuals who attend Alcoholics Anonymous, these findings suggest that community respondents meeting diagnostic criteria for alcoholism may not have significant social and occupational impairment in the long-term. Thus, the poor prognosis ascribed to conditions such as alcoholism derives in part from the clinician's illusion, that is, from treating chronic cases who stay in the service system.¹¹⁷

Another important aspect of the clinical picture is comorbidity. Psychiatric patients in treatment often meet criteria for more than one psychiatric disorder, sometimes labeled primary and secondary disorders. For example, patients with primary alcoholism often develop secondary depression during the course of the alcoholism. Schizophrenic patients discharged after their first lifetime admission often develop depression during the subsequent year. Patients with major depression often suffer from an accompanying anxiety disorder such as phobia or panic disorder. However, people often enter treatment precisely because they have more than one disorder. Community studies thus are able to complete the clinical picture regarding comorbidity. In this case, recent epidemiological findings confirm that multiple psychiatric disorders also co-occur in the general population.^{3,118} Examples of highly comorbid conditions include alcoholism and drug abuse, alcoholism and antisocial personality, obsessive-compulsive personality and panic disorder, depression and anxiety disorder, and depression and somatization.

► IDENTIFYING NEW SYNDROMES

By systematizing clinical observations, epidemiologists can potentially identify new syndromes. For example, until the early 1980s, depression was considered an adult disorder that rarely occurred during childhood. Several factors converged to increase the awareness

that children can become clinically depressed, including the increasing rate of adolescent suicide and suicide attempts, the increased frequency with which depression was observed in pediatric settings, and the high rates of depression reported in research on the offspring of clinically depressed parents. Recent epidemiologic findings suggest about 2% of preadolescents and 5–10% of adolescents suffer from clinical depression.¹¹⁹

Epidemiological studies of occupational exposures identified syndromes associated with specific toxic chemicals such as lead, cyanide, carbon monoxide, carbon disulfide, and mercury.¹²⁰ For example, the constellation of symptoms resulting from carbon monoxide (an exposure occurring in blast furnace workers, fire fighters, fork-lift truck operators, and others) includes disturbances in concentration, memory, impulsivity, and lack of insight into one's behavior. As noted, the phrase "mad as a hatter" stemmed from observations of specific types of tremors among workers in the hatting industry who were exposed to high levels of mercuric nitrate in Europe during the nineteenth century.

► EVALUATING MENTAL HEALTH SERVICES

This section provides a brief historical overview of American psychiatric service delivery, a discussion of factors associated with entry into treatment, and approaches to preventing mental disorders. It is not intended as an exhaustive review but rather as an overview of key issues.

Historical Overview of American Psychiatric Care

In 1841, when Dorothea Lynde Dix began her crusade on behalf of the mentally ill, there were only 18 hospitals in the United States devoted exclusively to the care of the mentally ill. The vast majority of psychiatrically ill individuals were in jails and poorhouses, kept at home, boarded out, or auctioned off to the highest bidder. Echoing Horace Mann's 1828 plea that the mentally ill be declared "wards of the state," Dix convinced the Massachusetts legislature that local communities had shown themselves incapable of caring for the mentally ill. Like other reformers, she did not hesitate to reinforce her arguments with the economic lure that decent treatment in small and geographically isolated state hospitals would cure psychiatrically disturbed individuals quickly, making them productive members of society instead of drains on the public purse. In 1843, the Commonwealth of Massachusetts voted to make all of the indigent mentally ill wards of the state and to enlarge Worcester State Hospital, a mental hospital established as a result of Horace Mann's efforts a decade before.

The Dix-Mann doctrine that the mentally ill should be wards of the state reached its most explicit expression with the passage of the New York State Care Act of 1890. This legislation provided for removal of the mentally ill from local poorhouses and jails to state hospitals, where they were to be supported and treated at state expense. The law further required each state hospital to admit all cases of mental illness from its district, regardless of prognosis. Following its initiation in New York, other states adopted the Dix-Mann principle of complete state care for the seriously mentally ill. A major consequence of this action was the isolation of mental patients and of psychiatry from the mainstream of medicine.

Although some state hospitals in the United States were established explicitly as custodial institutions, most attempted to apply moral treatment, and some closely approached that ideal. Even the best-managed hospitals, however, did not long continue to function as the small rural, therapeutic retreats envisioned by Dix and Mann. New asylums were built as older ones overflowed, and the demand for accommodation always seemed to exceed capacity. As chronic cases accumulated and new admissions rose, overcrowding led to deterioration in the standards of care. At the start of the 1900s, the "cult of curability" yielded to the notion, "once insane, always insane." Moral treatment precepts were forgotten, and behavior was controlled with physical restraints and seclusion.

The National Association for Mental Hygiene was founded in 1909, with the aim of improving the care and treatment of patients in mental hospitals. After World War I, the mental hygiene movement turned its attention to prevention by early detection and treatment of mental disorders, a strategy exemplified by its active support for the development of child guidance clinics and parental education. The rapid growth of child guidance clinics and other outpatient psychiatric services marked the beginning of organized community-based psychiatry in the United States, which had begun in the late nineteenth century in Europe. By the mid-1930s, nearly all state mental hospitals had at least one outpatient clinic.

In 1946, Congress passed the National Mental Health Act (Public Law 79-487), thereby creating the National Institute of Mental Health. For the first time, the federal government took responsibility for research, training of personnel, and assisting the states in prevention, diagnosis, and treatment of serious psychiatric disorders.

Having grown at a steady rate for over a century, the resident patient population reached an all-time high of 560,000 in 1955. The decline of resident mental patients began due to three factors: the introduction of neuroleptic drugs, which accelerated management and sometimes even recovery and enabled some patients to be treated at home; the introduction of the therapeutic community, or community-oriented treatment within the hospital, which reduced the demoralization of custodial care; and the geographic decentralization of large state mental hospitals, which led to closer relationships between state hospitals and local communities. Starting in 1960, a systematic policy of releasing patients was initiated, based on successful reforms in England, where a reduction of the patient census had preceded the use of neuroleptic drugs. Length of stay was also shortened for acute admissions. As the number of acute admissions increased, custodial hospitals were somewhat transformed into short-term intensive treatment centers. This "revolving door" situation highlighted the need for expanded community treatment. In the short period of about 25 years, mental hospital censuses decreased from 560,000 in 1955 to 214,065 in 1981.¹²¹

In 1955, Congress enacted the Mental Health Study Act (Public Law 84-182) to evaluate the "human and economic problems of mental illness." This act led to the establishment of the Joint Commission on Mental Illness and Health. The Commission's final report, *Action for Mental Health*, recommended that services for the mentally ill be expanded. The Commission recommended establishing (a) outpatient mental health facilities in communities to provide immediate care for acutely disturbed patients, (b) one clinic per 50,000 population, (c) inpatient psychiatric units in every general hospital with 100 or more beds, (d) maximum occupancy in state mental hospitals of 1000 beds, and (e) expanded mental health education to reduce the stigma associated with mental illness. In 1963, President Kennedy delivered a message to Congress on mental illness and mental retardation in which he proposed a national federally funded program for setting up comprehensive community mental health centers and for improving care in state hospitals. This set the stage for the passage of the Community Mental Health Centers Act of October 1963. The newly mandated community mental health centers had to provide five essential services: inpatient care, outpatient care, emergency services, partial hospitalization, and consultation and education. Over time, five additional services were to be added: diagnostic services, rehabilitation services, precare and aftercare services, training, and research and evaluation. The centers were to serve geographically defined catchment areas of 75,000–200,000 people. By 1980, 717 community mental health centers had been funded across the country (2000 had been envisaged), with the federal government investing more than 1.5 billion dollars.

In 1977, President Carter signed an executive order establishing The President's Commission on Mental Health to review and make new recommendations on the mental health needs of the nation. Among its 100 recommendations were the following: improving linkages between community support networks and mental health facilities; expanding services to children, minorities, the elderly, and the chronically mentally ill; the continued phasing down of large state mental hospitals; and the development of a case management system

by the states. In 1980, President Carter signed the resulting Mental Health Systems Act (Public Law 96-398) into law. However, the subsequent Omnibus Budget and Reconciliation Act of 1981 (Public Law 97-35) rescinded continued federal management and turned responsibility for provision of community mental health services to the states through the block grant. At present, in New York and other states, treatment of the chronically mentally ill, both young and old, is the primary focus of community mental health centers.

In the mid-1990s, the financial burden associated with mental disorders was estimated to be \$99 billion in direct and \$79 billion in indirect costs, calculated based on absenteeism, unemployment, social service utilization, related accidents, and crime. Together the direct and indirect costs comprised more than 10% of all health care costs in the United States.¹²² Indeed, the negative economic consequences exceeded the direct costs of treatment.¹²³ Treatment studies have been funded to improve patients outcomes and reduce this cost.

As we enter the twenty-first century, several issues raised by nineteenth and twentieth century reformers remain remarkably pertinent for public mental health. The first is the goal of keeping mentally ill people out of jails. In fact, correctional facility placement has become so pervasive that the rate of mental illness in prisons is 2–4 times greater in jails and prisons than in the general population. Meanwhile, correctional facilities do not have sufficient staff to provide adequate or appropriate treatment for the severely mentally ill in their midst.¹²¹ Second, nonprofit advocacy organizations have become more numerous, and with internet access, their mission and educational materials are readily accessible to families, patients, and physicians. Readers interested in finding specific organizations can check the website for the National Institute of Health's Substance Abuse and Mental Health Services Administration. Yet in spite of the ease of obtaining information, mental illness remains stigmatized in the general population and underdetected in primary care settings. Third, the Surgeon General's report on mental health¹²² emphasized that not only is evidence-based treatment important, but also age, sex, race, and culture must be taken into account. Yet, tailoring treatment to the needs of patients and their families is rarely accomplished. Fourth, most individuals with mental illness and even suicidal behaviors continue to be treated in the general medical or primary care sector. Yet medical students and general medicine residents receive even fewer hours of training on the diagnosis and treatment of mental illness and substance use disorders than was true of their predecessors.

Preventive Interventions

Two psychiatric disorders were eradicated through primary prevention efforts: pellagra psychoses and brain damage from measles and rubella.⁵ In the workplace, reductions in exposures to heavy metals have led to marked decreases in the occurrence of neuropathy or encephalopathy. Similarly, the passage of laws to reduce lead in paint in the United States has aimed at improving cognitive performance in children.

The increase in suicide in adolescents and young adults led to the creation of school-based programs aimed at preventing teen suicide.¹²⁴ The goals of these programs are to heighten awareness of the problem, to promote the identification of students at risk, and to provide information about mental health resources. Shaffer et al. studied 1000 13- to 18-year-old students from six high schools who were exposed to one of three programs. Although the three programs used significantly different techniques, the authors felt that they were not differentially effective, concluding that the true value of the programs was their screening function, in which 3% of the students reported that they were suicidal and in need of professional help.

Early detection is the cornerstone of secondary prevention. The most famous example in psychiatry is the elimination of general paresis (syphilitic psychoses) through antibiotic therapy. Secondary prevention programs have been implemented in the early phases of a variety of high-risk situations. Examples of such programs include ones aimed at reducing (a) psychosis in high risk adolescents, (b) substance abuse and delinquency in young adolescents with a history of poor

academic performance and disruptive behaviors; and (c) depression in high-risk groups, such as low-income mothers and adults undergoing major life changes.¹²⁵ In this regard, Kessler and colleagues have strongly advocated for developing interventions for secondary disorders given the high rate of comorbidity in the population.¹²⁶ The well-documented delays in initial treatment seeking¹²⁷ and continued unmet need for treatment, especially in underserved populations,¹²⁸ also support the importance of early detection and accessibility to care. Delays in treatment can lead to greater severity, and failure to treat conditions when they first arise, that is, in adolescence and young adulthood, can lead to social and economic consequences, such as school failure, teenage pregnancy, and unstable employment.

The workplace is a focal point of many secondary intervention programs. Many companies established Employee Assistance Programs and the like to assist troubled employees. The goal of these programs is to detect mental health problems at an early stage and offer interventions that might avert a full-blown psychiatric episode.^{129,130} Similarly, exercise and health programs aimed at reducing physical symptoms (e.g., smoking, obesity, high blood pressure) also are expanding in occupational settings. In light of the significant relationship between physical and mental health, it is believed that these programs will have a positive effect on the psychological well-being of employees.

Clinical trials focused on psychotherapeutic medications or other forms of therapy are examples of tertiary prevention efforts focused on treating symptoms and hence minimizing the disabilities and impairments in quality of life among patients with severe mental illness, particularly schizophrenia and mood disorders. For example, the NIMH developed a depression awareness program to educate psychiatrists, general practitioners, and the lay public about the symptoms and new treatments for mood disorders. A review of the vast psychiatric treatment literature is beyond the scope of this chapter; however, clinical drug trials are being conducted for an array of new medications targeted to symptoms of psychosis, depression, obsessive-compulsive symptoms, panic attacks, cognitive decline, and other disabling symptom complexes.

► CONCLUSION

Considerable progress has occurred in research on the epidemiology and prevention of mental disorders.^{131,132} Although most of the achievements have occurred at the level of descriptive epidemiology, analytic findings on variables associated with onset and course, including genetic factors, and an array of treatment intervention studies are also expanding.⁵ Recent advances in molecular genetics, brain imaging techniques, statistical methods, and measurement are having a major impact on the scope and focus of current research. Ultimately, the goal is to identify modifiable risk factors that can be translated into preventive interventions.

Childhood Cognitive Disability

Maureen S. Durkin • Nicole Schupf • Zena A. Stein • Mervyn W. Susser

Mental retardation or cognitive disability occurring in childhood is a condition with enormous public health implications for at least four reasons. One is its relative frequency; with prevalence as high as 1% or greater in most populations, mental retardation is among the most common childhood disability.¹⁻³ Another is its early onset and frequent life-long duration. A third is its socioeconomic impacts, which include adverse impacts on productivity and quality of life of affected individuals and caregivers as well as increased expenditures for medical care and residential services. A fourth reason is that prevention, whether primary, secondary, or tertiary, is attainable via public health interventions for nearly all forms of mental retardation. Examples of primary prevention include nutritional interventions such as iodine and folic acid supplementation and food fortification, immunization programs, and removal of environmental sources of lead exposure. Early identification followed by therapeutic interventions, for conditions such as Down syndrome and phenylketonuria (PKU), are examples of secondary prevention of mental retardation. Examples of tertiary prevention include early cognitive stimulation, special education, and habilitation to enhance functioning.

One of the challenges mental retardation poses to public health is that certain prevention strategies, highly effective in one respect, have had the paradoxical side effect of increasing the occurrence of mental retardation in the population in terms of either incidence (new cases) or prevalence (by means of improved survival). Examples of this paradox include mental retardation associated with inborn errors of metabolism, Down syndrome, and premature birth. These and other specific topics in mental retardation are discussed below, following an overview of definitions and prevalence.

► DEFINITION AND CLASSIFICATION

Mental retardation implies significant deficits, with onset early in life, in intelligence (as measured by standardized intelligence tests) and in adaptive behavior (e.g., communication, self-care, social interaction, school, and/or work).⁴ The deficits are recognized in the performance of social roles and age-appropriate tasks. The infant and preschool child may fail to achieve developmental milestones of sitting, responding to familiar faces, walking, talking, and sphincter control at expected ages. The schoolchild falls short of social expectations for classroom behavior and for reading, writing, and arithmetic. The adult may have difficulty in performing work within and outside the home, communicating, or understanding money, transport, and locality.

Functional limitations in mental retardation can potentially be identified at three levels: *impairment* (altered brain structure and/or function), *disability* (deficits in intellectual function and adaptive behavior), and *social participation* (limitations in social roles and opportunities experienced by persons with disabilities due to environmental conditions).^{5,6} One-to-one correlations between currently understood causes, identifiable impairments, and levels of disability and participation appear to be the exception rather than the rule. For

example, in people with mental retardation, identifiable neuropathological lesions often correlate weakly or not at all with specific causes and/or clinical/functional attributes.^{7,8}

The dominant approach to defining and classifying mental retardation is by severity of disability rather than by cause. The International Classification of Diseases (ICD-9, ICD-10)^{9,10} as well as the Diagnostic and Statistical Manual (DSM-IV-TR)¹¹ and former versions of the American Association on Mental Retardation classification⁴ distinguish four grades of severity defined in terms of IQ (Table 70-1). The most recent version of the American Association on Mental Retardation's classification system has moved away from distinguishing grades of intellectual deficit and toward defining severity in terms of the level of support required for optimal functioning (e.g., intermittent, limited, extensive, and pervasive levels of support).¹²

Classification based on etiology is increasingly used, as advances in cytogenetics, molecular and biochemical genetics, and brain imaging improve our ability to determine specific causes. Etiologic classifications have clear advantages for epidemiologic research and for primary prevention. They may also be preferable to functional classifications for assessing specific needs for appropriate medical care, rehabilitation, and other services.¹³ However, even with recent advances in knowledge and diagnostic capabilities, most cases of mental retardation cannot be attributed with certainty to a specific cause. Table 70-2 provides an outline of the categories of known causes of mental retardation.

► INCIDENCE AND PREVALENCE

Studies of the true incidence of mental retardation are not possible because only a minority of cases survive long enough to be identified and because the onset and recognition of disability are often insidious during the course of a child's development.^{14,15} The descriptive epidemiology of mental retardation is based largely on prevalence (the number of existing cases in a population at a given time) rather than incidence (the number of newly occurring cases during a given time period).

In describing the prevalence of childhood cognitive disability, it is useful to combine moderate, severe, and profound grades of intellectual disability into a single category of *severe* mental retardation (IQ below 50 or 55) and distinguish this from *mild* mental retardation (IQ between 50 or 55 and 70 or 75). Table 70-3 contrasts the major epidemiologic characteristics of these two classes. In developed countries, the prevalence of *severe* childhood mental retardation consistently ranges from 3 to 5 per 1000 (Table 70-4) and more than 50% of cases are attributed to genetic causes. *Mild* mental retardation in developed countries varies widely in prevalence, is generally more frequent than severe forms, is strongly associated with low socioeconomic status, and is rarely associated with known causes or with other neurologic disorders. A male excess is observed in both severe and

TABLE 70-1. CLASSIFICATION OF MENTAL RETARDATION BY GRADE OF SEVERITY OF INTELLECTUAL DEFICIT

Severity	ICD-9 ^a Code	ICD-10 ^b Code	Approximate IQ Range ^c
Mild	317.00	F70.0-F70.9	50–55 to 70–75
Moderate	318.00	F71.0-F71.9	30–35 to 50–55
Severe	318.10	F72.0-F72.9	20–25 to 35–40
Profound	318.20	F73.0-F73.9	<20–25
Unspecified	319.00	F79.0-F79.9	

^aWorld Health Organization. *International Classification of Diseases*. 9th ed. Geneva: World Health Organization; 1980.⁹
^bWorld Health Organization. *International Classification of Diseases—10th, 2nd ed.* Geneva: World Health Organization; 2006.¹⁰
^cPrecise IQ cut-points may vary to allow for differences between tests. Guidelines of the American Association on Mental Deficiency⁴ and the *Diagnostic and Statistical Manual (DSM-IV-TR)* of the American Psychiatric Association¹¹ recommend the use of these or similar cut-points as well as clinical judgment and assessment of adaptive skills in the diagnosis and classification of severity of mental retardation.

mild mental retardation, due in part to the contribution of X-linked forms of mental retardation (discussed below). The few estimates available from less developed countries point to elevated prevalence rates of severe mental retardation (Table 70-4). This may be due to the higher frequency in those settings of nutritional, traumatic, and infectious causes of brain damage and, in some populations, to factors such as consanguinity and advanced maternal age.¹⁶

Low socioeconomic status is the strongest and most consistent predictor of mild mental retardation but is usually found to have little or no association with the prevalence of severe mental retardation (Table 70-3).^{17,18} This pattern points to the role of poverty and social disadvantage in the etiology of mild mental retardation. Preschool programs providing social and intellectual stimulation may boost IQ and reduce the risk of mild mental retardation in vulnerable groups.^{19–22}

TABLE 70-2. MAJOR CATEGORIES OF KNOWN CAUSES OF MENTAL RETARDATION WITH SPECIFIC EXAMPLES OF EACH

Causal Category	Specific Examples
Chromosomal	Down syndrome Cri-du-chat
Single gene	Phenylketonuria (PKU) Fragile X syndrome
Hormonal	Hypothyroidism
Specific nutritional	Iodine
Deficiency/dietary factor	Folate
(prenatal)	Maternal PKU
Infection	
Prenatal	Rubella Toxoplasmosis
Perinatal	Syphilis Human immunodeficiency virus
Postnatal	Measles encephalitis
Toxic exposure	
Prenatal	Ionizing radiation Fetal alcohol syndrome Lead
Postnatal	Lead
Traumatic brain injury, anoxia	
Perinatal	Prolonged, obstructed labor Premature birth
Postnatal	Motor vehicle collision Fall Near drowning

Several cross-sectional studies of age-specific prevalence rates conducted in different decades and populations consistently show, for both severe and mild mental retardation, increasing prevalence with age during childhood followed by declining rates with advancing age throughout adulthood.¹ Severe mental retardation is much more likely than mild to be diagnosed during infancy. The increasing prevalence with age during childhood could be due to increases with age in the use of specialty services and in the probability of being included in agency records¹ as well as the likelihood of exposure to postnatal causes (infections, trauma). For severe mental retardation, excess mortality is responsible for the decline in prevalence with age after childhood. For mild mental retardation, the decline in prevalence may be partly due to mortality, but could alternatively be due to the fact that societies do not universally require of adults the cognitive skills they require of school children; a degree of recovery is also probable. Thus, many persons categorized as mildly retarded in school become indistinguishable from the general population during adulthood.

▶ **SELECTED CAUSES**

Chromosomal Anomalies

Chromosomal anomalies, including structural and numerical anomalies, are a major cause of severe mental retardation. Structural changes result from chromosome breakage and rearrangement and can be induced by a variety of exposures, including ionizing radiation, viral infections, and toxic substances. Numerical anomalies arise through nondisjunction during meiosis or mitosis or through lagging of chromosomes at anaphase of cell division. Among several types of abnormalities of chromosome number that occur, trisomies play the largest role in the etiology of mental retardation. As a whole, chromosomal anomalies contribute more to fetal loss than to live births and mental retardation. About 40% of miscarriages, 6% of stillbirths, and less than 1% of live births have been estimated to be chromosomally aberrant.²³ After 8 weeks gestational age, the proportion of chromosomal aberrations lost by miscarriage exceeds 90% for all but trisomy 21 (Down syndrome), XXX, XXY (Klinefelter’s syndrome), and XYY.²³ In Sweden, chromosomal anomalies, primarily Down syndrome, were reported to cause more than 30% of prevalent cases of severe mental retardation.^{24,25}

Down Syndrome

Down syndrome is the most common genetic cause of mental retardation and the leading known cause of severe mental retardation in developed countries.^{26,27} All cases of Down syndrome result from partial or complete duplication of chromosome 21 in the genome.²⁸ The most common form (95% of cases at birth) is standard trisomy, involving duplication of chromosome 21. In over 90% of these cases, the extra chromosome is of maternal origin, due to nondisjunction during meiosis.^{29–31} Translocation of chromosome 21 material to another chromosome (usually 13 or 18) and mosaicism (transmission of a cryptic trisomy 21 cell line from an unaffected parent) are rare causes of Down syndrome.^{32,33}

The most striking epidemiologic characteristic of Down syndrome is the marked increase in risk with increasing maternal age, from approximately 1 per 1500 live births at ages 20–24 to 1 per 600–700 live births at ages 30–34 to 1 per 50 live births at ages 41–45.³⁴ Increased availability of effective birth control in the 1960s was followed by reductions in the number and proportion of births to older women and corresponding reductions in the prevalence of Down syndrome at birth.³³ Also contributing to reductions in the frequency of Down syndrome births is the availability of prenatal diagnosis followed by therapeutic abortion.²⁶ Studies in multiple populations found this to reduce the number of infants born with Down syndrome by 6–8%.^{35,36} However, the era of decreased prevalence at birth has also been an era of increased longevity of persons with Down syndrome. The net effect of these two trends has been a rise in the prevalence of Down syndrome in adolescents and adults. It was estimated that even

TABLE 70-3. EPIDEMIOLOGIC CHARACTERISTICS OF SEVERE AND MILD MENTAL RETARDATION

	<i>Severe</i>	<i>Mild</i>
Prevalence range in childhood (/1000):		
Populations with advanced medical care	2.5–5.0	2.5–40.0
Less developed countries	5.0–25.0	(Estimates not available)
Life expectancy	Considerably shorter than general population	Somewhat shorter than general population
% with other neurodevelopmental or sensory disorders	About 85%	About one-third
% with other psychiatric disorders	Higher frequency than general population	Higher frequency than general population
% with known genetic cause	About 50%	Small percentage
% with unknown cause	Minority	Majority
Usual age at recognition	Infancy or preschool years	School age
Duration	Lifelong	May be restricted to school age
Male-Female ratio	Male excess (1.1 to 1.4:1)	Male excess (1.1 to 1.8:1)
Major demographic risk factors	Maternal age is a strong predictor of trisomies, which cause about 30% of severe mental retardation	Low socioeconomic status
Association with social class	Prevalence is relatively even across the social classes	Occurs predominantly in children of low social class

with improved screening and assuming increased use of selective abortion to prevent Down syndrome births, prevalence rates may be higher in the twenty-first century than ever before.²⁷

Despite the strong association between Down syndrome risk and maternal age, most Down syndrome births are to women under 35 because these women contribute the great majority of births. Thus, prenatal screening for Down syndrome is optimally provided for all pregnancies, regardless of maternal age. The discovery of safer and more practical screening methods for this anomaly during the first trimester of pregnancy, therefore, has been an important public health goal.^{37–39} The patented “integrated test” as a method of screening for Down syndrome (based on the integration of maternal age, first trimester measures of ultrasound fetal nuchal translucency and maternal serum pregnancy associated plasma protein A, and early second trimester measures of four maternal serum markers: α -fetoprotein, human chorionic gonadotropin, unconjugated estriol, and inhibin-A) has a sensitivity of 85% or higher and a false-positive rate as low as 1%.^{38,40,41} A disadvantage of this approach is that the final screening result is not available until the second trimester of pregnancy, when therapeutic abortions are less safe and acceptable than during the first trimester.³⁹ Positive prenatal screening results for Down syndrome are followed by diagnostic testing based on analysis of amniotic fluid or chorionic villus sampling, which also can detect fetuses with other chromosomal abnormalities, including other autosomal trisomies, sex chromosome abnormalities, and structural rearrangements.⁴² Prenatal screening for Down syndrome was shown to be a highly cost-effective method for preventing mental retardation worldwide.⁴³ Two factors inhibiting its widespread application, however, are that the required systems for providing prenatal care are not available in many populations, and it is not universally acceptable to therapeutically abort affected fetuses.⁴³

About one-third of children with Down syndrome have congenital heart defects and 2–5% have duodenal obstruction. Other conditions that occur with increased frequency in Down syndrome are childhood leukemia, recurrent infections, hypothyroidism, and seizure disorders. Mental retardation is virtually always present though with early intervention and inclusive education, impressive gains are seen in cognitive and social functioning of persons with

Down syndrome. Adults with Down syndrome show a variety of age-related changes in physical and functional capacities suggestive of premature or accelerated aging,⁴⁴ including changes in skin tone, hypogonadism, increased frequency of cataracts, increased frequency of vision and hearing loss, hypothyroidism, seizures, degenerative vascular disease, and early and severe Alzheimer’s disease.^{44–46} The increased life span of individuals with Down syndrome and accompanying age-associated morbidity have important consequences for medical care and community services as well as sustained support from family members who are facing new concerns about the need for prolonged care of offspring with Down syndrome.

X-Linked Mental Retardation

Sex-linked disorders arise from differences, between males and females, in gene expression from the sex chromosomes. Only males fully express genes located on the X chromosome. Early in embryonic development of females, each cell randomly inactivates either the maternal or paternal X chromosome. Thus, if a female is heterozygous for an X-linked mutant gene, on the average approximately half of her cells have the normal and half the abnormal allele as the functional member. This averaging of the effects of the two X chromosomes protects females from certain disorders transmitted on the X chromosome, such as hemophilia. Genes on the X chromosome are associated with a number of neurologic and cognitive disorders, including Lesch-Nyhan syndrome, Duchenne’s muscular dystrophy, X-linked hydrocephalus, Menkes’ syndrome (kinky hair disease), and fragile X syndrome; of these, fragile X syndrome is the most common known form of inherited mental retardation.

Fragile X Syndrome

A fragile site on the X chromosome, fra(X), was first identified in males from families with X-linked mental retardation. In cytogenetic studies, Lubs⁴⁸ described a constriction on the long arm of the X chromosome. Sutherland⁴⁹ showed that the fragile X site could be routinely observed as a gap or break in the X chromosome when culture media deficient in folate or thymidine were used, and the site has been

localized to Xq27.3. In 1991, the isolation of the fra(X) locus (FRAXA) located at the beginning of the FMR-1 gene permitted direct diagnosis at the DNA level.^{50–52} Understanding of the inheritance of this condition has changed accordingly and affords a unique opportunity to examine the influence of a genetic factor on development. Segregation analysis that followed the intergenerational passage of the FRAXA gene in affected families revealed an unusual pattern of inheritance.⁵³ Some males who carry the FRAXA genotype appear to be clinically unaffected and do not express the fragile site on cytogenetic testing. These nonpenetrant normal transmitting males (NTMs) transmit the mutation to daughters who, although unaffected themselves, may have affected children. Thus, grandsons of NTMs are often mentally retarded and granddaughters may show some cognitive impairment.⁵³

A risk of mental retardation depending upon the generation position within the family is known as the Sherman paradox: mothers and

daughters of nonpenetrant males, both obligate carriers of the gene and phenotypically similar, have differing penetrance in their offspring. Brothers of NTMs have low penetrance (approximately 9%) while grandsons and great grandsons have high penetrance (approximately 40–50%).⁵³

The molecular basis of the Sherman paradox has now been elucidated. The FRAXA site contains an exon of the FMR-1 gene responsible for the fragile X mental retardation. This exon includes a repetitive CGG sequence that demonstrates length variation in normal and in fra(X) individuals, and a cytidine phosphate guanosine (CpG) island that can be preferentially methylated in fra(X) cases.^{54,55} The length of the CGG repeat in genomic DNA correlates with risk for the fragile X syndrome. Normal individuals have fewer than 55 CGG repeats. NTMs and carrier females have “premutations,” in which the number of CGG repeats ranges from 55 to 200. Individuals with the fragile X phenotype show amplification to more than

200 CGG repeats and hypermethylation of the adjacent “CpG island” region; this is associated with lack of expression of FMR-1 mRNA.^{56,57} Thus DNA methylation is a critical feature of the fragile X phenotype.

Expansion of the premutation to the full mutation occurs only in female meiotic transmission;^{50,58,59} during oogenesis, risk for expansion to the full mutation increases with the number of repeats, in a dose-response manner.^{58,61} Hence women who have inherited the premutation are generally not cognitively impaired,^{49,61,62} yet they may transmit an expanded allele to their offspring, increasing the risk of fra(X). As CGG repeat is amplified, it becomes more unstable, leading to both mitotic and meiotic instability.^{50,55,60} In addition, several cases were found with atypical mutations at the FRAXA site, two involving a deletion and one a point mutation in the FMR-1 gene.^{61,63} Other fragile sites (FRAXD, FRAXE, FRAXF) are found close to the FRAXA site. FRAXE is associated with learning disabilities, but is caused by a different expanding trinucleotide repeat.⁶⁴

The full mutation is almost always associated with mental retardation in males. The level of cognitive disability can range from mild to severe. Other features of the fragile X syndrome phenotype include distinctive facial characteristics (elongated face, large ears, prominent forehead and jaw, and macrocephaly), macroorchidism in postpubescent males, hyperflexible joints, attention deficits, and autistic-like behaviors. A high proportion of females with the full mutation, though not necessarily mentally retarded, do exhibit selective cognitive deficits.⁶⁵ In addition, there is increasing evidence of a continuum or spectrum of effects in both females and males with premutations. For example, female carriers of the premutation have an increased risk for premature ovarian failure, and male carriers are at especially high risk for a recently identified neurodegenerative disorder known as the fragile X-associated tremor/ataxia syndrome or FXTAS.^{66,67} Hagerman and colleagues hypothesized that FXTAS results from a “toxic gain of function” because in persons with premutations characterized by an excessive number of CGG repeats, FMR1 mRNA is expressed at elevated levels, while those with full mutations lack FMR1 mRNA expression.⁶⁸

Prevalence of the Fragile X Syndrome. As mentioned, the fragile X syndrome is the most common known cause of inherited mental retardation. Recent population-based studies incorporating molecular diagnostic methods found that the prevalence of the full mutation ranges from approximately 1 per 2500 to 1 per 6000 males,^{69–71} and the prevalence of premutations is as high as 1 per 70 to 1 per 259 females and 1 per 810 males.^{72–76}
