

The Clinical Practice of Emergency Medicine 3rd edition (January 15, 2001): by Ann Harwood-Nuss (Editor), Allan B., MD Wolfson (Editor), Christopher H., MD Linden (Editor), Suzanne Moore, MD Shepherd (Editor), Phyllis Hendry, MD Stenklyft (Editor), Woffson By Lippincott Williams & Wilkins Publishers

By OkDoKeY

The Clinical Practice of Emergency Medicine

Contents

[Editors](#)

[Dedication](#)

[Preface](#)

[Contributing Authors](#)

[Introduction](#)

[The Approach to the Emergency Department Patient](#)

Robert L. Wears

SECTION I CHIEF COMPLAINT

Suzanne Moore Shepherd

[1. Chest Pain](#)

Robert Zalenski and Rebecca R. Roberts

[2. Abdominal Pain](#)

Beth Anne DeGennaro and Sheldon Jacobson

[3. Cough](#)

Frank Birinyi and Douglas A. Rund

[4. Dyspnea](#)

C. Keith Stone and D. Shannon Waters

[5. Fever and Night Sweats](#)

Harold A. Thomas Jr. and James H. Bryan

[6. Edema](#)

J. Stephan Stapczynski

[7. Approach to Coma and Transient Loss of Consciousness](#)

Rebecca A. Seip and Marcus L. Martin

[8. The Weak Patient](#)

Phillip G. Fairweather and Andy Jagoda

SECTION II SURGICAL EMERGENCIES

Ann Harwood-Nuss

PART I. Emergency Aspects of Ophthalmology

[9. The Ophthalmic Examination](#)

Geoffrey Brooker

[10. Acute Eye Infections](#)

Robert S. Porter

[11. Common Ophthalmic Medications](#)

Geoffrey Brooker

[12. Acute Visual Disturbances](#)

Catherine A. Marco

[13. Acute Angle-Closure Glaucoma](#)

William Bozeman

[14. Orbital and Periorbital Infections in Children and Adults](#)

David A. Kramer and Ronald S. Benenson

PART II. Emergency Aspects of Dental and Oral Surgery

[15. Toothache and Common Periodontal Problems](#)

Alan Hodgdon

[16. Postoperative Complications from Oral and Maxillofacial Surgery](#)

James T. Amsterdam

[17. Temporomandibular Joint Disease](#)

Barry H. Hender

[18. Dental, Oral, and Salivary Gland Infections](#)

James T. Amsterdam

PART III. Emergency Aspects of Otolaryngology

[19. Adult Epiglottitis](#)

Michael F. Murphy and Blaine A. Kent

[20. Acute Infections of the Adult Pharynx and Laryngitis](#)

William Levin and Gabriel R. Wilson

[21. Sinusitis](#)

Eric T. Boie

[22. Rhinitis](#)

Michael J. Foley and Gregory P. Moore

[23. Mastoiditis](#)

James A. Pfaff

[24. Nasal Hemorrhage](#)

Todd C. Rothenhaus and Ian D. Paul

[25. Foreign Bodies in the Ear, Nose, and Throat in Children and Adults](#)

Raquel M. Schears

[26. Acute Hearing Loss](#)

John Isaacs, Jr.

[27. Vertigo and Labyrinthine Disorders](#)

Eileen M. Raynor and Robert D. Herr

[28. Acute Otitis Media in Adults](#)

Harry W. Severance

[29. Acute Otitis Externa](#)

Harry W. Severance

[30. Nontraumatic Upper Airway Obstruction](#)

Joseph E. Clinton

[31. The Neck Mass in Adults and Children](#)

Ted A. McMurry

[32. Emergency Aspects of Head and Neck Neoplasms](#)

Eileen M. Raynor

PART IV. Emergency Aspects of General Surgery

[33. Emergencies of Artificial Conduits](#)

Karen DeFazio and Brian Mongillo

[34. Surgical Causes of Abdominal Pain](#)

Robert M. McNamara

[35. Abdominal Mass](#)

David D. Cassidy

[36. Abdominal Pain in the Elderly](#)

Diane M. Birnbaumer and Katherine Bakes

[37. Breast Masses and Breast Infection](#)

John M. Howell and Ellen M. Dugan

[38. Esophageal and Gastric Neoplasms](#)

Jonathan Glauser

[39. Acute Diseases of the Gallbladder](#)

Lance D. Wilson

[40. Surgical Causes of Jaundice](#)

Byron C. Scott and Jay L. Falk

[41. Acute Appendicitis](#)

Brian K. Snyder

[42. Bowel Obstruction](#)

Philip L. Henneman

[43. Hernias](#)

Sharon Elizabeth Mace

[44. Colonic Neoplasms](#)

Jonathan Glauser

[45. Colonic Diverticular Disease](#)

Michael D. Witting and Annie T. Sadosty

[46. Perianal, Rectal, and Anal Diseases](#)

Leonard Samuels

PART V. Emergency Aspects of Vascular Surgery

[47. Nontraumatic Carotid Artery Emergencies](#)

James W. Dennis

[48. Emergency Aspects of Peripheral Vascular Insufficiency](#)

Henry C. Veldenz

[49. Septic Thrombophlebitis](#)

Timothy C. Flynn

[50. Complications of Vascular Grafts](#)

Timothy C. Flynn

[51. Aortic Dissection and Thoracic Aortic Aneurysms](#)

Shawna J. Perry

[52. Abdominal Aortic Aneurysm](#)

Robert L. Wears

[53. Mesenteric Ischemia and Infarction](#)

Kendall Ho and Ron M. Walls

PART VI. Emergency Aspects of Orthopedic Surgery

[54. Painful Syndromes of the Hand and Wrist](#)

Jeffrey B. Nemhauser and Michael I. Greenberg

[55. Hand Infections](#)

Carl R. Chudnofsky

[56. Low Back Pain](#)

David Della-Giustina

[57. Common Foot Disorders](#)

Valerie Dobiesz Neylan and Louis G. Poulos

[58. Bone and Soft-Tissue Neoplasms](#)

Joseph A. Buckwalter

PART VII. Emergency Aspects of Neurosurgery

[59. Intracranial Neoplasms](#)

Collette Ditz Wyte and Elizabeth A. Hatfield

[60. Cranial Nerve Emergencies](#)

Michael T. Pulley

PART VIII. Emergency Aspects of Urology

[61. Male Urologic Infections](#)

David S. Howes and Erica E. Remer

62. Urinary Tract Infections in Women

Eric T. Boie, Deepi G. Goyal, and Annie T. Sadosty

63. Calculous Disease of the Kidney and Bladder

James E. Lingeman, Jeffrey A. Moody, Christopher P. Steidle, and Mark C. Adams

64. Genitourinary Neoplasms

Romano DeMarco and Michael O. Koch

65. Urinary Incontinence and Retention

Norman E. Peterson

66. Cutaneous Lesions of the Male Genitalia

Stephen W. Bretz

67. Acute Scrotal Mass

Robert E. Schneider

68. Miscellaneous Urologic Conditions

Douglas McGee

PART IX. Emergency Aspects of Obstetrics

69. Complications of Fertility Regulation Methods

Andrew M. Kaunitz

70. Pregnancy Testing

Howard A. Werman

71. Drugs in Pregnancy

Mary H. Stewart

72. Complications of Induced Abortions

James L. Jones and Andrew M. Kaunitz

73. Vaginal Bleeding in Early Pregnancy

Edward Newton and Sean O. Henderson

74. Ectopic Pregnancy

G. Richard Braen and Richard S. Krause

75. Common Medical Diseases in Pregnancy

John F. Huddleston and Donald C. Willis

76. Infections in Pregnancy

Carol C. Coulson

77. Hypertensive Disorders of Pregnancy

Sean O. Henderson and Edward Newton

78. Emergencies of Late Pregnancy

Moss H. Mendelson

79. Emergency Delivery and Related Topics

Lynnette Doan-Wiggins

80. Postpartum Emergencies

Moss H. Mendelson

PART X. Emergency Aspects of Gynecology

81. Gynecologic Causes of Abdominal Pain

Patrice M. Ringo

82. Pelvic Inflammatory Disease

Alfred Sacchetti

83. Non-Pregnancy-Related Vaginal Bleeding

Eric Anderson and H. Trent MacKay

84. Amenorrhea

Stuart P. Swadron and William K. Mallon

85. Vaginitis

Constance S. Greene

86. Gynecologic Cancers

Guy I. Benrubi, Robert C. Nuss, and Ann Harwood-Nuss

87. The Adnexal Mass

Robert C. Nuss

88. Sexual Assault

Gwendolyn L. Hoffman

SECTION III TRAUMA
Suzanne Moore Shepherd

PART I. General Considerations

89. General Principles of Trauma

Peter Rosen

90. Trauma Scoring Systems

Charles L. Emerman and Thomas E. Collins

91. Injury Prevention

B. Tilman Jolly

92. Out-of-Hospital Care and Transport of the Trauma Patient

Juan A. March and C. Crawford Mechem

93. Trauma Airway Management

Kevin R. Ward

94. Traumatic Shock

James Manning and Samir M. Fakhry

95. Wound Management

Judd E. Hollander and Adam Singer

PART II. System Considerations

96. Head Injuries

Pierre Borczuk and Stephen H. Thomas

97. Maxillofacial Injuries

Suzanne Moore Shepherd and Iris M. Reyes

98. Dental Injuries

Brigitte M. Baumann and Laura B. Thomas

99. Eye Trauma

William H. Shoff and Suzanne Moore Shepherd

100. Neck Injuries

Gerard R. Cox and Brigitte M. Baumann

101. Spinal Cord Injuries

Brian D. Mahoney

102. Pulmonary and Pleural Injuries

C. Keith Stone and Ron Forrest Koury

103. Blunt and Penetrating Cardiac Injuries

Lee W. Shockley

104. Great Vessel Injuries

Daniel S. Gabbay and Patrick M. Reilly

105. Bony Thorax and Diaphragm Injuries

Vincent J. Markovchick and Joanne Edney

106. Thoracic Esophageal Injuries

Brian Tiffany and Robert C. Jordan

107. Blunt Abdominal Trauma

Kevin M. Curtis and Vicente H. Gracias

108. Penetrating Abdominal Trauma

Vicente H. Gracias and Kevin M. Curtis

109. Genitourinary Trauma

B. Tilman Jolly and Scott D. Weir

110. Peripheral Vascular Injuries

Peter T. Pons

PART III. Orthopedic Considerations

111. Approach to Musculoskeletal Injuries

David F. Gaieski and Joseph Bernstein

112. Shoulder Injuries

Jeffrey Schaider and Robert Simon

113. Elbow Injuries

Jefferson D. Bracey and Alok Saxena

114. Hand, Wrist, and Elbow Injuries

Suzanne Moore Shepherd, Jeffrey Desmond, Carl R. Chudnosky, and William H. Shoff

115. Back Pain and Injury

Robert S. Hockberger and Martin O'Bryan

116. Pelvic Fractures

Paula S. Wadbrook and Charles V. Pollack, Jr.

117. Hip Injuries

Norberto Adame, Jr. and Timothy Seay

118. Knee Injuries

John E. Gough and Nicholas H. Benson

119. Injuries of the Ankle and Foot

Daniel R. Martin and Wenzel Tirheimer

PART IV. Special Considerations

120. Replantation

Steven C. Larson and Iris M. Reyes

121. High-Pressure Injection Injuries of the Hand

Paul Blackburn

122. Acute Compartment Syndrome

Steven C. Larson

123. Blast Injuries

J. Stephan Stapczynski

124. Trauma in Pregnancy

Andy Jagoda and Stuart G. Kessler

125. Burns

Janet Talbot-Stern

126. Hanging and Strangulation Injuries

Yevgeniy Gincheran and Edward T. Dickinson

127. Trauma in the Elderly

Suzanne Moore Shepherd and William H. Shoff

PART V. Special Procedures

128. Ultrasound

Sarah A. Stahmer and Verena T. Valley

SECTION IV GENERAL MEDICAL EMERGENCIES *Allan B. Wolfson*

PART I. Cardiovascular Disease

129. Cardiac Arrest and Resuscitation

Arthur B. Sanders

130. Acute Respiratory Insufficiency

Paul E. Pepe

131. Ischemic Heart Disease, Angina Pectoris, and Myocardial Infarction

James T. Nieman

132. Cardiogenic Shock

Brian R. Tiffany and Robert C. Jordan

133. Congestive Heart Failure and Cor Pulmonale

James T. Nieman

134. Bradyarrhythmias

Mary B. Staten-McCormick and David Overton

135. Tachyarrhythmias

Scott R. Votey, Mel Herbert, and Jerome R. Hoffman

136. The Patient with a Pacemaker or Implantable Cardioverter–Defibrillator

Robert M. Rodriguez

137. Valvular Heart Disease

Joseph P. Ornato

138. Acute Pericarditis and Cardiac Tamponade

Franklin D. Pratt and Howard A. Bessen

139. Deep Venous Thrombosis and Thrombophlebitis

Edward A. Panacek and J. Douglas Kirk

140. Infectious Endocarditis

Corey M. Slovis and Rebecca R. Roberts

141. Syncope

Jay M. Goldman and Thomas P. Martin

142. Hypertension

Katerina T. Parmele and Alison J. McDonald

PART II. Pulmonary Disease

143. Adult Respiratory Distress Syndrome

Darryl J. Macias and Joe Alcock

144. Pneumonia

Gregory J. Moran and David A. Talan

145. Pleural Effusion

Robert Sigillito and Peter M. C. DeBlieux

146. Asthma

Rita K. Cydulka and Michael A. Kaufman

147. Chronic Obstructive Pulmonary Disease

Erica E. Remer and David S. Howes

148. Lung Cancer

Marc Borenstein

149. Spontaneous Pneumothorax and Pneumomediastinum

Susan M. Dunmire

150. Pulmonary Embolism

Susan M. Dunmire

151. Hemoptysis

Steven J. Parrillo

152. Sarcoidosis

Steven J. Parrillo and Christopher C. Rose

PART III. Gastrointestinal Disease

153. Esophageal Disease

Charles M. Seamens and Allan B. Wolfson

154. Upper Gastrointestinal Bleeding

Edward A. Panacek

155. Peptic Ulcer Disease

Dale S. Birenbaum and David J. Vukich

156. Gastrointestinal Foreign Bodies

Valerie C. Norton

157. Pancreatitis and Pancreatic Cancer

David C. Seaberg and Allan B. Wolfson

158. Hepatitis

Joel M. Geideman and Mark J. Ault

159. Hepatic Failure and Cirrhosis

David M. Cline and E. Jackson Allison, Jr.

160. The Patient with a Liver Transplant

Eric Savitsky, Scott R. Votey, and Don Mebust

161. Nonsurgical Causes of Abdominal Pain

Darrell C. Sandel and Sheldon Jacobson

162. Inflammatory Bowel Disease

Howard A. Werman

163. Diarrhea and Proctitis

Philip N. Salen and Michael B. Heller

164. Lower Gastrointestinal Bleeding

Daniel T. Schelble and David J. Peter

PART IV. Renal, Metabolic, and Endocrine Disease

[165. Acid–Base Disturbances](#)

Robert Shesser

[166. Diabetic Ketoacidosis](#)

Michael D. Rush and Robert A. Schwab

[167. Hyperosmolar Hyperglycemic Nonketotic Coma](#)

Dana Pope and Leslie S. Zun

[168. Diabetes Mellitus](#)

Scott R. Votey and Anne L. Peters

[169. Hypoglycemia](#)

Scott R. Votey and Anne L. Peters

[170. Alcoholic Ketoacidosis](#)

Stephen L. Adams and Laura J. Bontempo

[171. Thyroid Emergencies](#)

T. Eugene Ragland and Robert C. Urbanic

[172. Adrenal and Pituitary Disorders](#)

Clare T. Sercombe and Louis J. Ling

[173. Disorders of Sodium and Water Metabolism](#)

Sandra A. Craig and John A. Marx

[174. Disorders of Potassium Metabolism](#)

Frank G. Walter and Elisabeth F. Bilden

[175. Disorders of Calcium, Magnesium, and Phosphorus](#)

Daniel R. Martin and Marc B. Schnapper

[176. Azotemia and Acute Renal Failure](#)

Todd C. Rothenhaus and Samuel A. McLean

[177. Chronic Renal Failure and Dialysis-Related Emergencies](#)

Allan B. Wolfson

[178. The Patient with a Renal Transplant](#)

Louis G. Graff

[179. Rhabdomyolysis](#)

Mark T. Steele

[180. Hematuria](#)

James P. d'Etienne and Steven A. Godwin

PART V. Infectious Disease

[181. Skin and Soft-Tissue Infections](#)

Alexander T. Trott

[182. Tetanus](#)

James J. Mathews and Kaveh Ilkhanipour

[183. Meningitis and Encephalitis](#)

Raymond J. Roberge and Richard Mark Kaplan

[184. Central Nervous System Abscess](#)

Ralph J. Riviello and Douglas A. Rund

[185. Gonorrhea](#)

Rodney Smith

[186. Syphilis](#)

Richard Wolfe

[187. Lyme Disease](#)

Edward B. Bolgiano and Robert A. Barish

[188. Rocky Mountain Spotted Fever](#)

Michael A. Gibbs

[189. Tuberculosis](#)

Gregory J. Moran and David A. Talan

[190. Infectious Mononucleosis](#)

David Anthony Jerrard

[191. Influenza](#)

Jonathan S. Olshaker

[192. Human Immunodeficiency Virus Infection and Related Disorders](#)

Richard E. Rothman, Catherine A. Marco, and Gabor D. Kelen

[193. Spinal Infections](#)

Ellen H. Talianferro and Allan B. Wolfson

[194. Toxic Shock Syndromes](#)

Frederick M. Schiavone

[195. Bacteremia and Septic Shock](#)

J. Stephan Stapczynski

[196. Infections in the Compromised Host](#)

Judith C. Brillman and Sarah A. Stahmer

[197. Parasitic Disease](#)

Richard J. Ryan

[198. Blood and Body Fluid Exposures in the Health-Care Worker](#)

Peter E. Sokolove

PART VI. Neurologic Disease

[199. Altered Mental Status and Coma](#)

Gregory L. Henry

[200. Organic Brain Syndrome](#)

Sandra M. Schneider

[201. Headache](#)

E. John Gallagher and Adrienne J. Birnbaum

202. Subarachnoid Hemorrhage

Phil Fontanarosa and Clifton Callaway

203. Cerebrovascular Disease

Phillip A. Scott and William G. Barsan

204. Peripheral Neuropathies

Phyllis A. Vallee and Kevin M. Reilly

205. Myopathies and Disorders of Neuromuscular Transmission

James J. Walter

206. Seizures

Andy Jagoda and Silvana Riggio

207. Demyelinating Disease

Adrienne J. Birnbaum

208. Parkinsonism

Brendan R. Furlong

209. Drug-Induced Hyperthermic Syndromes

Sandra M. Schneider

PART VII.

Hematology/Oncology

210. Bleeding Disorders

Kathleen C. Hubbell

211. Disseminated Intravascular Coagulation, Thrombotic Thrombocytopenic Purpura, and Hemolytic-Uremic Syndrome

Kathleen C. Hubbell

212. Sickle Cell Disease

Donald M. Yealy and Larry D. Weiss

213. Anemia

Louis S. Binder

214. Transfusion Reactions and Complications

Gregory W. Hendey

215. Hematologic Malignancies

Daniel Brookoff

216. The Cancer Patient in the Emergency Department

Daniel Brookoff

PART VIII.

Allergy and Immunology

217. Anaphylaxis

David N. Zull

218. Angioedema

Joyce M. Mitchell-Savinsky

219. Drug Allergy and Other Drug Reactions

Donna Kinser

PART IX.

Rheumatology

220. Monoarticular Arthritis

Alan C. Hefner and Stephen A. Coluciello

221. Polyarticular Arthritis

Harold A. Thomas, Jr. and Richard S. Hartoch

222. Multisystem Autoimmune Disease

Laurie Vande Krol and Theodore I. Benzer

PART X.

Dermatology

223. Papulosquamous Eruptions

John J. Kelly and William H. Spivey

224. Blistering Disorders

M. Andrew Levitt

225. Purpuric Eruptions

Steven M. Joyce and Stephen C. Hartsell

226. Urticaria

Theodore A. Christopher and Joseph D. Kim

227. Life-Threatening Dermatoses

Alan T. Forstater and Kenneth J. Neuberger

228. Pigmented Lesions and Skin Tumors

Thomas P. Graham and George W. Go

PART XI.

Psychiatry

229. Medical Clearance: Distinguishing Medical and Psychiatric Causes of Disturbed Behavior

Phillip I. Bialecki, Douglas A. Rund, and William R. Dubin

230. Depression and Suicide

Robert S. Hockberger and Roger Yang

231. Acute Psychiatric Illness in the Emergency Department

Douglas A. Rund and Phillip I. Bialecki

232. Factitious Illness, Malingering, and Conversion Disorder

Jeffrey Dubin and Mark Smith

SECTION V PEDIATRICS

Phyllis Hendry Stenklyft

PART I.

Resuscitation

233. Newborn Resuscitation

Brian P. Gilligan

234. Pediatric Resuscitation

John A. Brennan and Neena Gupta

235. Rapid-Sequence Induction in Children

Robert C. Luten and Phyllis Hendry Stenklyft

236. Shock

Lucian K. DeNicola and James H. McCrory

237. Vascular Access in Children

Talaat A. Abdelmoneim and Lucian K. DeNicola

PART II. Signs and Symptoms

238. Abdominal Pain

Javier I. Escobar II and Steven A. Godwin

239. Altered Mental Status

Lindsey Alan Johnson

240. Apnea

Ghazala Q. Sharieff

241. Chest Pain

Edward J. Bayne and Carissa J. Kostecki

242. Constipation

Elisa Alter Zenni

243. Crying, Fussy Infant

Naghma S. Khan and Agoritsa G. Baka

244. Dehydration

Naghma S. Khan

245. Diarrhea

Ghazala Q. Sharieff

246. Failure to Thrive

Marc Linares and Bruce J. Quinn

247. Fever and Petechiae

R. Kemp Crockett and Elizabeth Rincon

248. Fever of Acute Onset

Maureen D. McCollough and David A. Talan

249. Gastrointestinal Bleeding

Michael O. Gayle and Niranjana Kissoon

250. Headache

Laurie Jeanne Burton and Harold K. Simon

251. Heart Murmurs

Edward J. Bayne

252. Hematuria

Lina Abujamra and Madeline Matar Joseph

253. Intoxications

Jay L. Schauben and Dawn Ruskosky-Sollee

254. Limp

Jonathan I. Singer

255. Respiratory Distress

Bruce Quinn and Marc Linares

256. Seizures

Christopher S. Kennedy

257. Vomiting

Anthony P. Pohlgeers

PART III. Specific Diseases

258. Abuse: Sexual

J. M. Whitworth

259. Abuse and Neglect: Physical

J. M. Whitworth

260. Appendicitis

Maureen D. McCollough

261. Asthma

Jeffrey F. Linzer

262. Bleeding Disorders

James L. Harper and Paul A. Pitel

263. Bronchiolitis

Kathy N. Shaw

264. Cellulitis

Christopher S. Kennedy and Madhumita Sinha

265. Congenital Heart Disease, Congestive Heart Failure, and Other Cardiac Presentations

Randall M. Bryant

266. Croup and Epiglottitis

Timothy G. Givens

267. Diabetic Ketoacidosis

Timothy G. Givens

268. Diaper Rash

Lindsey Alan Johnson

269. Exanthems

Mary A. Heegenbarth

270. Eye Disorders

Janet G. Altevener and Kathryn McCans

271. Foreign-Body Ingestion

Linda L. Settle

272. Glomerulonephritis and the Nephrotic Syndrome

Asad Tolaymat and Anne Schaefer

273. Human Immunodeficiency Virus (HIV)

Ronald M. Ferdman and Jeffrey F. Linzer

274. Immunizations

Mary A. Hegenbarth and Hisham A. Omran

275. Impetigo

Jeffrey G. Michael and Jane F. Knapp

276. Infestations: Scabies, Lice, and Pinworms

R. Wayne Wolfram, Kevin R. Kowaleski, Eugene Izsak, and Amy S. Spangler

277. Intussusception

Jonathan I. Singer

278. Kawasaki Disease

James A. Wilde

279. Lymphadenitis

Nizar F. Maraqa and Mobeen H. Rathore

280. Meningitis and Encephalitis

James A. Wilde

281. Newborn Problems

Michael O. Gayle and Niranjan Kissoon

282. Nursemaid's Elbow

Julide Ayse Ozan

283. Osqood-Schlatter Disease

Todd Wylie

284. Otitis Externa

Katalin I. Koranyi

285. Otitis Media and Mastoiditis

Katalin I. Koranyi

286. Pertussis

Samir Midani and Hanif Kamal

287. Acute Pharyngitis

Karen Camasso-Richardson and Martha S. Wright

288. Pneumonia

David A. Schaeffer

289. Pyloric Stenosis

Maureen Campbell and Lisa Horton

290. Rheumatic Fever

Robert D. Schremmer and Jane F. Knapp

291. Sickling Syndromes

Paul A. Pitel and James L. Harper

292. Sinusitis

Elizabeth A. Wedemeyer and Vinay M. Nadkarni

293. Submersion Injuries

Madeleine Matar Joseph and Lisa Santer

294. Torticollis

Gregory G. Gaar

295. Urinary Tract Infections

Thomas G. McLoughlin, Jr.

296. Ventricular Shunt Problems

Naghma S. Khan and Geoffrey Jackman

PART IV. Pediatric Trauma

297. Multiple Trauma

Thom A. Mayer

298. Hemorrhagic Shock

Thom A. Mayer

299. Head Trauma

Dee Hodge III and Kimberly S. Quayle

300. Evaluation of the Cervical Spine

David M. Cosentino and Francis M. Fesmire

301. Abdominal Trauma

Khaled Mutabagani and Donna A. Caniano

302. Burns

Donna A. Caniano and Marc Downing

303. Fractures and Sports Injuries

Christopher S. Kennedy

304. Facial Trauma

Barry Steinberg

PART V. Administrative and Clinical Issues

305. Sedation and Pain Management

William F. Coombs

306. Emergency Medical Services for Children

Deborah Mulligan-Smith

[307. Dealing with Death or Catastrophic Illness](#)

Phyllis Hendry Stenklyft

[308. Optimal Pediatric Care in a Nonpediatric Emergency Department](#)

John P. Santamaria

SECTION VI TOXICOLOGY

Christopher H. Linden

[309. Approach to the Poisoned Patient](#)

William A. Watson and Christopher H. Linden

[310. Acetaminophen Poisoning](#)

Jeffrey Brent

[311. Anticholinergic Poisoning](#)

Jeffrey Brent and Kenneth W. Kulig

[312. Antidysrhythmic Drug Poisoning](#)

S. Rutherford Rose and James E. Cisek

[313. Antidepressant Poisoning](#)

Keith K. Burkhardt

[314. Antihistamine Poisoning](#)

Andis Graudins

[315. Antimalarial Poisoning](#)

J. Ward Donovan

[316. Aromatic Hydrocarbon Poisoning](#)

Jeffrey Tucker

[317. Barbiturate Poisoning](#)

Margaret M. McCarron

[318. Arsenic and Mercury Poisoning](#)

Jay L. Schauben

[319. Benzodiazepine Poisoning](#)

Thomas R. Caraccio, Howard C. Mofenson, and Robin McFee

[320. Beta-Blocker Poisoning](#)

Christopher H. Linden

[321. Calcium Channel Blocker Poisoning](#)

G. Randall Bond

[322. Carbamazepine Poisoning](#)

Marco L. A. Sivilotti

[323. Carbon Monoxide Poisoning](#)

Kent R. Olson

[324. Centrally Acting Antihypertensive Agent Poisoning](#)

James R. Roberts and Sharona Bryant

[325. Chemical and Biologic Warfare Agent Poisoning](#)

Michael J. Burns and Christopher H. Linden

[326. Cocaine](#)

Richard D. Shih and Judd E. Hollander

[327. Complications of Alcohol Abuse](#)

Cynthia K. Aaron and Thomas A. Brunell

[328. Complications of Injection Drug Use](#)

James A. Feldman and Susan S. Fish

[329. Complications of Parenteral Drug Therapy](#)

Robert P. Fern

[330. Corrosive Ingestions](#)

Robert P. Dowsett and Christopher H. Linden

[331. Cyanide Poisoning](#)

Alan H. Hall

[332. Digitalis Poisoning](#)

Richard D. Gerkin, Jr. and Thomas J. Higgins, Jr.

[333. Disk Battery Exposures](#)

Toby Litovitz

[334. Disulfiram Poisoning](#)

Edward P. Krenzelok

[335. Dystonic Reactions](#)

Mary A. McCormick and Anthony S. Manoguerra

[336. Ergot Alkaloid Poisoning](#)

Leslie S. Carroll and Donald B. Kunkel

[337. Ethanol, Isopropanol, and Acetone Poisoning](#)

Susan S. Fish

[338. Ethylene Glycol Poisoning](#)

Michael J. Burns and Francis P. Renzi

[339. Fluoride and Hydrofluoric Acid Poisoning](#)

Andis Graudins

[340. Food Poisoning](#)

Marc C. Restuccia

[341. Hallucinogen Poisoning](#)

Christopher H. Linden

[342. Halogenated Hydrocarbon Poisoning](#)

Mohamud R. Daya

[343. Herbicide Poisoning](#)

William J. Lewander and Christopher H. Linden

[344. Hydrogen Sulfide Poisoning](#)

Daniel R. Douglas and Martin J. Smilkstein

[345. Iron Poisoning](#)

Jeffrey R. Suchard and Steven C. Curry

[346. Irritant Gas Inhalation](#)

Philip A. Edelman

[347. Isoniazid Poisoning](#)

Alan D. Woolf

[348. Lead Poisoning](#)

Steven M. Marcus

[349. Lithium Poisoning](#)

Kenneth W. Kulig

[350. Local Anesthetic Poisoning](#)

Donna L. Seger and Heeten J. Desai

[351. Methanol Poisoning](#)

Dag Jacobsen

[352. Methemoglobinemia](#)

Steven C. Curry and David A. Tanen

Section of Emergency Medicine
Brown University School of Medicine
Department of Emergency Medicine
Rhode Island and Miriam Hospitals
Providence, Rhode Island

James L. Harper, MD
Assistant Professor
Department of Pediatrics
University of Nebraska Medical Center
Omaha, Nebraska

Richard S. Hartoch, MD
Assistant Professor
Department of Emergency Medicine
Oregon Health Sciences University
Portland, Oregon

Stephen C. Hartsell, MD, FACEP
Associate Professor
Department of Surgery
Division of Emergency Medicine
University of Utah School of Medicine
Salt Lake City, Utah

Ann Harwood-Nuss, MD, FACEP
Professor of Emergency Medicine
Associate Dean of Educational Affairs
University of Florida Health Science Center
Jacksonville, Florida

Elizabeth A. Hatfield, MD
Attending Physician
Department of Emergency Medicine
St. Lukes Hospital
Milwaukee, Wisconsin

Alan C. Heffner, MD
Department of Emergency Medicine
Carolinas Medical Center
Charlotte, North Carolina

Mary A. Hegenbarth, MD

Associate Professor
Department of Pediatrics
University of Missouri–Kansas City School of Medicine
Attending Physician
Division of Emergency Medicine
Children's Mercy Hospital
Kansas City, Missouri

Irvin N. Heifetz, MD
Assistant Professor
Department of Emergency Medicine
UMass Memorial Healthcare
Worcester, Massachusetts

Michael B. Heller, MD
Clinical Professor of Medicine
Temple University School of Medicine
Philadelphia, Pennsylvania
Department of Emergency Medicine
St. Luke's Hospital
Bethlehem, Pennsylvania

Sean O. Henderson, MD
Assistant Professor
Department of Emergency Medicine
University of Southern California
Medical Director–Main Emergency Admitting
Department of Emergency Medicine
LAC+USC Medical Center
Los Angeles, California

Gregory W. Hendey, MD, FACEP
Assistant Clinical Professor
Department of Medicine
University of California
San Francisco, California
Residency Director
Department of Emergency Medicine
University Medical Center
Fresno, California

Barry H. Hendler, DDS, MD
Associate Professor
School of Dental Medicine
Director of Continuing Medical Education
Co-ordinator of Laser and Cosmetic Surgery
Department of Oral and Maxillofacial Surgery
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Philip L. Henneman, MD, FACEP
Clinical Professor and Chair
Department of Emergency Medicine
Tufts University School of Medicine
Boston, Massachusetts
Baystate Health System
Springfield, Massachusetts

Fred M. Henretig, MD
Professor
Departments of Pediatrics and Emergency Medicine
University of Pennsylvania School of Medicine
Director
Section of Clinical Toxicology
Division of Emergency Medicine
Children's Hospital of Pennsylvania
Philadelphia, Pennsylvania

Gregory L. Henry, MD
Clinical Professor
Department of Surgery
Section of Emergency Medicine
The University of Michigan Medical School
Vice President
Emergency Physician Medical Group
Ann Arbor, Michigan

Mel Herbert, MD
Department of Emergency Medicine
University of California Los Angeles School of Medicine
UCLA Medical Center
Los Angeles, California

Dedication

To my parents, with love—Dr. Arthur Harwood and Nyta Harwood
Ann Harwood-Nuss

To my family; to my mentors; and to the emergency medicine residents
at the University of Pittsburgh,
who continue to teach me something new every day.
Allan B. Wolfson

To my family; friends; mentors; colleagues; and students, past,
present, and future.
And especially to my loving wife, Jeanne, an ED nurse and source of joy
and inspiration, without whose support I would not be able to do this.
Christopher H. Linden

To John, whose patience, humor, and love I treasure, and to the many colleagues, students, and residents who have contributed to my education and practice
happiness far more than I can ever repay. Enjoy!
Suzanne Moore Shepherd

To Jerry, Gerald, and Erin for their unconditional love, support, and patience; to my parents and neighbors; and to the staff
and patients of the Shands Jacksonville Pediatric Emergency Department.
Phyllis Hendry Stenklyft

Preface

The Clinical Practice of Emergency Medicine (CPEM) was written to serve as a comprehensive reference with a rapidly accessible collection of clinically relevant material. We have made every effort to ensure that the third edition is current, thorough, and readable, with little waste of words, features crucial in the setting of a busy emergency department. This uniquely formatted book was designed to include not only succinct discussions of basic disease processes and differential diagnosis, but also key information on the role of the consultant, patient disposition, indications for admission, acceptable alternatives to admission (i.e., outpatient treatment), guidelines for transfer, medico-legal issues, and clinical pitfalls. The Pitfalls section is particularly valuable in that it delineates the most common errors in the care of the emergency patient, as well as those points most critical for the reader to recall. It “gently reminds the busy clinician to be careful and rethink the issues in patient management one more time before discharge . . .”

As the editors planned the third edition, we made a conscious effort to respond to our readers' suggestions and observations about the first two editions. We also felt an obligation to respond to the changing environment of medicine.

As in the first two editions, the editors agreed that the text should be written by academic and practicing emergency physicians, those most capable of orienting the discussion toward the undifferentiated emergency patient. On occasion, however, we called upon our colleagues in other medical specialties to contribute certain areas of expertise. We are deeply appreciative of their efforts.

The preface would be incomplete without acknowledging the enormous time, talent, energy, and effort expended by the editors and contributing authors. There is a daunting sense of responsibility when one undertakes a task such as this. To produce a readable, accurate, concise work demands literally thousands of hours. When we see the text used in our busy Emergency Departments, whether to review therapy, disposition options, or pathophysiology, the rewards are obvious.

Ann Harwood-Nuss

CHAPTER 1

Chest Pain

Robert Zalenski and Rebecca R. Roberts

[Organ Systems](#)
[Differential Diagnosis](#)
[Major Emergency Entities](#)
[Acute Myocardial Infarction and Ischemia](#)
[Dissection of the Thoracic Aorta](#)
[Pulmonary Embolism](#)
[Tension Pneumothorax and Esophageal Rupture](#)
[Diagnostic Approach](#)
[Chapter References](#)

The challenge in accurately diagnosing chest pain arises from some important neuroanatomic facts. First, neither the quality nor the intensity of pain produced by the nerves coming from the thoracic viscera is specific for any single organ system. Spasm of the esophagus, ischemia of the heart, or distention of the great vessels can produce feelings of pressure, aching, or burning. Pain can be severe, minimal, or even absent during the course of life-threatening conditions such as an acute myocardial infarction.

Second, the location and radiation of the pain do not reliably identify the specific organ system involved. Thoracic organ pathology can produce pain that is referred outside the thorax to the epigastrium, neck, or jaw. Conversely, cervical pathology from a ruptured cervical disk can produce pain in the shoulder and around the clavicle. Abdominal pathology, such as a ruptured ectopic pregnancy, can produce chest and scapular pain due to diaphragmatic irritation.

The anatomic explanation for referred pain is simple: Somatic afferent nerves from the skin and muscle of the arms enter the same dorsal root nerve pools as the visceral afferent nerves from the heart, esophagus, and other thoracic organs. Activation of this nerve pool by visceral afferents can stimulate the somatic afferent nerves. The brain interprets the pain as coming from the arm, muscle, or joint innervated by the pooled somatic afferents. Pain from the heart can be perceived as pain in the upper inner arm, forearm, or axilla, because both areas synapse in the dorsal roots T1–T5.⁷ Also, because dorsal nerve segments overlap three segments above and below a particular level, thoracic pain can be referred to the neck or abdomen. Therefore, to identify the organ system and the disease process, the physician must rely on the duration and frequency of the pain, the setting in which it occurs, the aggravating and relieving factors, and associated symptoms.

ORGAN SYSTEMS

The five major thoracic organ systems are listed in [Table 1.1](#). The most common etiologies that affect these organs can be categorized as structural disruption, infarction or ischemia, infection, and inflammation.

Organ System/Etiology	Chest Pain	Associated Symptoms
LEADING CAUSES		
Acute myocardial infarction	Pressure, aching, burning	Dyspnea, palpitations, nausea, diaphoresis, pallor
Aortic dissection	Severe, tearing, ripping	Red pain, neurovascular deficits
Coronary artery disease	Sharp or nonlocalizing	None or mild
Pericarditis	Sharp, pleuritic	None, dyspnea
Myocarditis	Same as AMI or pericarditis	Dyspnea, palpitations, CVF
RESPIRATORY		
Pneumothorax	Sharp, pleuritic or central chest	Dyspnea, cough, hemoptysis, leg swelling, risk factor
Pneumonia	Variable, sharp, pleuritic	Dyspnea, cough
Pulmonary embolism	Variable	None, dyspnea, CVF, syncope, paralysis
Pleuritis	Sharp, pleuritic	Cough, fever, dyspnea
Chronic obstructive pulmonary disease	Variable	Cough, fever
Tumor	Chronic, variable	None, dyspnea, weight loss
ESOPHAGEAL		
Esophageal rupture	Severe, tearing	Swallowing, hematemesis
Esophageal spasm	Severe, tearing	None, nausea
Esophageal varices	Burning, tearing, tearing	None, hematemesis, ascites
ABDOMINAL ORIGIN		
Cholecystitis	Constant, related to food	Swallowing, abdominal pain, GI bleeding
Cholelithiasis	Constant or variable	Swallowing, abdominal pain, vomiting, fever
Ruptured ectopic pregnancy	Sharp, pleuritic	Abdominal pain, vaginal bleeding, shoulder pain
MUSCULOSKELETAL		
Myocardial infarction	Pain on exertion	None, dyspnea, pain referred to neck, distalities
Costochondritis	Sharp, pleuritic	Local tenderness and inflammation
Myocarditis	Burning, tearing, tearing	Electrocardiogram abnormalities, chest pain, pulmonary
Rib fracture	Burning, tearing, tearing	History of trauma

TABLE 1.1. Common Causes of Chest Pain

DIFFERENTIAL DIAGNOSIS

The historical features of chest pain are useful in establishing the “pretest” probability for each disease in the differential. Such probabilities guide the choice and interpretation of further diagnostic tests.

Acute myocardial infarction (AMI) produces a nonlocalized pressure, ache, or burning, the intensity of which ranges from severe pain to minimal discomfort. The pain is usually substernal and in the left chest, but can occur between the umbilicus and the neck. It frequently radiates to the shoulder or left arm and lasts several hours.

Stuttering presentations may last 12 to 24 hours. Determining the onset of constant pain is essential in deciding whether the patient is eligible for thrombolytic therapy. Dyspnea, diaphoresis, nausea, and weakness are frequently associated symptoms. Occasionally, pain is felt only in a referred area, such as the arm, or via the vagus nerve, in the ear. Elderly and diabetic patients often present without pain, and this diagnosis must be suspected with the presentation of syncope or confusion.¹

Pain features not suggestive of AMI include stabbing, knifelike sensations or radiation to areas outside of cervicothoracic nerve segments, such as the legs or flanks.⁵ Very brief pain (lasting less than 5 seconds) or pain that is clearly pleuritic or exactly reproduced by bending or palpation is not likely to be of cardiac origin.¹²

The pain of angina is similar to that of AMI but is of shorter duration. A clear exertional pattern is helpful to the diagnosis; pain can also be provoked by effort, emotion, or exposure to cold. Prompt relief within 5 minutes from sublingual nitroglycerin is suggestive of angina but can also occur with esophageal spasm or placebo. Pain that is relieved with exertion and brought on by rest is not anginal. Angina is unstable when it increases in severity (duration, intensity, frequency), occurs with reduced activity or at rest, or has been present for less than 4 weeks. This diagnosis requires hospital admission.

Aortic dissection classically produces a severe tearing pain in the anterior chest radiating to the back, flank, or arm. The patient sometimes feels pain traveling down the back as the dissection extends distally. Its onset is sudden, but it may be intermittent or wax and wane. Uncommonly, it presents as a myocardial infarction or as a chronic pain that has become worse. The pain has no relieving factors, and writhing, diaphoresis, dyspnea, nausea, and vomiting are commonly associated. Associated symptoms, such as weakness, paralysis, syncope, and numbness or pain in an extremity, are also common and more specific for dissection.

Pericarditis produces a sharp or aching pain in the precordium that may radiate to the scapula, neck, or shoulder. Unlike AMI, it has a long duration (days), and can be continuous and severe. It is usually made worse by lying down or breathing (thus the associated “shortness of breath”). Patients may insist on leaning forward to make themselves more comfortable.

Myocarditis can present with associated pericarditis. It also uncommonly masquerades as a myocardial infarction.¹³ Antecedent viral illness and younger age are diagnostic clues, but an in-hospital evaluation is necessary for definitive diagnosis of this uncommon cause of chest pain.

The most common presentation of pulmonary embolism (PE) is dyspnea, pleuritic pain, or hemoptysis.²⁰ About 85% of cases of PE present with one or more of these nonspecific symptoms. Tachypnea is common, but tachycardia is found in only a minority of proven cases of PE. Large pulmonary emboli can produce circulatory

collapse with syncope due to acute pulmonary hypertension and right heart failure. PE is mistaken for AMI about 7% of the time.¹⁹ Chest pain that is strictly reproducible is not consistent with PE.

Pneumothorax may produce a severe, sudden stabbing pain in the affected side, or it may be asymptomatic. It has no characteristic pain radiation. It is made worse by breathing, is relieved by splinting, and is associated with shortness of breath and nonproductive cough. Pleurisy, an inflammation of the parietal pleura, is similar but does not have the associated symptoms or radiographic findings. Pneumonia can also cause pleuritic pain, but its association with productive cough, shortness of breath (at rest or exertion), and fever is a helpful differentiating feature.

Pain may be due to an esophageal source. Pain from esophageal spasm is often indistinguishable from angina in quality, intensity, location, and radiation. Spasm has been described as a perfect mimic of acute ischemia. Esophageal reflux is a midline epigastric discomfort usually described as indigestion or burning. It lasts minutes to hours, and is worse after eating and lying down. It is associated with belching but not shortness of breath, and tends to be chronic.

Relief with antacids does not reliably rule out pain from cardiac ischemia. Esophageal rupture produces pain in the anterior chest, back, or epigastrium. Rupture occurs in the setting of increased barotrauma from retching or prolonged vomiting or coughing. Vomiting that occurs before the pain suggests esophageal rupture, not AMI.¹⁴ Dysphagia and occasionally hemoptysis are the initial symptoms. Life-threatening mediastinitis and sepsis develop if esophageal rupture goes untreated.

MAJOR EMERGENCY ENTITIES

The following immediately or potentially life threatening diseases of the thoracic organ systems must be considered in every patient who presents to the emergency department with chest pain.

Acute Myocardial Infarction and Ischemia

Occlusion of a coronary vessel resulting in death of heart muscle can present as a catastrophic condition, with malignant dysrhythmias, pump failure, or myocardial rupture, or as a completely compensated minimally painful state. It is by far the most common chest pain emergency, accounting for 40 of 1000 hospital admissions.² Although the Framingham study risk factors of smoking, hypertension, diabetes, family history, and elevated cholesterol further increase the likelihood of developing AMI or angina over a period of years, they are not helpful in making the diagnosis in the acute care setting. Nevertheless, the physician should document, for medicolegal purposes, the presence of risk factors in all patients with chest pain. The symptoms of coronary vasospasm may be very similar to those of AMI or angina due to occlusive disease.

Emergency physicians frequently evaluate pain associated with recent cocaine use. Such patients commonly have vasospasm, and indeed have a lower confirmed rate of myocardial infarction than non-cocaine-related admissions.³ Vasospastic ischemic pain is more common than AMI.

Electrocardiographically, even in patients without ischemia, ST segment elevation is present nearly 40% of the time due to repolarization abnormalities. Unless the presentation of AMI is classic, these abnormal baseline findings make it helpful to have an old ECG without ST elevation, or serial ECGs showing evolving ST elevation in the emergency department, before deciding to give thrombolytic therapy.

Thrombolytic therapy, percutaneous coronary interventions, adjunctive treatment with antithrombotic and antiplatelet agents, and treatment in the coronary care unit have significantly lowered case fatality and reinfarction rates, making it imperative to diagnose AMI in the emergency department. Unstable angina is just as important to recognize, because 10% to 20% of confirmed cases proceed to infarction. Heparin, glycoprotein IIB/IIIA and ACE inhibitors, and vasodilators, or more invasive procedures such as coronary revascularization and intraaortic balloon pumping, may be required to treat recurrent pain or associated heart failure or shock.

Dissection of the Thoracic Aorta

This disruption in the intimal layer of the aorta allows blood to track between the media and adventitia. Aortic rupture is an ever-present threat. Untreated dissection has a mortality rate of 90%; fortunately, it is responsible for fewer than 1 in 1000 hospital admissions.² Progression of the dissection can cause severe organ damage to the spine, brain, kidneys, bowel, and heart, including AMI and cardiac tamponade. The patient must be carefully examined for evidence of these complications. Hypertension is the most common risk factor, although younger patients with Marfan or Ehlers-Danlos syndromes may have dissection due to cystic medial necrosis.

Pulmonary Embolism

Pulmonary embolism (PE) is an obstruction of the pulmonary arterial system due to clot, which usually embolizes from deep femoral or pelvic veins. In addition to dyspnea, pleuritic pain, and hemoptysis, it can produce acute respiratory failure or right-sided heart failure, as evidenced by cyanosis, hypotension, increased jugular venous pressure, and a loud S2 or right heart gallop. The hospitalization rate is 2 in 1000.² Mortality from PE itself is uncommon and is usually due to recurrent emboli. Recognition of such predisposing conditions as immobilization, recent surgery, hypercoagulability, and low-flow circulatory states is critical to raising the clinician's diagnostic suspicion. A high degree of suspicion is especially important, because PE often presents with subtle, nonspecific findings.²²

Tension Pneumothorax and Esophageal Rupture

Tension pneumothorax occurs when air escapes from the lung into the thoracic cavity, shifting the mediastinum to one side and compromising right-sided heart filling. Dyspnea, diaphoresis, tachycardia, tachypnea, and hypotension commonly result. Jugular vein distention, tracheal deviation, decreased breath sounds, and percussion tympany are noted on physical examination. Pneumothorax may be spontaneous or secondary to trauma, infection (such as tuberculosis and AIDS), or the rupture of emphysematous blebs. Patients with tension pneumothorax require immediate needle thoracostomy and subsequent placement of a chest tube.

Esophageal rupture can occur in the cervical esophagus, but it usually occurs in the distal esophagus. Conditions associated with retching, vomiting, and coughing, such as ethanol abuse, hyperemesis gravidarum, and status asthmaticus, predispose patients to this rare but important disease.²¹

DIAGNOSTIC APPROACH

After verifying or establishing initial patient stability, the diagnostic approach proceeds from a consideration of age, sex, specific clinical presentation, and preexisting conditions or risk factors for the specific emergency entities. The history and physical examination are essential for differentiating these entities and detecting their complications.

The chest x-ray is key to the detection of pneumothorax, heart failure, pneumonia, and a widened mediastinum, as seen in aortic dissection. Mediastinal or subcutaneous air can be a clue to devastating conditions such as mediastinitis or esophageal rupture. Diagnosis of certain entities may require more advanced imaging modalities, such as CT scanning, MRI, angiography, or cardiography. Transesophageal echocardiography is sensitive, specific, and practical for the emergency department diagnosis of aortic dissection.⁹

Diagnosing PE continues to be clinically challenging.²² Arterial blood gas studies are useful to assess the severity of hypoxemia and response to therapy. A normal PO₂ is present about 10% of the time in the patient with PE. The Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study provided insights into the limitation of the ventilation/perfusion scan.¹⁸ If the clinical presentation and scan results are both high or low probability, the diagnosis can be confirmed or excluded with a high degree of confidence.

If the clinical probability is intermediate or high, then a low-probability or even a normal scan does not rule out PE, and angiography is suggested. More recently, new algorithms for the evaluation of suspected PE include testing for the predisposing deep venous thrombosis using ultrasound.^{8,11,15,22} Newer tests that appear promising for patients with nondiagnostic ventilation/perfusion scans include thin-slice spiral CT scans of the chest and quantitative D-dimer assays.^{6,10}

A 12-lead ECG may be of significant diagnostic value in many of the clinical entities under consideration when determining the cause of chest pain. In the patient with AMI, it may also help to guide therapy. On ECG, regional ST elevation of 1 mm (0.1 mV) in two leads is a requirement for the administration of thrombolytic therapy.

ST segment depression in leads opposite (i.e., reciprocal) to the ST segment elevation is helpful in confirming subtle ST elevation. Diffuse ST elevation with associated PR depression (most frequent in lead II) suggests pericarditis; low-voltage or electrical alternans suggests an effusion. In PE, the ECG most commonly shows T-wave inversions in the anterior leads.¹⁹ Serial ECGs may be useful with recurrent pain or to detect AMI evolution or reperfusion.

The emergency department ECG is a simple prognostic indicator for in-hospital complications. In stable, pain-free patients who are being admitted to rule out AMI, an ECG without ST segment changes, Q waves, T-wave inversion, or left bundle branch block is associated with a very low (less than 1%) incidence of life-threatening complications. When an ST segment elevation of 0.1 mV is present in the right ventricular lead V4R in the setting of inferior AMI, suggesting coincident right ventricular infarction, complication rates are higher than when it is absent.²³

Diagnostic decision tools, such as an algorithm for risk assessment in AMI⁵ or a single numerical probability for acute ischemia,¹⁶ have been developed and validated. More recently, Goldman and associates have developed and tested a new algorithm for predicting short-term complication rates using ECG findings, presence of heart failure, low blood pressure, and worsening angina.⁴

New approaches to the potentially ischemic patient in the emergency department are being implemented, such as the use of serial cardiac markers, continuous 12-lead ECGs, and early provocative testing (e.g., stress-testing the patient on an exercise treadmill).^{17,24} These are well suited for an "emergency chest pain center," a program of the emergency department organized specifically for treating and ruling out coronary syndromes.

The diagnostic value of the cardiac troponins is well established, but myoglobin has yet to find its diagnostic niche. Resting sestamibi scanning is an excellent modality for risk stratification, but emergency echocardiography to assess regional wall motion abnormalities has yet to find its role. These technologies were comprehensively reviewed in a recent NIH report.²⁵ It is hoped that these techniques will advance our ability to diagnose and exclude AMI and acute ischemia in the emergency department.

CHAPTER 2

Abdominal Pain

Beth Anne DeGennaro and Sheldon Jacobson

[Pathophysiology](#)
[Organ Systems](#)
[Differential Diagnosis](#)
[Major Emergency Entities](#)
[Diagnostic Approach](#)
[Common Pitfalls](#)
[Bibliography](#)

Evaluation of the patient with abdominal pain is one of the frequent problems encountered in emergency medicine, and one of the most challenging. The difficulties related to evaluation stem from several factors. Diverse processes involving intraabdominal as well as extraabdominal diseases may give rise to pain patterns that are similar because of the manner in which abdominal pain is perceived. Most conditions that produce abdominal pain usually evolve over time: Localizing signs or other significant acute intraabdominal symptoms acquire a characteristic pattern that will permit specific diagnosis.

PATHOPHYSIOLOGY

Pain produced by disease of the intraabdominal organs is either visceral or deep somatic. The afferent visceral neurons are mainly of the small C-fiber unmyelinated type that ascend in the sympathetic chain. The fibers enter the spinal cord by way of the dorsal root ganglia and travel with the somatic sensory fibers to the cerebral cortex.

Stimulation of the visceral afferent fibers, usually by chemical irritants or distention, is perceived as a poorly localized, aching pain. In general, visceral pain is referred to the abdominal wall in relation to the embryonic origin of the diseased organ. Diseases of organ systems derived from the embryonic foregut (the stomach, duodenum, liver, and pancreas) cause upper abdominal or epigastric pain. Midgut processes (the small bowel and right colon) present with periumbilical pain. Diseases of the hindgut-derived structure (the distal colon and urogenital system) cause lower abdominal pain.

Deep somatic pain results from irritation of the parietal peritoneum and mesenteric root. These structures are innervated by myelinated sensory afferent fibers distributed by way of the segmental peripheral nerves. Deep somatic pain is intense and well localized. The early periumbilical pain of appendicitis is typical of visceral pain, whereas the right lower quadrant pain caused by local peritoneal irritation is a deep somatic pain.

ORGAN SYSTEMS

The intraabdominal structures that give rise to abdominal discomfort are complex and varied. Pain may arise from perturbation of the intestinal tract, the biliary tree, the pancreas, the genitourinary system, the vascular system, the abdominal wall and its apertures, the vertebral bodies, and segmental nerves.

Abdominal pain can also be referred from contiguous body cavities or from distant sites. Thus, a patient with basilar pneumonia may present with abdominal pain, or a patient with an inferior myocardial infarction may present with epigastric distress.

Toxic-metabolic and systemic diseases can cause abdominal pain. Some of these are diabetic ketoacidosis, lead intoxication, porphyria, vasculitis, neurosyphilis, and familial Mediterranean fever.

DIFFERENTIAL DIAGNOSIS

In taking the history, note the nature of the onset of pain. Patients who have a rapid onset of severe pain with minimal time for pain buildup should be assumed to have a ruptured viscus until proven otherwise. It may represent a perforated peptic ulcer, a ruptured ectopic pregnancy, or a ruptured colonic diverticulum. In women the menstrual history must be documented, and menstruating patients with acute abdominal pain must be evaluated as if they have an ectopic pregnancy until proven otherwise.

Associated signs and symptoms may be as important as the pain pattern itself. Thus, the presence of vomiting and the type of vomitus and the presence of diarrhea, blood in the stool, obstipation, fever, dysuria, vaginal discharge, and vaginal bleeding must be determined.

Often, a logical sequence of events and associated signs and symptoms are fairly consistent among patients who undergo the same abdominal process. Patients with small bowel obstruction develop abdominal distention, nausea, and bloating, followed by vomiting, periumbilical colicky pain, and only late loss of bowel sounds and obstipation. The initial signs and symptoms are nonspecific and may be confused with those of gastritis or other nonspecific gastrointestinal infections. The evolution of the process, however, is fairly typical when taken in context.

The history should also detail the type, location, pattern, and referral of the pain; relieving and exacerbating factors; and prior occurrences. Note underlying significant medical problems and prior surgical problems and procedures. Therapeutic and recreational drug and alcohol use should be carefully defined. Finally, as with all emergency department patients, document avocational and vocational exposures.

The physical examination should include a rectal temperature, full vital signs including orthostatic vital signs, a cardiopulmonary evaluation, a genitourinary examination, an examination for hernias, and a complete abdominal and rectal examination.

The abdominal examination is much less precise than the cardiac and pulmonary evaluation because of the diffuse nature of visceral pain and in no small part because of the variability of pain thresholds. The patient presenting with a rigid abdomen, absent bowel sounds, and classic "peritoneal" signs offers little difficulty, but this classic presentation of the acute surgical abdomen is relatively uncommon.

The abdominal examination begins with the observation of the patient's position and breathing. This often neglected aspect of the clinical examination can yield vital information. One should be able to answer the following questions: Is the patient in respiratory distress? Is the abdomen distended? Does the abdomen move with respiration? Is there voluntary or involuntary guarding? Is there visible peristalsis? Is there evidence of an abnormal vascular pattern? Are the legs kept flexed? Is the patient icteric?

Auscultation of the abdomen for the presence or absence of bowel sounds is useful for diagnosing obstruction and perforation, but localization of bowel sounds to a specific quadrant of the abdomen is not. The presence of systolic rushes temporally associated with the patient's colicky pain can help in the diagnosis of early intestinal obstruction. The physician must listen for several minutes before truly saying that the bowel sounds are absent. In general, the statement that the patient has diminished or hyperactive bowel sounds has no intrinsic meaning except as an indication that bowel sounds are present.

In a patient with a distended abdomen and absent bowel sounds, "peritoneal irritation" becomes the major diagnostic entity; next, carry out light percussion of the abdomen to define areas of tenderness. Also, in a patient suspected of having ruptured a viscus, it is helpful to percuss the right upper quadrant for liver dullness, because liver dullness may be absent with free intraabdominal air. A false-positive sign can be seen, however, when a distended hepatic flexure overlies the liver. If peritoneal irritation is not suspected, percussion can be limited to the evaluation for hepatomegaly and splenomegaly, and for tympany in the case of bowel obstruction and distention.

Then proceed directly with light palpation for organomegaly, tenderness, and masses. If the patient has minimal discomfort with light palpation, the pressure should be gradually increased until the pressure itself becomes slightly uncomfortable. The examiner should attempt to localize the discomfort further by having the patient grade each sector of the abdomen. The presence of referred tenderness is an important sign of localized peritoneal irritation. In appendicitis, deep palpation in the left

lower quadrant can cause discomfort referred to McBurney's point (Rovsing's sign).

Next, examine the patient for inguinal, umbilical, femoral, and ventral hernias. The umbilical, inguinal, and femoral rings should be defined and explored. In all older patients, a bimanual examination of the epigastrium for an aortic aneurysm is mandatory. The pelvic and rectal examinations, including heme testing of stool, are then performed.

An intraabdominal source of discomfort must be differentiated from pain originating in the abdominal wall from such diverse conditions as a rectus muscle hematoma, a segmental neuropathy, or an internal hernia within the abdominal wall. This differentiation is facilitated by having a patient perform either a sit-up or a leg lift (Carnett's test). Deep palpation of the abdomen is performed while the patient is maintaining the maneuver. If the process is in the abdominal wall, the discomfort of palpation is increased, but with pain originating within the abdomen the discomfort is decreased. Once a full examination is performed, it is essential to remember that serial examinations of the abdomen are often the most helpful adjunct to the diagnosis and treatment of abdominal pain.

MAJOR EMERGENCY ENTITIES

Several abdominal conditions require immediate or urgent surgical intervention. Perforated viscus, ruptured abdominal aortic aneurysm, acute appendicitis, ischemic bowel, and strangulated hernia are included in this group. Identification of entities that mandate such emergent surgical care is imperative, and delays in diagnosis may prove costly. In addition, some conditions (e.g., small bowel obstruction and acute pancreatitis), although they may not necessarily require surgery, must be identified expeditiously so that hospitalization and appropriate supportive care can prevent morbidity and allow treatment of comorbid conditions.

About 50% of patients who present to an emergency department with abdominal pain cannot be diagnosed on the initial visit. Most of these patients have a minor, self-limiting illness for which a specific diagnosis is not possible or even necessary. Some patients, however, have a subacute presentation of a serious surgical or medical illness, and these patients must not be lost to follow-up. Having the same physician who established the initial baseline data follow the patient ensures that subtle changes will be readily detected.

If the patient is to be followed by a consultant, this person must see the patient in the emergency department before discharge or immediately after discharge. Follow-up should be as often as every 12 hours if the patient is not improving. If follow-up cannot be arranged or if patient compliance is an issue, the patient should be admitted to the hospital.

Because of the difficulty in evaluating these patients and the large number of possible diagnostic entities and pitfalls to diagnosis, an approach has evolved that casts a wide safety net and, it is hoped, minimizes the potential for serious errors or delays in diagnosis. In several situations, however, there is a high potential for serious errors in diagnosis and management. Patients in the "coronary-prone years" with upper abdominal pain must have an immediate electrocardiogram and cardiopulmonary examination in a manner completely analogous to the approach to patients who present with chest pain (see [Chapter 1](#)). The patient who presents with a leaking abdominal aortic aneurysm is often misdiagnosed on initial evaluation. To prevent this serious lapse in diagnosis, all older patients should have a bimanual examination for an upper abdominal expansile mass. In addition, all older patients presenting with an initial episode of "renal colic," usually with left flank as well as upper abdominal pain, should have an immediate emergency study to rule out a leaking aortic aneurysm.

The relative frequency of ectopic pregnancy requires that all premenopausal patients have a thorough evaluation for this condition. Patients with ruptured ectopic pregnancies can present with shock, shoulder pain, diffuse abdominal pain, and right upper quadrant pain, as well as with the typically localized lower quadrant pain.

DIAGNOSTIC APPROACH

Initial evaluation of any patient with abdominal pain must include a thorough history, a physical, and baseline laboratory studies. The most important issues in the history are the pain pattern and associated signs and symptoms. The diagnosis is evident in approximately one half of patients after this part of the evaluation is complete.

Most of the diagnostic tests available to the emergency physician that help to support acute evaluations are neither sensitive nor specific enough to play a significant role in the evaluation process. However, exceptions to this rule (such as the finding of free intraperitoneal air on the abdominal film) do exist. All diagnostic studies must be used judiciously in conjunction with a full history and physical exam. An initial evaluation plan should include a complete blood count, keeping in mind that a normal white blood cell count should not dissuade you from ordering a further workup; an increased white count will increase your suspicion for serious pathology.

All patients need a urinalysis, and all premenopausal women with abdominal pain should have a pregnancy test. Most patients require measurement of glucose, electrolyte, blood urea nitrogen, and creatinine levels to help guide fluid and electrolyte repletion, to provide a baseline for those who will receive intravenous medications or contrast media, and to assist in the diagnosis of metabolic disturbances that can present with abdominal pain. Determination of the serum lipase level is useful when pancreatitis is considered in the differential diagnosis. A lipase level is a more sensitive and specific test to obtain for suspicion of pancreatitis than an amylase level, as amylase can be produced by several organs and may be elevated in alcoholic patients without pancreatitis.

Serum transaminases, bilirubin, alkaline phosphatase, and a prothrombin time are helpful laboratory tests in patients with a tender right upper quadrant when the differential includes hepatitis as well as cholecystitis. Other specialized testing and imaging techniques of the abdomen, such as ultrasonography, CT scanning, and radionuclide scanning of the biliary tree, may be extraordinarily helpful in selected cases.

Plain films of the abdomen are useful in cases in which one is looking for free air in the abdomen and in patients in whom intestinal obstruction is a major consideration. The finding of appendicolithiasis, said to be diagnostic of appendicitis, is uncommon in adults, and its absence should not influence the decision-making process.

More than 90% of renal calculi are radiopaque; therefore, an abdominal film, in combination with ultrasonography, is helpful when considering the diagnosis of renal colic. An intravenous pyelogram or helical noncontrast CT should be obtained to confirm the diagnosis. Helical CT offers the added benefit of viewing other organ systems and is very helpful in evaluating the presence of an abdominal aortic aneurysm (AAA) and appendicitis.

Ultrasound has emerged as a useful bedside adjunct in the emergency department. Right upper quadrant scans will help in the diagnosis of gallstones and acute cholecystitis. Abdominal aortic aneurysms may be identifiable by ultrasound. Ultrasound remains the invaluable test of choice for rapid identification of ectopic pregnancies. Used in conjunction with KUB plain films, ultrasound can also be helpful in the evaluation of renal colic.

Helical CT scans are useful in the diagnosis of renal colic, appendicitis, diverticulitis, abdominal abscesses, and AAA. These exams may be performed with or without contrast, depending on the diagnosis in question and the patient's renal function. While the helical CT is a very useful tool, the emergency physician must remember not to send an unstable patient out of the department for this evaluation unless appropriate monitoring can be maintained.

Approximately 50% of patients will not have a definitive diagnosis made on their first visit. Patients in this group are usually not sick enough to require hospitalization and are followed as outpatients. After discharge, the problem remits spontaneously in most patients; a few (8% to 10%) continue to have pain and require further evaluation. In this group, a diagnosis is made on the basis of findings on diagnostic studies and reexamination. The choice of which imaging techniques to use is made on an individual basis: They include CT scanning, biliary imaging, intravenous urography, and upper and lower gastrointestinal series. At this point, peptic ulcer disease may be definitely diagnosed, and unsuspected pancreatic or biliary tract disease uncovered. Here, too, an occasional patient with inflammatory bowel disease has this diagnosis made based on radiographic or endoscopic findings. For persistent abdominal pain of unknown origin, diagnostic laparoscopy may prove to be useful.

The elderly patient who presents with abdominal complaints can become a diagnostic dilemma. Such patients may have intraabdominal free air or free pus within the abdomen, with few objective findings until late in their course. A "sluggish" leukocyte and febrile response to infection in the elderly may compound this diagnostic challenge. Elderly patients with ill-defined abdominal pain should also be evaluated for an ischemic bowel syndrome. The initial presentation of ischemic bowel is often that of midabdominal pain associated with nausea and vomiting and minimal objective findings. Metabolic acidosis is a characteristic early concomitant. If there is evidence of metabolic acidosis, an ileus pattern is present on the abdominal film, and no other diagnosis is probable, then immediate surgical consultation is

mandatory. Early angiographic and surgical intervention should reduce the very high mortality of this condition.

Some patients initially diagnosed as having gastroenteritis return with the classic findings of acute appendicitis or small bowel obstruction. A patient with gastroenteritis must have gastritis, manifested by vomiting, and enteritis, manifested by diarrhea. If the diagnosis of gastroenteritis is made without evidence of both upper and lower gastrointestinal involvement, the diagnostic accuracy is questionable, and major surgical conditions can be overlooked.

Once a definitive diagnosis has been made, few would argue against administering a potent analgesic agent to the patient with severe abdominal pain. The dogma that the "premature" administration of an analgesic agent may alter the abdominal examination and delay the diagnostic process is clearly incorrect. Several studies have shown that analgesia actually may help evaluation and diagnosis by decreasing patient anxiety, thus allowing a more accurate physical examination. Of course, if one is following a patient sequentially, the administration of analgesics requires that a new baseline be established for purposes of comparison. Exercise caution when discharging any patient with undiagnosed abdominal pain who has received narcotics for pain control.

COMMON PITFALLS

- Formulating a definitive diagnosis can be extremely difficult, for the aforementioned reasons. In addition, the difficulty in diagnosing more occult processes often results in a delay in diagnosis. Indeed, it is far better to follow these patients without a diagnostic label while workup is being pursued than to mislabel them initially. Once a patient is given a diagnostic label, extraordinary efforts and circumstances may be required before the erroneous label is reconsidered.

Cough is a common symptom faced by emergency department physicians. Often, the history and physical examination provide a diagnosis, effective treatment is recommended, and the patient is discharged home. In other situations, cough may herald a serious underlying condition, and hospital admission is required.

Cough is a protective mechanism. Along with the mucociliary elevator, cough acts to clear secretions and foreign material from the respiratory tree. Physiologically, the act of coughing is a reflex, initiated by stimulation of cough receptors. Receptors lie predominantly within the proximal portions of the pulmonary tree: the larynx, trachea, and larger bronchi. Smaller populations reside within the terminal bronchioles, as well as in the pharynx, sinuses, pleura, pericardium, and diaphragm. Receptors are activated by various factors: excess mucus production, environmental irritants (cigarette smoke, noxious gases, dust, allergens), aspiration, inflammation (secondary to microbial invasion), or thermal factors (hot or cold air). Cough receptors can also be mechanically stimulated by pressure or extrinsic tension exerted by tumor, adenopathy, or aortic aneurysm. Stimulation of cough receptors gives rise to afferents that are conveyed centrally by the vagus, glossopharyngeal, trigeminal, and phrenic nerves. A discrete central cough center has not been demonstrated.

The typical cough consists of an initial deep inspiratory phase. This is followed by glottic closure, contraction of the thoracic and abdominal expiratory muscles, and an increase in the intrapulmonary pressures. The sudden opening of the glottis provides for the explosive expiration of air at high velocities, with subsequent clearance of secretions and foreign particles. These high velocities vibrate the vocal cords, secretions, tracheobronchial walls, and adjacent lung parenchyma, creating the characteristic sound of a cough.³

CLINICAL PRESENTATION

A cough productive of purulent sputum is generally a reliable indication of infection within the respiratory tract. Infections involving the most proximal portion include sinusitis, pharyngitis, rhinitis, and the common cold. Although these infections are usually associated with a productive cough, initially the cough may be nonproductive. More distal infections include bronchitis, pneumonia, and abscess. With viral etiologies, the sputum is usually clear or mucoid; purulent sputum suggests bacterial involvement.

A predominantly nonproductive cough is usually seen with the inhalation of environmental irritants and nonrespiratory sources of cough. These include masses that exert extrinsic pressure on the trachea and bronchi, such as an aneurysm, tumor, foreign body, and adenopathy. Less common etiologies of cough include irritation of the diaphragm, pleura, or pericardium.

DIFFERENTIAL DIAGNOSIS

Cough and its character are not diagnostic. It is the association of cough with other signs and symptoms that is usually suggestive of the underlying pathology.

Urgent Causes

Chest pain (not associated with the cough itself) or dyspnea generally accompanies cough when urgent conditions are present. Congestive heart failure, usually of a mild degree, can present with cough as a predominant symptom. A careful history regarding cardiac risk factors, orthopnea, dyspnea, and dyspnea on exertion, along with a careful examination of the lungs and chest x-ray usually clarifies this situation. Pulmonary embolism can also present as cough, but the primary symptoms usually include chest pain (frequently pleuritic) and dyspnea. Another urgent consideration in the patient with cough is foreign body. Choking and stridor are typically present with large foreign bodies in the proximal airway, but cough may be the predominant symptom with a smaller or more distal foreign body.

Acute Causes

Upper Respiratory Tract

The most common etiology for cough in a normal person is a viral upper respiratory tract infection, the common cold. Common symptoms include rhinorrhea and sore throat; fever, chills, sweats, headache, hoarseness, sneezing, postnasal discharge, and constitutional malaise and myalgias may also be seen. Patients in whom severe headache and systemic complaints (myalgias, malaise) predominate are more likely to have influenza. Rhinitis should be considered in patients with significant nasal symptoms. A history of atopy, seasonal exacerbations, itchy and watery eyes, and a profuse thin rhinorrhea suggests an allergic rhinitis. Patients with conjunctival injection along with their cough, pharyngitis, fever, headache, myalgia, and malaise may have pharyngoconjunctival fever, typically caused by adenovirus.

Patients with sinusitis complain of head congestion, fullness, toothache, headache, or facial pain. They may or may not have rhinorrhea or postnasal drainage. Patients with laryngitis typically develop hoarseness and frequently have associated infection, either above or below the vocal cords. Cough secondary to tracheitis or tracheobronchitis is typically associated with substernal burning. Patients who have had a tonsillectomy occasionally develop lingual tonsillitis and complain of dysphagia, odynophagia, and a foreign-body sensation.

Lower Respiratory Tract

Acute bronchitis is a common cause of cough (or change in chronic cough) in emergency department patients. Sputum production is a hallmark of bronchitis. Hemoptysis can be caused by vigorous coughing in bronchitis, but it also raises the suspicion of pneumonia, pulmonary embolism, tumor, bronchiectasis, or tuberculosis. Productive sputum is also suggestive of pneumonia. Pain is not an unusual symptom in pneumonia, and not uncommonly precipitates the emergency department visit. In patients with pneumonia, the clinical appearance varies widely. Pneumococcal pneumonia, classically characterized by rust-colored sputum, presents with fever and shaking chills; the patient appears ill. Mycoplasmal pneumonia, on the other hand, is typically associated with low-grade fever, scanty mucus production, hacking cough, headache, and minimal systemic symptoms; affected patients may wait a week before seeking a medical evaluation. Aspiration pneumonia should be suspected in elderly or obtunded patients. Purulent and putrid sputum suggests an anaerobic infection such as a lung abscess. Sputum that is thick, tenacious, excessive, and difficult to expectorate is seen in bronchiectasis. These patients have a history of poorly treated and recurrent infections, resulting in impaired bronchial clearance and chronic colonization of the airways by microorganisms.

Cough is a symptom that all asthmatics experience as a consequence of their disease. Other symptoms of asthma, which can occur singly or in combination, are chest tightness, wheezing, and dyspnea. Patients with asthmatic bronchitis lack a history of asthma, but present with cough and bronchospasm. These patients, because they are unfamiliar with wheezing, frequently describe their chest as having "congestion." *Cardiac asthma* refers to those patients whose congestive heart

failure precipitates bronchospasm.

A wide variety of parenchymal pulmonary infections may manifest cough symptoms. Symptoms of tuberculosis include hemoptysis, weight loss, weakness, and fever. Specific fungal infections are associated with specific geographic regions. Coccidioidomycosis is common in the Southwest, and histoplasmosis in the Ohio and Mississippi River valleys. *Pneumocystis carinii*, *Mycobacterium tuberculosis*, and *Mycobacterium avium* complex are associated with decreased host resistance from chemotherapy and other forms of immunosuppression, and with underlying HIV infection.

Chronic Causes

Acute illnesses such as the common cold seldom last longer than 3 weeks. Patients who present with symptoms of longer duration should be considered to have chronic cough. Chronic bronchitis is the most common cause of chronic cough. By definition, chronic bronchitis requires a chronic productive cough for 3 months in each of 2 consecutive years.² The cough is typically worse on arising in the morning. Superimposed acute infection changes sputum color and quantity. Although tumor can produce a cough, bronchogenic carcinoma is not a common cause of chronic cough. Primary bronchogenic cancer should be suspected in smokers with a change in their cough, persistent hoarseness, clubbing, weight loss, evidence of metastatic disease, or the triad of chest pain, cough, and hemoptysis.

In patients who do not smoke and who have a normal chest x-ray, postnasal drainage is the most frequent cause of chronic cough. This postnasal drainage is usually secondary to sinusitis and rhinitis. The cough is short, frequent, and worse at night or when the patient is supine. Allergic etiologies are associated with seasonal exacerbations. Asthma, in addition to causing acute cough, is another common cause of chronic cough. Cough and wheezing occurs in all asthmatics; however, dry cough without wheezing is the sole symptom of cough-variant asthma. Patients with cough-variant asthma, like classic asthmatics, demonstrate airway hyperresponsiveness with pulmonary function testing.⁷ Gastroesophageal reflux disease is also capable of causing a chronic cough as an isolated symptom. Less common etiologies of cough include mediastinal masses such as tumor (thymoma, thyroid cancer, teratoma, neurofibroma, Hodgkin disease, metastatic malignancy) and granulomatous disease (tuberculosis, sarcoid).

Some patients complain of a persistent cough following a respiratory tract infection. This has been described as postinfectious cough, and is attributed to airway inflammation with or without transient airway hyperresponsiveness.⁵ The diagnosis is one of exclusion. Pertussis patients initially develop a nonspecific upper respiratory tract infection; as the upper respiratory tract symptoms wane, severe coughing paroxysms develop. Adult pertussis patients, unlike children, lack the characteristic inspiratory whoop at the end of a coughing paroxysm. Cough is an adverse side effect of all angiotensin converting enzyme inhibitors, including captopril (Capoten), lisinopril (Zestril, Prinivil), enalapril (Vasotec), fosinopril (Monopril), quinapril (Accupril), ramipril (Altace), moexipril (Univasc), trandolapril (Mavik), and benazepril (Lotensin).⁶

EMERGENCY DEPARTMENT EVALUATION

History

The most common cause of cough is a viral upper respiratory tract infection, the common cold. The cough is secondary to secretions from the nasopharynx stimulating cough receptors in the hypopharynx and larynx. Therefore, patients should be carefully questioned if the cough represents a throat-clearing maneuver, if they note a sensation of a throat tickle or secretions draining from the back of the nose into the throat, and if there is nasal congestion or discharge. The cough may last 2 to 3 weeks. A cough lasting longer than 3 weeks is unlikely to be an acute viral upper respiratory tract infection, except with back-to-back infections.

Patients with a cough lasting longer than 3 weeks have chronic cough. Chronic bronchitis is the most common etiology. Chronic bronchitis patients invariably have a long history of smoking and usually note a productive cough on awakening. Postnasal drainage, in addition to being the most common cause of an acute cough, is also the most common etiology of chronic cough in patients without chronic bronchitis. Bronchospasm should be suspected in those patients whose cough follows exposure to cold air, strong odors, smoke, or exercise. Gastroesophageal reflux disease is suggested in patients with heartburn, a sour taste in the mouth, and persistent regurgitation. Pertussis should be suspected in patients who present with severe paroxysms of cough following an upper respiratory tract infection.

Sputum production is indicative of a microbial infection within the respiratory tract. A predominantly nonproductive cough should lead the emergency physician to consider etiologies other than infection. Angiotensin converting enzyme inhibitors are capable of causing a troublesome cough in 6% to 14% of patients taking any of the antihypertensives from this class.⁶ Patients with malignancy may have pulmonary metastasis, because the lung is the most common metastatic site.

Physical Examination

A general body habitus demonstrating cachexia and weight loss suggests chronic and potentially life threatening conditions. Abnormal vital signs, such as elevated temperature, tachypnea, abnormal pulse oximetry, and tachycardia, should heighten the suspicion for significant underlying pathology.

With upper respiratory tract infection, the nasopharynx may be swollen and erythematous, with secretions. The oropharynx may have a cobblestone appearance, and drainage or mucus may be seen adherent to the posterior pharyngeal wall. Tonsillar exudates may be seen in pharyngitis. In patients at risk for immunocompromise, the oropharynx should be inspected for candidiasis. Sinusitis presents with sinus tenderness; rhinorrhea may or may not be present. One should palpate the neck for adenopathy secondary to metastasis or infection.

Inspection of the lungs can ascertain an expanded anteroposterior diameter in patients with chronic bronchitis. With an acute exacerbation of chronic bronchitis, retractions (subcostal, intercostal, suprasternal, and supraclavicular) may be noted. Auscultation determines the presence of bronchospasm from any cause, such as asthma, acute or chronic bronchitis, congestive heart failure, pneumonia, or pulmonary embolism. Patients with localized rales may have early consolidation and inflammation from pneumonia; alternatively, the rales may be secondary to proximal obstruction by foreign body, tumor, or adenopathy. Pleural rub is associated with pulmonary embolism, lobar pneumonia, pulmonary infarction, and pleuritis. Breath sounds diminish when any process obstructs sound transmission from the patient's airways to the listener's ears. This finding is due most commonly to pneumonia and pleural effusion. Dullness to percussion clinically confirms this diagnosis. The patient should be examined for adenopathy if there is suspected malignancy, immunocompromise, or HIV infection.

Laboratory and Radiographic Evaluation

The laboratory and radiographic evaluation is dependent on the suspected underlying pathology as well as host factors. A chest x-ray is indicated for those patients with chronic cough, risk factors, significant underlying morbidity, and an abnormal physical examination, and for those with abnormal pulse oximetry. Comparison of current x-ray films with old films may help to make a new diagnosis or measure progression of disease. Pneumonias present not only with frank infiltrates, but also with interstitial patterns and pleural effusions. In the immunocompromised, *Pneumocystis carinii* pneumonia should be suspected in the setting of hypoxia and a normal or near-normal chest x-ray.

Cardiac asthma should be considered in patients with cardiomegaly and increased vascular markings. Aspiration pneumonia is usually seen in the dependent areas of the lung, reflecting the patient's position at the time of the aspiration. Tumor and abscess can also be found. A primary tumor may be subtle, with metastatic disease in the mediastinum more prominent radiographically. Other findings in patients with tumor include atelectasis and pleural effusions. Metastases to the lung parenchyma tend to be multiple and bilateral.

In patients with a change in a chronic cough, a chest x-ray should be obtained in order to eliminate the possibility of a mediastinal tumor or adenopathy. Bronchogenic carcinoma is very unlikely when the chest x-ray is normal. Adenopathy may compress or deviate the trachea and mainstem bronchi. Bilateral hilar adenopathy, frequently out of proportion to a patient's symptoms, may be seen in sarcoidosis. Cavities, with air-fluid levels can be secondary to bacteria, fungi, and tuberculosis. The lung apex is the usual site of tuberculosis. Rib fractures (particularly at the lateral portion of the rib), pneumothorax, and pneumomediastinum are occasionally seen with severe paroxysms of coughing.

Patients without significant underlying illness who present with cough and involvement limited to the upper respiratory tract generally do not require further evaluation beyond the history and physical examination, provided that their vital signs (including pulse oximetry) are normal. On occasion sinus films or soft-tissue neck films are obtained. Sinus films may demonstrate air-fluid levels, and mucosal thickening of the maxillary sinuses may be appreciated in patients with chronic sinusitis. Sinus

films may be normal, however, in patients with sinusitis.

Neck films using a soft-tissue technique are helpful when evaluating patients for lingual tonsillitis and epiglottitis. Soft-tissue air on neck films can be seen with pneumomediastinum; these patients complain of neck pain after forceful coughing. The effect of the associated Valsalva maneuver may be rupture of a pulmonary bleb, with dissection of air along the bronchial tree to the mediastinum and subsequently into the neck.

The sputum Gram stain and culture and sensitivity studies are essential for appropriate antibiotic selection and management of infectious pneumonias. If the patient is unable to produce sputum spontaneously, a specimen may be induced by the respiratory therapist. Sputum staining for acid-fast bacilli can be diagnostic, and sputum cytology is a low-risk diagnostic test when neoplasm is suspected. Cultures for pertussis should be obtained from the posterior nasopharynx, using nasopharyngeal swabs.

Blood work may be obtained for emergency department patients felt to be potential admissions. Bacterial infections may result in elevation of the white blood cell count with a left shift, but lack of an elevated count does not exclude bacterial infection. The elderly, particularly in the face of an overwhelming infection, may fail to generate a leukocytosis. A viral infection, on the other hand, manifests lymphocytosis with a normal or depressed white blood cell count. A marked leukocytosis with an increase in lymphocytes characterizes pertussis. An elevated eosinophil count may be seen with parasitic infiltration, eosinophilic pneumonia, or allergies. An arterial blood gas is indicated when pulse oximetry is abnormal. If *Legionella* is suspected, a urine for *Legionella* antigen may be collected.

Immunocompromised adults, especially those with AIDS or at risk for AIDS, should receive a chest x-ray and pulse oximetry. A CD4 count should be drawn if none has been done recently; a CD4 lymphocyte count greater than 200/ μ L makes clinically significant opportunistic lung infection unlikely.

EMERGENCY DEPARTMENT MANAGEMENT

The emergency department physician should attempt a reasoned approach to determine the underlying cause, because specific therapy of cough has a high likelihood of success. When urgent conditions are present, cough is usually associated with significant dyspnea and chest pain, and the patient appears ill. In these situations, a brief history can be obtained from the paramedics, family, or patient regarding cardiac and pulmonary disease, medications, and similar events in the past. A physical examination can be carried out quickly regarding the body habitus, neck veins, auscultation of the lungs and heart, and peripheral edema. An i.v., supplemental oxygen, and cardiac monitoring, if not already begun by the paramedics, are established immediately.

In nonurgent situations, the basis for management begins with the history and physical examination. An older patient with productive cough, tachypnea, fever, and mental obtundation deserves a prompt portable chest x-ray. An i.v. is established, supplemental oxygen is begun, and labwork, old charts, and old chest-rays are ordered. For patients found to have pneumonia, antibiotics may be started in the emergency department once sputum has been obtained. If a specimen cannot be obtained or induced within 1 hour, antibiotics are nevertheless started. In the elderly with acute cough, it is especially important to have a high index of suspicion for serious disorders such as congestive heart failure, pulmonary embolism, and aspiration, because the classic signs and symptoms may be absent or minimal.

The management of the older patient who does not appear quite so ill can proceed with the labwork, chest x-ray, and old charts and old chest x-rays being ordered in the routine fashion. Usually, this scenario involves an older patient with a cough and underlying chronic disease, such as lung or heart disease.

For the previously healthy patient who does not appear ill, and whose vital signs (including pulse oximetry) are unremarkable, evaluation is frequently limited to the history and physical examination. Asthmatics are treated in the usual fashion, with inhaled beta-2-agonists and steroids. Patients felt to have asthmatic bronchitis or cough-variant asthma should have a chest x-ray and usually benefit from inhaled beta-2-agonists. Pre- and posttreatment peak expiratory flows are helpful to monitor their response to treatment.

DISPOSITION

Hospital admission to a general medical bed is usually warranted in those patients with hypoxemia and lower tract diseases such as pneumonia, asthma, chronic bronchitis, abscess, and tumor. A cardiac monitor may or may not be required if the patient has heart disease. Hospital admission is also indicated if i.v. medications such as antibiotics are necessary. The final criterion for hospital (or observation unit) admission is the appearance of critical illness. These are generally older patients who are vulnerable to bacteremia, sepsis, complications from their medications, and worsening of their clinical condition. Their chest x-rays may appear normal initially, but after i.v. hydration, pneumonia becomes apparent on subsequent films.

Consultation with a specialist is indicated for those patients with serious and significant exacerbations of their underlying disease, such as chronic bronchitis. Consultants also may be utilized for patients with less common etiologies of cough, such as lung abscess and tuberculosis, so that appropriate antibiotics, antituberculous agents, and isolation procedures can be promptly initiated. Patients without hypoxemia suspected of having *Pneumocystis carini* pneumonia may be discharged, provided that arrangements have been made for outpatient continued diagnostic workup and provided that the patient can be followed closely for progression of disease and toxicity.

If transfer to another hospital is necessary, patients may be transferred, provided their conditions have been evaluated and they are stable. Ground transport should have oxygen, i.v., and cardiac monitoring capabilities when appropriate. For patients transferred with conditions such as pneumonia, the first dose of antibiotics should be started in the emergency department prior to transport.

Patients with acute cough felt to have a cold and viral upper respiratory tract infection may be reassured and discharged. Antitussives shown to be effective toward postnasal drainage include the antihistamine–decongestant combinations, dexbrompheniramine maleate/pseudoephedrine sulfate (Drixoral Cold & Allergy) 6 mg/120 mg b.i.d. and azatadine maleate/pseudoephedrine sulfate (Trinalin Repetabs) 1 mg/120 mg b.i.d.⁵ Sedation is the primary side effect. Initiating therapy once a day at bedtime for several days prior to b.i.d. therapy may be helpful. Some improvement in cough is usually seen in several days to 2 weeks after the initiation of therapy.

Acute sinusitis patients with postnasal drainage also benefit from these same antihistamine–decongestant combinations, along with antibiotics and nasal decongestants such as 0.05% oxymetazoline hydrochloride (Afrin, Dristan) b.i.d. for 2 to 3 days. Safe and effective treatment of allergic rhinitis includes intranasal corticosteroids such as Flonase (fluticasone), 50-mg spray b.i.d., and second-generation nonsedating antihistamines such as fexofenadine (Allegra), 60 mg b.i.d., or loratadine (Claritin), 10 mg q.d. Optionally, a nasal spray such as 0.05% oxymetazoline hydrochloride may be used b.i.d., but for no more than 3 to 5 days. Its continued use for more than 5 to 7 days may result in rhinitis medicamentosa.⁸ Outpatient allergy testing may be useful in patients who have allergic rhinitis, a seasonal component to a cough, or a cough associated with specific allergens, such as pollen or animal dander.

Patients with bronchitis or pneumonia (and normal pulse oximetry) may be discharged with appropriate prescriptions and instructions regarding follow-up with their personal physician. Older patients with the potential for worsening of their clinical condition should see their physicians in 2 to 3 days. Ipratropium bromide (Atrovent), administered q.i.d. via a metered-dose inhaler and spacer device or via nebulization, and smoking cessation are effective antitussives in chronic bronchitis. Cough-variant asthma patients may be discharged after instruction on the use of an albuterol metered-dose inhaler administered via a spacer device, two puffs q.i.d. Daily inhaled antiinflammatories, such as cromolyn (Intal) q.i.d. or corticosteroids (Vanceryl) b.i.d. are usually beneficial. A short course of oral corticosteroids may be necessary for refractory cases.⁷

For cough induced by angiotensin converting enzyme inhibitor, switching to another angiotensin converting enzyme inhibitor or decreasing the dose is usually not beneficial. Angiotensin II receptor antagonists such as losartan (Cozaar) or valsartan (Diovan) may be used as an alternative, or a different class of hypertensive agent can be prescribed.^{1,6} Resolution of angiotensin converting enzyme inhibitor cough usually occurs within 4 weeks after discontinuing the drug.⁶ Patients felt to have postinfectious cough do not require specific treatment; the cough is self-limited and resolves spontaneously.

In patients without a history of chronic bronchitis, whose chest x-rays are normal, and who do not take angiotensin converting enzyme inhibitors, chronic cough is almost always secondary to postnasal drainage, asthma, or gastroesophageal reflux disease.⁴ Effective treatment of postnasal drainage includes dexbrompheniramine maleate/pseudoephedrine sulfate, 6 mg/120 mg b.i.d., or azatadine maleate/pseudoephedrine sulfate, 1 mg/120 mg b.i.d. If the postnasal drainage is secondary to a chronic sinusitis, then antibiotics and a nasal decongestant such as 0.05% oxymetazoline hydrochloride are given in addition to the antihistamine–decongestant combination. The nasal decongestant is recommended b.i.d. for 5 days, the antihistamine–decongestant b.i.d. for a minimum of 3 weeks. Asthmatics are treated in the usual fashion, with beta-2-agonist aerosols delivered by hand-held metered-dose inhalers and a spacer device, or administered by a

nebulizer. Steroids, either inhaled or oral, are also indicated. For patients felt to have chronic cough secondary to gastroesophageal reflux disease, antireflux measures and acid suppression with H₂ antagonists, proton pump inhibitors, or prokinetic drugs are indicated.

Nonspecific antitussives may be prescribed when the underlying etiology of cough is unknown, or when the definitive therapy has not had a chance to work. Antitussives shown to be effective include codeine, 30 to 60 mg PO q.d. or 20 mg PO b.i.d.; dextromethorphan, 10 to 20 mg q.i.d. for 10 days or 20 mg b.i.d. for 3 days; and the combination dexbrompheniramine maleate/pseudoephedrine sulfate, 6 mg/120 mg b.i.d. ⁵

COMMON PITFALLS

- The most common etiology of cough in emergency department patients is a viral upper respiratory tract infection, the common cold.
- In patients with cough secondary to postnasal drainage, the combination of a first-generation antihistamine and a decongestant is more effective than the newer non-sedating antihistamines, probably because the newer agents lack the anticholinergic properties of the older first-generation antihistamines.
- Patients who complain of chest congestion should be examined carefully for wheezing.
- Chronic cough (i.e., lasting longer than 3 weeks) is seen most frequently in chronic bronchitis.
- All angiotensin converting enzyme inhibitors are capable of causing a chronic cough.
- In patients without chronic bronchitis and a normal chest x-ray (and who do not take angiotensin converting enzyme inhibitors), the three most common causes of chronic cough are postnasal drainage, asthma, and gastroesophageal reflux disease.

Dyspnea refers to difficult, labored, or uncomfortable breathing. Dyspnea is a symptom of many disorders that involve alterations or abnormalities in gas exchange, pulmonary circulation, respiratory mechanics, O₂-carrying capacity of the blood, or cardiovascular function. Dyspnea results when ventilatory demand exceeds respiratory function. A mismatch between supply and demand of oxygen and failure of CO₂ elimination is at the basis of dyspnea.

A person with normal breathing capacity may require a large increase in ventilatory demand before dyspnea is produced. On the other hand, in a person with a preexisting diminished respiratory capacity, a small increase in ventilatory demand may produce significant shortness of breath (SOB). Because the perception of dyspnea is also mediated by psychological and cultural factors,² it may be helpful to assess breathing difficulty in terms of diminished ability to perform specific daily functions, such as housework or climbing stairs.

The pathophysiology of dyspnea is complex. However, an understanding of the basic principles behind respiration is necessary to understand the cause and treatment of dyspnea in a given disorder. Chemoreceptors in the blood and brain, as well as mechanoreceptors in the airways, lungs, and chest wall, are involved in the automatic regulation of the level and pattern of breathing.² The carotid and aortic bodies and central chemoreceptors in the medulla sense changes in the partial pressure of oxygen (PO₂), partial pressure of carbon dioxide (PCO₂), and pH of the blood and transmit signals back to brainstem respiratory centers that adjust breathing. These receptors cause changes in the rate of ventilation¹² to maintain blood–gas and acid–base homeostasis.² In most individuals, the most profound stimulus to the central nervous system respiratory control center is normally the arterial carbon dioxide tension (PCO₂). An increase in PCO₂ of 1.5 mm Hg from the normal level of 40 mm Hg may produce a doubling of ventilation. Arterial oxygen tension and pH are other factors that significantly influence ventilation. In the patient with chronic obstructive pulmonary disease (COPD) and hypercarbia, the arterial oxygen tension may be the most influential factor affecting respiratory drive.

Afferent impulses from vagal receptors in the airways and lungs also exert important influences on the level and pattern of breathing. Feedback of afferent information from lung and chest wall mechanoreceptors provides respiratory motor and premotor neurons with important information regarding the mechanical status of the ventilatory pump, as well as changes in length and force of contraction of the respiratory muscles.² Elastic resistance of the lung to stretch, airway flow resistance, and tissue friction must be overcome for breathing to proceed. Elastic resistance is the most significant of these factors at normal respiratory rates. At rates faster than 15 breaths per minute, airway resistance becomes more important.

Listed in [Table 4.1](#) are the most frequently encountered causes and the most common etiologies of acute dyspnea seen in the emergency department (ED). Dyspnea may result from respiratory, cardiovascular, hematologic, neuromuscular, metabolic, or psychogenic derangement. Most commonly, cardiovascular and respiratory disorders are the cause, with the degree of derangement proportional to the resultant dyspnea.

UPPER AIRWAY OBSTRUCTION	NEUROMUSCULAR
Angioedema	Guillain-Barre syndrome
Epi-glottitis	Myasthenia gravis
Foreign body	METABOLIC/SYSTEMIC
CARDIOVASCULAR	Anaphylaxis
Congestive heart failure	Anemia
Pulmonary edema	Hyperthyroidism
Cardiac tamponade	Septic
Acute coronary ischemia	Acidosis
Cardiac dysrhythmias	Salicylate intoxication
Pulmonary embolism	Obesity
PULMONARY	PSYCHOGENIC
Aspiration	Hyperventilation syndrome
Asthma	
COPD exacerbation	
Pneumonia	
Pneumothorax	
Pleural effusions	
Adult respiratory distress syndrome	
Toxic inhalation	

TABLE 4.1. Causes of Acute Dyspnea

CLINICAL PRESENTATION

Patients presenting to the ED with dyspnea often complain of SOB. Depending on their level of distress and any preexisting respiratory problems, they may appear comfortable or may exhibit varying degrees of distress. Once the initial examination assures that the airway is patent and oxygenation adequate, a thorough history must be obtained.

Pertinent questions in the history can provide valuable information and diagnostic clues to the cause of dyspnea. The duration of dyspnea; associated chest pain or palpitations; precipitating factors such as exertion, exercise, or anxiety; associated paresthesias of the mouth and fingers; the number of pillows the patient uses to sleep; concomitant coughing or sputum production; exercise tolerance; tobacco use; recreational drug use; and occupational history are several important factors that can help narrow the differential diagnosis.¹² Trepopnea, the presence of dyspnea in one lateral position but not the other, may be the result of unilateral lung disease, unilateral pleural effusion, or, occasionally, chronic obstructive pulmonary disease (COPD). Paroxysmal nocturnal dyspnea, breathlessness that occurs while sleeping, is usually associated with left ventricular failure. Orthopnea, or the presence of dyspnea in the recumbent position, is also associated with left ventricular failure, but can be associated with COPD.

Although, in most patients, dyspnea may be readily apparent to the examiner, certain populations are not able to relay a history of shortness of breath. The very young, the very old, and those with diminished mental capacity may present only with tachypnea¹¹ or an altered level of consciousness. In these patients, it is important to keep respiratory difficulty in the differential diagnosis. On physical examination, the patient's vital signs, mental status, assumed position, use of accessory muscles, conjunctival and mucous membrane color, skin and nailbed color, upper airway examination, neurologic examination, and cardiovascular and pulmonary examinations may give valuable clues to the etiology. Problems with oxygenation may be easily revealed by pulse oximetry, and difficulty with CO₂ elimination may be revealed by arterial blood gas determination in the patient who is unable to relay an adequate history.

DIFFERENTIAL DIAGNOSIS

Upper Airway Obstruction

Obstruction of the upper airway may be the consequence of a diverse group of entities, including foreign-body aspiration, epiglottitis, croup, angioedema, peritonsillar or retropharyngeal abscess, or neuromuscular dysfunction. The nature of the presenting picture depends on the site and degree of the obstruction, as well as the underlying cause. Cough, stridor, dyspnea, aphonia, or hoarseness may be present. Although many of these conditions do not usually cause complete airway obstruction, rapid deterioration is possible in these patients, and the emergency physician must be ready to provide immediate airway intervention.

Epiglottitis is an important cause of respiratory distress due to upper airway obstruction, although it is seen significantly less frequently with the use of HiB vaccine. The incidence is greatest in children 2 to 4 years old. The onset is characteristically abrupt, with a mild upper respiratory infection progressing within hours to high fever, lethargy, and difficulty in swallowing oral secretions. Respiratory distress and stridor are the most consistent signs. Restlessness, anxiety, and tachycardia are also often present.

In adults, the presentation of epiglottitis is typically less dramatic, and dyspnea may be minimal or absent. Fever and sore throat are the most common complaints. Consequently, the diagnosis is often delayed in adults.

Congestive Heart Failure

Congestive heart failure (CHF) is a clinical condition that develops when cardiac output becomes insufficient to meet systemic metabolic demands.¹ Acute failure of the left ventricle to eject a normal quantity of blood may cause fluid to accumulate in the pulmonary interstitium, alveoli, and bronchioles, thereby producing pulmonary edema. In addition to interfering with gas exchange, transudation of fluid into the perialveolar spaces reduces pulmonary compliance. Acute precipitating factors of CHF include increased Na intake, noncompliance with CHF medications, acute myocardial infarction (MI), arrhythmia, or anemia. The most common causes of CHF are coronary artery disease and hypertension,¹ although valvular heart disease, cardiomyopathy, and renal failure are other common entities.

The patient with dyspnea of cardiac origin generally presents to the ED with complaints of dyspnea on exertion that is relieved by rest. Other pertinent information obtained on history includes the presence of orthopnea, paroxysmal nocturnal dyspnea (PND) relieved by standing or walking, peripheral edema, and fatigue.

The physical examination may reveal jugular venous distention (JVD), rales, diminished breath sounds, cardiac gallop, cardiac arrhythmias, peripheral edema, hepatomegaly, and ascites.¹ Pulmonary edema may also lead to bronchospasm and cardiac wheezing, so-called cardiac asthma. Chest radiography may reveal cardiomegaly, pulmonary vascular redistribution, Kerley B lines, pleural effusion, and peribronchial cuffing. An uncommon but quickly fatal cardiac cause of dyspnea is ventricular septal rupture post-MI. Although rare, prompt diagnosis is crucial if potential life-saving measures, such as surgery, are to be employed.¹⁷

Chronic Obstructive Pulmonary Disease

The American Thoracic Society defines *COPD* as a disease state characterized by the presence of airflow obstruction due to chronic bronchitis or emphysema.³ The airflow obstruction is often continuous and progressive and, in contrast to asthma, dyspnea is usually always present. *Chronic bronchitis* is defined as the presence of a chronic, productive cough for 3 months in each of 2 successive years in which other causes of chronic cough have been eliminated.³ *Emphysema* is defined as abnormal permanent enlargement of the air spaces distal to the terminal bronchioles, accompanied by destruction of bronchiolar walls but without obvious fibrosis.³ Although COPD is a chronic disorder, exacerbations of diminished respiratory function often bring patients to the ED.

COPD exacerbations are usually caused by a worsening of airflow obstruction due to increased bronchospasm, increased sputum production from superimposed respiratory infection, environmental irritants (such as tobacco smoke), or cardiovascular deterioration. The patient may present with progressive dyspnea, increased sputum production, and audible wheezing. Hypoxemia, tachypnea, cyanosis, and agitation may be seen. Signs of hypercarbia, such as confusion, stupor, inadequate respiratory effort, or apnea, may be seen and indicate severe compromise with impaired gas exchange.³ These patients attempt to improve ventilation by sitting forward, using pursed-lip exhalation, and using accessory muscles of respiration in order to overcome the increase in airflow resistance that accompanies bronchoconstriction and dynamic airway collapse.¹⁰ Auscultation may reveal a combination of diminished breath sounds, a prolonged expiratory phase, wheezes, or rales. The chest radiograph may reveal an increased anterior-posterior diameter, flattened diaphragms, hyperinflated lungs, attenuation of the peripheral lung markings, and, in cases of superimposed infection, an infiltrate.

Asthma

Asthma is a chronic inflammatory disease, clinically characterized by recurrent episodes of wheezing, chest tightness and discomfort, dyspnea, and cough. Exacerbation is characterized by an early phase, which chiefly consists of bronchospasm, edema, and obstruction; and a late phase, which is caused primarily by the inflammatory response. Numerous triggers may cause an exacerbation. Among them are respiratory infections, allergens, cold air, exercise, cigarette smoke, emotional stress, outdoor pollutants, and other factors associated with seasonal changes.¹⁵ Viral upper respiratory infections may be the most common cause of acute asthma exacerbations.¹⁵ Duration of symptoms for greater than 24 hours suggests a greater component of inflammation in the absence of any evidence of infection.

Patients with an asthma exacerbation present to the ED with the complaints of SOB, wheezing, cough, and chest tightness.¹⁵ The physical examination may reveal an increased AP diameter of the chest due to air trapping, tachypnea, wheezing, and mild-to-severe respiratory distress. Auscultation may be misleading in the case of severe obstruction; wheezing may be absent, as bronchial airflow is diminished to such an extent that no sound is audible. Chest radiographs may be normal, reveal signs of airway obstruction (such as in COPD), demonstrate a pneumothorax or pneumomediastinum, or, in the case of a precipitating infection, reveal an infiltrate.

It is important to remember that the preeminent contributing factor to death in acute asthma remains the failure to administer appropriate treatment, typically because the patient or physician underestimates the severity of the attack.¹⁵ Therefore, it is important to treat not only based on the patient's symptoms, but also based on clinical parameters and ancillary studies.

Pneumonia

Pneumonia classically presents as an acute febrile illness with cough and purulent sputum production. Dyspnea results from alveolar obstruction secondary to sputum production, bronchiole obstruction due to mucous plugging, increased work of breathing, and hypoxia.

Pneumonia should be suspected in patients with newly acquired lower respiratory symptoms (cough, sputum production, and/or dyspnea), especially if these symptoms are accompanied by fever, altered breath sounds, and rales.⁴ *Streptococcus pneumoniae* remains the most common etiology of community-acquired pneumonia, even in the immunocompromised host.⁴ Patients with atypical pneumonia caused by *Mycoplasma pneumoniae*, *Legionella pneumophila*, and *Chlamydia psittaci* may present with an insidious or subacute onset, moderate fever, and less purulent sputum. Headache, nonproductive cough, myalgias, arthralgias, and malaise may predominate.⁴ Immunosuppressed patients may present with staphylococcal pneumonia or pneumonia caused by opportunists such as *Pneumocystis carinii*, mycobacteria, or fungal organisms.

The physical examination in pneumonia may reveal rales, egophony or vocal resonance, increased vocal fremitus, or bronchial breath sounds. A chest radiograph may demonstrate lobar consolidation, as in bacterial pneumonia; patchy infiltrates, suggesting staphylococcal pneumonia, *Haemophilus influenzae*, or gram-negative pneumonia; interstitial infiltrates, suggesting *Mycoplasma*, *Legionella*, or *Pneumocystis*; or cavitary lesions, as in tuberculosis;⁶ or, as seen in up to 30% of *Pneumocystis carinii* pneumonia (PCP), it may be entirely normal.⁴ A sputum Gram stain performed in the ED may also provide valuable clues to the cause of the pneumonia. Early recognition is important, so that appropriate antibiotic treatment may be rendered promptly.

Pneumothorax

Pneumothorax, or air in the pleural cavity, can occur spontaneously or as the result of trauma. Normally, the visceral and parietal pleura are in close apposition, but

when the potential space between the two is occupied by gas, the lung can no longer fully expand. Depending on the amount of air within the pleural space, respiratory compromise results. Spontaneous pneumothorax typically occurs in tall, thin, young males. The cause of the pneumothorax is the rupture of a subpleural bleb, which is usually apical in location. Spontaneous pneumothorax also may be seen in patients with asthma, COPD, and tuberculosis, and in AIDS patients with PCP. Traumatic pneumothorax results from blunt or penetrating injury to the chest. Hemothorax, pulmonary contusion, and bronchial rupture⁹ may accompany the pneumothorax.

Patients may present to the ED in obvious respiratory distress or may complain of dyspnea and chest pain. Auscultation may reveal unilateral diminution of the breath sounds associated with increased tympany on percussion. Signs of imminent cardiovascular collapse, such as hypotension, mediastinal shift, and the aforementioned findings, may herald a tension pneumothorax, which should be promptly relieved prior to any further examination or diagnostic studies. Subcutaneous emphysema also may be present. Chest radiography may reveal an obvious pneumothorax or may be more subtle. In the supine patient, the only sign of a pneumothorax may be an abnormally prominent costophrenic angle on the AP or PA view. A spontaneous pneumomediastinum also may present as dyspnea or chest pain. Although uncommon, this entity should be suspected in the setting of cocaine freebasing or inhalational drug use.¹³

Pulmonary Embolism

Pulmonary embolism (PE) is an obstruction of the pulmonary artery or one of its branches by an embolus, usually a blood clot derived from the leg or pelvic veins. The diagnosis of PE is often subtle and may be difficult. Despite attempts to identify a reliable, cost-effective, and readily available test to use in the noninvasive diagnosis of PE, significant inadequacies of both sensitivity and specificity have hindered all such efforts to date.⁸

The most common symptom in a patient with PE is dyspnea. Chest pain and cough are also not infrequent complaints.¹⁶ Frequent signs of PE include tachypnea and tachycardia. Although embolism may present as pulmonary infarction, with the acute onset of pleuritic pain, hemoptysis, and an audible pleural friction rub, such a presentation is uncommon. PE may also mimic other entities. Associated fever and cough may suggest pneumonia, while associated rib tenderness or pleuritic chest pain may suggest a musculoskeletal etiology.

Clinical suspicion plays a key role in the decision to pursue an evaluation for acute PE.¹⁶ Patients at high risk include those who have had a previous PE or DVT, a recent surgery, or a recent immobilization; those with a malignancy or cardiopulmonary disease; those with lower extremity or pelvic trauma; and women during pregnancy or in the postpartum period.¹⁶ Laboratory analysis should include an arterial blood gas, which may reflect hypoxemia and/or hypocarbia. The arterial–alveolar oxygen gradient is classically increased and, in combination with blood–gas analysis, may contribute to the formulation of a higher clinical suspicion.⁸ A ventilation–perfusion scan, spiral computed tomography scan, and pulmonary angiogram, used in conjunction with the clinical pretest probability and duplex Doppler evaluation of the lower extremities, will help the physician determine the likelihood of the presence of PE and the necessity of anticoagulation and admission.

Psychogenic Hyperventilation

Dyspnea can also occur as a somatic manifestation of psychiatric disorders, such as anxiety disorder, with resultant hyperventilation.¹² Patients with hyperventilation syndrome are often seen in the ED. Tachypnea and anxiety are the predominant findings. The patient may complain of paresthesias around the mouth and the fingers. Carpopedal spasm also may be present. The patient may give a history of obtaining relief of dyspnea with exertion, which is not a typical feature of organic disorders producing difficulty breathing. The presence of respiratory alkalosis without hypoxemia on arterial blood–gas analysis is characteristic, as is a normal arterial–alveolar oxygen gradient. Given that a number of important processes produce respiratory alkalosis (e.g., salicylate, intoxication, PE, and anemia), psychogenic hyperventilation should be a diagnosis of exclusion.

EMERGENCY DEPARTMENT EVALUATION

The most important initial treatment in the evaluation of dyspnea is to secure the airway and assure oxygenation and circulation. In cases of obvious severe distress, this may mean endotracheal intubation and mechanical ventilation, whereas mild-to-moderate distress may warrant only the use of oxygen initially. Once the ABCs have been addressed, the physician should perform a rapid, complete history and physical examination, as the cause of the dyspnea may be readily identified.¹²

It is important to remember that many of the common diseases that produce dyspnea share many physical findings. Intermittent adventitious sounds (crackles or rales) are heard in a variety of illness, such as COPD, CHF, and pulmonary fibrosis, and are not specific for any one disease entity. Continuous adventitious sounds (wheezes) may also be produced by a variety of illnesses (Table 4.2), and are almost always a sign of airflow obstruction. Stridor (a loud and harsh-sounding wheeze with a crowing or musical sound of fixed pitch) can be heard, predominantly during inspiration, when the trachea, bronchus, or larynx is obstructed. The presence of other signs and symptoms, such as fever and purulent sputum production in pneumonia, or JVD and gallop rhythm in CHF, significantly supplement the auscultatory findings in establishing the diagnosis in a dyspneic patient.

Pulse oximetry is an easy, noninvasive monitoring technique that allows continuous, reliable measurements of oxygen saturation while avoiding repeated arterial punctures.¹⁴ Every person that presents to the ED complaining of dyspnea should have his or her oxygen saturation recorded. Use of the pulse oximeter does have several limitations, however. First, because of the shape of the oxyhemoglobin dissociation curve, measurement of oxygen saturation is relatively insensitive in detecting changes in PaO₂ at high levels of oxygenation. In patients receiving supplemental oxygen, for example, a substantial drop in PaO₂ may be unaccompanied by any change in saturation. In addition, the curve has a steep downward slope normally commencing at a saturation of 91% corresponding to a PaO₂ of 60 mm Hg, and even relatively modest desaturation below this level represents a significant decline in PaO₂.¹⁴ The curve may also shift due to changes in body temperature and pH. Pulse oximetry may be inaccurate in reflecting oxygen saturation in the presence of high carboxyhemoglobin levels, methemoglobinemia, severe anemia, and low-perfusion states. Finally, pulse oximetry does not relay any information regarding PCO₂.

Measurement of arterial blood gases may be necessary in evaluating patients who present with dyspnea. Blood gases demonstrate the severity of gas exchange impairment and are useful as diagnostic tools, as well as for establishing a baseline for monitoring therapy. In disease states such as COPD and asthma, measurement of the carbon dioxide level and degree of acidosis can provide valuable information about the severity of the exacerbation and may be more helpful than oxygen saturation at guiding treatment. The physician should use discretion, however, when obtaining blood gases. In cases of mild dyspnea due to asthma or COPD exacerbation, a normal oxygen saturation on room air pulse oximetry, and other noninvasive diagnostic studies, such as spirometry (FEV1 or FVC), may be adequate.

If a blood gas is obtained, the A-a oxygen gradient may be calculated. The most common formula used for calculation is as follows:

$$A-a = [150 - (1.2 \times PCO_2)] - \text{arterial } PO_2$$

This formula is accurate at sea level, where the alveolar partial pressure of oxygen is 150 mm Hg. The normal gradient should be around 10 in a young person and may increase to no more than 20 as a person ages. A quick way to calculate a patient's normal A-a gradient is to add one-tenth of the patient's age plus 10. Patients in whom hypoxemia is caused by alveolar hypoventilation alone, such as those with drug overdose or neuromuscular disease, have a normal A-a gradient. On the other hand, in hypoxemia produced by ventilation-perfusion mismatch, right-to-left shunting, and diffusion barrier, such as typically occur in COPD, parenchymal lung disease, PE, and pneumonia, the A-a gradient is increased.

The chest radiograph is a valuable diagnostic tool in elucidating the cause of dyspnea and should be obtained in most cases. Diagnostic radiographic findings can be expected in certain entities, such as pneumonia, PE, and pneumothorax. However, the chest radiograph may be entirely normal, even when significant illness is manifested by dyspnea, such as with PE.

Chest radiographic findings may also be minimal in certain conditions, such as aspiration or toxic inhalation, when the study is obtained as part of the initial evaluation. Also, the presence of radiographic abnormalities does not necessarily imply that a given illness is producing the current episode of dyspnea. For example, the radiograph of the patient with COPD manifests various abnormalities, but a given episode of dyspnea may be unrelated to the chronic findings displayed on the radiograph. In addition, the presence of chronic radiographic changes in such instances may render the appearance of acute disease processes, such as CHF or pneumonia, less apparent.

Special views of the chest may be in order in certain circumstances. An expiratory view may accentuate the presence of a small pneumothorax, because the constant volume of the intrapleural air is accentuated by the reduced size of the hemithorax on expiration. The lateral decubitus view may confirm the presence of a pleural effusion. Inspiratory-expiratory, or positional, films may indicate a bronchial foreign body. Other radiographic studies, such as a lateral view of the neck in suspected epiglottitis, also may be in order.

Measurement of the pulsus paradoxus may prove helpful to the physician in detecting certain causes of dyspnea, such as pericardial tamponade or pediatric asthma.⁵ The paradoxical pulse is obtained by inflating a blood pressure cuff above the systolic pressure, then slowly deflating it until the first systolic sound is heard during expiration. After noting this pressure, the cuff is further deflated until systolic sounds are heard throughout the respiratory cycle. The difference of pressure is normally 4 to 5 mm Hg, and pulsus paradoxus is present when the value is greater than 10. This test is accurate in identifying patients with moderate-to-severe asthma.

Peak flow meters are inexpensive instruments that provide a rapid bedside measure of airway function,¹⁵ and may provide additional useful information during the management of asthmatic patients. With proper instruction on use and good patient cooperation, the physician can make a rapid and objective assessment of the patient's condition and can also use sequential peak flow measurements as an additional measure of the effectiveness of therapy. Knowledge of the patient's baseline peak flow is the best guide to therapy.¹⁵

Other diagnostic studies may be helpful when evaluating a patient with dyspnea. An ECG can show abnormalities of heart rate and rhythm, or evidence of ischemia, injury, or infarction.¹² An ECG also may be helpful in evaluating patients with a suspected pulmonary embolus, although suggestive changes are present in only a minority of patients. Anemia is an important cause of dyspnea,⁷ and a check of the patient's hemoglobin or hematocrit may be useful as part of the workup. Rarely, bedside laryngoscopy or bronchoscopy may provide a definitive diagnosis, especially in the case of upper airway obstruction or suspected foreign body.

EMERGENCY DEPARTMENT MANAGEMENT

Management of the dyspneic patient in the ED depends on the patient's baseline respiratory status, the cause of the current respiratory decline, and the degree of respiratory distress. The goal of the treatment of dyspnea is to correct the underlying disorder causing the symptoms. Unfortunately, in many patients, treatment of the underlying cause is ineffective or only partly effective, and dyspnea persists.¹⁰ (Specific therapies can be found in the chapters devoted to each of the differential diagnoses.)

Every patient who complains of SOB should have pulse oximetry performed and, at least initially, be provided with supplemental oxygen. If the clinical condition warrants mechanical ventilation, the physician must be prepared to intubate promptly and should have all necessary material at the patient's bedside. The history and physical examination will suggest the choice of other appropriate diagnostic studies; that is, suspected pneumonia will require the performance of a chest radiograph and sputum Gram stain and culture, or a patient with a history of chest pain will need to have an ECG performed to help evaluate the likelihood of significant ischemic heart disease. Once a preliminary diagnosis is made, treatment should be appropriately tailored to alleviate the patient's SOB. A patient with COPD or asthma exacerbation may benefit from inhaled beta-adrenergic agents and intravenous or oral steroids.^{3,15} A patient in CHF may benefit from nitrates and diuretics.¹ Many of the disorders producing dyspnea share similar ED interventions, although the underlying pathologies may be different.

DISPOSITION

The disposition of the dyspneic patient depends on the cause of the respiratory difficulty, the severity of the respiratory compromise, and the success of the ED treatment. Any patient with continuing dyspnea, despite treatment, should be admitted for further evaluation. Depending on the clinical condition and diagnosis, the patient may need observation in the general ward, on telemetry, or in the intensive care unit. The patient may be safely discharged home if he or she has improvement in or resolution of SOB and an appropriate diagnosis, such as mild asthma exacerbation, has been made. When considering discharge in dyspneic patients, it is important to assure that they are back to their baseline respiratory status, will be able to obtain the medications prescribed, are capable of caring for themselves at home, and will have adequate, prompt follow-up care.

COMMON PITFALLS

- Do not rely on pulse oximetry alone to gauge a patient's respiratory status; it gives no information about pCO₂.
- If a tension pneumothorax is suspected, do not wait for radiographic confirmation before decompressing the pleural space.
- The chest radiograph may be totally normal in PE.
- Do not withhold oxygen for fear of blunting the hypoxic respiratory drive in a patient with COPD; correct the hypoxia first.
- Absence of wheezing in a patient with asthma or COPD in respiratory distress indicate severely obstructed airways.

ACKNOWLEDGMENT

The authors gratefully acknowledge the contribution of George Sternbach, who wrote the previous version of this chapter.

Humanity has but three great enemies: fever, famine, and war; of these, by far the greatest, by far the most terrible, is fever.
Sir William Osler

Fever is one of the oldest and most widely recognized signs of disease and accounts for approximately 6% of adult and 20% to 30% of pediatric visits to the emergency department. While the exact temperature that constitutes a fever is debatable, most consider a rectal temperature of 38°C in children and a temperature of 38.3°C in adults to represent a fever. Although fever has been recognized as a pathologic sign for at least 2500 years, and despite Sir William Osler's acclamation, it is still unclear whether fever represents the physician's ally or foe.

Regulation of body temperature is under the control of the preoptic area of the anterior hypothalamus. This area acts like a thermostat, continuously balancing heat production and heat loss. It constantly receives input from central receptors, which monitor the temperature of blood perfusing the brain, and peripheral receptors, which monitor skin temperature.

Heat production is controlled in several ways. The basal metabolic rate is under the direct control of the hypothalamus and can be varied, depending on the demand for heat production. The basal metabolic rate may be altered by varying the level of circulating thyroxine, which increases cellular metabolism. In addition, the fastest and most sensitive way in which the body increases heat production is by increasing muscle activity (shivering when cold, or the shaking chill of a fever).

The principal method of body heat loss is to vary the volume of blood flowing to the skin's surface. Blood flow to the fingertips can vary more than 100-fold over different environmental temperatures. The exocrine sweat glands can also contribute to heat loss. Sweating cools the body by vaporization (conversion of a liquid to a vapor). After acclimatization to a hot environment, up to 4 L of sweat can be produced each hour.

The hypothalamic thermostat has an inherent set-point of about 37°C. The normal circadian rhythm exhibits daily variations of up to 2°C. Temperatures are lowest around 4 a.m. and then gradually increase until they peak between 6 and 10 p.m. The reason for this circadian rhythm is unclear, but, unlike other circadian rhythms, such as cortisol secretion, it is not reversed in shift workers who are awake at night and sleep during the day. Most fevers follow this pattern, being higher in the evening and lower in the morning.

Elevation of the hypothalamic set-point appears to be mediated by cytokines. Exogenous pyrogens such as microorganisms, as well as toxins and metabolic byproducts of these organisms, act to stimulate the release of cytokines from lymphocytes, monocytes, and macrophages. While the detailed mechanism by which cytokines produce fever is not clear, it is believed that they travel via the bloodstream to the hypothalamus, where they act to increase prostaglandin synthesis, primarily prostaglandin E2 (PGE2). The resulting increase in prostaglandins causes an elevated cyclic adenosine monophosphate (cAMP) level, resulting in an elevated hypothalamic set-point. This elevated set-point increases body temperature by affecting peripheral vasoconstriction and internal heat production. Fever is maintained until pyrogen levels fall or until prostaglandin production is inhibited. Aspirin, ibuprofen, and acetaminophen exert their antipyretic effects by blocking central hypothalamic prostaglandin synthesis, without any effect on circulating endogenous pyrogen. Corticosteroids can block the release of endogenous pyrogen as well as inhibit prostaglandins, but are nevertheless relatively weak antipyretics.

Cytokines produced in response to pyrogens include interleukins (ILs), tumor necrosis factor (TNF), and interferons (IFNs). Because of the complex interaction between cytokines, the exact role each plays in the production of fever is difficult to establish. Different pyrogens appear to induce different cytokines. It is generally believed that bacteria and their products of metabolism typically provoke release of IL-1. However, an intravenous injection of lipopolysaccharide (a compound used to model systemic bacterial infections) induces a large rise in IL-6 while minimally increasing IL-1 and TNF.³ In contrast, viral proteins appear to stimulate IFN. In addition to elevating temperature, IL-1 induces the liver to produce acute phase reactants, including C-reactive protein (CRP), which are responsible for the elevated erythrocyte sedimentation rate (ESR) associated with some fevers. IFN, although a potent pyrogen, does not enhance production of acute-phase reactants. Although not supported by data, this is the rationale behind the expectation of an elevated ESR and CRP level with a bacterial fever but not with one of viral etiology.

Other physiologic parameters that affect body temperature are exercise, the menstrual cycle, and the environmental temperature. Strenuous exercise can significantly elevate temperature. During a race, marathon runners may have temperatures as high as 41°C. There is a rapid fall to normal, usually over 30 minutes, after cessation of activity. At ovulation, there is a 0.5°C increase in temperature that persists until just before the next menses. In a group of normal volunteers, elevation of the room temperature from 20°C to 30°C resulted in an increase in rectal temperature from 36.7°C to 37.3°C.

Not all elevations of body temperature necessarily constitute a fever. A true fever is an elevation of body temperature caused by a change in the hypothalamic set-point. This new elevated set-point causes the body to engage its normal heat-generating mechanisms to elevate the temperature until the new set-point is reached. In contrast, in hyperthermia a true fever does not exist; rather, the body attempts to maintain a normal temperature, but its homeostatic mechanisms are overwhelmed. Some causes of hyperthermia include heat exhaustion or heat stroke, vigorous exercise, hyperthyroidism, hypothalamic stroke or tumor, burns, malignant hyperthermia, and the use of amphetamines, phenothiazines, or anticholinergic drugs. In adults, temperatures greater than 41.5°C almost always represent hyperthermia and not a true fever. Additionally, in middle-aged to elderly patients who present with what appears to be a septic syndrome, chronic salicylate intoxication should be considered. Fever above 38°C, an elevated white blood cell count with an associated bandemia, decreased systemic vascular resistance, and evidence of multisystem organ failure all have been documented in cases of chronic salicylate intoxication. A careful inquiry into a history of a chronic inflammatory condition or chronic use of one of the myriad salicylate-based antiinflammatory agents (e.g., aspirin, Pepto-Bismol, salsalate, oil of wintergreen) is important in avoiding the significant morbidity and mortality associated with this condition.

The phenomenon of night sweats represents a nocturnal fluctuation in the hypothalamic set-point, causing a slight rise in body temperature that leads to reactive perspiration. Night sweats are most commonly related to tuberculosis or lymphoma, but are also seen in elderly patients with disorders of catecholamine excess and in solid malignancies. Gobbi and colleagues evaluated temperature fluctuations in patients with Hodgkin disease who complained of night sweats and found that their body temperature rose 0.5°C to 1.5°C within 30 minutes before sweating began. The temperature fluctuations were not enough to awaken the patients, but the discomfort related to the sweating was.⁷

Many metabolic abnormalities are associated with the febrile state. There is a 7% increase in the basal metabolic rate for each 0.55°C increase in temperature. Fever

alone can cause significant proteinuria as well as achlorhydria, both of which resolve when the fever resolves. Fever increases both the oxygen tension (PO_2) and the carbon dioxide tension (PCO_2), and shifts the oxyhemoglobin dissociation curve to the right, resulting in lower oxygen saturation. Fever also seems to lower the seizure threshold, causing febrile seizures in children without a predisposition to epilepsy. Fever also can cause reactivation of latent herpes simplex infections (fever blisters).

The value of fever to the host remains a subject of debate, but evidence suggests that fever may have a significant protective effect. Neutrophils and lymphocytes are most active at elevated temperatures. In addition, higher temperatures decrease the level of serum iron, a substrate that many bacteria need in order to replicate. When iron levels are experimentally kept in the normal range, increased mortality is noted for a given inoculum of bacteria. Fever also seems to inhibit certain viruses, such as coxsackievirus and poliovirus. Experimental evidence on poikilotherms also suggests the benefit of fever. Lizards and goldfish exhibit a higher mortality when kept in a cooler environment and infected with bacteria. Both seek a warmer environment after infection, and those allowed to do so demonstrate significantly greater survival. The only two human infections in which elevation of temperature is of proven value are neurosyphilis and disseminated gonorrhea. Interestingly, neither of these diseases is associated with a significant natural fever.

There is, however, some evidence that argues against a protective effect of fever. Mice infected with tetanus spores or streptococci had decreased survival with an elevation of temperature. Mice and possibly humans are more susceptible to pneumococcal infections when febrile.

CLINICAL PRESENTATION

Most febrile patients present to the emergency department with a chief complaint of fever. However, some patients may present with more generalized complaints. Elderly patients may complain of general malaise or not feeling well; parents may bring in infants who are eating poorly or appear lethargic. In these patients, fever may be an incidental finding.

In children, fevers documented at home should be treated as real, even in the absence of a documented fever in the emergency department. Additionally, in children with subjective fevers, one study showed that mothers have an overall accuracy of 79%, with positive and negative predictive values of 68% and 88%, respectively.⁸ Further, bundling of infants has been shown to have no effect on the rectal temperature of healthy infants, so elevated rectal temperatures should not be attributed to bundling.⁹

DIFFERENTIAL DIAGNOSIS

Infection

Infection is the most common cause of fever. Infection may originate in any portion of the body and lead to a febrile response. Much of the emergency physician's time is spent ascertaining the source of the fever and attempting to differentiate a viral from a bacterial etiology.

Drug Fever

While any drug can cause a febrile reaction, penicillin and penicillin analogues are the most frequent causative agents. The fever typically begins 7 to 10 days after the patient starts taking the drug, and there is an associated rash in 18% of cases and eosinophilia in 22% of cases. Drugs that are commonly associated with a drug fever are listed in [Table 5.1](#). Drug fever is always a diagnosis of exclusion.

ANTIBIOTICS
Carbapenems
Penicillins
Streptogramins
Tetracyclines
Trimethoprim-sulfamethoxazole

Clonidine
Insulin

TABLE 5.1. Drugs Commonly Associated with Drug Fevers

Neoplastic Diseases

While many different malignancies and tumors may produce fever, leukemia, Hodgkin disease and non-Hodgkin lymphoma, hepatoma, and atrial myxoma are the most common. Because the underlying disease or its treatment often leaves the patient immunosuppressed, however, it is important to eliminate occult infection as the etiology of the fever.

Central Nervous System Lesions

Structural lesions, head trauma, and strokes can cause elevated temperature either by direct destruction of the hypothalamic thermoregulatory center (hypothermia is more likely) or, more commonly, by blood irritating of the central receptors in the preoptic area.

Rheumatologic and Connective Tissue Disorders

Fever may be the only initial manifestation of many connective tissue and rheumatologic disorders. In systemic lupus erythematosus (SLE), fever is the initial symptom in 5% of the cases. In older patients, temporal arteritis may present as recurrent fevers with no identifiable source.

Drug Ingestion

Drugs associated with elevated temperature include cocaine, amphetamines, belladonna alkaloids, tricyclic antidepressants, and monoamine oxidase inhibitors. As discussed previously, older patients with chronic salicylate poisoning are also prone to fever.

Pulmonary Embolus

Approximately two-thirds of patients with a pulmonary embolus will exhibit a fever. While the majority of these fevers are low grade, temperatures may exceed 39.5°C in up to 10% of the cases.

Factitious Fever

Factitious or self-induced fever should be suspected if the history is suspicious, if other vital signs do not correlate with the degree of fever, or if the patient does not appear ill. Patients may have an underlying psychiatric disorder, such as a personality disorder or psychosis, or there may be an issue of secondary gain (e.g., work avoidance). Factitious fever is most common in females. Many are health care professionals or have a medical background. The easiest way to detect a factitious fever is to simultaneously measure temperatures at two or more body sites (e.g., oral and rectal), or measure the temperature of a freshly voided urine sample, which

should reflect the true core temperature.

EMERGENCY DEPARTMENT EVALUATION

At presentation, it is important to obtain an accurate temperature measurement. Unfortunately, this measurement is commonly overlooked for the sake of convenience. Recorded temperatures may vary widely depending on the method used to obtain them. Rectal temperatures have long been the gold standard, but because of the invasiveness and relative difficulty of obtaining them, easier methods, such as oral, axillary, and tympanic temperatures, are often employed. Multiple studies have shown that none of these alternative methods consistently provides a temperature comparable to the rectal temperature. In addition, there appears to be no standard correction factor that may be used to improve their accuracy.

The rectal temperature, which most accurately reflects the core temperature, tends to be, on average, 0.7°C higher than a simultaneously obtained oral temperature. Oral temperatures can, in fact, vary more than 1.6°C, depending on where the probe is positioned in the mouth. In addition, the respiratory rate also influences oral temperatures. Tandberg and Sklar¹⁷ found that the oral temperature decreased by almost 0.5°C for each increase of 10 in the respiratory rate. Kresovich-Wendler and associates¹⁵ evaluated several characteristics in patients who were found to be afebrile on oral temperature measurement (mean temperature, 37.4°C) but febrile on rectal temperature measurement (mean temperature, 39.2°C). The two variables that most accurately predicted a wide disparity between the two measurements were a heart rate above 115 beats per minute and the presence of mouth breathing.¹⁵

While axillary temperatures are generally felt to be approximately 1°C lower than rectal temperatures, they have repeatedly been shown to be unreliable and miss many patients with significant fevers. In a large study² of over 1100 pediatric patients, there was a greater discrepancy between axillary and rectal temperatures shortly after the onset of fever (1.04°C) than 2 hours after a temperature elevation (0.53°C). In addition, this study showed there was no reliable correction factor that would allow conversion of axillary to rectal temperatures.²

The latest innovation for obtaining temperatures is the tympanic thermometer. Although this method is frequently employed because it is noninvasive and rapid, numerous studies in both adults and children have shown that temperatures obtained tympanically are a poor reflection of the rectal temperature. In one study of pediatric patients less than 6 years old, the correlation between rectal and tympanic temperatures was best ($r = 0.83$) in afebrile patients (T less than 100.5°F) and significantly worse ($r = 0.61$) in febrile patients.¹³ Like oral and axillary temperatures, no single correction factor will allow conversion of tympanic to rectal temperatures. The discrepancy in this study was present despite the use of the rectal equivalency setting on the tympanic thermometer.

A patient with a low-grade fever may suffer from an acute, life-threatening condition, while another with a much higher temperature may have a benign viral infection. The source of the fever may be readily apparent, or it may remain undiagnosed after weeks of sophisticated evaluation. While pediatric patients often require a more extensive evaluation, history and physical alone can identify the etiology of a fever in the majority of adults.

History

Important points in the history include

1. Associated symptoms (e.g., vomiting, dysuria, cough, shortness of breath, joint pain, rashes)
2. Duration and magnitude of fever
3. Close contacts with similar illness
4. Occupational, travel, or recreational exposure
5. History of diseases associated with immunocompromise (e.g., HIV), diabetes, chronic renal failure, blood dyscrasia, alcohol or drug abuse, chronic lung disease, or cardiac valve disease
6. Presence of medical hardware (e.g., prosthetic valves)
7. History of recent hospitalizations, which might suggest nosocomial infections
8. Current medications, particularly antibiotics and antipyretics, and duration of use
9. Allergies

Physical Examination

The most important observation on the physical examination is the general overall appearance and mental status of the patient. Specifically, does the patient look well or toxic? Does the patient have an altered mental status, which might indicate infection or sepsis, especially in the elderly? Vital signs should be obtained, including pulse oximetry in selected patients with respiratory signs or symptoms. In the presence of a fever, the pulse can be expected to increase by 10 beats per minute for each 0.55°C increase in temperature. Some diseases are associated with a relative bradycardia for the degree of fever (pulse-temperature dissociation). This association is classically seen with typhoid fever, but it can be seen in legionnaire disease, mycoplasmal infections, drug fever, factitious fever, and some viral syndromes. In addition, patients taking beta-blockers may have no change in their pulse in response to a fever. The earliest sign of septic shock is an inappropriately elevated pulse. Tachypnea and dyspnea are suggestive of pulmonary disease, while tachypnea without dyspnea may indicate sepsis or metabolic acidosis of any cause. The history will frequently direct the physician to the most likely source of the infection. In the absence of localizing symptoms, a thorough examination should be undertaken. The entire body should be examined for rashes, skin breakdown or decubiti, cellulitis, "track marks," or lymphadenopathy. Rashes may suggest a viral exanthem, vasculitis, meningococemia, Rocky Mountain spotted fever, Lyme disease, or toxic shock syndrome (staphylococcal or streptococcal). Lymphadenopathy associated with fever may suggest malignancy, autoimmune disorders, or infection. Tender, localized adenopathy is usually associated with an infection in the region drained by the involved nodes. The most common cause of acute generalized adenopathy is infectious mononucleosis. Nodes secondary to malignancy are usually painless, rubbery, and firm.

The head and neck should be examined for scleral icterus, which might indicate hepatitis or cholecystitis. Examination in and around the ears may reveal otitis externa or media, or suggest mastoiditis. The oropharynx may show evidence of pharyngitis, peritonsillar or retropharyngeal abscess, or periodontal infection. Sore throat, drooling, and fever may suggest epiglottitis in children or adults. While children should be examined in the operating room, the adult epiglottitis may be visualized by direct or indirect laryngoscopy in the ED.

The chest should be examined for indications of a pulmonary or cardiac cause of fever. Localized rales or rhonchi suggest pneumonia. As x-ray findings frequently lag behind physical findings, an early pneumonia may not be visible on x-ray. A pericardial rub is indicative of pericarditis, and a new heart murmur should suggest endocarditis, especially in intravenous (i.v.) drug users. However, functional murmurs may increase due to fever-induced tachycardia.

The abdomen should be examined for signs of peritoneal irritation or ascites. Localized pain may suggest cholecystitis, appendicitis, pancreatitis, or diverticulitis. Suprapubic pain suggests a urinary tract infection. A rectal examination may demonstrate evidence of a perirectal abscess or prostatitis. In patients with a urethral discharge, a detailed sexual history should be obtained. A swollen or painful testicle suggests epididymo-orchitis or torsion. In women, a pelvic examination should be performed to evaluate for sexually transmitted diseases, cervical motion or upper tract tenderness suggestive of pelvic inflammatory disease, or tuboovarian abscesses.

Examination of the musculoskeletal system is often overlooked in febrile patients, but examination of the spine may reveal tenderness suggestive of osteomyelitis, discitis, or epidural abscess (especially in i.v. drug users). A detailed examination of the extremities may demonstrate a septic or inflamed joint, or it may suggest osteomyelitis, myositis, or deep venous thrombosis. In i.v. drug users, skin-popping and track-mark sites should be examined for evidence of cutaneous abscesses, crepitation suggestive of soft-tissue infection, and infected pseudoaneurysms.

Laboratory Evaluation

While no test exists that easily identifies patients with serious infections, a thorough understanding of certain basic laboratory tests can greatly enhance patient evaluation. The white blood cell (WBC) count is the oldest and best-known screening test used to differentiate serious bacterial infections from other disorders. In adults, however, its discriminatory value is not as great as most expect. In a study of febrile adults with unexplained fever after careful physical examination, only 56% of those subsequently shown to have a bacterial source had a WBC count over 15,000/μL. In addition, an elevated WBC count is nonspecific. Neutrophilia can occur secondary to emotional or physical stress, acute or chronic inflammation, benign or malignant tumors, myeloproliferative disorders, asthma, seizures, or medications

such as steroids, lithium, or epinephrine. Neutrophil counts over 30,000/ μ L have been reported secondary to strenuous exercise, seizures, and lithium use.¹⁵ In addition, patients with low WBC counts (less than 1,000/ μ L) are at significant risk for occult bacterial infections.

A "left shift" is only slightly more useful. A total neutrophil band count greater than 1500/ μ L was found in approximately one-third of patients with unexplained fever, of which only half proved to have bacterial infections. Table 5.2 lists the effect of several noninfectious processes on the WBC count. From these data, it is apparent that the WBC count is neither sensitive nor specific for bacterial infection.

Cause	WBC Count	Comment
Burns, fractures, epinephrine injection	Leukocytosis with neutrophilia but no "left shift"	WBC increase immediate; lasts 2-3 h
Corticosteroids, Cushing syndrome	Leukocytosis with neutrophilia, "left shift," eosinopenia	Onset 18 h after oral dose; duration 24 h after last dose
Diabetic ketoacidosis	Leukocytosis with "left shift"	Up to 25,000/ μ L
Addison disease	Lymphocytosis, neutropenia, eosinophilia	

TABLE 5.2. Noninfectious Processes That May Alter WBC Counts

Certain changes in neutrophil morphology are associated with bacterial infections. Toxic granulations are small, dark cytoplasmic inclusions found in 75% of bacteremic patients. They can also be seen in patients with vasculitis and in those who are on chemotherapy. Döhle bodies are round or oval cytoplasmic inclusions seen in 29% of bacteremic patients, as well as in patients with burns, trauma, or neoplasms, or during pregnancy. Cytoplasmic vacuolization has the best correlation with significant bacterial disease. In one study, 91% of patients with more than 10% vacuolization had bacteremia. Cytoplasmic vacuolization has not proved useful in pediatric studies.

Measurement of acute-phase reactants, ESR and CRP, is often used to help recognize patients with serious occult infections. The results can be misleading, as these tests are neither sensitive nor specific. The ESR is often used as a screening test for temporal arteritis, bacterial endocarditis, tuberculosis, osteomyelitis, and occult bacteremia in children.¹¹

A major disadvantage of the ESR is the 1-hour time to complete the test (ESR is the distance, in millimeters, that red blood cells in citrated blood fall in 1 hour). In a recent study of 192 patients,¹¹ no patients with elevated sedimentation rates (greater than 20 mm in males, greater than 30 mm in females) had an ESR less than 5 mm at 30 minutes. Therefore, values less than 5 mm at 30 minutes should allow the physician to conclude that the ESR is normal while waiting only half the normal time of the test.¹¹ When the ESR is elevated, no conclusion can be made prior to the 1-hour time frame.

Several newer tests have been developed to measure the ESR more rapidly (e.g., the zeta sedimentation rate, which determines the ESR in 4 minutes). Unfortunately, these tests require more expensive equipment, and they are not accurate at high ESR values.

CRP, an acute-phase reactant in serum, is more sensitive and specific and rises faster than the ESR, but again it is not particularly useful in the emergency department. While many small studies have indicated that an elevated CRP may be useful in detecting acute intraabdominal infections, a recent metaanalysis of 22 studies using CRP to aid in the diagnosis of appendicitis found a combined sensitivity and specificity of only 62% and 66%, respectively.¹⁶ The individual studies showed a wide range of sensitivities (40% to 99%) and specificities (27% to 90%), believed to be due in part to the wide variation of cut-off values used. With the few exceptions noted previously, both the ESR and CRP are probably best used for following the resolution of a known disease.

There is no consensus on the value of screening for streptococcal pharyngitis in febrile patients with a sore throat. Throat cultures may be falsely positive (in the case of a carrier state) or falsely negative. The sensitivity of commercial rapid streptococcal screens varies between 55% and 96%, with specificities between 50% and 98%. In addition, the rapid screens test only for streptococcal disease and not for other causes of pharyngitis, such as gonococcus, *Chlamydia*, or *Mycoplasma*. Consequently, it is debatable whether cultures or rapid screens should be obtained or whether treatment should be based solely on clinical suspicion (sore throat, fever, lymphadenopathy, lack of other upper respiratory tract symptoms, or recent exposure to group A streptococcus).

An appropriately performed urinalysis demonstrating pyuria and bacteriuria in patients with suprapubic pain, dysuria, frequency, or hesitancy supports a diagnosis of urinary tract infection (UTI). In young adult women, urine cultures are probably not necessary at the time of initial diagnosis. In older women, men, children, and patients with comorbid diseases, and in cases resistant to therapy, urine cultures are recommended. In one study of febrile children less than 1 year old,¹² the frequency of a UTI was approximately 5%, whether or not a UTI was suspected. In this study, the sensitivity of pyuria (greater than 5 WBC/hpf) and bacteriuria on urinalysis for detecting a UTI was 54% and 86%, respectively.¹² In addition, in adults in whom there is a high clinical suspicion but a negative urinalysis, urine cultures should be obtained and initial treatment based on the degree of suspicion. The formation of significant levels of nitrites or leukocytes in the urine occurs over time (up to 6 hours), and individuals with urinary frequency may thus have a falsely negative urinalysis.

Because acute diarrhea is usually self-limited, stool evaluation is rarely helpful or necessary. In the evaluation of chronic diarrhea, traveler's diarrhea, or antibiotic-associated diarrhea, or in cases in which there are a cluster of causes, evaluation for fecal leukocytes is the most useful test. The presence of fecal leukocytes is 82% sensitive and 83% specific for detecting bacterial diarrhea.⁶ Stool should be tested for *Clostridium difficile* toxin if there is a history of recent antibiotic use. The presence of ova or parasites is indicative of a parasitic etiology for diarrhea. In patients with presumed viral or benign disease, stool cultures are probably not necessary in the absence of fecal leukocytes. Cultures are indicated in any patient who appears toxic, has been exposed to other patients with enteritis, or is at risk for unusual pathogens or parasitic diseases. In travelers from malarious areas, malaria should also be considered, as it may present with fever, gastrointestinal (GI) symptoms, and anemia, but without cells in the stool.

Like many laboratory tests, there is no consensus on the value of routine blood cultures in febrile patients. The incidence of bacteremia in the emergency department has been reported to vary from 2.6% to as high as 10.7% of febrile patients. The higher figures generally come from tertiary referral centers, the lower figures from community hospitals. Most community hospitals report approximately equal numbers of gram-positive and gram-negative bacteremia, whereas university centers report a much higher incidence of gram-negative bacteremia. Mortality from bacteremia ranges from 20% to 40%; there are no data, however, on mortality for clinically unsuspected bacteremia.

Several studies have shown that blood culture results rarely alter the treatment of patients with either community-acquired pneumonia (CAP) or nosocomial pneumonias. In one study of 517 patients admitted for CAP, cultures were positive in only 6.6% (34) of patients, and of those the culture results altered therapy in only seven patients (1.4% of the total). Of these seven, six were already on drugs to which the organism was sensitive, and the change was made to a cheaper, narrow-spectrum drug.⁵

Sklar and Rusnak¹⁶ examined the value of outpatient blood cultures in febrile adults discharged from the emergency department. In this study, 5 of 86 patients subsequently proved to have positive blood cultures. All were contacted, and four were subsequently admitted. No long-term morbidity was noted.¹⁶ Of these patients, three were diagnosed with endocarditis and one with pyelonephritis. The fifth patient, who refused to return for admission, had presumed pneumococcal endocarditis. Each of the patients with endocarditis had identifiable risk factors (two with murmur and a history of rheumatic fever, one on dialysis and with a murmur, and one i.v. drug abuser). Other studies have shown that patients with underlying illnesses, most commonly diabetes, are at greater risk for bacteremia, and this study seems to support those findings. Therefore, it might prove prudent to limit outpatient blood cultures to febrile patients who have underlying diseases or risk factors

For inpatients, the current recommendations are to obtain cultures in patients with fever and signs of sepsis (hypotension, tachycardia, fevers, chills), in those with altered mental status, in ill-appearing patients with unexplained leukocytosis, and in immunocompromised patients. In addition, some recommend blood cultures to

identify the causative organism in pneumonia, osteomyelitis, meningitis, or septic arthritis, but in general, it is preferable to obtain cultures directly from the infected site. Cultures are rarely helpful adjuncts in the management of immunocompetent patients with simple infections such as cellulitis, orchitis, dental infections, and most CAPs.

Lumbar puncture to obtain cerebrospinal fluid (CSF) for analysis is recommended in patients with fever, headache, photophobia, and signs of meningeal irritation such as nuchal rigidity or Kernig's or Brudzinski's sign. However, signs of meningeal irritation are frequently absent, especially in the very young or old; one must have a low threshold to perform a lumbar puncture in these patients. The CSF should be routinely analyzed for protein, glucose, Gram stain, and cell count with differential. In selected cases, a VDRL/RPR for syphilis, viral cultures, or tests for bacterial antigens should be added.

Various antigenic tests are available; they have the advantage of identifying a specific organism when positive. Latex agglutination is rapid, economical, and noninvasive. Better results are obtained with urine than with serum or CSF, presumably because the antigens are more concentrated in urine. Unfortunately, these tests historically have had a high specificity (greater than 99%) but a low sensitivity. The sensitivity is best for *Haemophilus influenzae* and group B streptococci (61% and 67%, respectively) and much worse (7%) for *Streptococcus pneumoniae*.¹ Fortunately, children have much less morbidity with pneumococci than with *H. influenzae*. In addition, the importance of detecting *H. influenzae* has diminished with the decline in documented cases as a result of the introduction of the *H. influenzae* vaccine. While there may be a theoretical advantage in identifying the causative organism, one study¹ has shown that, in clinical practice, treatment and disposition decisions are made without utilizing the latex agglutination results. Latex agglutination is less useful in adults because they are at risk for many more pathogens. Commercial reagents are available only for *Streptococcus pneumoniae*, *Neisseria meningitidis*, *H. influenzae*, and group B streptococci.

Enzyme-linked immunosorbent assay (ELISA), an immunologic test, is much more sensitive in detecting pneumococci than is latex agglutination. The ELISA is positive in 76% of cases. Quicker means of identifying organisms grown in blood cultures is also available. DNA probes have been developed that, when mixed with the growth from positive blood culture bottles, directly and rapidly identify *Staphylococcus aureus*, *S. pneumoniae*, *Escherichia coli*, *H. influenzae*, *Enterococcus* sp., and *Streptococcus agalactiae*. This method uses a chemiluminescent probe that detects the rRNA of the target organism.

Radiologic Studies

Routine chest radiographs are commonly obtained in patients who present with fever without an obvious source. This practice is largely based on studies that show lack of auscultatory findings in up to 25% of patients with infiltrates on chest radiographs. Better sensitivity should be obtained, however, when auscultatory findings are correlated with respiratory symptoms such as tachypnea, shortness of breath, or cough. In infants and children, chest radiographs are currently recommended only in patients with fever and signs or symptoms of a lower respiratory tract infection (e.g., rales, rhonchi, wheezing, retractions, tachypnea, stridor, cough). In one study⁴ of 197 febrile infants less than 3 months old, 40 had no respiratory signs or symptoms. Radiographs in these 40 were normal in all but four, and the only abnormality present in these four was hyperinflation.

Signs or symptoms should guide the need for other radiologic studies. Plain films may reveal osteomyelitis in patients with fever and bone pain, but bone scans are more sensitive. Abdominal radiographs may identify free air (bowel perforation), appendicoliths or focal ileus (appendicitis), thumbprinting or gas in the bowel wall (mesenteric ischemia), or pneumobilia or gallstones (cholecystitis). Patients with fever and abdominal pain may benefit from an ultrasound to evaluate for the presence of cholecystitis, pelvic inflammatory disease, or a tuboovarian abscess. Computed tomography scans should be used in selected patients to evaluate for appendicitis, abdominal abscess, or diverticulitis. Magnetic resonance imaging should be considered in i.v. drug abusers with back pain and fever to rule out epidural abscess.

EMERGENCY DEPARTMENT MANAGEMENT

While antipyretics are frequently used in febrile patients who are significantly uncomfortable or tachycardic, their use should always be weighed against any potential benefit of the fever, as well as the inherent toxicity of the medication. In spite of popular belief, the response to antipyretics does not allow the differentiation between serious (e.g., bacterial) and nonserious (e.g., viral) infections. In addition, some practitioners believe there is an unwarranted phobia of fever in children, resulting in knee-jerk administration of antipyretics without first judging the overall appearance of the child (i.e., when febrile, does the child look toxic, or is he or she active and playful?). When a decision is made to use antipyretics and there are no contraindications, adults should receive oral doses of 650 to 1000 mg acetaminophen or 800 mg ibuprofen. Children should receive 15 to 20 mg per kilogram acetaminophen orally or 30 to 40 mg per kilogram rectally. Ibuprofen dosed at 10 mg per kilogram orally may be used in children over 6 months of age. Because of the potential for dehydration in febrile infants less than 6 months old, ibuprofen is not recommended because it may increase the risk of kidney damage.

The choice of antibiotics should, when possible, be based on the type and site of infection. Septic patients should be started on broad-spectrum antibiotics after appropriate specimens for culture are obtained. Suggested antibiotic regimens for the initial treatment of sepsis are listed in [Table 5.3](#). It is probably best not to initiate antibiotics in a febrile patient with an unknown source who appears nontoxic or is not thought to be septic.

Patient	Antibiotic
Neonate (<1 wk old)	Cefotaxime (50 mg/kg i.v. q12h) plus ampicillin (25 mg/kg i.v. q6h)
Neonate (1 wk-2 mo)	Cefotaxime (50 mg/kg i.v. q6h) plus ampicillin (25 mg/kg i.v. q6h)
Infant/child	Cefotaxime (50 mg/kg i.v. q6h) or ceftriaxone (100 mg/kg i.v. q24h)
Adult	Ticarcillin/clavulanic acid (3.1 g i.v. q6h) or piperacillin/tazobactam (3.375 g i.v. q6h) or imipenem (500-1,000 mg i.v. q6h) or meropenem (1 g i.v. q6h)

TABLE 5.3. Suggested Antibiotic Regimens for the Initial Treatment of Septic Patients

DISPOSITION

When considering the disposition of the febrile patient, the single most important consideration is his or her general health. A young person with no medical problems has a very slight chance of developing a serious infection (with the exception of i.v. drug abusers). As the age and presence of underlying medical problems increase, the chance of serious occult infection increases and makes admission advisable. Keating and associates¹⁴ found that 95% of patients who were older than 60 years and had a temperature above 101°F (38.3°C) on admission to the emergency department had a serious infection, with 92.5% requiring admission. Wasserman and colleagues¹⁸ reported that the sensitivity and specificity of fever (37.5°C or greater) as an indicator of bacterial infection in an elderly patient were 50% and 86%, respectively. The sensitivity and specificity of a WBC count above 14,000/μL were 44% and 88%, respectively, and the sensitivity and specificity of a band percentage on the differential of 6% or higher were 32% and 93%, respectively. All patients with fever, elevated WBC, and bandemia meeting the previously described criteria were diagnosed with bacterial infections. Only 6% of the patients with none of the criteria described were diagnosed with bacterial infection.¹⁸

Any patient with unexplained fever and neutropenia or malignancy should be admitted for a full "septic" workup. Patients with diabetes are at special risk, as discussed, as are patients who are taking corticosteroids. Alcoholics are also considered to be immunosuppressed and at increased risk. They have many alterations in their host defenses and may require admission for infections that are often treated on an outpatient basis among other populations.

The postsplenectomy patient is at special risk for developing clinically inapparent bacteremia, usually from *S. pneumoniae*. Such patients often have fever and a flulike syndrome as their only complaints. Even when these patients are promptly diagnosed and started on antibiotics, there is a 50% to 75% mortality; they should all be encouraged to be immunized against *S. pneumoniae*.

If good follow-up can be arranged, specimens for cultures can be obtained in the emergency department, and the nontoxic, low-risk patient can be discharged and rechecked in 24 hours, when initial culture results become available. Continued follow-up or contact is necessary until cultures are confirmed negative.

COMMON PITFALLS

- When a fever is important to the evaluation and management of a patient, the temperature should be obtained rectally.
- Do not ignore parental reports of fever in infants who are afebrile on arrival to the emergency department.
- Do not attribute fever in infants to overbundling.
- In adults and the elderly, the WBC count should be interpreted cautiously when used to judge the seriousness of an infection.
- The response to antipyretics does not help differentiate serious from nonserious infections.

[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Edema is the presence of increased interstitial (extravascular) fluid that becomes clinically detectable. Edema may be localized to one portion of the body or generalized throughout many areas of the body. Severe generalized edema is termed *anasarca*. An increased amount of interstitial fluid may also accumulate in potential body cavities, such as the pleural space or peritoneal cavity, producing the conditions of hydrothorax or ascites, respectively. The amount of fluid necessary to produce detectable edema depends on its distribution. Localized edema of the lips (like that seen with acute allergic angioedema) is evident with the accumulation of only a few milliliters, whereas the generalized edema of congestive heart failure (CHF) requires an increase of several liters of body water to be detected.

The pathogenesis of edema is intimately connected with the concept of total body water and its division into various components. Total body water is responsible for approximately 70% of body weight; roughly two-thirds is intracellular, and one-third is extracellular. Extracellular water is approximately one-fourth intravascular and three-fourths interstitial. Because water is freely diffusible across most cell membranes, there is a constant exchange between these compartments. Under steady-state conditions, the relative amounts found in each compartment are determined by the interplay between hydrostatic and oncotic forces as represented by the Starling equation.

Fluid accumulation = $K[(P_c - P_{if}) - s(p_p - p_{if})] - Q_{lymph}$ with

K = hydraulic conductance
 P_c = mean intracapillary hydrostatic pressure
 P_{if} = mean interstitial hydrostatic pressure
s = reflection coefficient of oncologically active macromolecules
 p_p = plasma oncotic pressure
 p_{if} = interstitial fluid oncotic pressure
 Q_{lymph} = lymphatic flow

Intravascular hydrostatic pressure tends to force fluid out of vessels into the interstitium, and plasma oncotic pressure tends to draw it back. The usual intensity of these forces *in vivo* is such that there is bulk flow of fluid out of the capillaries into the interstitial space. Overexpansion of the interstitial volume and clinical edema are prevented by the lymphatics, which return excess interstitial fluid to the vascular space. The edematous disorders can be classified according to which component of the Starling equation is deranged.

Increased capillary permeability can be due to mechanical, toxic, chemical, thermal, immunologic, or radiation damage to vascular endothelium.¹ Edema associated with focal inflammation or infection is produced by increased capillary permeability caused by the chemical or immunologic mediators of inflammation. As capillaries become more permeable, plasma protein leaks into the interstitial space and interstitial oncotic pressure rises, drawing more fluid out of the vessels. A new steady state is reached when increased interstitial pressure balances the other forces. Edema fluid resulting from capillary leak has a relatively high protein content and tends not to “pit” under the examiner’s fingertip pressure.¹

Vasomotor tone provided by the autonomic nerves is an important factor in maintaining the integrity of the venous and lymphatic microcirculation. Neurologic illness or injuries that affect the autonomic nervous system can promote the development of edema. Patients with hemiplegic cerebrovascular accidents (CVAs) tend to develop unilateral edema on the paralyzed side, especially if the involved side is dependent. Likewise, vasodilation—either local or systemic—can lead to the development of edema. Nonsteroidal antiinflammatory agents, monamine oxidase inhibitors, beta-adrenergic blockers, and other vasodilators may produce edema as a side effect.

Increased capillary hydrostatic pressure can be generalized due to an elevated systemic venous pressure, which unbalances the Starling equation throughout the systemic circulation. Edema usually becomes manifest where the hydrostatic forces are greatest—in the legs during upright posture. Many systemic causes of edema lead to renal retention of sodium and an increase in total body water, further exaggerating the formation of edema. Increased capillary hydrostatic pressure can be localized to a portion of the vascular system due to venous outflow obstruction, venous valvular incompetence, or prolonged upright posture. Patients with venous hypertension have increased skin blood flow and a defective vasoconstrictive response to upright posture; both are associated with a marked increase in capillary filtration. Prolonged dependency of the legs without muscle activity will cause edema in healthy people.

Reduced plasma oncotic pressure is usually due to decreased levels of plasma albumin, the most oncologically active plasma protein. Conditions such as starvation, malabsorption, protein-losing enteropathies, cirrhosis, nephrotic syndrome, and severe catabolic states may cause hypoalbuminemia. Edema from hypoalbuminemia tends to pit slowly but easily and to accumulate in the soft tissues about the eyelids, especially when the patient is supine.

In most capillary beds, the interplay between hydrostatic and oncotic forces is such that there is a consistent flow of fluid out of the vascular system into the interstitial space. The accumulation of excess interstitial fluid is prevented by lymphatic flow, but if the regional lymphatics are blocked, then edema can develop.⁸ Because of the high protein content that develops in the interstitial space, lymphedema tends to be brawny, nonpitting, and resistant to treatment. Lymphedema tends to accumulate in the interstitial tissues, whereas edema from venous disease collects in the subfascial areas. In primary lymphedema, the problem appears to be an abnormality in the cutaneous and subcutaneous lymphatic channels. Secondary lymphedema is caused by obstruction of lymph flow in the regional lymph nodes or lymphatic channels. In Western countries, the most common causes of lymphedema are neoplastic infiltration, surgical resection, and irradiation of regional lymph nodes.⁸

In some conditions, edema develops without clear-cut imbalances in the Starling equation. These include hyperthyroidism, hypothyroidism, and idiopathic (cyclic) edema. Idiopathic edema is a syndrome with several manifestations, the most characteristic being edema formation during orthostasis, with resolution during recumbency. Weight gains of more than 4 lb during the day are common. The syndrome is found almost exclusively in women of childbearing age. Edema formation is aggravated by several factors, including the menstrual cycle, obesity, increased salt ingestion, heat, prolonged standing, and drugs ([Table 6.1](#)). The most consistent observation in attempting to unravel the pathogenesis of idiopathic edema has been that of an increase in capillary permeability with loss of effective arterial volume when the patient is in an upright position. As discussed later, this leads to expansion of body water and greater edema. Some patients initially thought to have idiopathic edema may have subclinical hypothyroidism. Others may have subtle CHF or edema caused by wearing tight clothes.

Table 6.1
Table with 1 column and multiple rows of text, likely a list of factors or conditions related to idiopathic edema.

TABLE 6.1. Classification of Edema According to Cause (Example)

In understanding the production of edema, it is important to distinguish between primary events (such as diminished cardiac output or decreased serum albumin levels) and secondary responses. Many, if not most, of the primary processes lead to a decrease in effective arterial volume by reducing blood volume or cardiac output. This diminished arterial volume leads to renal underperfusion and increased retention of sodium. To preserve normotonicity, water excretion also decreases. The resultant overexpansion of body water tends to restore effective arterial volume, albeit at the expense of overexpansion of the other fluid compartments, especially the interstitial space. For example, edema caused by cirrhosis tends to be initially localized in the abdomen because the portal venous system is obstructed. However, as ascites volume increases, effective arterial volume decreases, and secondary renal retention of sodium leads to expansion of total body water. Therefore, a disorder that may initially be localized can become generalized. Although edema can be distinguished as that which is usually generalized or usually localized, exceptions are common.

CLINICAL PRESENTATION

Edema is clinically important because it motivates patients to seek medical attention. Occasionally, localized or generalized edema can produce serious or life-threatening effects when vital organs are obstructed. For example, laryngeal edema can cause asphyxia. In some patients with chronic obstructive pulmonary disease (COPD), peripheral edema may be a marker of pulmonary decompensation with right-sided heart failure.¹⁴ Other complications directly attributable to edema include local skin breakdown, respiratory compromise, and cardiovascular impairment.

Because hydrostatic forces are important in producing or exacerbating edema, generalized edema due to a number of causes (particularly CHF) is usually first noted in dependent body parts, such as the feet and pretibial areas when the patient is sitting or standing and the presacral areas if the patient is bedridden. Edema caused by hypoalbuminemia tends to accumulate in the periorbital loose tissues, and patients first notice puffiness about the eyes on arising in the morning. Some patients may notice tightness in the hands when edema of the fingers makes it difficult to slip rings on and off. Edema caused by increased hydrostatic pressure or hypoalbuminemia is usually soft and pitting. Lymphedema, edema caused by increased vascular permeability, and edema seen with thyroid disease tend to be firm and nonpitting. Primary lymphedema, or edema of systemic etiology, may be uncomfortable but is usually not frankly painful.

Another cause of lower extremity swelling is lipedema, a lipodystrophy that can be confused with lymphedema.¹¹ Lipedema produces symmetric swelling with soft fatty tissue, extending from the proximal thighs to the ankles, exhibiting prominent malleolar fat pads, but sparing the feet. Lipedema is more common in women, and produces soft, minimally pitting swelling that is often tender. Other family members may be affected. Lipedema does not produce the skin changes common in lymphedema. Lipedema also does not appear to predispose the limb to infection, whereas lymphedema may be complicated by episodes of cellulitis.

Edema confined to a single limb is usually due to obstruction of the draining veins or lymphatics.⁷ Patients with hemiplegic CVAs may develop unilateral edema due to loss of autonomic innervation to the paralyzed side of the body, and the edema is more prominent when the affected side is dependent. Asymmetric leg edema, usually on the left side, may also be seen in elderly bedridden patients due to iliac vein obstruction.¹² Unilateral extremity edema can be seen in limbs with arteriovenous fistulas (placed for hemodialysis) or arterial bypass grafts (performed for ischemic disease).¹³ In both cases, edema appears to result from arterial pressure reaching the venous and capillary beds, promoting fluid extravasation due to increased intravascular pressure. Lymphatic disruption during arterial exposure may also play a role. Edema of the neck, face, and shoulders is common in superior vena caval obstruction. Isolated facial edema can be seen with angioedema and other allergic reactions.

Sustained edema produces changes in the overlying skin, causing it to thicken and eventually become scarred. Occasionally, edema may produce local vasodilation and a slight erythematous appearance of the skin, but marked redness or warmth usually indicates local inflammation or infection. Prolonged venous stasis leads to a change in skin pigmentation and, occasionally, skin breakdown and chronic ulceration (usually just above the medial malleolus).

DIFFERENTIAL DIAGNOSIS

Edema is one of the classic signs of inflammation. A major differential diagnostic consideration, therefore, in patients with edema is whether focal inflammation or infection is present. The problem is complicated by the observation that patients with one cause of edema (such as CHF or cirrhosis) may be susceptible to other causes of edema (such as deep vein thrombosis or cellulitis). Clues to inflammation or infection include marked redness, warmth, significant pain, and lymphangitis.

Several disorders may present with leg pain and swelling, mimicking some of the edematous disorders. Erythema nodosum, an inflammatory disease involving the cutaneous and subcutaneous blood vessels, may present with acute (less than 72-hour) unilateral or bilateral lower extremity edema. A leaking or ruptured popliteal (Baker's) cyst of the knee may produce calf swelling and pain. An acute tear of the medial head of the gastrocnemius muscle presents as pain in the medial mid-calf area and may mimic deep venous thrombosis. Reflex sympathetic dystrophy often presents with swelling as an early sign, in addition to the other symptoms of burning pain, hyperesthesia, and skin changes. Malignancies of bone, cartilage, and soft tissues may produce unilateral limb swelling.

An important suspicion is the possibility of the development of an acute venous obstruction in a patient with chronic leg edema caused by CHF or venous insufficiency. Helpful clues include a sudden increase in edema over a short time (less than 72 hours), erythema and/or warmth, and increased edema confined to one leg.

EMERGENCY DEPARTMENT EVALUATION

The initial assessment of edema should focus on the following issues: (1) the distribution, (2) the presence of pitting versus nonpitting, (3) the time course of its onset, (4) the pattern of progression, (5) any variability throughout the day, and (6) the presence of associated erythema, warmth, or pain.^{3,5,7,9}

The first distinction to make is whether edema is generalized or focal. Focal edema is usually caused by local venous obstruction, lymphatic obstruction, or inflammation.⁷ Marked warmth, redness, and pain indicate inflammation. The sudden onset of edema in the face or lips is typical of allergic angioedema or angioedema associated with angiotensin converting enzyme (ACE) inhibitors or other drugs.⁶ The incidence of ACE-inhibitor angioedema has been estimated to be one to 12 cases per 1000 patients treated.¹⁵ Most cases present within 1 week after onset of therapy. Unilateral leg edema is most commonly caused by chronic venous insufficiency.⁷ Other clues that support this diagnosis are chronic skin changes, hyperpigmentation, and ulcerations.

Generalized edema is common in a number of systemic diseases and functional abnormalities. In CHF, other signs of left or right heart failure will usually be evident, such as cardiomegaly, elevated jugular venous pressure, hepatojugular reflux, third and fourth heart sounds, and pulmonary rales. Patients with cirrhosis who develop edema usually have other stigmata of liver disease and ascites. In patients with generalized edema, the urine should be checked for the presence of protein and cells. Moderate-to-large proteinuria detected with a standard urine dipstick strongly suggests renal disease. Patients with acute glomerulonephritis or acute renal failure occasionally present with edema. Chronic renal failure is a rare cause of edema, because most patients can balance their fluid status despite markedly low urine output. Measurement of serum albumin levels is necessary to detect patients in whom hypoalbuminemia (less than 2.5 g/dL) is a causative factor.

The production of pitting requires firm pressure over a bony area for at least several seconds. Slow pitting and recovery are common in hypoalbuminemia-related edema. Nonpitting edema is characteristic of lymphedema, increased vascular permeability, and thyroid disease, and is sometimes seen in long-standing cases of edema due to other causes.

Edema that develops over 24 to 48 hours is most consistent with acute inflammation or venous obstruction.^{7,9} Lower extremity edema, often asymmetric, is common in elderly patients who live in chronic care facilities. A predisposition to left-sided edema has been noted.¹² Compression of the left common iliac vein and the accompanying lymphatics by the right iliac artery were proposed to explain this observation. If no obstructive cause can be found on physical examination (inguinal or supraclavicular lymphadenopathy, abdominal or pelvic mass, or signs of deep venous thrombosis), further investigation of elderly patients with asymmetric or

unilateral left-sided edema is not felt to be warranted.

Recurrent edema is characteristic of idiopathic edema. Variability of edema throughout the day is often seen because of the influence of hydrostatic forces in edema formation, but it is most marked in idiopathic edema. The diagnosis of idiopathic edema requires the exclusion of other causes and is supported by an abnormal water-loading test. Normally more than 65% of a standard oral water load (20 mL/kg) is excreted within 4 hours, regardless of body position. Patients with idiopathic edema excrete a normal amount when recumbent but excrete less than 65% when they remain upright during the 4 hours.

Pain is unusual in primary lymphedema. It is also unusual in other systemic causes of edema.

The inguinal lymph nodes should be checked for enlargement. Venous valvular incompetence can be checked with the Brodie-Trendelenburg test.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment is directed toward the underlying cause, as identified by the clinical evaluation. There is little benefit, and potential harm, to the empiric treatment of edema with diuretics. Drug-induced iatrogenic edema is common and, when possible, the responsible drugs should be changed or stopped. Angioedema is treated with beta-adrenergic agonists, antihistamines, and steroids.⁶ Angioedema secondary to ACE inhibitors is generally refractory to epinephrine, antihistamines, and steroids.^{4,10} The only treatment that has been shown to be clearly beneficial is discontinuation of the agent. Those patients with venous and arterial disease who present with peripheral edema and chronic skin ulcers benefit from layered compression bandage therapy and should be referred to a wound treatment specialist for evaluation.^{2,5}

DISPOSITION

Patients with edema may require admission for evaluation and treatment of the underlying cause, such as CHF, COPD, or cirrhosis. Patients with angioedema affecting the upper airway should be observed closely; such swelling may suddenly worsen. ACE-inhibitor-induced angioedema is usually refractory to treatment, may persist, and may relapse after improvement.⁴ It is prudent that patients with angioedema of the face and neck be observed carefully; overnight observation or hospitalization is common practice. Patients with angioedema affecting solely the face, without evidence of airway involvement, and who improve dramatically while in the emergency department, can be discharged after a period of observation.

COMMON PITFALLS

Edema is a sign, not a diagnosis. The common pitfalls associated with the assessment of edema are

- Failing to distinguish between focal and generalized distributions of edema
- Ignoring the local complications of edema
- Failing to detect the presence of cellulitis in patients with chronic edema
- Failing to elevate a swollen body part to promote resolution of edema
- Using diuretics overzealously to treat edema
- Failing to educate the patient about the causes of edema and the value of simple measures, including bed rest and dietary salt restriction

PATHOPHYSIOLOGY

Consciousness is the result of the interaction between the reticular activating system and the cerebral cortex. The general state of alertness and wakefulness occurs in the reticular activating system, a group of neurons in the brain stem. The cognitive functions, or an awareness of the environment, are a cerebral cortical function. For a human to be fully conscious, both of these systems must be functioning.

An altered level of consciousness may be clinically characterized as a progression through various stages. Drowsiness or lethargy may be the first change seen: There is slightly decreased wakefulness and decreased interaction with the environment. The patient may be aroused by verbal stimuli. A worsening in the severity of these changes leads to obtundation, which may progress to stupor, in which the patient may be awakened only briefly by vigorous stimulation. Coma is the state in which the patient cannot be awakened by any environmental stimuli.

ORGAN SYSTEMS

Central nervous system (CNS) function can be impaired at a cellular or structural level. If impaired at a structural level, there is focal destruction of the CNS anatomy. This may result from increased intracranial pressure, with mechanical compression of CNS structures, or from direct destruction due to tumors, trauma, or intracerebral hemorrhage. A malfunction in almost any of the other organ systems may impair CNS function at a cellular level. This dysfunction may occur with hypothyroidism or adrenal insufficiency; with disturbances of electrolyte regulation, which produce hypo- or hypernatremia or hypercalcemia; or with other metabolic disturbances, such as hypoglycemia or hyperosmolar states. Illnesses resulting in renal or hepatic damage may cause uremia and hepatic encephalopathy. Hypoxia from a pulmonary or cardiac etiology may also affect CNS function. Hypotension with decreased intracranial perfusion may result from a cardiac etiology, sepsis, or volume loss from gastrointestinal (GI) bleeding or organ trauma.

Due to the interrelationships between various organ systems, CNS dysfunction may result from a combination of organ system failures, such as hepatorenal syndrome or a large myocardial infarction causing hypotension and heart failure, with resulting pulmonary compromise and hypoxia. External environmental or toxic insults may also cause CNS depression at the cellular level through a direct toxic effect or secondarily through damage to other organ systems.

In general, when the CNS is impaired at a cellular level, diffuse CNS depression ensues, producing no focal findings on the clinical examination. Two exceptions are hypoglycemia and hepatic failure, in which focal findings may be seen. Pupillary light reflexes remain intact, except when the CNS depression is caused by toxins that affect pupillary size, such as anticholinergics or opiates.

There may be focal findings on examination when a destructive process causes structural damage to a specific area of the CNS. However, a localized problem may also cause a secondary diffuse process. This may be seen with the postictal state following a seizure, in cerebral edema secondary to a tumor, or in a subarachnoid hemorrhage secondary to a ruptured aneurysm.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of coma is extensive. In the emergency department, a thorough history and physical examination will help narrow the possibilities. The list of etiologies may be divided into several groups ([Table 7.1](#)).

Category	Etiology
Structural	Trauma, tumor, stroke, hemorrhage
Metabolic	Hypoglycemia, hyperglycemia, electrolyte imbalances, uremia, hepatic encephalopathy
Toxic	Alcohol, drugs, salicylates
Systemic	Cardiac, pulmonary, renal, hepatic failure
Other	Seizures, syncope, hyperventilation

TABLE 7.1. Differential Diagnosis of Transient Loss of Consciousness and Coma

MAJOR EMERGENCY ENTITIES

In the evaluation of any patient with mental status changes or frank coma, an hypoxic etiology must always be considered and ruled out. After evaluating and treating for hypoxia, other major emergency entities must be considered.

Hypoglycemia

A common cause of altered mental status is hypoglycemia. This is most common in patients on insulin therapy. It may be due to dosage errors, missed meals, a change in exercise pattern, or erratic absorption from injection sites. Interaction with other drugs, such as alcohol, beta-blockers, or salicylates, may also lead to hypoglycemia. The oral hypoglycemic agents, including the first- and second-generation sulfonylureas and newer agents such as troglitazone, may also produce hypoglycemia. The half-life of these agents is long, so the patient should be admitted for appropriate glucose supplementation and careful monitoring.

The following drugs can potentiate the action of the oral hypoglycemics: clonidine, ethanol, beta-blockers, monoamine oxidase inhibitors, sulfonamides, coumarin anticoagulants, and salicylates. Ethanol and salicylates are two common substances that may, by themselves, induce hypoglycemia. The predominant cause of hypoglycemia until age 2 is salicylate ingestion; alcohol predominates in the succeeding 8 years. Insulin and the oral hypoglycemics, alone or with alcohol,

predominate until age 50. Over age 60, the oral hypoglycemics are the most important cause.

Renal or hepatic disease with impairment of function increases the risk that a patient will develop hypoglycemia. Beta-blockers may inhibit the warning signs for hypoglycemia, although sweating is minimally affected. Hypoglycemia may also be seen in other medical conditions, such as sepsis.

When blood glucose levels begin to fall (50 to 70 mg/dL), symptoms of CNS excitation appear; these may include anxiety, tremor, sweating, and occasionally hallucinations. With a fall to the range of 20 to 50 mg/dL, further symptoms appear, including clonic convulsions, loss of consciousness, hyperreflexia, pupillary dilation, and tachycardia. As the glucose level continues to fall, progressive CNS depression and coma may occur. Brain stem reflexes are preserved until late. Primitive movements such as sucking and pouting movements of the lips, forced grasping, or extensor plantar responses may be seen as cortical control is removed. Loss of consciousness is usually preceded by a period of confusion, but it may occur suddenly. Focal neurologic signs may be present during a hypoglycemic episode due to the effect on cells that are especially sensitive or lack an adequate arterial blood supply.

Hyperglycemia

At the other end of the spectrum is diabetic ketoacidosis (DKA). This may be seen in the emergency department as the initial presentation of new-onset juvenile diabetes, in a known diabetic with poor compliance, or in a diabetic with a precipitating stressful event, such as infection. Acute myocardial infarction or treatment with steroids may also be a factor. A history of polyuria, polydipsia, nausea, vomiting, or abdominal pain may be obtained. Weight loss may be a complaint in new-onset diabetes. The patient is commonly dehydrated. Acetone breath or Kussmaul respirations may be present. Mental status changes, including coma, may be seen.

Hyperosmolar hyperglycemic nonketotic coma is more typically seen in an older patient with an undiagnosed or mild type II diabetes who experiences a precipitating severe illness. Gram-negative pneumonia, uremia with vomiting, and acute viral illness are the most commonly reported predisposing conditions. The patient typically has a longer history of symptoms before admission than in DKA and commonly presents in a coma. Mortality figures vary from 40% to 70%, in contrast to 1% to 10% in DKA.

Adrenal and Thyroid Emergencies

Adrenal and thyroid emergencies are not commonly seen in the emergency department, but it is important to keep them in mind in the differential diagnosis of coma, as life-saving treatments are available. In a patient with suspected myxedema coma, a history may reveal prior symptoms of hypothyroidism. The patient may have a history of thyroid problems, such as Graves disease, which may result in hypothyroidism. The treatment of Graves disease with radioactive iodine is associated with a relatively high incidence of eventual hypothyroidism. A surgical scar on the neck should alert the physician to the possibility of thyroid or parathyroid dysfunction. A history of noncompliance with thyroid medications may be obtained from the family.

Clinically, hypothermia to 36°C or less may be seen, blood pressure may be normal or hypotension may occur, and the pulse is generally bradycardic. Periorbital and pretibial nonpitting edema and macroglossia may be present. The patient's hair may be dry, with loss of the lateral eyebrows. The cardiac examination may be consistent with a pericardial effusion. On neurologic examination, the muscle relaxation phase of the deep tendon reflexes is classically delayed. Laboratory studies may reveal hyponatremia, hyposmolality, and an elevated creatine phosphokinase.

Thyroid storm rarely presents as coma. Confusion, agitation, or occasionally hallucinations may occur. Hyperthermia above 38°C and tachycardia, with or without cardiac failure, are noted. A precipitating event such as trauma or infection must be sought.

Acute adrenal crisis may occur due to an acute exacerbation of chronic adrenal insufficiency, rapid cessation of chronic steroids, or adrenal hemorrhage, which is usually secondary to sepsis. Stressors such as infection, trauma, or surgery may precipitate an adrenal crisis. Nausea, vomiting, abdominal pain, and fever may be noted. Hypovolemic shock may develop, and the mental status may deteriorate into lethargy and coma. An Addison disease patient maintained on chronic glucocorticoid replacement may not develop dehydration and hypotension until late in the course of adrenal crisis, as mineralocorticoid secretion is usually preserved.

Hypertension

In a patient with severe hypertension who presents with mental status changes, the cause may be primary hypertensive encephalopathy or an intracranial bleed. A subarachnoid hemorrhage due to a ruptured aneurysm or an arteriovenous malformation usually presents with diffuse findings. The patient may have only mild preceding mental status changes but may present comatose. The classic history is the sudden onset of a severe headache associated with nausea and vomiting. A patient may give a history of prodromal headaches in the preceding weeks. Sudden transient loss of consciousness is seen in 45% of patients. If a subarachnoid hemorrhage is suspected and the computed tomography (CT) scan is negative, a lumbar puncture must be performed. In a small percentage of patients with subarachnoid hemorrhage, the CT scan is normal.

Toxic Causes

Overdose of a wide variety of medications or illicit substances may produce a variety of mental status changes that may progress to coma. Appropriate diagnosis requires an adequate history and familiarity with the constellation of signs and symptoms that may appear in specific toxicologic emergencies.

High doses of benzodiazepines may produce sedative–hypnotic effects. Cardiac depression is usually minor, as is respiratory depression; however, respiratory depression may become a problem if benzodiazepines are combined with other CNS depressants, in the elderly, or in patients with underlying respiratory disease. Opiates and barbiturates produce more severe respiratory depression. Hypotension is commonly seen with barbiturate overdoses and may also be seen with opiates. Miosis is usually present with opiates (an exception is meperidine, in which mydriasis may be seen). Glutethimide, formerly used as a sedative–hypnotic, has properties similar to those of the barbiturates; patients generally present with dilated pupils, and the drug tends to produce a fluctuating level of consciousness. The coma may be prolonged, lasting up to several days. Pulmonary edema is most commonly seen with intravenous heroin overdose, but may be present in other opiate or barbiturate intoxications. Cutaneous bullae and hypothermia may occur with barbiturate overdoses.

Alcohol intoxication, depending on the degree of tolerance, may produce a somnolent, difficult-to-arouse patient with varying degrees of respiratory depression. Ingestion of substitute substances such as methanol, ethylene glycol, or isopropyl alcohol may also occur. Ingestion of isopropyl alcohol can present as stupor in a known alcoholic or as an encephalopathy of unknown cause in persons with hidden addictions. Along with CNS depression, GI effects (abdominal pain, gastritis, nausea, or vomiting) and cardiac toxicity can occur. The major metabolite of isopropyl alcohol is acetone; as such, the severe anion-gap metabolic acidosis seen in methanol and ethylene glycol poisoning is not seen with isopropyl poisoning. In methanol intoxication, the patient may present with visual changes ranging from blurred vision to blindness. Calcium oxalate crystals may be present in the urine of patients who have ingested ethylene glycol. The osmolal gap should be calculated; any discrepancy that cannot be attributed to ethanol ingestion must be explained.

Ingestion of tricyclic antidepressants may produce rapid mental status changes, seizures, and cardiovascular effects. Sinus tachycardia is most commonly noted. The QRS complex may become widened. Atrial and ventricular dysrhythmias may occur. Anticholinergic effects such as delayed gastric emptying, decreased bowel sounds, and mydriasis may be present.

Acetaminophen and salicylate levels should always be obtained. A history of prior tinnitus and vomiting may lead the clinician to suspect salicylate intoxication. Chronic salicylism in the elderly is often subtle. Respiratory alkalosis in adults or metabolic acidosis in children may be seen.

Carbon monoxide or cyanide inhalation should be suspected if the patient has been involved in a fire. Carbon monoxide poisoning should also be suspected in colder weather, particularly if the patient or others in the household have experienced flulike symptoms. Arterial blood gas levels may show a normal PO₂, but the measured hemoglobin saturation will be low. Cyanide interferes with the cellular use of oxygen; therefore, mixed venous PO₂ will be high, as cells cannot use the available oxygen. Cyanide also causes a severe metabolic lactic acidosis.

DIAGNOSTIC APPROACH

The initial assessment of a patient presenting with coma or transient loss of consciousness should be performed in a relatively short time and should be focused on

stabilization. The state of consciousness is determined by both the cerebral cortical and midbrain ascending reticular activating systems. Key observations will help confirm whether the disease is of the brain stem or hemispheres.

Before the patient arrives in the emergency department, field personnel should assist with airway support and administer oxygen. The spine is immobilized and stabilized. Intravenous access is obtained, and cardiac monitoring is ongoing. Bedside evaluation of blood sugar is performed, and the patient should receive glucose if hypoglycemic. Any of the support mechanisms not performed by field personnel are initiated immediately in the emergency department.

The history, physical examination, and serial neurologic examinations are of utmost importance. Often, however, little information is available before intervention is required to protect the brain against irreversible damage. Life-threatening and reversible processes causing coma or altered level of consciousness should be addressed; these include hypoxia, hypoglycemia, poisoning, infections, increased intracranial pressure secondary to trauma, and other mechanisms, such as alteration in body temperature. Evaluation of the cardiorespiratory status and blood glucose takes precedence over investigation of other potential etiologies. Avoid giving a large glucose load to a patient who may not be hypoglycemic, because it may worsen any brain injury.

The history is obtained while stabilizing the patient. Information should include the abruptness of change in mental status, preceding events, medical history, current medications, and use of toxic agents. The clothing should be checked for suicide notes and drug bottles, and any medical alert tags should be noted. After the ABCs have been addressed, the patient is evaluated for signs of head trauma, including pupillary asymmetry and reactivity, hemotympanum, and Battle's sign. The level of consciousness is documented, and the Glasgow Coma Scale used to quantify the patient's condition. Vital signs, including a core body temperature, are assessed.

Examination of the patient's eyes may be the single most important assessment in the evaluation of coma. An unresponsive patient who has open eyes may appear awake but may actually be in a state of akinetic mutism. These patients may be abulic (with long delays in response to stimulation) secondary to hydrocephalus, frontal meningioma, metastatic or primary tumor, hemorrhage, or contusion. Other causes of akinetic mutism include psychiatric disorders such as catatonia and dissociative states, and the "locked-in syndrome," which refers to patients who are paralyzed but in fact awake. This syndrome may be due to pontine infarct, but high cervical spinal cord injuries and severe drug-related dystonias can be causative. The fundi are examined for lack of venous pulsation or other evidence of papilledema, which would suggest increased intracranial pressure.

Eye movements are generated by the brain stem. The shape and size of pupils and their reactions are recorded. Reactive asymmetric pupils differing in size by 1 to 2 mm can be seen in 10% of normal people. Pupils are more likely to remain equal and reactive in cases of metabolic and drug etiology; a fixed, unilaterally dilated pupil suggests transtentorial herniation. Local trauma or topical mydriatics can also cause unilateral dilation. The patient with a possible head or neck injury presents a problem with the performance of the doll's-eye maneuver (oculocephalic reflex).

Ice water caloric testing (oculovestibular reflex) can be performed to induce nystagmus, in which the slow phase is driven by the brain stem and the fast phase is driven by the cortex. This test, done correctly in a comatose patient, helps differentiate a brain stem lesion from a hemispheric lesion. If the brain stem is normal, the eyes will turn conjugately toward the side where ice water is flushed into the ear. This is the slow phase of the eye movement. If the hemispheres are intact, the slow phase of eye movement will be followed by a fast phase, in which the eyes move away from the side of the water infusion. This fast phase is a jerking movement. Stimulation of the cornea will cause an eye blink if the fifth and seventh cranial nerves are intact, another method to evaluate brain stem function.

Respirations are observed. Apneustic breathing, characterized by deep inspiration followed by a long apneic phase and only a few breaths per minute, suggests brain stem failure. Ataxic breathing is an ominous sign of brain stem failure. Normal or Cheyne-Stokes respiration indicates good brain stem function. However, Cheyne-Stokes respiration may be due to bilateral dysfunction of structures deep in the cerebral hemispheres or diencephalon, bilateral cerebral infarctions, or hypertensive encephalopathy. When Cheyne-Stokes respiration is noted, metabolic diseases as well as incipient transtentorial herniation should be considered.

The neck is flexed to check for nuchal rigidity if there is no contraindication. Rigidity of the neck suggests meningeal inflammation due to meningitis or subarachnoid hemorrhage. Empiric antibiotic coverage is immediately initiated in cases highly suspicious of meningitis. Antibiotic coverage should not be delayed by the diagnostic workup (i.e., inability to perform lumbar puncture due to delay in obtaining a head CT).

The patient's posture is noted. Decorticate and decerebrate posturings are abnormal postures that may be recognized in the comatose patient. Decorticate posturing, characterized by flexor positioning of the upper extremities and extension, internal rotation, and plantar flexion in the lower extremities, suggests injury to the brain above the level of the midbrain. Decerebrate posturing is characterized by arms that are extended, adducted, and hyperpronated; legs that are extended with feet plantar flexed; clenched teeth; and opisthotonus. Decerebrate posturing occurs in patients with infarcts of the brain stem rostral to the midpons and also in patients with large cerebral hemorrhages that destroy or compress the lower thalamus and midbrain. This motor pattern typically emerges in the wake of lesions of the internal capsule or cerebral hemisphere that interrupt the corticospinal pathways. Clinical disease patterns often cloud the demarcation between decerebrate and decorticate posturing, and motor responses can shift back and forth depending on the location of the lesion and pressure effects on the upper brain stem.

Suggested steps in the management of the comatose patient are as follows:

1. Establish and maintain airway patency and protect the patient from aspiration.
2. Administer oxygen.
3. Provide adequate ventilation.
4. Support circulation.
5. Establish intravenous access and draw blood for rapid glucose determination; evaluation of electrolytes, calcium, and renal and liver function; drug screen; blood gas determination; complete blood count; magnesium; thyroid function studies; platelet count; prothrombin time; and partial thromboplastin time.

If indicated by the rapid glucose determination, administer glucose as 25 to 50 mL of 50% dextrose solution to adults and 2 mL per kilogram of 25% dextrose solution to children. To avoid precipitating acute Wernicke-Korsakoff syndrome in a thiamine-deficient patient, give 100 mg thiamine in conjunction with the glucose. Patients should receive multivitamins in the initial bag of intravenous solution. Give 2 to 4 mg of naloxone intravenously in adults, and 0.01 to 0.1 mg per kilogram in children. Measures to decrease intracranial pressure include hyperventilation to reduce PCO_2 to about 26 to 30 mm Hg and administration of intravenous mannitol (0.5 to 1.0 g per kilogram). Fluid restriction may be necessary, and ultimately cerebrospinal fluid may need to be drained by intraventricular catheter. Seizures are treated and seizure precautions taken. Normalize body temperature. An electrocardiogram is obtained, pulse oximetry applied, and a Foley catheter placed.

After the initial treatment of reversible causes and stabilization, definitive workup and therapy are instituted to prevent further CNS damage. In addition to diagnostic laboratory studies, plain radiographs (cervical spine series, chest x-ray), head CT scan and magnetic resonance imaging, carotid duplex studies, Doppler studies, and a lumbar puncture may prove helpful.

There are three primary pathologic processes that produce coma: expanding mass lesions that secondarily destroy the reticular activating system, brain stem lesions that directly damage the reticular activating system, and metabolic disorders that disrupt brain stem function.

The mnemonic AEIOU-TIPPS ([Table 7.2](#)) helps organize the approach for specific treatment and antidote administration. In carbon monoxide poisoning, patients immediately receive high-flow oxygen. Hyperbaric treatment may also be indicated. Patients suspected of meningitis receive intravenous antibiotics without delay. Patients intoxicated with ethanol receive supportive care and careful observation, and determination that methanol, ethylene glycol, or isopropyl alcohol is not responsible for their presentation. All metabolic causes, such as hypothyroidism, adrenal insufficiency, and electrolyte abnormalities, receive specific treatment.

A – alcohol
E – epilepsy, electrolytes, encephalopathy
I – insulin
O – opium
U – urea (metabolic)
T – trauma
I – infection
P – psychiatric
P – poison
S – shock
T for tumor, and **E** for environmental causes such as heatstroke, hypothermia, and high-altitude injuries should also be considered.

TABLE 7.2. Mnemonic for Coma and Transient Loss of Consciousness

Operable lesions are definitively treated by a neurosurgeon and may include clipping of aneurysms, resection of arteriovenous malformations, and evacuation of hematomas, abscesses, and tumors. Nimodipine may help prevent brain injury and improve outcome after subarachnoid hemorrhage. In subarachnoid hemorrhage patients who exhibit sustained systolic blood pressure greater than 180 mm Hg, antihypertensive treatment may be beneficial. Elevated blood pressure should be managed in ischemic stroke, but caution must be used, because the response to therapy may be exaggerated. In ischemic stroke patients, various neuroprotective agents are currently being evaluated. The use of tissue plasminogen activator within 3 hours of stroke onset should be appropriately considered.

The approach to coma and transient loss of consciousness must be systematic. Orderly evaluation, with simultaneous stabilization, is of the utmost importance. Early recognition and correction of reversible causes and prevention of further brain damage by definitive intervention are the basic principles of treatment in patients with altered consciousness.

COMMON PITFALLS

- Not approaching the patient with transient loss of consciousness in a systematic fashion
- Not intervening in a timely fashion to prevent reversible causes of brain damage
- Not observing hypoglycemic patients who take oral hypoglycemic agents for an appropriate amount of time or providing adequate glucose supplementation

[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Patients presenting to the emergency department with a complaint of weakness pose a great diagnostic challenge for the physician. This nonspecific complaint has myriad causes, and a systemic evaluation is critical. Specific attention to potentially life-threatening etiologies is the principal focus, and diligence in data gathering is essential to the establishment of a diagnosis. A detailed history and physical examination guide the selection of diagnostic studies in these challenging cases. Though rarely encountered, when approaching the patient with a complaint of weakness, consideration is given to disorders such as botulism, myasthenia gravis, and Guillain-Barré syndrome because of their associated high morbidity and mortality. The emergency physician should have a high clinical suspicion for these and all other disorders that can precipitously compromise the respiratory and functional status of their patients. Accepting the challenge and proceeding in an organized fashion can offer great reward for the patient and physician.

The complaint of “dizziness” may accompany that of “weakness,” and, at times, patients use these terms interchangeably. There is considerable overlap in their etiologies. In the ambulatory care setting, dizziness is the most common presenting complaint in patients over the age of 75. ¹ *Weakness* is defined as a decrease in muscle strength or power. It may be a focal symptom, involving a single muscle group, or it may be generalized. Dizziness is imprecisely interpreted by patients and may be used to describe lightheadedness, disequilibrium, disorientation, confusion, or vertigo. The emergency physician must appreciate the distinction between these symptoms and endeavor to understand the patients' intended meaning. This chapter specifically addresses those patients who present with a complaint of “weakness.”

EMERGENCY DEPARTMENT EVALUATION

An exhaustive history and physical examination must often be performed to uncover the subtle details essential in establishing the cause of a patient's complaint of weakness. The patient's definition of *weakness* must first be clarified. Whether the weakness is focal muscle weakness or generalized fatigue must be determined early in the evaluation. If muscular weakness is meant, then the clinician must determine whether it is focal or generalized, proximal or distal. The history of present illness should focus specifically on the acuity of onset and duration of symptoms, exacerbating and mitigating factors, and presence of associated symptoms. ⁴ Sudden onset of weakness may suggest botulism, while a slower progression may suggest the Guillain-Barré syndrome or myasthenia gravis, although these illnesses may also have accelerated courses. The weakness of myasthenia gravis may fluctuate, and a careful history is needed to elicit a progression of symptoms throughout the day or an association with exercise or repeated activity, such as chewing or combing one's hair. Recent illness, other medical problems, recent vaccination, occupational history, travel history, history of tick bites, use of medication, and use of recreational drugs are important in assessing the patient complaining of weakness. A thorough review of systems should include inquiry about recent weight loss, fever or sweats, visual changes (including diplopia), difficulty swallowing, joint or muscle pain, palpitations, change in bowel habits, and skin rashes.

The patient's age is an important consideration in developing the differential diagnosis in a patient with weakness. The elderly have a higher incidence of comorbid medical conditions than do their younger counterparts and are at higher risk of acute central nervous system and cardiovascular events. They are more likely to present with occult infections and metabolic disorders that are symptomatically manifested as weakness. ⁴ In the pediatric age group, infantile botulism and intussusception are two rare but important considerations. Infantile botulism may be seen in children days old to over 1 year of age. This variant of botulism is much more common than food-borne or wound botulism, and it presents with weakness, poor tone, poor suck, or constipation.

On the physical examination, orthostatic monitoring and oxygen saturation should be included in the vital signs. Supplemental oxygen is indicated if hypoxemia is present; the airway must be secured if there is a potential for imminent compromise. Tachycardia, with or without hypotension, suggests volume depletion or toxic drug ingestion. Rectal temperature measurement is particularly important, because infection frequently presents with nonspecific complaints, such as weakness. A blood glucose level should be obtained early during the evaluation, as hypoglycemia may present with an array of symptoms, including weakness. The ears, sinuses, thyroid, and cardiac status should be assessed, and there should be a careful evaluation for signs of trauma, which may suggest physical abuse. A rectal examination, including a guaiac test for occult blood, is recommended.

The neurologic examination begins early in the course of the patient's evaluation with the assessment of the mental status. Altered mental status, including confusion, slowness, or agitation, may represent underlying disease or toxic exposure; suspicion of cognitive defects should prompt a formal mental status evaluation. Cranial nerve testing in the patient with a complaint of weakness focuses on the motor examination. Ptosis, usually symmetric but sometimes unilateral, can be an early sign of myasthenia. When myasthenia is a consideration, having the patient hold an upward gaze for several minutes is helpful in assessing for fatigue. Difficulty with accommodation can be the earliest sign of weakness due to botulism and does not occur with myasthenia. Diplopia due to weak oculomotor muscles must be assessed, with an emphasis on the evaluation of the sixth cranial nerve. The abducens is the longest cranial nerve and the most sensitive to toxins such as botulism or to increased pressure from intracranial mass lesions.

The remainder of the neurologic examination in the patient complaining of weakness concentrates on motor strength, deep tendon reflexes, and assessment for muscle atrophy and fasciculations. Upper and lower motor neuron diseases present with the important distinguishing characteristics listed in [Table 8.1](#). Upper motor neurons arise in the cerebral cortex and their axons extend through the subcortical white matter, internal capsule, brainstem, and spinal cord, where they synapse directly with lower motor neurons or interneurons, fine-tuning motor activity. Lower motor neuron cell bodies lie in the brainstem motor nuclei and anterior horn of the spinal cord. Their axons extend to the skeletal muscles they innervate. The weakness of upper motor neuron disease is generally unilateral, the Babinski sign is present, muscle tone is increased, deep tendon reflexes are increased, and no fasciculations are visible or palpable. In general, distal muscle groups are more severely affected than are proximal groups.

Clinical	Upper Motor Neuron	Lower Motor Neuron
Weakness	Weakness greater in the arm extensors and leg flexors; weakness often on only one side	Weakness often in one muscle group; extensor same as flexor
Deep tendon reflexes	Increased	Decreased
Muscle tone	Increased	Decreased
Fasciculation	None	Present
Muscle atrophy	None	Severe
Babinski sign	Present	Absent

TABLE 8.1. Upper Versus Lower Motor Neuron Weakness

Lower motor neuron disease affects single muscle groups. Flexors and extensors are equally compromised in an extremity. Deep tendon reflexes and muscle tone are decreased with lower motor neuron disease. Absent reflexes may also indicate Guillain-Barré syndrome or other systemic processes such as hypothyroidism or hypokalemia. Muscle atrophy and fasciculation are long-term results of lower motor neuron lesions. The presence of fasciculations with upper motor neuron signs,

such as hyperreflexia, is suggestive of amyotrophic lateral sclerosis. Fasciculations in the setting of a toxic exposure point to organophosphate poisoning. [Table 8.2](#) lists the Medical Research Council's strength grading from 0 to 5, which permits standardization of documentation between examiners.

Grade	Definition
5	Normal strength
4	Active movement against gravity and resistance
3	Active movement against gravity (no resistance from physician)
2	Active movement with gravity eliminated (no resistance from physician)
1	Flicker or trace contraction
0	No visible or palpable contraction

TABLE 8.2. Medical Research Council Grading of Strength

Lower motor neuron diseases can arise from a muscle-based disorder, a neuropathic-based disorder, or a myoneural junction source. [Table 8.3](#) illustrates several symptoms, physical signs, and laboratory findings that distinguish the etiologies of lower motor neuron weakness. Weakness due to a myopathy tends to involve proximal muscle groups, while neuropathic disease (Guillain-Barré syndrome) affects distal muscle groups. Myoneural junction diseases have a more distal distribution and are particularly inclined to affect respiratory and bulbar muscle groups (myasthenia gravis and botulism).

Clinical	Myopathy	Neuropathy	Myoneural junction
Distribution	Proximal > distal	Distal > proximal	Diffuse, especially bulbar and respiratory muscles
Reflexes	Decreased	Decreased	Normal
Sensory involvement	-	+	-
Atrophy	±	±	-
Fatigue	±	±	+
Serum CPK	Normal to elevated	Normal	Normal

CPK, creatine phosphokinase.

TABLE 8.3. Myopathy Versus Neuropathy Versus Myoneural Junction Disease

When psychogenic weakness is considered in the differential diagnosis, several maneuvers may be helpful. Weak muscles give way to pressure in a smooth fashion, but psychogenic weakness usually results in a jerking or sudden release. In a patient with upper extremity weakness from organic disease, making a fist should not result in wrist extension (unless there is an isolated lesion of the flexor tendons); in functional states, the wrist extends as the patient tries to make a fist. In patients with psychogenic bilateral lower extremity weakness, attempts to lift one leg against resistance result in the other leg firmly thrusting downward, while in patients with organic disease, the downward thrust is diminished or absent.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the weak patient is extensive, and no single list can cover every possible cause. Division of the etiologies into broad categories, such as infectious, toxic, metabolic, endocrinologic, structural, mechanical, and rheumatologic, permits a more organized approach to this extensive list. A complete history and physical examination should direct the physician to one of these categories. Other diagnostic testing may then be used to further hone the diagnosis.

All infections can potentially cause weakness, either through nonspecific mechanisms, such as those seen with mononucleosis or hepatitis, or from specific toxins affecting neuromuscular function, such as those in poliomyelitis, botulism, Guillain-Barré syndrome, or tick paralysis. Sinus and ear infections can affect the labyrinthine system and produce lightheadedness or vertigo. The human immunodeficiency virus can directly or indirectly cause the full spectrum of weakness, from nonspecific fatigue to neuropathies and myelopathies. Chronic fatigue syndrome, thought to be viral in origin, requires an extensive workup to exclude all other processes before the diagnosis can be established, and it is not a diagnosis that should be made in the emergency department. ⁶

Toxins, including prescription drugs, can produce generalized weakness: There are usually no focal findings on examination ([Table 8.4](#)). In one study of 106 patients with a chief complaint of weakness or dizziness, 9% of all patients and 20% of those over age 60 had symptoms attributed to prescription medications. ⁷ Drugs associated with vasodilation, bradycardia, or diuresis can produce orthostatic blood pressure changes, and patients who are taking them may present with the complaint of weakness. Other drugs can cause myopathies or neuropathies. Carbon monoxide poisoning commonly presents with weakness, emphasizing the importance of a complete occupational and social history in evaluating the patient. Toxins that act at the neuromuscular junction, such as the organophosphates and the carbamates, can cause weakness, fasciculations, or paralysis. Heavy metal poisoning presents with diffuse weakness that is slowly progressive and often associated with CNS findings.

MYOPATHIES
Steroids
Alcohol
Heroin
Chloroquine
Ipsosulfonamide
Diuretics
Laxatives
Amphotericin
o-penicillamine
Cimetidine
Procainamide
NEUROPATHIES
Carbon monoxide
Heavy metals
Polychlorinated biphenyls
Isotretinoin
Hexachlorocyclopentadiene
Gold
NEUROMUSCULAR JUNCTION DISEASE
Organophosphates
Carbamates

TABLE 8.4. Commonly Used Drugs and Other Substances Associated with Weakness

All metabolic derangements can present with weakness, including hypoxia and alterations in serum glucose, potassium, sodium, and calcium. ⁸ Hypokalemia may be induced by drugs or gastrointestinal losses, or it can be secondary to familial periodic paralysis. Familial periodic paralysis, which may also be due to hyperkalemia, is characterized by profound weakness that often spares the respiratory muscles. ⁹ Anemia often presents with a complaint of weakness and lightheadedness due to the associated decreased oxygen delivery and hypotension.

Hypothyroidism is the most common endocrine cause of weakness and is often initially misdiagnosed. Thyrotoxic periodic paralysis can present with weakness as a primary complaint, probably mediated through hypokalemia.² Adrenal insufficiency, perhaps the most life-threatening endocrine etiology of weakness, may present with hypotension, hyperkalemia, and hyponatremia. It is a diagnosis that must be considered in weak patients on chronic steroid therapy. Diabetics often complain of weakness. Weakness in these individuals may be due to either hypo- or hyperglycemia or to a neuropathy. Neuropathies predispose to silent myocardial infarction and to vasomotor instability.

Weakness is a prominent complaint of most rheumatologic diseases and occasionally is the primary presenting symptom. Systemic lupus erythematosus, polymyositis, dermatomyositis, polymyalgia rheumatica, and particularly myasthenia gravis must all be considered in patients presenting with symmetric weakness.

Structural lesions often cause focal weakness. Lesions in the spinal canal can result in weakness that is symmetric and distal to the site of compromise. Lesions in the frontal lobes, basal ganglia, and cerebellum can cause disequilibrium. Brainstem infarcts can present with difficulty with swallowing, talking, or respiration, in addition to weakness.

Mechanical causes of weakness are associated with lightheadedness or presyncope and include postural hypotension, carotid and vertebral artery insufficiency, cardiac dysrhythmias, vasovagal events, and states of decreased cardiac output.

Radiographic and Laboratory Examination

Clinical suspicion gathered from the history and physical examination guides further testing. In general, a complete blood count, serum chemistry, and urinalysis are obtained. A sedimentation rate is helpful if rheumatologic disease is suspected. A Monospot test, liver function tests, and thyroid function tests are sometimes indicated. Heavy metal screening and red blood cell acetylcholinesterase level are required in selected cases, but these are rarely available to the emergency physician while the patient is in the department. Carboxyhemoglobin is indicated in suspected cases of carbon monoxide poisoning. A serum creatine phosphokinase and aldolase are helpful in cases of suspected myopathy.

Pulse oximetry and arterial blood gas analysis are indicated in cases of suspected pulmonary dysfunction. Pulmonary function testing, including vital capacity and maximum inspiratory force, is recommended when respiratory muscle compromise is suspected. An electrocardiogram and cardiac monitoring have a low diagnostic yield in patients with generalized weakness, though they may be helpful when dysrhythmias or electrolyte abnormalities are suspected. Rarely, more specialized laboratory testing is indicated in the evaluation of the weak patient in the emergency department. Patients with suspected Guillain-Barré syndrome require cerebrospinal fluid analysis. This characteristically exhibits fewer than 50 lymphocytes per milliliter, a normal sugar, and an elevated protein. A Tensilon test should be considered in patients with suspected myasthenia gravis. Computed axial tomography or magnetic resonance imaging with intravenous contrast best evaluates structural lesions in the brain or spinal canal.

EMERGENCY DEPARTMENT MANAGEMENT

The focus of the emergency physician's approach to the patient complaining of weakness is to rule out the life-threatening diagnoses, specifically those diagnoses that can progress to cardiopulmonary compromise (Table 8.5). After airway patency is established, patients are assessed for adequacy of respiration. Certain patients, based on the history and physical examination, must be assessed for hypoxemia, hypercapnia, or carboxyhemoglobinemia. Assessment of pulmonary function with measurements of tidal volume and vital capacity may be valuable, especially in patients with suspected myasthenia gravis; patients with a vital capacity less than 1.5 L are possible candidates for intubation.

Case	History	Physical	Laboratory	Treatment
Myasthenia gravis	Chronic weakness, improves with rest	Double vision, muscle fatigue, improves with rest	Positive Tensilon test	Thymectomy, AChE inhibitors
Guillain-Barré	Rapid weakness, progressive weakness distal to proximal	Distal sensory loss, but reflexes, normal	CSF with elevated protein, <50 WBC	Supportive care, plasma exchange, gamma globulin
Botulism	Acute onset, cranial, ptosis, double vision	Flaccid or double vision	None	Supportive care, respiratory
Adrenal insufficiency	Acute weakness associated with stress	Hypotension, hyperpigmentation	Hypokalemia, hyponatremia	Hydrocortisone
Organophosphate poisoning	Occupational exposure, progressive weakness	Miosis, fasciculations, muscarinic dysfunction	Decreased RBC AChE	Atropine, pralidoxime
Carbon monoxide poisoning	Occupational or social exposure	Neurologic symptoms, headache, dizziness	Striated	100% oxygen, hyperbaric oxygen
Hypokalemia	Fatigue, GI or renal loss	Diffuse weakness	Low serum potassium	Potassium

AChE, acetylcholinesterase; CSF, cerebrospinal fluid; WBC, white blood cells; RBC, red blood cells; Q, questionnaire.

TABLE 8.5. Acute Life-Threatening Causes of Weakness

Potentially unstable patients require intravenous access, pulse oximetry, and cardiac monitoring. Regular reassessment throughout the emergency department stay is necessary to avoid missing deterioration in the patient's status. Specific interventions depend on the diagnosis. Sedating drugs should be avoided in anxious patients who are hypoxemic. Drugs that interfere with myoneural junction function, such as the aminoglycosides, should be avoided in patients with suspected myasthenia gravis. Hypoglycemia is treated with dextrose, and hypokalemia with potassium. Hydrocortisone, 100 mg intravenously, should be given to patients with suspected adrenal insufficiency. Patients with periodic paralysis do not have a total body deficit of potassium, but instead have an alteration in intra- and extracellular potassium levels; therefore, the potassium must be carefully corrected to avoid inducing hyperkalemia. Patients who are weak due to toxins require specific antidotes when available. Significant carbon monoxide poisoning is an indication for hyperbaric oxygen treatment; organophosphate poisoning requires the use of atropine and pralidoxime. Heavy metal poisoning is treated with chelation therapy.

DISPOSITION

Patients with progressive symptoms or those with suspected or confirmed disease with a known progressive course, such as myasthenia gravis, Guillain-Barré, or botulism, must be admitted to an intensive care setting regardless of their initial appearance. Early consultation with appropriate specialists is recommended, and a comprehensive management plan should be determined. No laboratory tests should be ordered unless results will be available before emergency department discharge or careful follow-up has been arranged.

COMMON PITFALLS

- Not taking the complaint seriously, and thus not performing a detailed history and physical examination
- Failing to obtain a drug and toxin exposure history and missing an occupational exposure, drug-induced myopathy, or drug-induced adrenal insufficiency
- Diagnosing a psychogenic etiology or the chronic fatigue syndrome in the emergency department
- Not recognizing absent reflexes as an early manifestation of the Guillain-Barré syndrome
- Failing to distinguish periodic paralysis from hypokalemia induced by drugs, gastrointestinal loss, or other etiologies

[Slit-Lamp Examination](#)
[The Ocular Fundus Evaluation](#)
[Disposition](#) [Role of the Consultant](#)
[Common Pitfalls](#)
[Bibliography](#)

Ocular emergencies usually create an atmosphere of mystery, intrigue, and fear for the nonophthalmic physician. One should approach the eye and the visual system with the same basic thought processes as for other body systems ([Fig. 9.1](#)).

Figure 9.1. Cross section of the eye.

HISTORY

Often, the history provides enough information to establish a reasonable differential diagnosis, allowing the physician to focus on the appropriate segment of the visual system. Key historical points include age, trauma, family history, systemic illnesses, occupation, allergies, and ocular history. It is essential to know whether the patient had any previous visual problems or wears glasses.

Common Complaints

Pain and Discomfort

It is often difficult to identify the source of pain because of the sensory overflow from various segments of the fifth cranial nerve (e.g., acute angle-closure glaucoma may present with pain in the frontal sinus region). Discomfort may be localized according to specific symptoms. Discomfort related to the anterior ocular surface or lids usually involves burning, itching, tearing, and foreign-body sensation. Orbital or periorbital discomfort may involve eye muscle fatigue, sinus congestion, and vascular headaches, all of which are nonocular causes. These, along with ocular and intracranial pathology, are best described as dull aches or pressure. Ocular inflammatory disorders (including episcleritis, scleritis, and acute glaucoma) are common, but intracranial pathology (arteritis, aneurysm, pituitary apoplexy, and tumors) is not.

Photophobia

Photophobia is a common type of discomfort particular to ophthalmic disease. It is the hallmark of uveal inflammation (e.g., iritis or uveitis of any cause). It may also occur in corneal, retrobulbar, and meningeal inflammatory conditions.

Discharge

Discharge is due primarily to anterior surface disorders and is addressed in [Chapter 10](#).

Tearing

Tearing, most often reflex in origin, indicates abnormal surface irritation from dysfunctional lubrication (chemical and infectious sources) and injured epithelium (corneal foreign body or abrasion). The dry-eye syndrome is therefore a common cause of tearing.

Redness and Swelling

Redness and swelling are signs of congestion; they may be due to the release of inflammatory mediators. Allergens and infectious agents contribute to anterior surface signs. The orbital outflow disorders (congestive) are of concern; they include trauma, thyroid ophthalmopathy, orbital cellulitis, orbital inflammatory syndromes, cavernous sinus thrombosis, and fistulas. Intraocular inflammation tends to cause circumlimbal redness (ciliary flush) or generalized redness, but usually does not cause swelling. Exceptions to this are endophthalmitis and some cases of scleritis.

Changes in Appearance

A sense of urgency arises most often when there is an acute change in appearance. A common example is the subconjunctival hemorrhage. Although usually benign, it may be more ominous in the setting of possible penetrating trauma. Swelling and mass effect are noted with chalazia and dacryocystitis (over the lacrimal crest region). Proptosis may be due to a retrobulbar mass effect (thyroid ophthalmopathy, mucocele, tumor, and fistula).

Visual Disturbances

Visual disturbances are a frequent complaint and are often related to a nonocular cause. Blurred vision may originate from refractive errors all the way through the visual system to occipital cortex disorders. A good clinician should use the history as a starting point in the evaluation. *Glare* or *halos* are common disturbances. They are usually the result of light-scatter phenomena from unclear ocular media (mucinous tear film, corneal edema of any cause, corneal epithelial abnormalities, cataract, or vitreous haze). *Spots* or *floaters* are commonly degenerative opacities within the vitreous; they may, however, indicate red or white blood cells in the aqueous or vitreous. The sudden appearance of floaters may be clinically important.

Transient visual loss is a potentially serious problem. If unocular, consider the anterior circulation and pathways. If binocular, consider generalized hypoperfusion,

Figure 9.3. Performing confrontation fields.

Figure 9.4. Amsler grid.

Because the central retina and optic nerve are essentially a color projection system, even simple analysis of color perception may help isolate the problem. Color vision testing can be performed using many techniques, but in the emergency setting, the testing of the central red saturation is a good way to localize the problem to the central retina or optic nerve. Using the red bottle top of a dilating or cycloplegic agent (e.g., tropicamide [Mydracil] or phenylephrine hydrochloride [Mydrin]), the examiner can ask the patient to quantitate the “degree” of red seen in each eye (“If this is a dollar’s worth of red in the good eye, how much is it worth in the other?”). If the response reveals desaturation, macular or optic nerve disease may be present.

THE PHYSICAL EXAMINATION

Every physician should develop proficiency using the penlight. A bright penlight is helpful for pupil evaluation and is also useful in assessing the lids and anterior surface of the eye. Loupe magnifiers should be used if available. Many penlights are equipped with a cobalt blue filter that can be used with fluorescein application. The light should be moved across the eye to perceive the glassy reflective surface of the cornea. Epithelial abrasions and edema can be identified from the discontinuity in the reflections. It is useful to compare the findings with those of the other eye. The patient should be asked to look up while the lower lid is pulled down to evaluate the lower cornea and globe. *Foreign bodies commonly are located under the upper lid.* The examiner should look for discharge and areas of inflammation.

Fluorescein is a stain picked up by severely damaged or absent epithelial cells (corneal abrasion). It changes color in the presence of abnormal pH. A dark flow in a green-yellow background is seen if aqueous humor is present from a corneal laceration.

Slit-Lamp Examination

The anterior segment of the eye is best examined with the slit-lamp biomicroscope. The view of the anterior segment anatomy is astounding under high magnification. In the presence of injury or infection, the slit-lamp examination is mandatory. The patient’s head is positioned in the chin rest, with the forehead against the bar. The black line on the right vertical pole next to the patient’s face is aligned with the level of the eyes. The examiner sets the oculars (usually to 0) and then adjusts the interpupillary distance, as with binoculars. The light source is moved to 45 degrees from the examiner–patient axis, and the chassis is adjusted forward or backward to bring the eye into focus. The examination is started on low magnification (10×). Once the eye is in focus, the magnification may be increased. Fine adjustments are made with the joystick. On some models, the up–down control is on the joystick. The beam is adjusted to a slit rather than a full circle. The three-dimensional box seen on the cornea shows the 0.5-mm thickness. With the slit lamp, the extent and level of corneal injuries can be assessed. The lids, conjunctiva, cornea, anterior chamber, and irises of both eyes should be examined systematically.

The *lid margins* may demonstrate information related to “the red eye.” Lacerations may be appreciated, especially in the nasal canthal region, where the identification of a canalicular laceration is critical.

The *conjunctiva* has epibulbar and tarsal components. The examiner should look for discharge, follicles (lymphoid aggregates characteristic of certain viral, toxic, or allergic conditions), chemosis (subconjunctival fluid swelling), and hyperemia. Small foreign bodies can be swept from under the upper lid during the slit-lamp examination.

The examination of the *cornea* involves the following:

1. Epithelium: to detect abrasions, edema, ulcers, and foreign bodies
2. Stroma: to detect primarily edema, but also deep ulcers, deep scars, and penetration
3. Endothelium: to detect keratic precipitates (white cells on the endothelium). These precipitates are a hallmark of iritis. Penetration through this layer is called a *laceration*.

The size and shape of the findings are noted. A drawing of front and side views is helpful.

The *anterior chamber* is bounded by the cornea and iris and is filled with aqueous. Its depth can be assessed by adjusting the slit beam. By narrowing the beam into a small column of light, the examiner may see a cellular reaction (iritis) as well as flare (light scatter caused by inflammatory proteins in the aqueous). Red or white blood cells may be present in the anterior chamber. Red blood cells usually result from trauma; the layering of these cells in the anterior chamber is called a *hyphema*. Sometimes, pigment dispersion (granules of pigment) is difficult to differentiate from mild diffuse red blood cells. White blood cells are present in iritis; the layering of these cells in the anterior chamber is called a *hypopyon*.

The *iris–lens* examination involves noting pupil dysfunction, which may include traumatic tears in the sphincter or adhesions to the anterior lens capsule (posterior synechiae). The iris may plug corneoscleral lacerations (thereby peaking the pupil) or be torn at its root (iridodialysis). Opacities of the lens are defined as cataract opacities and may be due to many causes. Injury to the anterior capsule of the lens in penetrating trauma has diagnostic and surgical significance, because these lenses generally become rapidly opaque and incite tremendous inflammation.

The Ocular Fundus Evaluation

The ophthalmoscope can be used to magnify the anterior surface of the eye, using the higher, black-numbered lenses. Impaired view may be due to cloudy media

(e.g., corneal and lens opacities, and vitreous blood), but it can also be due to unusual refractive errors. One tip for better viewing is to have the patient wear his or her corrective lenses while undergoing this test. It is expected that the refractive correction has made the patient “normal-sighted.” If the examiner and patient are “normal-sighted,” generally a -2 or -3 lens (the red 2 or 3) allows a comfortable view of the fundus.

The *optic nerve head* should be evaluated for margins, shape, and cup. The examiner should be aware of anomalies, such as small disks with little or no cup and central vessels with multiple early bifurcations. Spontaneous venous pulsations should be noted. Hemorrhages and blurred margins can be critical findings, and should be compared with findings in the other eye. The *macula* should be examined with attention to the presence of hemorrhages, exudates, and edema. It is important to note if these findings are generalized (diabetic or hypertensive retinopathy) or localized (any vascular retinopathy, especially occlusive disease). It is difficult to determine the layer of retinal bleeding, especially when the bleeding is subretinal. Deep hemorrhages tend to be small and irregular. Superficial hemorrhages are flame-shaped. Edema makes the retina look gray-white. In central retinal artery occlusion and other causes of a thickened nerve fiber layer of the retina (e.g., Tay-Sachs disease), one will see a distinctive, central red area called the *cherry-red spot*. This represents the visualization of the normal choroidal circulation through the one area of the retina where the nerve fiber layer is absent (fovea centralis).

Recognition of vascular retinopathies has important implications. The *retinal vessels* are a mirror of the body's microcirculation in a host of systemic processes.

Finally, *intraocular pressure* should be evaluated. The intraocular pressure is to the eye what the blood pressure is to the cardiovascular system. Normal values range from 10 to 21 mm Hg, and are measured in various ways:

Indentation tonometry. The Schiøtz tonometer is cumbersome, can spread infection, and may create its own trauma, but it is relatively easy to use.

Applanation tonometry. The applanation tonometer is accurate, easy to use, and mounted on most slit lamps. [Figure 9.5](#) shows the hand-held model.

Figure 9.5. Hand-held applanation tonometer (left) and tonometer pen (right).

Tonometer pens are electronic devices that are easy to use and relatively accurate, but very expensive (see [Fig. 9.5](#)).

Noncontact tonometers are for screening only; they may be inaccurate.

Pneumotonometers are effective and relatively easy to use, but somewhat expensive to maintain; they must be calibrated.

Manual assessment of the tensions may be crude and inaccurate. The eyeball is palpated through closed lids in a gentle balloting motion. Each eye is compared with the other. The examiner's eye may be used as a control. By measuring the intraocular pressure with a tonometer and then doing finger tensions, the examiner may become more proficient. *This method should be avoided in recently operated globes or if lacerations are suspected.*

DISPOSITION

Role of the Consultant

The urgency of referral depends on multiple factors. Through a careful history and physical examination, the emergency physician should be able to arrive at a diagnosis. Medicolegally, one can never be faulted with a phone consult with the ophthalmologist, documenting the details. Providing the necessary information to the ophthalmologist is the key to an effective consultation. The minimum information the consultant needs includes the patient's age, chief complaint, ocular history (and any pertinent medical history), and visual acuity in both eyes, as well as any other pertinent findings.

COMMON PITFALLS

- In the setting of trauma, epibulbar (subconjunctival) hemorrhage associated with a history of high-velocity or potentially lacerating objects (e.g., glass, metal) suggests the possibility of ocular penetration, especially if the vision is diminished (vitreous hemorrhage).
- A key piece of information often missing on the emergency department evaluation is the patient's visual acuity. Each eye must be assessed while occluding the other. The use of a pinhole is extremely useful when vision is reduced. Improved vision through the pinhole suggests routine referral for refraction and glasses, thus avoiding an unnecessary urgent consultation or expensive diagnostic testing.
- “Red-top” ocular medication bottles are mydriatic–cycloplegic agents. The vast majority of dilated pupils presenting in the emergency setting are pharmacologic in origin. Other findings, such as horizontal diplopia, motility disturbance, and ptosis of the lid, suggest more serious neuroophthalmic etiologies.
- Headache is a common complaint, and may have an ocular origin. Be aware that shared sensory influx from a host of anterior cranial and facial structures (e.g., the paranasal sinuses) can refer pain to the orbit and periorbital regions.
- Anterior visual pathway and carotid circulation problems tend to be associated with unocular visual loss; posterior pathways and vertebrobasilar circulation problems often present with binocular complaints (check for hemianopia).
- Penlight diagnoses are difficult. Use the slit-lamp biomicroscope, if available, to examine the eye. Turn the light intensity rheostat down low when turning on the slit lamp to avoid blowing out expensive bulbs and also to reduce patient discomfort from high-intensity light.
- Excess fluorescein should be avoided when evaluating ocular surface problems or checking intraocular pressure.
- Avoid the indiscriminate use of topical antibiotics in serious ocular infections without first obtaining adequate samples for culture and sensitivities.
- The emergency physician should not be afraid to use topical anesthetics to aid in the evaluation of the eye, especially in the setting of trauma (to reduce lid spasm). However, these agents retard corneal epithelial wound healing; hence, discharging a patient with a topical anesthetic is a medicolegal risk and should always be avoided.
- Pupillary dilation may be essential to visualize the posterior segment of the eye (optic disk and retina) for proper diagnosis. A weak mydriatic should be used and *documented in the record*. Tropicamide 0.5% or 1.0% should be used because it is short-acting (4 to 6 hours) and relatively easy to reverse with miotics. The incidence of precipitating angle-closure glaucoma in the general population is extraordinarily low (about 2:10,000). If there is concern with regard to this problem or compromising the pupillary examination neurologically, the appropriate specialist should be called to assist in the decision.
- Topical corticosteroids, used alone or in combination with other topical medications, should be used only after proper consultation by phone.
- Even though ocular medications are most often delivered topically, there are significant systemic side effects seen with certain agents, especially those that treat glaucoma (e.g., beta-blockers). Punctal compression, to avoid drainage down the nasolacrimal system into the posterior nasopharynx (subsequently swallowed), will reduce this problem.

[Common Pitfalls](#)

[Bibliography](#)

The red eye poses a diagnostic challenge to everyone, including the ophthalmologist. Infection is only one cause, and a diligent search must be made for other etiologies. This chapter addresses ocular infections of the anterior surface (conjunctiva and cornea). Intraocular infections also occur, but are much rarer and are not discussed in detail.

Conjunctivitis is the inflammation of the mucous membrane that covers the anterior sclera and inner eyelids. Infection of the conjunctiva is one of the most common causes of red eye treated in the emergency department, and usually is viral or bacterial. Most cases are self-limited, but serious complications can occur. The conjunctiva contributes to the formation of the tear film, and severe conjunctivitis may result in scarring and an abnormal tear film. Because the precorneal tear film is an important optical surface determining clarity of vision, treatment must be accurate and the patient followed carefully.

Keratitis is an inflammation of the cornea. The corneal epithelium may be involved in a superficial manner (with punctate erosions or ulceration), or there may be deeper involvement with infiltration. Quite often there is simultaneous involvement of the conjunctiva as well. Keratitis is usually quite painful and can be associated with either viral or bacterial disease. The intact corneal epithelium is normally an effective barrier against bacterial organisms, with several exceptions, including *Neisseria gonorrhoeae*, *Corynebacterium diphtheriae*, *Listeria monocytogenes*, and *Haemophilus aegyptius*. However, any damage to the corneal epithelium can permit access by a wide variety of other organisms. Because corneal scarring is one of the leading causes of blindness worldwide, aggressive, appropriate treatment is essential.

Endophthalmitis is infection or inflammation of the intraocular tissues. This can result from direct inoculation or hematogenous spread of organisms. *Panophthalmitis* is the term used when infection also involves the orbital soft tissues. These conditions typically require subconjunctival or intravitreal as well as systemic antibiotics and must be managed by an ophthalmologist.

VIRAL PATHOGENS

There are three viral pathogens of particular note: the adeno-viruses, herpes simplex, and herpes zoster viruses.

Adenovirus infection is very common and highly transmissible. Infection starts in one eye and several days later becomes bilateral, with significant watery discharge and follicles ([Fig. 10.1](#)). Preauricular adenopathy is common, and there is marked discomfort, which may persist for weeks. It is quite common to see serious progression as the immunologic response increases. Development of pseudomembranes may indicate corneal injury not present on the initial examination. Epidemic keratoconjunctivitis is caused by adenovirus types 8 and 19 and is highly contagious. This is the classic "pinkeye."

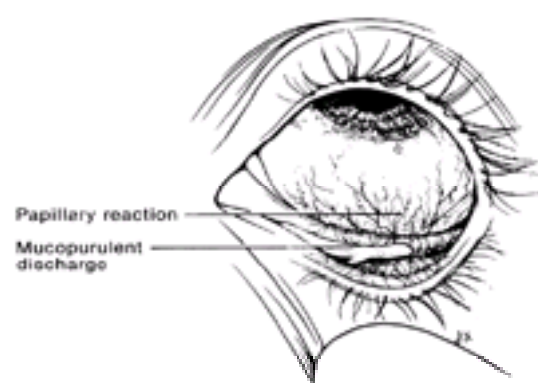

Figure 10.1. Viral infection.

Occultly contaminated equipment in ophthalmology offices is a leading cause of outbreaks. Contact with infected persons in physicians' offices, emergency departments, and schools is also a source. The period of contagion is roughly 2 weeks after onset of symptoms. Adenoviral keratoconjunctivitis does not respond to topical antiviral agents. Supportive care includes isolation, cool compresses, ocular decongestants, lubricants, and a broad-spectrum antibiotic to prevent secondary overinfection. Evaluation of therapeutic response is not always easy. Knowledge of the course of this condition will ease patient expectations as to the therapeutic response. Progressive visual loss, increasing discomfort, and pseudomembrane formation are indications for urgent referral. Reduced discharge, swelling, and hyperemia indicate therapeutic success.

Herpes simplex conjunctivitis may present with unilateral conjunctival hyperemia associated with a clear discharge. Other findings may include lid vesicles or ulcerations in early or primary cases. Corneal spread can occur rapidly, resulting in a dendritic ulcer ([Fig. 10.2](#)). Ophthalmologic consultation is indicated once the diagnosis is made. In simple, early epithelial herpes, mechanical debridement is an important aspect of treatment and should be done by an ophthalmologist. Topical vidarabine 3%, trifluorothymidine 1%, or idoxuridine 0.5% may be used in consultation with the ophthalmologist.

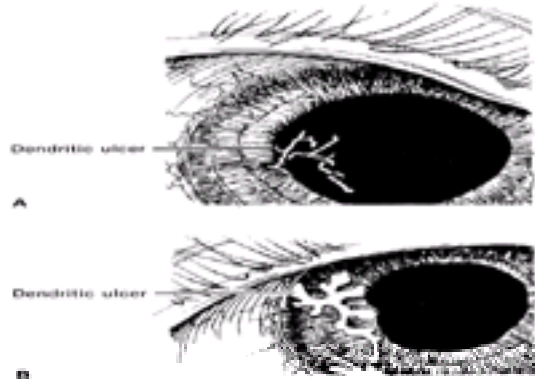

Figure 10.2. Herpes simplex keratitis. **(A)** Early epithelial dendritic ulcer. **(B)** More advanced or geographic ulcer.

Herpes zoster ophthalmicus, ocular involvement, should be suspected, especially if the nasociliary branch of the fifth cranial nerve is involved. Punctate keratopathy, lid vesicles, or dendritic infiltrates may be present. In fact, herpes zoster may mimic herpes simplex. Early ophthalmologic consultation may be indicated. Systemic steroids to avoid postherpetic neuralgia should not be administered by an emergency physician. Topical cycloplegics and steroids are beneficial. There is evidence that systemically administered acyclovir may diminish the severity of the process and postherpetic neuralgia when administered early in the course of the disease. When iritis is present, intraocular pressure may be elevated.

Bacterial Pathogens

The pathogens of greatest clinical importance and frequency include *Staphylococcus*, *Haemophilus*, pneumococci (and other streptococci), *Neisseria gonorrhoeae*, diphtheroids, coliforms, *Pseudomonas*, *Proteus*, and *Moraxella*. Of lesser frequency, but still important, are Parinaud's oculoglandular syndrome (cat-scratch fever) and luetic and tuberculous disease. Mucopurulent conjunctivitis is most commonly caused by *Staphylococcus aureus*, followed by *Streptococcus pneumoniae* and *Haemophilus influenzae*. The onset is often acute and unilateral but may rapidly become bilateral. Crusting of the lids is common. Epidemic forms can be caused by pneumococci and *Haemophilus*. Gram stain and culture are usually unnecessary unless the case is quite severe, is unresponsive to therapy, or occurs in a compromised host.

Treatment consists of warm compresses, lubricants, and broad-spectrum antibiotics (drops during the day and ointments at bedtime). Commonly used antibiotics include sulfa-cetamide 10%, gentamicin 0.3%, Polytrim, and Neosporin. The sulfa drugs are less sensitizing than neomycin. Chloramphenicol is least sensitizing. Bacterial conjunctivitis should be notably improved in 48 hours.

Gonococcal conjunctivitis usually causes unilateral conjunctival hyperemia, a severe purulent discharge with associated edema, and erythema of the lids. The population at risk includes neonates, sexually active adults, and health-care workers. The incubation period is from 1 to 3 days. Culture and Gram stain should be done and will reveal gram-negative intracellular diplococci. The patient should be seen by an ophthalmologist immediately and may require admission for systemic therapy and frequent irrigation of the eye, because the gonococcus can penetrate the intact cornea. Topical antibiotics, irrigation, and parenteral penicillin or cephalosporins are used. Single-dose ceftriaxone may allow for selected outpatient therapy.

Pseudomonas aeruginosa is a very aggressive ocular pathogen, producing an adherent mucopurulent, yellow-green exudate and a "ground glass" appearance of the cornea adjacent to the ulcer. Perforation and extension of the infection to the sclera are major concerns.

Fungal Pathogens

The common fungal pathogens include *Actinomyces*, *Aspergillus*, *Blastomyces*, *Candida*, *Coccidioides*, *Mucor* (in diabetics), and *Sporothrix*. Fungal infection is generally not fulminant. Patients taking corticosteroids and those with suppressed immune systems are at risk. A history of trauma involving vegetable matter is important. Beneath the corneal infiltrate, an endothelial plaque may be seen. The hypopyon associated with this type of corneal infection may contain fungal elements. Gram and Giemsa stains and cultures are essential. Fungal blepharoconjunctivitis can be controlled with lid hygiene and compresses. If the physician identifies fungal elements on corneal ulcer smears, natamycin 5% suspension (Natacyn) should be given every hour after appropriate consultation.

Rickettsial Disease

It is difficult to diagnose rickettsial disease of the eye. Rocky Mountain spotted fever and scrub typhus can cause anterior surface ocular problems. History, other lesions, clinical suspicion, and complement fixation may aid in the diagnosis. Treatment may be curative with systemic tetracycline or chloramphenicol.

Chlamydia

Mucopurulent inclusion conjunctivitis is extremely common, especially in sexually active young adults (Fig. 10.3). The diagnosis is made by the lack of organisms on Gram stain and a positive immunofluorescent antibody screen. The presence or history of a urethral discharge may suggest concomitant gonococcal disease. Conjunctival scrapings may be helpful acutely. Systemic therapy is necessary and includes erythromycin or tetracycline, 1 g daily (250 mg every 6 hours) for 3 to 4 weeks (doxycycline 100 mg b.i.d. is preferred). Ocular therapy (topical sulfa or erythromycin) is supportive only and not curative. Partners should be referred for treatment. Neonatal inclusion conjunctivitis occurs several days to 2 weeks after birth. The treatment is similar, but topical therapy with sulfacetamide 10%, q.i.d. for 3 weeks, is more effective. Systemic therapy with erythromycin is necessary in the neonate due to concomitant pneumonitis. Trachoma continues to be a major cause of inflammatory blindness worldwide, although it is not prevalent in the United States.

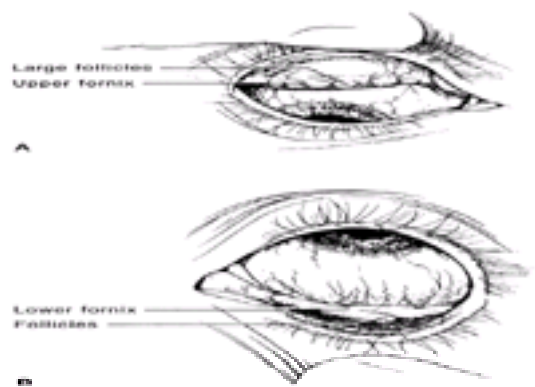

Figure 10.3. Inclusion conjunctivitis (*Chlamydia*).

Parasitic Disease

Acanthamoeba is a growing concern, especially in contact lens wearers. Pediculosis (*Phthirus pubis*) affects the lids, brows, and ocular surface. Toxocariasis (*Toxocara*) and toxoplasmosis (*Toxoplasma*) are principally diseases that affect the retina and uvea.

Clinical Presentation

The hallmark of anterior surface infection is the red eye. In addition, discomfort, discharge, lid crusting, sticking, photophobia, and visual loss are often seen. Unfortunately, there are many noninfectious causes of these symptoms as well (Table 10.1), and there is much overlap of findings. A careful history can be helpful in sorting them out. Inquire about known eye conditions, contact lens use, previous trauma, use of eye medications, and contact with infected people. Symptoms of systemic illness or infection are particularly important, especially any that might increase suspicion of an immunocompromised state.

Visual Disturbance	Associated Condition	Typical Presentation
Pain	Corneal abrasion, foreign body, chemical burn, infection, trauma	Acute onset, localized to the eye
Photophobia	Conjunctivitis, uveitis, keratitis, trauma	Acute onset, associated with redness and tearing
Discharge	Bacterial conjunctivitis, viral conjunctivitis, allergic conjunctivitis	Acute onset, associated with redness and tearing
Tearing	Allergic conjunctivitis, dry eye syndrome, trauma	Acute onset, associated with redness and itching
Blurred vision	Conjunctivitis, uveitis, keratitis, cataract, glaucoma	Acute onset, associated with redness and tearing
Diplopia	Strabismic amblyopia, refractive error, trauma	Acute onset, associated with redness and tearing
Floaters	Posterior vitreous detachment, retinal tear, retinal detachment	Acute onset, associated with redness and tearing
Halos	Cataract, glaucoma	Acute onset, associated with redness and tearing
Decreased visual acuity	Cataract, glaucoma, retinal detachment, optic neuritis	Acute onset, associated with redness and tearing

TABLE 10.1. Differential Diagnosis of Selected Causes of Visual Disturbance

Eye infections can be bilateral or unilateral. Herpetic disease is usually unilateral. Adenoviral infections generally start in one eye and “ping-pong” to the other after several days. Post-traumatic iritis is limited to the injured eye, but be alert for secondary infection of a traumatic corneal lesion. Allergens tend to involve both eyes.

Most of the inflammatory and infectious eye conditions cause a discharge, but purulent discharge should increase suspicion of bacterial infection. History of trauma involving vegetable matter (e.g., tree branch) may implicate fungal disease as the cause of infection. Contact lens wearers are especially prone to all types of infectious disease, as well as to ischemic injury from overwear syndrome and toxic infiltrates from old or contaminated lenses.

DIFFERENTIAL DIAGNOSIS

Although infection is a common cause of the red eye, many processes mimic infectious disease of the anterior ocular surface (see Table 10.1):

- Allergic reactions
- Airborne irritants
- Foreign bodies
- Chemical or thermal burns
- Medicamentosis (common)
- Trauma
- Vascular conditions (carotid–cavernous sinus fistulas, blood dyscrasias)
- Orbital inflammatory or congestive diseases (e.g., thyroid ophthalmopathy)
- Glaucoma (acute and neovascular)
- Uveitis (includes episcleritis or scleritis)
- Neoplasia (squamous and meibomian cell carcinoma)
- Mucocutaneous syndromes (ocular pemphigoid, Stevens-Johnson syndrome)
- Dry eye syndromes

This is a sizable list because many conditions cause a release of vasoactive substances (e.g., histamine and prostaglandins), resulting in redness, discharge, or both. To complicate matters, however, these noninfectious conditions may create a milieu conducive to secondary bacterial infection. For example, any irritation may cause the patient to rub the eye and either transfer agents from the hand or create mild trauma, serving as a nidus for infection. Conversely, certain bacteria (most often staphylococcal lid infections) are occasionally associated with hypersensitivity reactions.

EMERGENCY DEPARTMENT EVALUATION

After taking a careful history, as described, visual acuity testing of both eyes is the first step in the physical examination of the eye. This should be performed prior to instillation of any medication. After this, direct inspection of the eye, followed by slit-lamp examination, should be done with attention to the following anatomic structures.

Lids

Crusting of the lids is common in bacterial overgrowth, infection, and dermatologic conditions (seborrhea). Ulcerations are common in herpetic and staphylococcal infections. Lice (*Phthirus*) may also be seen. Lid eversion should be performed if indicated (foreign body, pseudomembranes).

Conjunctiva

Note the presence of chemosis or discharge (serous, mucoid, or mucopurulent). Follicles represent lymphoid aggregates, which are a hallmark of acute adenoviral disease, but are, on occasion, seen in other cases of infectious, toxic, and allergic conjunctivitis. Membranes, or fibrinous pseudomembranes, are seen in severe conjunctivitis associated with adenovirus, occasionally in other conditions (such as *S. pneumoniae* and diphtheria), and rarely in herpetic disease. Hemorrhage is usually petechial but may be more extensive, as in adenovirus, hemorrhagic conjunctivitis virus, *Haemophilus*, and *S. pneumoniae*. An acute, markedly purulent conjunctivitis should be thoroughly and rapidly evaluated before treatment. Corneal perforation is possible, especially in conditions such as gonococcal disease.

Cornea

The hallmark of epithelial injury, especially in viral disorders, is punctate areas of cell loss. These appear as stained specks with fluorescein and are diagnostic of adenovirus (superficial punctate keratopathy). However, many other conditions may mimic this, including herpetic disease, so consider additional clues. Ulceration implies a larger epithelial defect and is important to identify. Immediate referral is indicated in this setting because of the potential for permanent scarring or perforation. The ulceration description should include size, shape, and anterior stromal involvement. Herpetic ulcers are usually dendritic or geographic. Bacterial and fungal ulcers tend to be round with fluffy white borders and extend into the anterior stroma (Fig. 10.4). They are usually associated with a purulent discharge and lid-sticking. Infiltrates are epithelial, subepithelial, or stromal collections of inflammatory cellular debris that are nonspecific but common in viral (adenoviral, herpetic), chlamydial (inclusion), bacterial (in association with the ulcerative defect), and hypersensitivity reactions (small and near limbus).

Figure 10.4. Bacterial or fungal corneal ulcer.

Anterior Chamber

The presence of white blood cells in the aqueous is the hallmark of iritis (uveitis), which occurs with severe anterior surface infections (herpetic disease, adenovirus). The grading of the reaction (1+ to 4+) of these cells correlates with the severity of the iritis. Layering of the cells in the anterior chamber is called a *hypopyon* and is a hallmark of severe ulceration of the cornea and endophthalmitis. Usually seen with bacterial and fungal infection, *a hypopyon warrants immediate consultation and referral*. In the presence of a small corneal ulcer without hypopyon, *consult first*. After stains and cultures have been performed, cover with “heavy” topicals (e.g., topical ciprofloxacin [Ciloxan 0.3%] every 30 to 60 minutes). Fortified drops are most often used and are prepared by the pharmacy. If a hypopyon is present, or the ulcer is large or multiple, this is an ocular emergency, and the ophthalmologist should be called. Infectious ulcers of the cornea tend to be more central, whereas hypersensitivity immune ulcers (e.g., rheumatoid and staphylococcal) tend to be peripheral.

Other Physical Findings

Preauricular lymphadenopathy is an important sign of adenoviral conjunctivitis, but it may be seen in severe bacterial infection (streptococcal and neisserial). It is classically seen in Parinaud’s oculoglandular syndrome, in which the nodes are very large and tender and occasionally draining. Distant skin ulcerations or vesicles, including the lids, suggest herpetic disease (simplex or zoster), as well as impetigo. *Moraxella* and *Staphylococcus* tend to cause ulceration and maceration in the lateral canthal regions.

Diagnostic Aids

Fluorescein

The ocular surface is stained with a moistened, sterile fluorescein strip and viewed with a slit lamp. A small quantity is used. The examiner should look for areas of epithelial loss on the conjunctiva and cornea. The noninfected eye is stained first.

Rose Bengal

Rose bengal is not used as frequently, but it does indicate devitalized epithelium. A small amount should be used; a slit lamp is generally required. It is occasionally helpful in the diagnosis of herpetic ulcers. The dendritic pattern of a herpetic ulcer may appear similar to that of a healing corneal abrasion. The margins of a healing abrasion are healthy, with proliferating epithelial cells, and do not stain with rose bengal. The margins of a herpetic dendritic ulcer contain actively infected epithelial cells that are devitalized and pick up the red stain.

Laboratory Studies

Routine conjunctival infections are not cultured, but it is appropriate, in the setting of a severe or unusual purulent conjunctivitis, to perform Gram and Giemsa stains of the material. After cultures, conjunctival scrapings should be taken. A flamed platinum spatula that has cooled is gently scraped across the anesthetized tarsal conjunctiva. The material is spread thinly on a glass slide. Corneal scraping of ulcers must be performed at the slit-lamp biomicroscope, preferably by an ophthalmologist; it is essential before initiation of antibiotics. Conjunctival cytology of cell types and the identification of intracytoplasmic inclusions are also helpful. In culturing organisms, blood, chocolate, and Sabouraud dextrose agar, and thioglycollate broth are basic media for corneal ulcers. *At a minimum, culturettes of conjunctival exudates should be placed into liquid culture media*. Viral and chlamydial studies are available at large medical centers but are generally not performed in the emergency setting. Deeper ocular infections (endophthalmitis) typically require culture of the anterior chamber and/or vitreous prior to treatment. This should be performed by an ophthalmologist. Evaluation of other body fluids is occasionally necessary. For example, a urethral discharge may help determine a possible gonococcal or Reiter’s conjunctivitis.

EMERGENCY DEPARTMENT MANAGEMENT

It is important to avoid contagion. In the setting of ocular infection, it is essential to maintain clean equipment and to avoid checking the intraocular pressure, unless absolutely necessary, because of the risk of spreading contamination with the tonometer. The emergency physician is at risk to contract or spread these highly contagious diseases and should be fastidious about hand-washing. Appropriate medical excuses need to be offered to school-age children and health-care workers.

[Table 10.2](#) lists antibiotics for topical use. It is important to avoid mixing bacteriostatic antibiotics (e.g., erythromycin) with bactericidal antibiotics (e.g., bacitracin). Certain bacteriostatic antibiotics (e.g., sulfa) can be bactericidal at the high levels delivered in topical preparations; therefore, hospital sensitivity profiles may not be reliable.

TABLE 10.2. Antibiotics for Topical Use

Be aware of antibiotics with increased sensitizing ability. Neomycin, a major component of Neosporin, is highly sensitizing and should be avoided. It may mask evaluation of response as well as create reactions that look worse than the original condition. Sulfa agents, bacitracin, and aminoglycosides can create a similar picture, but much less frequently. There have been cases of Stevens-Johnson–like reactions to topical sulfa. By prescribing only a small amount at a time and no

multiple refills, patient retention of old medications that may be contaminated can be avoided.

Severe anterior surface disorders can result in iritis, with the potential to cause subsequent scarring of the pupil to the lens (posterior synechiae), as well as iris to cornea (peripheral anterior synechiae). Cycloplegics are essential and improve patient comfort. Longer acting cycloplegics (scopolamine, homatropine, and atropine) may be necessary. Although cortico-steroids play an important role in the management of iritis and may reduce corneal scarring, their use in the emergency setting is controversial, and they should be used only in consultation with the ophthalmologist.

It is important to understand the immunologic inflammatory consequences after proper antibiotic coverage (usually corneal infiltrates). Ophthalmologic referral is indicated because of the possible indication for corticosteroid therapy.

The goal should be to do a thorough examination and treat ocular infection in a way that will least harm the patient. Sulfacetamide 10% or Polytrim solutions given four to six times daily for several days will clear most simple surface infections. Gentamicin, tobramycin, and several quinolone solutions are currently available and are extremely helpful, but they may be more beneficial when reserved for special situations. Chronic use will cause eye toxicity and permit resistant organisms and fungal overgrowth. Drops are aesthetically superior and provide high levels quickly; however, they are cleared by tear drainage too quickly. Ointments reduce this clearing effect as well as the irritation, but cause blurred vision. Use of ointments (polymyxin–bacitracin combinations) may be particularly helpful at bedtime. For the previously stated reasons, drops are better used in adults, but ointments may be more efficacious in children.

DISPOSITION

Role of the Consultant

Immediate consultation is indicated in the following circumstances:

Purulent conjunctivitis associated with a corneal infiltrate, ulcer, or hypopyon. Risk factors include trauma and contact lens history.

A hyperacute conjunctivitis with a history or Gram stain suggesting gonococcal disease

Membranous conjunctivitis. Secondary injury to the cornea or severe corneal epithelial injury may occur.

Consultation within 24 to 48 hours:

Relatively severe conjunctivitis or keratitis that suggests possible herpetic disease, especially if it is near the visual axis

Consultation within 3 to 7 days:

Bacterial conjunctivitis that does not improve within 48 hours

Viral disease that is nonmembranous with intact vision. Adenoviral disease (e.g., epidemic keratoconjunctivitis) may show persistent signs of involvement for weeks!

Indications for Admission

Emergency admissions are rare, but are required for endophthalmitis; occasionally, severe or recalcitrant corneal ulcers, and *Neisseria* conjunctivitis with corneal infiltrates may also require hospital admission. It is uncommon to admit a patient with herpes simplex or zoster. The principal goal for admission is systemic therapy, frequent topical antibiotic administration, and subconjunctival or intravitreal injections. Topical therapy may need to be administered every 30 to 60 minutes (and prepared fortified).

Special Considerations

Outpatient care may be possible, but many patients are incapable of intensive care at home. Most patients with corneal ulcers should be rechecked in 24 hours. Moderately severe cases of bacterial conjunctivitis should be seen in 48 to 72 hours. Referral should be based on progression of the disease, lack of response, increased pain, and decreased vision.

COMMON PITFALLS

- *The red eye is not always infected!*
- High-risk situations for purulent conjunctivitis should be sought and include conjunctival pseudomembranes, posttraumatic reaction, and contact lens wear.
- Multiple antibiotics are often used when progression of the infection is really due to hypersensitivity (Neosporin) or toxicity to the drug. Prolonged therapy creates the same risk as overtreating systemic infection with regard to the emergence of resistant organisms or fungal growth.
- Initiating antibiotic therapy before diagnostic studies are performed may force the ophthalmologist into “shotgun” therapy.
- The indiscriminate use and distribution of topical anesthetics and corticosteroids are to be condemned

[Bibliography](#)

The information provided here describes representative therapeutic preparations for many ocular conditions. Please refer to compendiums such as the *Physician's Desk Reference for Ophthalmology* for a thorough listing with pharmaceutical manufacturers' specifications. Frequency of medication applications depends on the agent used and the severity of the condition being managed.

DIAGNOSTIC MEDICATIONS

These agents facilitate the ability to examine the eye.

Stains

These are topical solutions that highlight epithelial abnormalities of the cornea and conjunctiva.

Fluorescein: Sterile paper strips are preferred to the 2% solutions, owing to ease of contamination of the latter.

Rose bengal: This 1% solution stains devitalized corneal–conjunctival epithelium; it is helpful in differentiating a herpetic corneal ulcer from a healing abrasion.

Anesthetics

These are topical solutions that promote patient cooperation for the examination; they are also used in conjunction with the aforementioned stains. Anesthetics are usually required for determining intraocular pressure.

Tetracaine hydrochloride (Pontocaine): 0.5% to 1.0% solution, lasts for 15 minutes; may sting

Proparacaine hydrochloride (Ophthetic, Ophthaine): 0.5% solution, less irritating

Cocaine (0.25% to 0.5%): Effective but highly toxic to the corneal epithelium

Mydriatics and Cycloplegics

These are used diagnostically or therapeutically to dilate the pupil (mydriasis) and/or paralyze the ciliary body (cycloplegia). This permits evaluation of the internal ocular structures and gauges the baseline refractive error of the eye by blocking accommodation. In addition, these agents prevent synechiae formation (adhesions of the iris to lens and cornea) by reducing intraocular inflammation through stabilization of the blood–aqueous barrier. These agents are capped in *rea*.

Phenylephrine hydrochloride (Neo-Synephrine, Mydrin): Vasoconstricts the surface vessels and dilates the pupil without cycloplegia; 2.5% solution is the strength recommended because of a higher incidence of cardiovascular side effects with 10%. Dilation capability varies, used alone, and may last up to 4 hours, depending on the amount of pigmentation of the iris.

Tropicamide (Mydriacyl 0.5% and 1.0%): Provides an excellent short-term dilation of the pupil, plus cycloplegia (4 to 6 hours). Relatively easy to reverse (if concerned about potential angle-closure glaucoma); used most often by ophthalmologists

Cyclopentolate hydrochloride (Cyclogyl 0.5%, 1.0%, and 2.0%): Best short-term cycloplegic for determining refractive error, may last for 6 hours up to a day!

Homatropine hydrobromide (1%, 2%, and 5%): Lasts for a few days and is useful for short-term on low-level inflammation (iritis) caused by trauma or abrasions

Scopolamine hydrobromide (Hyoscine 0.25%): Lasts for 3 to 5 days and is more effective for long-term inflammation seen postoperatively or in severe uveitis

Atropine sulfate (0.25% to 2.0% solution, 0.5% and 1.0% ointment): Lasts for 10 to 14 days; most commonly used postoperatively and in severe uveitis. Corneal epithelial and systemic toxicities are important to note.

THERAPEUTIC AGENTS

Lubricants

The precorneal tear film is the most important layer of the eye with regard to comfort and vision. Abnormalities of this complex multilayered film are responsible for a large percentage of surface complaints (burning, itching, foreign-body sensation, epiphora, and blurred vision that vacillates with blinking). Artificial lubricants are an effective but temporary treatment for any condition that causes this “dry-eye syndrome.”

Artificial tears: These agents ([Table 11.1](#)) usually contain various methylcellulose compounds, but synthetics are available. Trends toward successful use involve the “thickness” of the solution and single-use, nonpreserved packets. Frequency of use, especially when preserved, multiuse bottles are selected, can have limited return on symptoms. Overall, these agents not only are benign, but also relieve most anterior surface irritation from any cause. *Be liberal in dispensing these agents!*

Agent in Solution	Trade Name Concentration	Preservative
Carboxymethylcellulose	Refresh Tears (0.3%)	Boric acid
	Refresh Plus (0.3%)	Preservative-free
Hydroxyethylcellulose	Carboxyl (1%)	Preservative-free
	Comfort Tears (0.8%)	Benzalkonium chloride
Hydroxypropylmethylcellulose	Advisonair (0.4%)	Thimerosal
	Tear Guard	Preservative-free
	Optigel Plus/Opigel Tears (0.3%)	Benzalkonium chloride
	Refresh (0.3%)	Benzalkonium chloride
	Ultratan	Benzalkonium chloride
	Born Tears (0.3%)	Preservative-free
	Tears Natural (0.3%)	Benzalkonium chloride
	Tears Natural II	Sodium borate
	Tears Natural Plus	Preservative-free
	Nature's Tears (0.4%)	Benzalkonium chloride
OptClear (0.4%)	Benzalkonium chloride	
Polyvinyl alcohol	OptClear PF (0.4%)	Preservative-free
	Liquiline (1.4%)	Chlorbutolol
	Hydro Tears (1%)	Benzalkonium chloride
	Hydro Tears PF (1%)	Preservative-free
	Alone Tears (1.4%)	Benzalkonium chloride
	City Eyes (1.4%)	Benzalkonium chloride
Chlorine	Mullein (0.3%)	Benzalkonium chloride
	Tears Plus II (4%)	Chlorbutolol
Polycarbophil	City Eye (0.3%)	Preservative-free
	AquaSole	Preservative-free

TABLE 11.1. Artificial Tear Preparations

Bland lubricating ointments (Hypotears, Lacri-Lube): Especially helpful for lubrication during sleep or conditions with incomplete lid closure (e.g., general anesthesia, seventh-nerve palsies). Nonpreserved varieties without lanolin are preferable.

Antibiotics

Refer to [Table 11.2](#).

TABLE 11.2. Antibiotics for Topical Use

Antiinflammatories

These agents are used most often to suppress allergic (i.e., immunologic) reactions of the eye of all types, both externally and internally. It may be necessary to suppress severe external inflammation to avoid corneal scarring or permanent tear-film abnormalities. Within the eye, these agents help to prevent scarring (synechiae) and subsequent development of glaucoma. Topical application often allows excellent penetration into the anterior chamber. This category is divided into steroid and nonsteroid (NSAID) varieties.

Steroid Antiinflammatory Agents

These are very effective in blocking pathways of inflammation. A significant portion of the population will raise their intraocular pressure in response to prolonged use of these agents (generally 2 weeks or more). Because of this and infectious concerns, ophthalmic initiation and follow-up may be necessary.

Medrysone 1% (HMS): Mild steroid, few side effects. Used for surface allergy problems

Fluorometholone 0.1% (FML): Slightly more potent, with fewer side effects than prednisolone and dexamethasone. As fluorometholone acetate 0.1% (Flarex), potency comparable to prednisolone acetate 1% due to better penetration

Rimexolone 1% (Vexol): Similar profile to that of fluorometholone, but with a lower propensity to raise intraocular pressure

Loteprednol etabonate 0.5% (Lotemax): Relatively new preparation with high potency and lower propensity to raise intraocular pressure.

Prednisolone acetate and phosphate 0.125% and 1.0% (Pred Mild, Pred Forte, Inflammase Forte): Potent and highly effective for anterior segment inflammation. High risk for side effects (intraocular pressure and infection, especially herpes simplex facilitation)

Dexamethasone 0.1% (Decadron): Potent and highly effective. Very high risk for side effects

Nonsteroidal Antiinflammatory Agents

Recent emphasis on these therapies used topically have paralleled systemic usefulness. Although there is therapeutic overlap, the Food and Drug Administration has recommended indications for each of these agents.

Flurbiprofen 0.03% (Ocufen): Used to keep the pupil dilated during cataract surgery

Diclofenac 0.1% (Voltaren): Used for postoperative inflammation after cataract surgery

Ketorolac 0.5% (Acular): A product developed for allergic conjunctivitis

Suprofen 1% (Profenal): Used to keep the pupil dilated during cataract surgery

Antibiotic–Steroid Combinations

A number of products are available with broad-spectrum antibiotics combined with varying concentrations of potent topical corticosteroids (e.g., TobraDex tobramycin/dexamethasone) both in drop and ointment forms. These formulations may be helpful in postoperative circumstances, but they should be reserved for other conditions, with ophthalmic consultation.

Antiglaucoma Agents

These either suppress aqueous production or increase outflow facility, or both. Because the ciliary body and muscle are critical determinants of the intraocular pressure (with regard to aqueous production and outflow), autonomic agents and their blockers may affect the intraocular pressure. Carbonic anhydrase inhibitors

block aqueous production because this enzyme is essential in the active production of aqueous humor. The most recent addition to the management regimen includes topical prostaglandins, which act in a different manner by reducing outflow through a uveoscleral route.

Miotics (cholinergic agonists): *Pilocarpine* 0.5% to 10%; *carbachol* 0.75%, 1.5%, and 3.0%; *echothiophate iodide* (phospholine iodide) 0.06% to 0.25%: Rarely cause systemic problems, but use of depolarizing agents in general anesthesia (succinylcholine) is contraindicated in patients taking phospholine. Miotics make the pupils small; usually capped in *green* (pilocarpine and carbachol).

Adrenergic agents: *Epinephrine* compounds 0.5% to 2.0%, *dipivalyl epinephrine* 0.1% (Propine): Tolerance develops commonly, and the eyes turn red! These products have *white* caps.

Alpha-2 agonists: *Apraclonidine* 0.5% and 1.0% (Iopidine), *brimonide tartrate* 0.2% (Alphagan): Reduce aqueous production and may increase uveoscleral outflow. Alphagan has fewer side effects. As with most adrenergic agents, ensure that the patient does not have a problem with cardiovascular sensitivity. Beware of use with MAO inhibitors.

Beta-blockers: *Timolol* 0.25% and 0.5% (Timoptic), *betaxolol* 0.25% (Betoptic-S), *levobunolol* 0.5% (Betagan), *metipranolol* 0.3% (OptiPranolol), and *carteolol* 1% (Ocupress): Most have *yellow* caps and may cause beta-blocker side effects (heart and lung). Betoptic is cardioselective (beta-1) and has fewer side effects, but also has less ocular efficacy. Cardiac sensitivity and adverse effects on libido and serum cholesterol are reasons to swing toward use of newer agents.

Carbonic anhydrase inhibitors: *Oral Agents*: *Acetazolamide* (Diamox 250-mg tablets, 500-mg capsules) and *methazolamide* (Neptazane 50 mg) are the principal agents used. These are mild diuretics and may facilitate potassium depletion when given chronically. If glaucoma therapy is given systemically, the incidence of side effects goes up dramatically. These agents are sulfa-related compounds; therefore, allergic reactions can occur. They may also precipitate renal stones in susceptible patients. *Topical Agents*: *Dorzolamide hydrochloride* 2% (Trusopt), and *brinzolamide* 1% (Azopt) offer fewer side effects, but they are not as efficacious in reducing the intraocular pressure as are the oral agents. Dorzolamide also comes in a combination form, with the beta-blocker timolol, as Cosopt.

Osmotic agents: *Oral glycerin* (Osmoglyn) 50% to 75% (1.0 to 1.5 g/kg) over ice, frequently produces nausea and vomiting; *isosorbide* 45% (Ismotiv), 1.5 g/kg, will lower the pressure adequately over 1 to 2 hours, a preferred agent in diabetic patients. A rapid response is most often accomplished with a 20% solution of mannitol, 1 to 2 g/kg i.v. over 30 to 45 minutes. These agents are used emergently to shrink the vitreous and rapidly lower the intraocular pressure. It is essential to know the patient's fluid, renal, and cardiovascular status before using these compounds.

OCULAR ALLERGIC CONDITIONS

Surface reactions to a host of airborne agents (e.g., pollen, dust) and irritants can cause conjunctival swelling (chemosis), redness, itching, and tearing. Management of these reactions should start conservatively with cool compresses and decongestant–antihistamine combinations. More aggressive therapy can involve more potent topical antihistamines, mast-cell inhibitors, topical NSAIDs (see previous discussion), and corticosteroids.

Ocular Decongestants

These agents, many of which are available over the counter, are topical solutions used to whiten the eye. Although overtly effective, the utilization of these agents often hinders timely diagnosis and treatment of the condition that presents as “the red eye.” Chronic use of these agents causes tolerance and eventual worsening of the vascular dilatation. A few of these agents may also include a mild topical antihistamine, which may be a useful way to initiate therapy for mild allergic phenomena. When an antihistamine is present, the decongestant product will usually include the suffix “-A” to indicate such.

Naphazoline hydrochloride (Naphcon, Vasocon, others): Contain preservatives that may be sensitizing

Phenylephrine hydrochloride (Prefrin, Relief, others): These compounds are not as stable, and are also preserved (except for Relief).

Tetrahydrozoline hydrochloride (Murine, Visine, others): Available over the counter, also preserved

Oxymetazoline hydrochloride (OcuClear, Visine L.R.): Similar to tetrahydrozoline but more potent

Antihistamines

Along with the combination antihistamines used with the previously noted decongestants, these agents have been marketed specifically for ocular allergy management.

Levocabastine hydrochloride 0.05% (Livostin): Very effective, but does sting on administration

Emedastine difumarate 0.05% (Emadine): Has effects similar to those of previous agent

Mast-cell Stabilizers

Seasonal allergy disorders usually revolve around IgE-mediated (Type I) hypersensitivity reactions. This involves the release of histamine and many vasoactive substances that create the signs and symptoms of allergy. By blocking the mast-cell release of these vasoactive substances, symptomatology is relieved. Because this affects only unsensitized mast cells, the effects of these agents take days to weeks to work properly.

Cromolyn sodium 4% (Crolom, Opticrom): Used extensively in Europe, became popular in the United States in 1980s, especially in the management of vernal conjunctivitis

Lodoxamide tromethamine 0.1% (Alomide): May have somewhat different mechanism of action (calcium influx on mast cell), but almost as effective

Olopatadine hydrochloride 0.1% (Patanol): Has inherent antihistaminic effects and also appears to have mast-cell–stabilizing capability

COMMON PITFALLS

- Avoid the indiscriminate use of topical antibiotics in serious ocular infections without first obtaining adequate samples for culture and sensitivities.
- Topical corticosteroids, used alone or in combination with other topical medications, should be used only after proper consultation by phone.
- Even though ocular medications are most often delivered topically, there are significant systemic side effects seen with certain agents, especially those that treat glaucoma (e.g., beta-blockers). Punctal compression, to avoid drainage down the nasolacrimal system into the posterior nasopharynx (subsequently swallowed), will reduce this problem.

[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Loss of vision, whether unilateral or bilateral, partial or complete, is an emergent ophthalmologic complaint, and requires rapid and thorough evaluation and management. Emergent evaluation includes taking the relevant ocular history, examination of the eyes and other relevant systems, pertinent laboratory evaluation, determination of the differential diagnosis, and rapid institution of appropriate therapy. Consultation with an ophthalmologist and/or other appropriate specialists is often indicated.

CLINICAL PRESENTATION

Patients with visual loss or visual disturbance may present with a variety of symptoms. Typically, any degree of visual loss is disturbing to the patient and may lead to early evaluation; however, some patients may procrastinate and not seek medical evaluation. A thorough history can be crucial and the most efficient approach to the wide differential diagnosis of visual disturbances.

Several historic points may be particularly useful in determining the etiology of symptoms. The onset of symptoms, whether gradual or abrupt, transient or persistent, constant or waxing and waning, may be of importance. The unilateral or bilateral nature of the disturbance, and association of pain, may be valuable in the differentiation of certain disorders. Associated symptoms, including systemic symptoms (fever, weakness, rash, etc.), previous history of similar symptoms, history of trauma, and other ocular symptoms, including eye pain, redness, discharge, and so forth, should be sought when obtaining historical information from the patient.

DIFFERENTIAL DIAGNOSIS

Visual disturbance or visual loss may represent any of myriad clinical disorders. Some of the more common entities are summarized in [Table 12.1](#). In general, any abnormality of the cornea, lens, vitreous, retina, optic nerve, optic tract, optic radiations, or occipital cortex should be considered.

TABLE 12.1. Differential Diagnosis of Selected Causes of Visual Disturbance

EMERGENCY DEPARTMENT EVALUATION

Complete details of the ophthalmologic examination are included in [Chapter 9](#). Specifically, when evaluating the patient with loss of vision or visual disturbance, of primary importance are visual acuity and visual field testing.

Visual acuity can be measured with a Snellen eye chart. The acuity of each eye should be tested independently, with the patient's usual visual correction, if available. For patients who normally wear corrective lenses, but which are unavailable for testing, pinhole testing can be easily performed by creating a device with paper and "pinholes" created with an 18-gauge needle. For patients unable to adequately read from the eye chart, their ability to count fingers, detect movement, and perceive light and dark should be evaluated.

Visual field testing can be useful in determining the extent of visual loss and in developing the appropriate differential diagnosis. Eyes should be tested independently. The confrontation technique may be employed, in which the examiner presents variable numbers of fingers in various visual fields, and asks the patient to count the fingers, while maintaining a forward gaze. Each quadrant should be tested for both eyes. More advanced visual field testing can be performed by an ophthalmologist.

Additionally, the examination should evaluate the external and slit-lamp appearance of the cornea and conjunctiva, and trauma, foreign bodies, hyphema, infection, corneal opacities, and other abnormalities should be ruled out. Intraocular pressure (IOP) should be measured, using a hand-held tonometer, applanation tonometry, or Schiøtz tonometer. Glaucoma is discussed in greater detail in [Chapter 13](#).

Pupils should be evaluated, utilizing the swinging flashlight test. Pupillary response can be valuable in differentiating afferent from efferent defects. The normal response is bilateral pupillary constriction in response to bright light in either pupil.

Fundusoscopic examination should be performed using a hand-held ophthalmoscope. Pupillary dilation may be required to perform an adequate examination of the retina. In particular, the optic disc, macula, and retina should be evaluated for any abnormalities.

Radiographic evaluation (including magnetic resonance imaging [MRI] or computed tomography [CT]) may be indicated in cases in which intracranial pathology or mass lesions involving the optic nerve or globe are suspected. Patients presenting with complaints related to loss of vision require a complete ophthalmologic examination, which should include measurement of visual acuity, visual field testing, tonometry, and slit-lamp examination.

EMERGENCY DEPARTMENT MANAGEMENT

Numerous disease processes can produce visual disturbance or visual loss. The most commonly encountered are discussed next. This discussion is not an exhaustive review of ophthalmologic disorders, but a summary of salient points relevant to the emergency physician.

Inflammatory Processes

Giant-cell Arteritis

Giant-cell arteritis (GCA), an inflammatory disease of medium and large arteries, typically affects patients over the age of 60, with a female predominance of 3:1. Peak incidence occurs between the ages of 70 and 80. Patients may present with malaise, headache, fever, anorexia, jaw claudication, pain over the temporal or occipital arteries, and painless visual loss secondary to ischemic optic neuropathy, or cranial nerve palsies. Diagnostic tests include an elevated erythrocyte sedimentation rate (ESR) (typically 80 to 100 mm within the first hour; elevated in 98% of documented cases) and an abnormal temporal artery biopsy. Findings and symptoms may be atypical (ESR may be normal, there may be no visual involvement, etc.) Early administration of corticosteroids (80 to 120 mg of prednisone per day, or intravenous methylprednisolone, 1 g per day) may prevent blindness and other long-term visual defects, as well as contralateral eye involvement (common within 10 days without treatment), and may provide dramatic pain relief. Patients may have a 34% chance of improvement in visual function after steroid therapy.⁸ A biopsy should be performed within 7 to 10 days of steroid initiation, although a negative biopsy does not exclude GCA.^{14,16}

Optic Neuritis

Optic neuritis is an inflammatory disorder from varying etiologies, including multiple sclerosis, sarcoidosis, systemic lupus erythematosus, leukemia, syphilis, collagen vascular diseases, alcohol abuse,¹³ idiopathic, or other causes.⁵ Most patients (65%) have pain with eye movement. Typically, there is an afferent pupillary defect, and elevation of the optic disc may be seen on funduscopic examination. Visual field defects may be noted. Although treatment with oral steroids has not been shown to be beneficial (and may even be harmful), treatment with intravenous methylprednisolone may be indicated for patients with suspected multiple sclerosis. Although steroids do not affect recovery, they have been shown to delay the onset of symptoms of multiple sclerosis. Consultation with an ophthalmologist is indicated for patients with suspected optic neuritis.⁵

Uveitis

Uveitis, inflammation of the iris, ciliary body, or choroid, may cause visual impairment. Uveitis may be caused by Reiter syndrome, ankylosing spondylitis, sarcoidosis, tuberculosis, collagen vascular disorders, and other diseases. Treatment with topical corticosteroids and cycloplegic agents is often effective. Systemic steroids may be indicated in severe cases. Therapy of the underlying disorder should be undertaken.^{5,6}

Vascular Events

Central Retinal Artery Occlusion

Central retinal artery occlusion (CRAO) often presents with sudden, painless visual loss (Fig. 12.1). There may be a history of transient visual loss prior to this event. The cause is often due to emboli from carotid plaques, cardiac valves, fat emboli, arteriosclerosis, or a host of other underlying disorders, including such entities as collagen vascular disease, hypotension, sickle cell disease, and GCA. Elderly patients are more commonly affected, and men are more commonly affected than are women. Visual loss is typically profound, with 90% of patients sustaining losses that range from counting fingers to light perception. An afferent pupillary defect may be present. Physical findings include pallor of the involved retina, “cherry-red spot” of the fovea, “boxcars” of the arterioles, and opacification of the superficial retina. Branch RAO may occur and may present with sudden loss of visual field and reduction in visual acuity. The long-term prognosis is related to the duration of symptoms prior to resolution. Full vision may be restored if resolved within 1 to 2 hours.¹² Treatment is often unsatisfactory, but should be offered, and it may include intermittent globe massage in an attempt to dislodge an embolus (moderate pressure for 5 seconds and release for 5 seconds), anterior chamber paracentesis (to decrease IOP and increase retinal perfusion), intravenous acetazolamide (to decrease IOP), inhaled carbogen (oxygen–carbon dioxide mixture of 95%/5%) to induce retinal vasodilation and increase retinal pO₂,¹⁵ Hyperbaric oxygen and nifedipine have also been reported as successful therapies.¹ Other treatment offered by an ophthalmologist may include ophthalmic artery infusion of urokinase or tissue plasminogen activator.¹⁰

Figure 12.1. Central retinal artery occlusion.

Central Retinal Vein Occlusion

Patients with central retinal vein occlusion (CRVO) typically present with painless, sudden loss of vision. (Fig. 12.2). Most patients are over the age of 50, and many also have significant cardiovascular disease. Other associated disorders include hypertension, glaucoma, venous stasis, diabetes mellitus, and collagen vascular disorders. Physical findings may include retinal hemorrhage, which may be pronounced and diffuse, venous dilatation, cotton-wool spots, and optic disc edema. Treatment is often unsuccessful, but should include a careful evaluation of the probable etiology in order to prevent contralateral eye involvement. Spontaneous resolution may occur in some cases. Treatment offered by an ophthalmologist may include panretinal laser photocoagulation.

Figure 12.2. Central retinal vein occlusion.

Branch RVO may occur, and may have segments of intraretinal hemorrhage. Complications may include macular edema, ischemia, and neovascularization with associated vitreous hemorrhage. Laser photocoagulation has an important role in the treatment of branch RVO, which has a better prognosis. ⁴

Amaurosis Fugax

Amaurosis fugax, a unilateral transient obstruction of a retinal artery, may cause temporary loss of vision (up to 15 minutes). The visual loss is often described by the patient as a curtain being drawn across the visual field. Amaurosis fugax is usually caused by cholesterol emboli or fibrin-platelet emboli, and may be associated with carotid artery disease, cardiac arrhythmias, anemia, sickle cell disease, hypertension, or episodic hypotension. Carotid and cardiac studies may be indicated to determine the source of the emboli. Treatment with aspirin should be initiated, and ophthalmologic consultation obtained.

Ischemic Optic Neuropathy

Ischemic optic neuropathy is typically found in patients over the age of 50, and often presents with painless decreased visual acuity. This disorder may result from an infarction of the optic nerve (90% of cases) or from GCA (10% of cases). An afferent pupillary defect may be found, as well as a pale, elevated optic disc.

Vitreous and Retinal Disorders

Vitreous Hemorrhage

Vitreous hemorrhage typically presents with acute unilateral painless loss of vision, and may be accompanied by symptoms of “floaters” or “cobwebs.” Associated visual disturbances may be mild or severe, depending on the extent of the hemorrhage. The normal red reflex of the fundus is absent. Diffuse, dark, particulate opacities may be seen, or if severe, a black uniform reflex (“eight ball hemorrhage”) will be seen instead of the normal retinal red reflex. Vitreous hemorrhage may be associated with numerous disorders, including diabetes, trauma, malignancy, CRVO, leukemia, anemia, and thrombocytopenia. Management includes ophthalmologic consultation and treatment of any underlying condition.

Diabetic Retinopathy

Diabetic retinopathy may be divided into proliferative and nonproliferative. It may occur in Type I or Type II diabetes mellitus. Nonproliferative diabetic retinopathy is a progressive microangiopathy. Symptoms may be mild or nonexistent, and may include hue discrimination abnormalities, scotomas, contrast sensitivity, or a variety of other visual complaints. Physical findings include multiple hemorrhages throughout the retina and macular edema. Proliferative retinopathy refers to ischemia as a result of microvascular occlusions, and may present with cotton-wool spots, retinal vein beading, and irregular dilation of the retinal capillary bed. Sudden visual loss may occur with massive vitreous hemorrhage from fragile neovascularization or from retinal detachment. Treatment by an ophthalmologist is indicated, and may include laser photocoagulation.

Retinal Detachment

Retinal detachment refers to a separation of the two layers of the retina: the pigment epithelium and neurosensory retina ([Fig. 12.3](#)). The most common type, rhegmatogenous, occurs as a result of tears, holes, or breaks in the sensory layer of the retina. It may be associated with advancing age, male gender, significant myopia, diabetes mellitus, sickle cell disease, or ocular contusion or penetrating injury, or it may be idiopathic. Additionally, exudative or traction types of retinal detachment may be seen. Symptoms include photopsia (light flashes), floaters, or a shower of black dots in the periphery secondary to hemorrhage into vitreous humor, or a sensation of a shadow or curtain obscuring the visual field. Visual acuity may be normal if the macula is unaffected, or severely impaired if involved. On examination, the detached area may appear gray, opaque, or translucent. Folds may be seen. Vessels may appear dark red. Ophthalmologic consultation is indicated, and therapy may include diathermy, laser photocoagulation, or other intraocular surgical therapies. Symptoms often resolve within 1 week.

Figure 12.3. Retinal detachment.

Macular Degeneration

Macular degeneration is the most common cause of permanent blindness among older patients. The incidence is associated with advanced age, family history, tobacco history, race (Caucasian), and gender (slight female predominance). The etiology is unknown. Symptoms include blurred vision, visual distortion, scotoma, or central visual loss. Physical findings include drusen (yellow-white deposits beneath the pigment epithelium) and clumps of pigment throughout the macula. Treatment includes laser photocoagulation and the use of low-vision aids, under the care of an ophthalmologist. ^{2,12}

Neurologic and Structural Disorders

Cerebrovascular Accident

Cerebrovascular accidents (CVAs) and transient ischemic attacks may be associated with visual loss. A bilateral homonymous hemianopsia may result from involvement of the optic tract or occipital lobes. Involvement of both occipital lobes may produce complete blindness (cortical blindness). Treatment should be initiated in consultation with a neurologist.

Other Etiologies of Cortical Blindness

Cortical blindness may be caused by such entities as ischemia, mass lesions, hydrocephalus, anoxia, encephalitis, meningitis, edema, or hemorrhage into the occipital lobe(s).^{3,11} Evaluation should be conducted promptly, and may include CT, MRI, and lumbar puncture.

Compression of the Optic Chiasm

The optic chiasm may be compressed by mass lesions such as pituitary adenomas, meningiomas, craniopharyngiomas, or aneurysms. These patients may present with bitemporal hemianopsia. Treatment of the underlying disorder should be undertaken by the appropriate consultant.

Infectious Processes

Although some infectious processes cause symptoms of visual disturbance (such as blurring), most are not associated with reduction of visual acuity or loss of peripheral visual fields.

Cytomegalovirus Retinitis

Cytomegalovirus (CMV) retinitis may present with sudden or gradual visual loss when the infection invades the macula. It is seen primarily in immunocompromised patients, such as those with AIDS, or those on chemotherapy, or after organ transplantation. Findings include retinal hemorrhagic areas combined with zones of white retinal necrosis (“tomato and cheese pizza” appearance). Early treatment with intravenous antiviral therapy (foscarnet or ganciclovir) is indicated, in consultation with an ophthalmologist.¹⁷

Glaucoma

Patients with glaucoma may present with acute or chronic visual loss. Visual field testing may indicate a diminished perception in the nasal region. Optic nerve pallor and cupping is seen on examination. Elevated IOP (often 50 to 70 mm Hg) is typically found. Early initiation of therapy is indicated and includes a miotic (e.g., pilocarpine), topical beta-blocker (e.g., timolol), a carbonic anhydrase inhibitor (e.g., acetazolamide), mannitol or glycerin, and topical steroids. A more detailed discussion of glaucoma is found in [Chapter 13](#).

Malignancies of the Eye

Although space does not permit a detailed study of ophthalmologic malignancies, it is prudent for the emergency physician to have an awareness of the spectrum of malignancies that may affect vision. Benign intraocular tumors may include retinal angiomas or astrocytic hamartomas. Malignant intraocular tumors include retinoblastoma (tumor of childhood, usually under age 1, presenting with leukocoria or strabismus) and malignant melanoma. Metastatic tumors may involve the eye, most often with choroidal metastasis. Patients with cancer of the breast, lung, gastrointestinal tract, melanoma, kidneys, prostate, and thyroid may have choroidal metastases.⁹ Complications of intraocular malignancies that affect vision include hemorrhage from tumor vascularization, retinal detachment, retinal degeneration, and retinopathy. Abnormal physical findings should alert the physician to the importance of timely ophthalmologic follow-up.

Toxicologic Effects

Methanol Toxicity

Methanol toxicity is associated with transient visual disturbances. Symptoms and signs usually occur within 18 to 48 hours of the ingestion. Associated symptoms include nausea, vomiting, headache, or abdominal pain. Findings include hyperemic, swollen optic discs, with retinal edema. A cherry-red spot may be observed.⁷ Treatment of methanol toxicity is discussed in [Chapter 351](#).

Other Toxins

Numerous other toxins that may be associated with visual disturbances include carbon monoxide, lead, salicylates, sulfonamides, ergots, tin, quinine, barbiturates, chemotherapy, and nitroglycerin. Visual loss is usually bilateral, and therapy consists of the appropriate treatment of the underlying condition.¹⁴

Eye Disorders Associated with Systemic Disease

Patients with vascular disease may develop hemorrhages of various types, including preretinal, linear, punctate, subretinal, and white central hemorrhages (Roth's spots). Additionally, there may be acute ocular ischemia due to infarction of the optic disc (ischemic optic neuropathy), which presents with sudden visual loss, and a pale, swollen optic disc. It may be caused by GCA, hypertension, or arteriosclerotic disease. Other causes of ocular ischemia may include choroidal infarction, retinal infarction, and transient retinal ischemia (amaurosis fugax). Patients with AIDS may present with toxoplasmosis, candidal endophthalmitis, herpes zoster ophthalmicus, or optic neuropathy.

Many other systemic disorders are associated with abnormal ocular complaints, and include metabolic, infectious,⁴ endocrine, autoimmune, granulomatous, hematologic, vascular, malignancies, connective tissue, and other disorders. Generally, the primary disorder should be treated, and ophthalmologic consultation should be obtained in a timely fashion.

Functional Visual Loss

The diagnosis of functional visual loss should always be a diagnosis of exclusion. There may be a variety of complaints, but no abnormalities are seen on examination. The swinging flashlight test, IOP, and external and funduscopic examinations are normal. Optokinetic responses may be tested in a cursory fashion in the emergency department by passing a tape measure, or sheet of paper with prominent vertical lines, rapidly before the affected eye(s). Another simple test involves placing a mirror before the patient's face and rocking the mirror from side to side. The presence of optokinetic nystagmus (following movements with rapid returns to the primary position of the eye) indicates that vision is present. Additionally, patients feigning blindness may demonstrate an inability to oppose outstretched forefingers while bringing outstretched arms together; this ability would not ordinarily be affected by blindness. Additional tests to differentiate organic from functional visual loss should be conducted by an ophthalmologist.

DISPOSITION

For the majority of patients with acute visual loss, consultation with an ophthalmologist is indicated. The severity and nature of the disease process will dictate whether emergent or urgent consultation is necessary. Patients considered for hospital admission should be those who require intravenous medications, surgery, or other invasive procedures, or for whom serious worsening of vision is imminent.

COMMON PITFALLS

- Failure to consider the diagnosis of glaucoma in atypical presentations
- Failure to measure intraocular pressure
- Failure to test visual fields adequately
- Failure to administer steroids rapidly to patients with giant cell arteritis
- Delay in treatment of central retinal artery occlusion

Glaucoma is a group of disorders characterized by an intraocular pressure (IOP) elevated to a degree sufficient to result in loss of vision. The clinical presentations and underlying pathologic mechanisms within this group of disorders are diverse. The two common classifications of primary glaucoma—open-angle glaucoma and angle-closure glaucoma—occur in about one of 50 Americans over age 35, and represent overall the second leading cause of blindness in the United States. ²²

Primary angle-closure glaucoma accounts for 6% of all patients with glaucoma, and occurs in 0.6% of the general population. Primary acute angle-closure glaucoma is less common among Blacks than among Whites; however, the chronic form is more common in Blacks, Eskimos, and Southeast Asians. Women are affected three times more often than are men.

There are three clinical types of primary angle-closure glaucoma. The chronic form is often subtle and difficult to diagnose, with a gradual visual loss over a prolonged period. The sub-acute, or intermittent, form is characterized by periodic episodes of mild pain, blurred vision, and halos. In contrast, manifestations of the acute form of angle-closure glaucoma are dramatic, with the sudden onset of unilateral ocular pain and decreased visual acuity. Without appropriate therapy, acute angle-closure glaucoma is devastating and can result in blindness within a few days. A high index of suspicion by the astute emergency physician will lead to prompt diagnosis and treatment of acute angle-closure glaucoma.

AQUEOUS HUMOR DYNAMICS AND THE ANTERIOR CHAMBER ANGLE

Aqueous humor is produced by the ciliary body. In the normal eye, the aqueous humor first fills the posterior chamber and then passes between the posterior surface of the iris and the lens to enter the anterior chamber (Fig. 13.1). The iris touches the lens only at the pupillary margin. ² Once the aqueous humor circulates within the anterior chamber, it leaves through the trabecular meshwork of the anterior chamber angle and enters Schlemm's canal (Fig. 13.2). The aqueous then passes from Schlemm's canal to episcleral vessels by way of collector channels in the sclera (Fig. 13.3). The level of IOP at any time represents a balance between the rate of formation of aqueous humor and the resistance to outflow from the anterior chamber. In glaucoma, the elevated IOP is due to an obstruction to outflow from the anterior chamber, rather than to higher-than-normal rates of aqueous production.

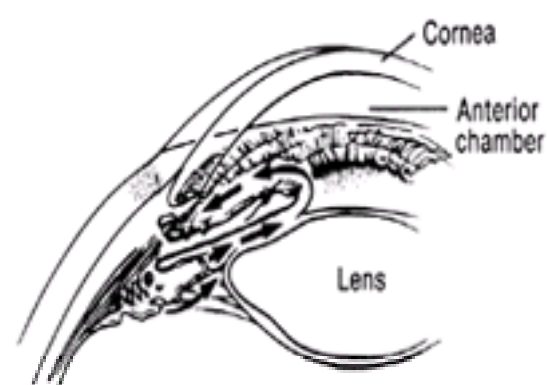

Figure 13.1. Normal anterior chamber angle. Aqueous passes from the posterior chamber through the pupil into the anterior chamber and out through the trabecular meshwork.

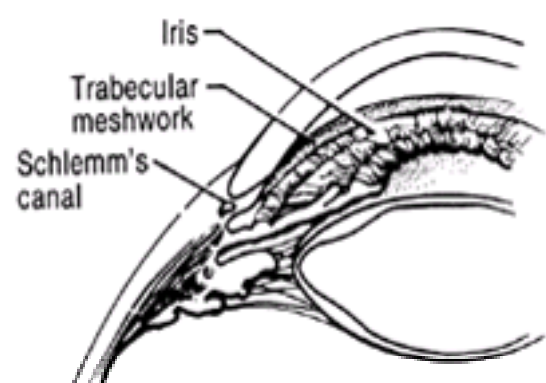

Figure 13.2. Normal appearance of anterior chamber angle.

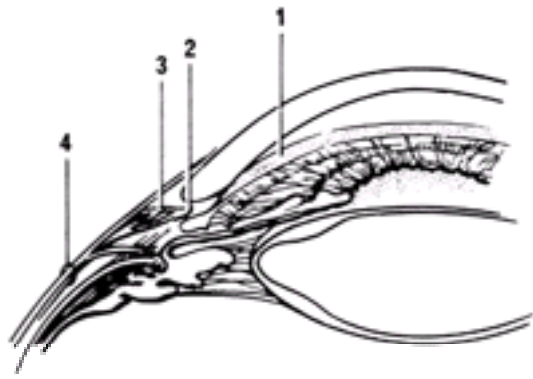

Figure 13.3. Pathway of aqueous out of the anterior chamber is through (1) the trabecular meshwork, (2) Schlemm's canal, and by way of (3) collector channels to (4) the episcleral vessels.

Obstruction to outflow from the anterior chamber occurs in both open-angle and angle-closure glaucoma. The location and mechanism of the resistance to outflow distinguish these two conditions. In open-angle glaucoma, the angle is open, and the aqueous has access to the trabecular meshwork to exit the anterior chamber. Although the exact nature of the resistance to outflow is not completely understood, the obstruction to outflow is located in the tissue between the trabecular meshwork and Schlemm's canal. In angle-closure glaucoma, the peripheral iris touches the trabecular meshwork and blocks the flow of aqueous to the trabecular meshwork. This apposition between the iris and the trabecular meshwork may be temporary or may become permanent if pathologic adhesions develop. These adhesions, known as peripheral anterior synechiae, can occur in eyes with narrow angles, inflammation, fibrovascular proliferation, and previous surgical intervention ([Fig. 13.4](#)).

Figure 13.4. Peripheral anterior synechiae (PAS). These abnormal adhesions of the iris to the trabecular meshwork are seen in angle-closure glaucoma.

Predisposition and Pathophysiology

Several anatomic features predispose an eye to angle-closure glaucoma. A shallow anterior chamber, which results in excessive narrowing of the entrance to the angle, can be occluded more easily than an anterior chamber of normal depth. In a shallow anterior chamber, the area of lens–iris contact is greater than normal. This lens-to-iris apposition impedes the flow of aqueous from the posterior chamber to the anterior chamber through the pupil. A pressure differential results between the posterior and anterior chambers, with a slightly higher pressure in the posterior chamber. This condition, known as relative pupillary block, produces a forward bowing of the peripheral iris and results in contact between the iris and the trabecular meshwork, thereby closing the angle ([Fig. 13.5](#)).

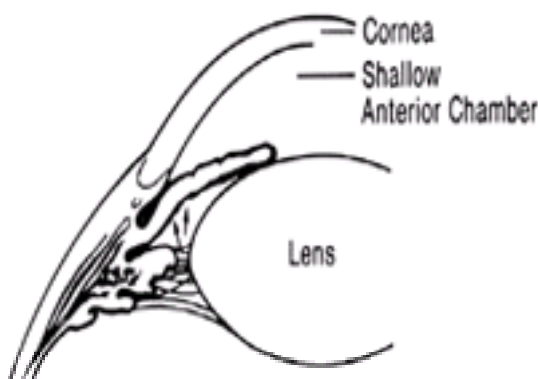

Figure 13.5. Angle closure with pupillary block. The angle is closed as the iris is pushed up against the trabecular meshwork.

Eyes prone to develop greater-than-usual degrees of pupillary block are at risk to develop angle-closure glaucoma. Hyperopic (farsighted) eyes are smaller than average (shorter anterior-to-posterior length). These eyes have greater iris-to-lens contact and an increased risk for angle-closure glaucoma. In addition, the lens size and position are major factors in the degree of relative pupillary block. For example, the development of a cataract may thicken the lens and increase the contact of the posterior surface of the iris to the lens, resulting in an increase in pupillary block. These anatomic relations—the size of the eye and the position of the lens—predispose to angle closure. The actual event that triggers an attack of acute angle closure is often identified as a pharmacologic or physiologic event that alters the balance between the aqueous humor dynamics and the pathologic anatomic relations.

In predisposed eyes, pupillary dilatation is the most significant event that can precipitate an acute angle-closure attack. During dilatation, the peripheral iris becomes more flaccid and may be pushed against the trabecular meshwork, closing the angle. There is usually sudden and complete blockage to aqueous outflow. When the pupil is midedilated, 5 to 7 mm, both relative pupillary block and peripheral laxness of the iris are greatest.¹⁵ If the pupil continues to dilate beyond the midposition, the peripheral chamber angle deepens as pupillary block is reduced. Such a widely dilated pupil may be at risk to develop angle closure if it assumes the precarious midedilated position during constriction.

Pupillary dilatation may occur in response to pharmacologic agents or physiologic situations, such as low illumination, stress, and fatigue.^{9,20} Two general classifications of topical and systemic medications most often implicated in precipitating acute angle-closure glaucoma are the parasympatholytics and the sympathomimetics. Parasympatholytics, such as atropine, and sympathomimetics, such as 10% phenylephrine, as well as many over-the-counter medications with anticholinergic or sympathomimetic activity, can produce pupillary dilatation and precipitate angle closure ([Table 13.1](#)).^{5,11,18} Although uncommon, a third class of medications that can induce angle closure comprises the topical parasympathomimetics, such as pilocarpine. Often used to treat angle closure, topical parasympathomimetics that produce miosis can, in some eyes, aggravate relative pupillary block by increasing the area of surface contact between the iris and the lens. However, in general, miotics tend to make the peripheral iris more taut and decrease the forward bowing into the peripheral angle.

	Exophthalmos	Reactive	Iritis	Acute Angle-Closure
Visual Acuity	Normal	Normal/Blurred	Normal/Blurred	Marked decrease in vision
Eye	None or mild	Mild to severe	Mild to severe	Severe associated with
Discharge	None	"Mucous"	"Mucous"	aqueous and mucus
Conjunctiva	Diffuse injection	Perilimbal injection	Perilimbal injection	None to heavy
Pupil	Normal	Normal	Constricted	Normal peripheral vessel
Cornea	Clear or fine punctate	Mild to moderate	Mild to severe	diffuse associated with
Intraocular Pressure	Normal	Normal	Elevated	diffuse injection
Anterior Chamber	Normal depth	Normal depth	Normal depth	Shallow
	no cells	no cells	no cells	Shallow both eyes are
				shallow
				Normal to moderate cell
				no KP present

TABLE 13.3. Differential Diagnosis of Acute Angle-Closure Glaucoma

Figure 13.7. Differential diagnosis of the painful eye.

Glaucomatocyclitic Crisis

The chief complaint in glaucomatocyclitic crisis is recurrent attacks of visual blurring and halos. IOP is elevated and the conjunctiva moderately injected. In contrast to acute angle-closure glaucoma, pain is an occasional complaint but not a prominent feature. Additionally, the anterior chamber is deep, few cells are present in the anterior chamber, and keratic precipitates are on the corneal endothelium.

Neovascular Glaucoma

Patients with neovascular glaucoma often present with a chief complaint of a painful red eye that has had severe loss of vision months before inflammation of the eye occurred. Clinical findings include high IOP, corneal edema, anterior chamber inflammation, and usually a normal-depth anterior chamber.

Neovascular glaucoma is usually secondary to one of several retinal disorders, and occasionally is associated with other ocular or extraocular conditions. The two most common associations are proliferative retinopathy of diabetes mellitus and retinal vascular occlusion. The underlying stimulus for neovascularization is hypoxia. The neovascularization of the iris, known as rubeosis iridis, can be seen on slit-lamp biomicroscopy as randomly oriented vessels on the surface of the iris. ²³ These vessels typically progress to the anterior chamber angle, where a fibrovascular membrane covers the trabecular meshwork, preventing outflow of aqueous. ²¹ In the early stage of neovascularization, the anterior chamber depth is normal. Only actual examination of the angle structures by gonioscopy, a technique using the slit lamp and a mirror to view the angle, would reveal the vascular membrane. If the neovascularization is progressive, a secondary form of angle closure develops as the fibrovascular membrane contracts, pulling the iris to the trabecular meshwork, which leads to the development of peripheral anterior synechiae. Anterior chamber depth is often normal, but it can be shallow in the periphery.

To distinguish neovascular glaucoma from acute angle-closure glaucoma, a history of diabetes mellitus or previous severe loss of vision before the acute attack is helpful. Also, the pupil is often miotic, and tufts of neovascular vessels may be evident.

Acute Iritis

The clinical presentation of acute iritis with secondary glaucoma is typically mild-to-moderate pain, photophobia, and blurred vision. The onset is gradual, in contrast to acute angle-closure glaucoma. Clinical findings may mimic angle closure, with conjunctival perilimbal injection (the conjunctiva adjacent to the cornea) and corneal edema. Distinguishing characteristics include miotic pupil, keratic precipitates, and a normal anterior chamber depth (Fig. 13.8).

Figure 13.8. Acute iritis. This eye demonstrates the perilimbal injection and corneal edema that is common to both acute iritis and acute angle-closure glaucoma. The constricted miotic pupil seen here is characteristic of acute iritis.

Phacolytic Glaucoma

The typical patient with phacolytic glaucoma presents with the acute onset of a unilateral painful red eye. Similar to angle-closure glaucoma, the examination reveals a high IOP and conjunctival injection. The cornea may be either edematous or clear at the time of presentation. In contrast to acute angle-closure glaucoma, the anterior chamber depth appears normal, there is moderate-to-marked anterior chamber cell reaction, keratic precipitates are present, and a mature or hypermature (liquid cortex) cataract can be seen (Fig. 13.9). The cause of phacolytic glaucoma is the release of soluble lens protein into the aqueous, which leads to elevated IOP. With the availability of modern cataract surgery, phacolytic glaucoma is a rare cause of acutely elevated IOP.

Figure 13.9. Phacolytic glaucoma. This eye demonstrates the milky-white lens of a hypermature cataract.

Lens Particle Glaucoma

Lens particle glaucoma is associated with either spontaneous or traumatic disruption of the lens capsule. The presentation in the setting of spontaneous disruption is the acute onset of a unilateral painful red eye. In the case of trauma, either surgical or accidental, the onset is soon after the inciting event. The IOP is elevated, the conjunctiva injected. In contrast to angle-closure glaucoma, the anterior chamber is of normal depth, the pupil is often miotic, and lens cortical material is present in the anterior chamber ([Fig. 13.10](#)). The particulate lens material reduces outflow in the trabecular meshwork, with resultant increased IOP. ⁴

Figure 13.10. Lens particle glaucoma. The fluffy white material seen here in the anterior chamber is lens cortex. This eye had a spontaneous rupture of the lens capsule in a mature cataract.

Intumescent Lens

Characterized by a gradual, painless loss of vision in the involved eye over many years, intumescent lens is associated with the development of an advanced cataract. The patient presents to an emergency department when secondary angle closure occurs as the cataract changes configuration by absorbing water and swelling. Similar to acute angle-closure glaucoma, the anterior chamber depth is shallow, the IOP is elevated, and the eye is painful. In contrast to acute angle-closure glaucoma, the intumescent (swollen, mature) lens is readily evident ([Fig. 13.11](#)).¹⁶ This is a rare cause of secondary angle closure.

Figure 13.11. Intumescent lens. The large opaque cataract is associated with an acute-onset glaucoma.

EMERGENCY DEPARTMENT EVALUATION

History

A careful history is an essential part of the emergency department evaluation of acute angle-closure glaucoma, to establish the diagnosis and plan appropriate therapy. Question the patient about the following factors:

Onset of symptoms (sudden, gradual, subsequent to accidental or surgical trauma)

Previous symptoms similar to those of the current complaint (brief episodes of pain, blurred vision, and halos around lights)

Visual acuity in the affected eye as well as in the fellow eye

Pain in or about the eye

Discharge or secretions from the eye (tearing is common with ocular pain; however, a purulent discharge may indicate an infectious cause)

Medical history of asthma or congestive heart failure and history of drug allergies (particularly sulfa drugs).

Physical Examination

Visual Acuity

Visual acuity is probably one of the most important evaluations done during the ocular examination. If a distance or near visual acuity cannot be recorded due to inability to read the chart, the following should be recorded, including the distance at which each is tested: finger counting, hand motions, light perception, or no light

perception. As is often the case in evaluating an acutely painful red eye, severe lacrimation or blepharospasm may prevent the examiner from testing visual acuity. These problems can be temporarily relieved in some cases with a topical anesthetic such as proparacaine hydrochloride or tetracaine hydrochloride.

Lids and Adnexa

The lids and adnexa are first observed. Edema and erythema of the lids are common to most of the conditions that present with a painful red eye. Some clues to diagnosis may include the following:

1. An enlarged preauricular node in the setting of viral conjunctivitis
2. Localized swelling in the lid that is painful, as in a hordeolum (stye)
3. Lid edema and erythema in association with fever, indicating periorbital or orbital cellulitis (history of paranasal sinus infection or previous trauma)
4. Proptosis associated with lid edema and erythema, indicating orbital cellulitis (check for fever) or cavernous sinus thrombosis (check for cranial nerve involvement)
5. Decreased visual acuity associated with lid edema and erythema (consider acute angle-closure glaucoma, neovascular glaucoma, and lens-induced glaucoma).

Conjunctiva

The conjunctiva is often nonspecifically injected; however, observation of the pattern of injection may be of some assistance. Perilimbal injection may indicate acute iritis or angle closure. Segmental injection characterizes episcleritis, and diffuse injection more commonly typifies keratoconjunctivitis. The presence of purulent discharge should alert the physician to a possible infectious cause ([Fig. 13.12](#)).

Figure 13.12. Acute red eye with purulent discharge.

Cornea

A slit-lamp examination, using a small quantity of fluorescein, helps identify corneal disease such as keratitis, ulcer, erosion, or foreign body as a possible cause of the painful red eye. Corneal edema, either epithelial (hazy) or diffuse stromal (steamy), should be noted. The rapid elevation of IOP is often associated with corneal decompensation.

Anterior Chamber

Assessment of the anterior chamber depth is essential in the evaluation of the painful red eye and the diagnosis of acute angle-closure glaucoma. An accurate determination can be done with gonioscopy, a technique performed by an ophthalmologist. In the emergency department, an adequate estimation of the anterior chamber depth can be accomplished with an oblique flashlight and a slit-lamp examination.

Oblique Flashlight Test. To perform the oblique flashlight test ([Fig. 13.13](#)), a penlight is directed to the temporal side of each eye, perpendicular to the corneal limbus. The examiner shines the light across the eye from the temporal side. In an eye with a normal-depth anterior chamber, the entire iris is illuminated. In an eye with a narrow angle or shallow anterior chamber depth, a shadow is cast on the nasal side of the iris. ²²

Figure 13.13. Flashlight test for wide and narrow angles. **(A)** Wide angle: Entire iris is illuminated. **(B)** Narrow angle: Only temporal half of iris is illuminated. (Photo courtesy of D.R. Anderson, M.D.)

Slit-Lamp Examination. The central and peripheral anterior chamber depth can be estimated during the slit-lamp examination. Van Herick and associates developed a technique for making this estimate. A narrow slit beam of light is directed obliquely to allow an estimate of corneal thickness and of the distance between the corneal beam to the beam on the surface of the iris. The anterior chamber depth is measured and expressed in terms of corneal thickness ([Fig. 13.14](#)). When the depth is less than one-fourth of the corneal thickness, the anterior chamber angle is extremely narrow. If the angle is closed, the iris will be seen in contact with the cornea. Both the affected and the nonaffected eye are evaluated. The fellow eye in acute angle-closure glaucoma may vary slightly but will have similar anatomic relations and appear narrow. If a unilateral shallow chamber is detected, the diagnosis of acute angle-closure glaucoma is doubtful.

Figure 13.14. Shallow anterior chamber estimation using narrow slit beam on slit-lamp examination.

Pupils

The size and shape of the pupil and its reaction to light are recorded for each eye. Unequal pupil size (anisocoria) is noted, specifically with respect to the involved, red, painful eye (see [Table 13.2](#)). A mid-dilated nonreactive pupil is characteristic of acute angle-closure glaucoma. In contrast, the pupil in acute iritis is miotic (constricted) and poorly reactive (see [Fig. 13.8](#)).

Lens

A mature (opaque) or hypermature (liquid cortex) lens may be associated with lens-induced glaucoma (see [Fig. 13.9](#), [Fig. 13.10](#) and [Fig. 13.11](#)). Phacodonesis, movement of the lens, indicates a dislocated or subluxed lens. This may occur secondary to trauma,⁷ or it may be part of a systemic syndrome, most notably Marfan syndrome. The dislocated lens may increase pupillary block and result in a secondary angle-closure glaucoma.

Intraocular Pressure

The range of IOP considered normal is from about 10 to 21 mm Hg (mean, 16 ± 2.5 mm Hg).²⁰ Three commonly used tonometers available in the emergency department are the air-puff noncontact tonometer, the Schiøtz tonometer, and the applanation tonometer.

Air-Puff Noncontact Tonometer. The air-puff tonometer measures the IOP without the application of topical anesthesia and without contact between the instrument and the eye. A 3-millisecond puff of air is blown against the cornea. The pressure is calculated by the amount of corneal flattening. This tonometer is not as accurate as the Schiøtz or applanation tonometer, but it has the advantage of use without contact with the eye.

Schiøtz Tonometry. Schiøtz, or indentation, tonometry determines IOP by measuring the indentation of the cornea produced by a known weight. Each instrument is accompanied by a graph that expresses the scale readings in millimeters of mercury. To perform Schiøtz tonometry, the patient is placed in a supine position and a drop of a local anesthetic, such as proparacaine hydrochloride or tetracaine hydrochloride, is instilled. The patient is asked to look upward and fix on some object in the distance. While separating the lids, the instrument is gently placed in a vertical position directly over the cornea, and the plunger is allowed to rest completely on the eye. With the instrument held steady, the pointer will stay fixed at a value on the scale. Readings between 3 and 6 with a 5.5-g weight will be accurate. Readings below 3 are inaccurate, and a 7.5-g weight should be added. Falsely elevated IOPs are associated with excessive lid squeezing or inadvertent pressure on the globe. Falsely low IOPs are associated with high myopia (nearsightedness), thyroid disease, and previous ocular surgery.

Applanation Tonometry. The applanation tonometer is usually mounted on a slit-lamp biomicroscope, but it can be hand-held. In applanation tonometry, the cornea is flattened, and the IOP determined by measuring the applanating force and the area flattened. To perform applanation tonometry, a local anesthetic and fluorescein are instilled into the lower cul-de-sac. Correctly positioned at the slit lamp, with the chin in the chin rest and the forehead firmly against the headband, the patient is asked to look straight ahead. Using the cobalt blue light, the examiner gently contacts the anterior corneal surface with the tonometer tip ([Fig. 13.15](#)). On contact, two fluorescein semicircles are seen. The semicircles should be aligned by turning the calibrated dial until the inner border of each semicircle just touches. This reading is multiplied by 10 and is the measurement of the IOP in millimeters of mercury.

Figure 13.15. Applanation tonometry. (A) The tonometer tip should just contact the patient's cornea. (B) Viewed through the slit lamp are two fluorescent semicircles aligned edge to edge.

Laboratory Studies

Due to vagal stimulation with the sudden increase in IOP, patients with acute angle-closure glaucoma frequently present with nausea and vomiting. The duration and severity of these symptoms may necessitate obtaining appropriate studies to assess metabolic imbalance and dehydration. In elderly patients on multiple medications, including diuretics, serum electrolyte levels should be measured before initiating medical treatment with carbonic anhydrase inhibitors or hyperosmotics.

EMERGENCY DEPARTMENT MANAGEMENT

Acute angle-closure glaucoma is an ophthalmic emergency. Once the diagnosis has been established in the emergency department, the immediate goal is twofold: to obtain appropriate consultation with an ophthalmologist and to decrease the elevated IOP. If examination by an ophthalmologist is imminent, therapy should be delayed. However, if prompt consultation is unavailable, therapy to decrease IOP should be initiated.

Therapy to reduce IOP is directed at decreasing aqueous production, increasing aqueous outflow, and reducing vitreous volume by dehydrating agents. A combination of topical agents and systemic medications directed toward these three goals is often effective in reducing IOP. The therapeutic options used in the medical management of acute angle-closure glaucoma are discussed next. The exact therapy used should be tailored to each patient's medical status.

Corneal Indentation

When IOP is 50 mm Hg or greater, topical miotics are ineffective due to ischemia of the iris constrictors. In this situation, a quick maneuver to lower IOP is corneal indentation.¹ As the cornea is indented, the aqueous is displaced and forced into the peripheral anterior chamber, which temporarily opens the angle. This results in an immediate decrease in IOP and, on occasion, can abort an attack. If, however, the attack is long-standing, it is unlikely that the aqueous can be forced through regions of iris to the trabecular meshwork adhesions (peripheral anterior synechiae). The advantages of corneal indentation are that it is rapid and may break an attack without additional medical intervention. The disadvantage is that corneal epithelium may be disrupted, which can complicate further therapy.

Corneal indentation is performed with topical anesthetics, and the patient is seated or in a reclining position. Any smooth instrument or a cotton-tipped applicator can be used, but the Goldmann applanation prism is readily available and easily held. The prism is held with the fingers to the patient's cornea and firm pressure applied for about 30 seconds ([Fig. 13.16](#)).

Figure 13.16. Corneal indentation with applanation prism. (From Anderson DR. Corneal indentation to relieve acute angle-closure glaucoma. *Am J Ophthalmol* 1979;88:1091, with permission.)

Topical Therapy

Timolol Maleate

Timolol maleate (Timoptic solution, 0.25% and 0.5%) is a nonselective beta-blocker. Lowering of IOP occurs by decreasing aqueous humor formation. Timoptic solution should be used with caution in patients with known conditions that are contraindications for the use of systemic beta-blockers, such as asthma, heart block, and heart failure. Side effects include decreased pulse rate, bronchial spasm, and altered mental state. *The recommended dosage for treating acute angle-closure glaucoma* is Timolol 0.5% solution, one or two drops at 10- to 15-minute intervals initially for three doses, and then one drop every 12 hours.

Pilocarpine Hydrochloride 1% and 2%

Pilocarpine is a direct-acting parasympathomimetic miotic agent. The mechanism of action in acute angle-closure glaucoma is mechanical. With miosis, the peripheral iris is pulled taut and away from the trabecular meshwork. Ocular side effects include a brow ache and diminished night vision. Systemic side effects, such as sweating, tremors, bradycardia, and hypotension, are uncommon in routine use of pilocarpine. However, these complications have been observed as a result of too frequent administration in the treatment of acute angle-closure glaucoma. *The recommended dosage for treating acute angle-closure glaucoma* is pilocarpine 2%, one drop every 30 minutes until the pupil constricts, and then one drop every 6 hours. *Note:* Miotics cause congestion of the iris stroma and aggravate inflammation; for this reason, concentrations higher than 2% are seldom used in an acute attack. Pilocarpine is not recommended if the diagnosis of acute angle-closure is unclear, or if the patient presents with a unilateral shallow anterior chamber.

Prednisolone Acetate

Topical corticosteroids reduce inflammation. The complications of long-term steroid use are not seen in the acute situation. *The recommended dosage for treating acute angle-closure glaucoma* is prednisolone acetate 1% (PredForte), one drop every 30 minutes to 1 hour until surgical treatment is completed.

Apraclonidine

Apraclonidine is a topical alpha-2 agonist used in chronic glaucoma. IOP is lowered by reduction of aqueous humor production, and effects are additive to those of topical beta-blockers.⁹ Success in acute angle-closure glaucoma treatment has also been reported, and its use should be considered.⁸ *The recommended dosage for treating acute angle-closure glaucoma* is Apraclonidine 0.5% solution, two drops (single administration).

Systemic Therapy

Acetazolamide

Acetazolamide is a carbonic anhydrase inhibitor that inhibits aqueous humor formation. Similar to sulfonamides, it must be given with caution in patients who have a history of allergy to sulfa drugs. Metabolic and, possibly, respiratory acidosis can occur with the use of carbonic anhydrase inhibitors; this medication should be avoided in patients with significant respiratory disease. Hypokalemia can be seen with acute therapy. *The recommended dosage for treating acute angle-closure glaucoma* is acetazolamide (Diamox), 500 mg i.v. every 12 hours; or if a patient can tolerate oral administration, acetazolamide (250-mg tablets), 500 mg PO every 6 hours.

Mannitol

Mannitol is a hyperosmotic that can be administered parenterally. It can aggravate or precipitate congestive heart failure and should be used cautiously in patients at risk for this problem. Mannitol lowers IOP by increasing the blood osmolality. This creates a gradient between the blood and the vitreous and draws water from the vitreous cavity. Side effects include headache, mental confusion, congestive heart failure, and dehydration. *The recommended dosage for treating acute angle-closure glaucoma* is mannitol 20%, 1 to 2 g/kg i.v. over 30 to 60 minutes.

Glycerin and Isosorbide

These hyperosmotic agents can be administered by mouth in patients able to tolerate oral medications. Glycerin should be avoided in diabetic patients because it can produce hyperglycemia and ketosis. Isosorbide is not metabolized to sugar and is a useful oral hyperosmotic in diabetics. *The recommended dosage for treating acute angle-closure glaucoma* is glycerin 75% (Glyrol), 1.0 to 1.5 g/kg PO (on ice with juice), or isosorbide 45% (Ismotic), 1.5 g/kg PO. *Note:* The hyperosmotic agents (mannitol, glycerin, and isosorbide) should not be used simultaneously.

Surgical Therapy

The definitive treatment of angle-closure glaucoma is release of pupillary block by an iridectomy. Laser iridectomies have replaced incisional iridectomies.¹³ Laser surgery is usually completed after the resolution of acute angle-closure glaucoma. At times it is necessary to perform an iridectomy emergently in an eye that is medically unresponsive.¹² These cases generally involve patients who have delayed medical attention longer than 24 hours.

DISPOSITION

Role of the Consultant

Acute angle-closure glaucoma is an ophthalmic emergency. Consultation with an ophthalmologist should occur immediately.

Indications for Admission

Intractable Pain, Nausea, and Vomiting

Due to vagal stimulation as a consequence of the rapid and severe elevation of IOP, patients who present with acute angle-closure glaucoma are systemically ill and

usually require admission. Analgesic and antiemetic agents may be given if the patient is having severe pain, nausea, or vomiting.

Intensive Medical Therapy and Monitoring

Parenteral administration of medications should be done in the hospital so that the patient can be closely observed for possible untoward reactions. IOP should be monitored every 2 to 3 hours to reevaluate whether the eye is responding to medical therapy. If the eye is responding and IOP is decreasing, then therapy should be continued. If the eye is not responding well to medical maneuvers and the IOP remains elevated, laser surgery (either iridectomy or iridoplasty) should be done within 2 to 4 hours.¹⁷

Transfer Considerations

If the initial receiving hospital cannot obtain an ophthalmology consult, therapy should be initiated and the patient transferred. This should be conducted expeditiously, because delay in treatment is detrimental to the visual prognosis.⁶

COMMON PITFALLS

- The diagnosis of acute angle-closure glaucoma is often difficult and delayed because the systemic complaints of pain, nausea, and vomiting are given primary attention. The overzealous treatment of these complaints (i.e., administration of analgesics and anticholinergics) may hinder a careful ophthalmologic examination and can exacerbate an angle-closure attack.
- Any patient with a painful red eye and decreased vision is considered an ophthalmic emergency and requires prompt consultation with an ophthalmologist.

ACKNOWLEDGMENT

The authors gratefully acknowledge the contribution of Alana L. Grajewski and Richard K. Parrish II who wrote the previous version of this chapter.

Orbital and periorbital infections are relatively rare and affect children more frequently than adults. When they do occur, they can be life-threatening. The terms *orbital cellulitis* and *periorbital cellulitis* are often used interchangeably, although the single most important step in managing these diseases is to differentiate the two. *Orbital (postseptal) infection* is anatomically defined as inflammation of any of the tissues within the orbit posterior to the orbital septum. A more anatomically correct term than periorbital cellulitis is *preseptal cellulitis*. This term includes any inflammation anterior to the orbital septum, a sheetlike layer of fascia that separates the orbit from the eyelids (Fig. 14.1). Preseptal cellulitis is invariably present in orbital infection, as are chemosis and proptosis.

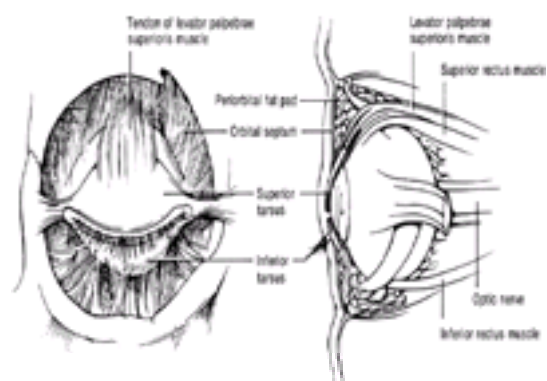

Figure 14.1. View of orbit—orbital septum.

ETIOLOGY

Seventy-five percent of all cellulitides (periorbital and orbital) have an identifiable predisposing factor, and 50% are directly attributable to sinusitis, upper respiratory tract infection, and otitis media with effusion.

The orbit is a cone-shaped cavity, and the inferior, medial, and superior walls are immediately adjacent to the paranasal sinuses. It is easy to see why infections can lead to cellulitis (Fig. 14.2).

Figure 14.2. Perinasal veins (valveless) and cavernous sinus.

The bacterial pathogens involved in orbital and periorbital cellulitis are presumed to be the same pathogens causing the predisposing condition: chronic or acute sinusitis; upper respiratory tract infection; localized skin infection or inflammation, including chalazion, hordeolum, dacryocystitis, and impetigo; trauma; otogenous and dental infections; postsurgical infections; and many other rarer causes. In the minority of patients from whom bacterial pathogens are isolated, *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Streptococcus pneumoniae*, and streptococcal species including microaerophilic *Streptococcus milleri* are most commonly cultured. Other occasionally reported pathogens include *Moraxella catarrhalis*, nontypable *Haemophilus influenzae*, *Bacteroides* spp., *Peptostreptococcus* spp., *Eikenella corrodens*, and *Pseudomonas aeruginosa*, as well as mixed bacterial cultures. Even when there is strong evidence of hematogenous spread, blood cultures are positive only 11% to 34% of the time.

The advent of *H. influenzae* type B (HiB) vaccine has changed the age-related etiologies of orbital and periorbital cellulitis. In two series of children with orbital or periorbital cellulitis, the only positive cultures for HiB were recorded prior to 1988 and in patients who did not receive the HiB vaccine. Streptococcal species are now the most commonly isolated pathogens in children. In the setting of local infection or trauma, regardless of age, *S. aureus* or beta-hemolytic streptococci are likely to be causative. Older patients tend to have staphylococcal and streptococcal infections. In the setting of sinusitis, the causative organisms are those usually involved in either chronic or acute sinusitis. Anaerobes tend to predominate in chronic sinusitis (Fig. 14.3).

Figure 14.3. Orbital cellulitis (from sinusitis).

CLINICAL PRESENTATION

Patients experiencing orbital infection have ocular pain and to varying degrees exhibit internal and external ophthalmoplegia, pupillary paralysis, and decreased visual acuity, even to the point of blindness. They may also develop increased intraocular pressure and loss of sensation along the trigeminal nerve (V1 and V2). Preseptal cellulitis, chemosis, and proptosis are present. Diffuse impairment of extraocular movements occurs when the globe is displaced by abscess.

Patients with preseptal cellulitis present with erythema, edema, warmth, and closure of the palpebral fissures; one or both eyes may be involved. Fever is more common than in orbital infection. In contrast to orbital infection, there should be no complaints of ocular pain, pain with movement of the globe, or ocular tenderness, or any limitation of globe mobility. If present, these symptoms suggest postseptal (i.e., true orbital) infection.

Immunocompromised Patients

Mycotic infections can present as an orbital infection in diabetic or other immunocompromised patients, as well as in patients with physical conditions causing metabolic acidosis, such as renal failure, cirrhosis, leukemia, and lymphoma. The patient usually presents with complaints of sinus congestion, rhinitis, and facial and orbital pain, and on examination may have proptosis, ophthalmoplegia, and visual loss. These infections are important because, although uncommon, orbital phycomycosis can cause thrombotic vasculitis, necrosis, and rapid orbitocerebral extension and can be fatal in 75% of patients. *P. aeruginosa* infections in immunocompromised patients reportedly can cause a necrotizing infection similar to the mycotic infections, with equally poor prognosis.

Pediatric Versus Adult Presentations

The literature does not allow for detailed differentiation between these two groups. In general, patients with periorbital cellulitis tend to be younger than those with orbital cellulitis, although orbital cellulitis has been described in neonates. Both infections are more common in childhood, both present acutely, and both may appear in a subacute form due to inadequate antibiotic therapy.

DIFFERENTIAL DIAGNOSIS

The patient who presents with apparent periorbital cellulitis should be presumed to have orbital cellulitis until the latter can be ruled out. Nearly 75% of all patients with an “acute orbit” have periorbital cellulitis. The other 25% have orbital cellulitis, subperiosteal abscess, orbital abscess, or cavernous sinus thrombosis. Differentiating among these serious infections is difficult because they share many features.

A *subperiosteal abscess* presents much like orbital cellulitis. There may be significant tenderness between the orbital margin and the globe itself. Extraocular movement impairments may be limited to a particular muscle group, with the eye “looking away” from the intraorbital location of the abscess. The globe may be displaced by the abscess.

An *orbital abscess* resembles orbital cellulitis. It is located in the postseptal tissues. Ophthalmologic findings of venous congestion and disk edema may be more prominent than in orbital cellulitis. Pus may spread into the lid and conjunctiva. There is pronounced exophthalmos, ophthalmoplegia, and visual impairment. The globe may be displaced due to mass effect.

Cavernous sinus thrombosis frequently presents unilaterally, followed by bilateral axial proptosis with paralysis of cranial nerves III, IV, and VI. It is extremely difficult to distinguish from orbital cellulitis until infection spreads across the anterior and posterior intercavernous sinus and bilateral involvement occurs. Dilatation of the episcleral veins is a classic feature and the first sign of worsening beyond orbital involvement. Venous engorgement of the fundus and pupillary fixation and dilatation also suggest cavernous sinus thrombosis.

Periorbital cellulitis may be confused with *allergic periorbital swelling*. If there is uncertainty about the diagnosis, the swelling and erythema should be marked with a pen, epinephrine or diphenhydramine administered, and the patient reexamined in 2 hours. Cellulitis frequently spreads across the pen lines, whereas the swelling in the allergic patient who receives epinephrine or diphenhydramine should regress.

EMERGENCY DEPARTMENT EVALUATION

Diagnosing the cause and extent of inflammation is problematic. While performing the physical examination, remember the following:

1. Pure preseptal (periorbital) cellulitis may present with sufficient swelling to inhibit visual acuity and ocular motility.
2. Fever is absent in as many as 24% of all patients with preseptal and postseptal infections.
3. Unilateral involvement is the rule rather than the exception for both periorbital and orbital cellulitis.

Blood cultures should be taken for children, but are of little value for adults. For orbital cellulitis, blood cultures are negative in two-thirds of children and in 90% to 95% of adults. Cultures of eyelid aspirates and eye secretions also correlate poorly with blood culture results and are *not* useful unless there is a clear source of cutaneous infection. Cultures of cerebrospinal fluid are recommended only for infants in whom meningeal signs are clearly present.

Sinus films do not differentiate between orbital cellulitis and orbital abscess and have been replaced by computed tomography (CT) scan. CT scanning of the orbit is advocated in all children with periorbital swelling in whom postseptal infection cannot be ruled out by examination. Most authors advocate obtaining coronal as well as axial CT views to locate superomedial subperiosteal or orbital abscesses that might be missed on axial views alone. There is no advantage to using contrast rather than noncontrast CT scanning. CT scans identify a subperiosteal abscess or orbital abscess in only 80% of cases. Diagnosis of orbital infection remains a clinical one. CT scanning does contribute to the selection of a surgical approach for abscess drainage once the patient has been admitted, or if the patient has failed to improve on parenteral antibiotics. Ultrasound has been advocated because of its lack of ionizing radiation and its ability to discriminate between fluid and soft-tissue density. A magnetic resonance scan offers another alternative for identification of patients requiring surgical treatment.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment should not be delayed in favor of extended diagnostic workup. In adults, if the infection appears to be localized to the preseptal tissues only and is not severe, antibiotics can be given orally on an outpatient basis. Antibiotics should cover *S. aureus*, group A *Streptococcus*, and Enterobacteriaceae. First-generation cephalosporins or penicillinase-resistant synthetic penicillins should be given. For the adult with signs of serious infection, first-generation cephalosporins, penicillinase-resistant synthetic penicillins, or second- or third-generation parenteral cephalosporins and vancomycin or ticarcillin/clavulanate or ampicillin/sulbactam

are appropriate alternatives.

In children, only the mildest cellulitis should be treated on an outpatient basis. Even this is controversial; some authorities recommend admission and parenteral antibiotics for all children with periorbital cellulitis. Either cefuroxime 20 to 30 mg/kg/d every 12 hours or amoxicillin/clavulanate potassium (Augmentin) 40 mg/kg/d every 8 hours may be used with equal efficacy. In cases of trauma or infection in which the suspicion of staphylococcal infection is high, dicloxacillin 25 to 40 mg/kg/d every 6 hours or, in the penicillin-allergic patient, erythromycin 40 mg/kg/d every 6 hours may be given. The condition should be treated for at least 7 to 10 days. If the infection appears to be secondary to sinusitis, treatment should last at least 2 to 3 weeks and antibiotic coverage should be aimed at organisms that cause sinusitis (anaerobic bacteria). If outpatient treatment has been selected, the patient should be reexamined the next day, preferably by a specialist.

If there is any question about the extent of the infection, intravenous antibiotics should be initiated without delay. In the child under age 5 in whom sinusitis is believed to be the source or in whom no clear cause can be found, antibiotic coverage for gram-positive cocci, including resistant *S. pneumoniae*, should be initiated until culture results are available.

Most authors also advocate coverage for anaerobes, including *Bacteroides* spp. and microaerophilic *S. milleri*. The most frequently recommended combination is a beta-lactamase-resistant penicillin, such as nafcillin 150 mg/kg/d every 6 hours, and chloramphenicol 50 to 100 mg/kg/d every 6 hours (this dose is halved for neonates). Alternatively, a high-dose second-generation cephalosporin active against gram-positive organisms, such as cefuroxime 75 to 100 mg/kg/d every 8 hours or cefotaxime, may be used along with metronidazole for anaerobic coverage. *Ampicillin is no longer recommended*. The dose of cefuroxime should be increased to 240 mg/kg/d in cases of associated meningitis.

In the penicillin-allergic patient, either vancomycin 40 mg/kg/d every 6 hours or clindamycin, combined with chloramphenicol, is a reasonable choice. For patients with infection clearly related to a skin lesion, nafcillin is recommended. For the penicillin-allergic patient, vancomycin is recommended.

DISPOSITION

Role of the Consultant

Any sign of true orbital (postseptal) infection in patients of any age mandates hospital admission for intravenous antibiotic treatment. It should prompt an urgent otolaryngologic and ophthalmologic consultation as well. The infected orbit may need emergency surgical exploration and drainage if there is no improvement within 24 to 48 hours, or if visual acuity worsens.

Indications for Admission

Mild preseptal cellulitis in the adult may be treated on an outpatient basis, but only if the patient can be reexamined by an ophthalmologist the next day. If a trial of outpatient treatment is chosen, the first dose of the selected oral antibiotic should be given before discharge from the emergency department. If the periorbital swelling is considerable or involvement deep to the preseptal tissues is evident, intravenous antibiotics should be started in the emergency department before admission to the hospital, in consultation with the admitting physician. Children with periorbital cellulitis should be assessed with caution; only the mildest of infections may be managed on an outpatient basis.

Transfer Considerations

Transfer is required if orbital cellulitis is suspected and an ophthalmologic surgeon is unavailable. The emergency physician should arrange immediate transfer while antibiotics are being given. An advanced life-support unit is necessary only in severe cases, such as a patient with signs of cavernous sinus thrombosis.

COMMON PITFALLS

- The most important action is to differentiate periorbital (preseptal) from orbital (postseptal) infection. All but the mildest cases of periorbital cellulitis warrant admission.
- Periorbital cellulitis may be easily confused with allergic periorbital swelling.
- Tests that are of *little value* in differentiating periorbital from orbital cellulitis include white blood cell counts and sinus films, cultures of eyelid aspirates or eye secretions, routine cerebrospinal fluid cultures (in the absence of meningeal signs), and blood cultures in adults.
- CT scanning is the diagnostic test of choice. Contrast-enhanced CT appears to be no more useful than noncontrast CT in differentiating the type and extent of infection.
- Ultrasound may be less useful in children under age 4 because of redundant mucosa in the young child.
- Antibiotic coverage should be directed at the underlying etiology, most commonly sinusitis. Consider coverage for resistant *S. pneumoniae*.

Pain in the jaw and other facial structures is a common presenting complaint in most emergency departments. It is the job of the emergency physician to determine which of these complaints demands immediate therapy and which can be ameliorated until a dentist or oral-maxillofacial surgeon is available. The majority of dental-related problems can be treated with simple therapy.

A thorough medical history and review of systems should be obtained before oral examination and treatment begin. Many chronic diseases, from clotting disorders to cancers, can be manifested by oral problems. In addition, fatal anaphylaxis can occur from antibiotics prescribed for oral infections, just as in cases of severe systemic diseases. Because manipulation of the oral cavity causes transient bacteremia, certain patients should be identified to receive antibiotics before invasive procedures.

The information presented here is restricted to those patients whose main pathology is confined to the oral cavity. If obvious facial cellulitis, fever, or Ludwig's angina is present, the reader is referred to [Chapter 18](#), "Dental, Oral, and Salivary Gland Infections."

TOOTH ANATOMY

To understand how an apical abscess develops and how other common tooth pathologies cause pain, it is important to briefly review some points about tooth anatomy. First, the enamel is the hard outer surface of the teeth. When the enamel is intact, it is white and shiny.

Under this surface lies the dentin. It is off-yellow and sensitive to both pain and infection. It is composed of dentin tubules, which connect this structure directly to the pulp cavity, where the nerve and blood supply of the tooth live. The dentin, then, is a very important structure. When it is exposed by either caries or trauma, it should be covered. This reduces pain and lessens the chance for infection, which can track along the tubules to the dental pulp.

The periodontal ligament is an important structure for holding the tooth in position. This structure is very cellular and fragile. This is why when a tooth is knocked out of the mouth, the tooth may be held under running water to remove gross contamination but should not be scrubbed. The scrubbing process removes the periodontal ligament, and the tooth will then not "take" when reinserted.

Teeth are numbered, usually by the method of [Fig. 15.1](#). In other words, numbering starts with the third molar at the posterior of the right upper jaw, proceeds forward and around to the third molar of the left upper jaw, then drops down and proceeds forward from the left third molar of the lower jaw, ending with the no. 32 tooth, the posterior third molar of the lower right jaw. The more practical method is just to name the tooth involved, keeping in mind the dental formula. The dental formula states that the mouth can be divided into four quadrants, each having the following teeth: a central incisor, a lateral incisor, a canine tooth, two premolars, and three molars (the last, or third, molar is the wisdom tooth). Using this simple formula, all of the teeth can be properly identified.

Figure 15.1. Identification of teeth (dental arches widely spread).

ORAL EXAMINATION

Emergency department management is based on a thorough history, as described, and an adequate physical examination of the mouth. First, the patient's general appearance should be noted, concentrating on facial symmetry. Evaluate for facial edema, localized external areas of tenderness, erythema, and obvious lesions. The lymph nodes in the neck, including the submandibular and preauricular regions, are palpated.

With a tongue blade in each hand, with good lighting from either a headlamp or a good overhead light, both hands should be free to feel in the mouth and hold the tongue blades. After you have gloved and are holding a tongue blade in each hand, ask the patient to open his or her mouth. Evaluate first for trismus. This is noted almost immediately by the inability to fully open the mouth. The distance can be objectively measured by the distance between the central incisors, usually greater than 35 mm, but it is acceptable to estimate the ability of the patient to open the mouth. When mouth opening is limited by pain, it usually indicates infection in the muscles of the face and is an indication for further examination.

Proceeding from the outside in, and from the anterior of the mouth toward the back, evaluate the soft-tissue structures for pathology. Do this first before looking at the teeth, because most tooth pathologies cause problems with the surrounding gingiva. Begin at the inferior lip, looking for erosions, state of dentition, erythema, abscess, and areas of inflammation. Then proceed to the posterior mucosa, and evaluate the posterior oropharynx, then the tongue. Evaluate the actual teeth, focusing on areas noted in the initial visual inspection or by evaluating areas of pain described by the patient. There are ways to use heat or cold to stress the nerves of the teeth, but the percussion test works the best and is relatively sensitive. Simply percuss the occlusal surface of the tooth, and if the nerve is inflamed, this will usually elicit pain. When you elicit tenderness on examination in an area, be specific. This helps in determining whether tooth pathology is old or new and helps guide

therapy. It is helpful to keep in mind that old, dead teeth are usually not painful, because the root of the tooth is already dead. The acutely infected and dying teeth are painful.

After the gingiva and tooth structures are evaluated with the tongue blades, focus on the area of pathology, carefully identifying the pathology noted. Look closely at the tooth surfaces and the gingiva associated with the suspected tooth, and attempt to move the tooth. Loose teeth and recession of the gingival structures indicate advanced periodontal disease. Palpate the tongue and floor of the mouth and examine the mucosa for lesions. If the mouth is unusually dry, make note of this as well.

With the history and physical examination conducted in an organized manner, the following diseases can be diagnosed and appropriate management begun. Pathologies described are divided into those of the actual teeth versus those of the supporting structures of the teeth.

DISEASES OF THE TEETH

Dental Caries

Dental caries, or tooth decay, are the most common cause of toothache seen in the emergency department and the most common cause of tooth loss worldwide. This is obviously not an acute process, but eventually the pain increases until often the patient "can't take it any longer." Pain is associated with exposure of the dentin and, in advanced cases, with irritation of the pulp. Associated periodontal disease may contribute to the pain. The whole process is caused by a complex interaction of susceptible teeth, with bacteria, mostly *Streptococcus mutans*, in the proper acidic media. As such, caries of the teeth, as well as periodontal diseases in general, are bacterial in nature. Plaque is associated with this process; build-up of plaque and lack of proper dental care are largely responsible for this preventable disease.

The patient usually complains of dull pain, often exacerbated by hot or cold foods. Percussion of the involved tooth and evaluation of the associated mucosa will help determine appropriate pain medication prior to referral. Unless pulpitis or other pathology is evident on examination, antibiotics are not indicated. Definitive therapy involves excavation and filling (by a general dentist) of the dental areas involved.

Pulpitis

Pulpitis is inflammation of the confined structures of the pulp cavity. The most common cause is extension of infection from dental caries. The most common symptom is pain, as the vascular and nerve bundles lie herein. The patient complains of severe pain, often throbbing and shooting in character. The pain is exacerbated by thermal changes. Pulpitis is usually acute, but chronic pulpitis also can occur. Here the pain is less intense and less temperature sensitive. Emergency department treatment includes adequate analgesia and arranging for follow-up care by a dental practitioner. In cases of severe pain, urgent dental consultation may be advisable. Definitive treatment involves excavation and filling of the underlying dental caries, and usually a root canal. Root canal therapy removes the structures of the root (the nerve and vascular bundle) and thereby may avoid tooth extraction. Endodontic therapy is expensive and requires patient compliance.

Periapical Abscess

When dental caries are left unchecked for prolonged periods, the infection tracks to the pulp cavity, causing pulpitis. Over time, this is followed by extension of the infection to the cancellous bone of the dentoalveolar ridge. Here the infection usually spreads to the buccal, lingual, or palatal cortical bone and can usually be seen and palpated. Clinically, the tooth is usually nonvital and is sensitive to both percussion and thermal testing. It is important to identify a periapical abscess, as it is readily treated with incision and drainage (I and D) by experienced emergency physicians or by a dental consultant.

The area is identified by erythema, tenderness, and distension. Apical block anesthesia is done by injecting a small volume of lidocaine in the soft gingival sulcus near the root of the tooth, and incision and drainage can be carried out easily under this simple local anesthesia. Drainage of this infection can prevent the further tracking of the infection to other areas of the face and neck. As with any abscess, I and D is the treatment of choice, as antibiotics do not penetrate well into the area of abscess. After I and D, and after any oral procedure, the patient should swish and spit with warm salt solution until the spit is clear and a quick reexamination of the mouth can be performed.

After drainage of an abscess, the antibiotic of choice is penicillin (penicillin V potassium 500 mg q.i.d. or 1 g b.i.d.) or clindamycin 350 mg q.i.d. Erythromycin or another macrolide is also an acceptable choice. The patient should be given instructions for a follow-up visit with a dental consultant within 1 to 2 days.

Definitive treatment involves either extraction of the tooth or excavation and filling of the underlying dental caries, followed by root canal. The procedure chosen depends on the health of the involved teeth and supporting structures, and how compliant the patient is expected to be. Root canal therapy requires a patient who can comply with more than one office visit and follow instructions.

A common pitfall of periapical abscess occurs when the emergency physician attempts to avoid an I and D of the abscess by treating the patient with antibiotics. This is often related to a certain lack of experience or knowledge and puts the patient at risk for extension of the infection.

PERIODONTAL DISEASES

Periodontal disease is often thought of as gum disease. Actually, the periodontium consists of the supporting structures of the gingiva, periodontal ligament, and alveolar bone. Periodontal disease is actually a group of diseases. The two most important in terms of frequency are gingivitis and periodontitis. The most common cause of periodontal disease is poor dental hygiene, with the subsequent build-up of plaque, resulting in both dental caries and subsequent periodontal disease. As with dental caries, bacterial interplay with susceptible structures precipitates the inflammation and degeneration of the structures affected. Many systemic diseases also are associated with periodontal diseases, the most common being insulin- and noninsulin-dependent diabetes, human immunodeficiency virus (HIV) infection, and cardiovascular diseases. Additionally, hormonal factors and drug reactions can cause specific types of periodontal disease.

Neither gingivitis nor periodontitis is by itself an emergency, but the complications of these diseases result in many emergency department visits each year, so a basic understanding of these processes is important.

Gingivitis

Gingivitis is an inflammatory process of the gingiva, characterized by a change in the normal contour of the gingiva, with erythema, edema, and, often, discharge. Despite changes in the gingiva, the junctional epithelium that covers the inferior portion of the tooth is maintained intact and the tooth is not loosened. Treatment of gingivitis is local containment of the plaque (which is a causative factor), or treatment of the systemic disease, when it is a factor.

Periodontitis

Periodontitis is also an inflammatory condition of the gingival tissues, but is characterized by loss of attachment of the periodontal ligament and the bony support of the tooth. It is thought to represent an extension of gingivitis, although only a few gingivitis sites make this transition. The destruction of these supporting structures of the tooth does not proceed in a steady manner, but seems to progress in bursts related to unknown factors. In the elderly, periodontitis continues to be a significant cause of tooth loss. Evidence of periodontitis should be noted on examination and the patient referred to a dentist for evaluation and treatment.

Periodontal Abscess

When periodontitis is advanced, the associated bone loss can result in localized pockets forming around the tooth. These pockets can become infected, resulting in pain, erythema, and frank abscess. This type of abscess differs from the periapical abscess, because the tooth may still be healthy and no caries need be present.

Initial treatment consists of local anesthesia, usually an apical block, followed by I and D by either the emergency physician or dental consultant. Antibiotics are usually not indicated unless the abscess is extensive. The patient should be referred to a dentist for further management, which usually involves physical removal of the periodontal pocket by excision or curette.

Pericoronitis

Pericoronitis is inflammation, usually followed by infection, of the gingival tissue overlying the crown of an impacted tooth. As the tooth attempts to erupt through this gingiva (operculum), the area becomes inflamed and secondarily infected. This usually involves the wisdom teeth (third molars), and the severity can range from mild inflammation to a significant, spreading facial infection.

Emergency treatment is based on severity, but usually involves oral antibiotic administration of penicillin (penicillin V potassium 500 mg q.i.d. or 1 g b.i.d.), or clindamycin 350 mg q.i.d. Erythromycin or another macrolide is also an acceptable choice. Adequate pain medications should be given and urgent referral to an oral surgeon should be made. Definitive treatment usually involves excision of the impacted tooth.

Acute Necrotizing Ulcerative Gingivitis

Acute necrotizing ulcerative gingivitis (ANUG), also called trench mouth, is an intraoral infection characterized by erythema and hyperemia of the gingiva, fetid breath, bleeding gums, and friability of the mucosa. White plaques and areas of ulceration are usually evident and a pseudomembrane that bleeds with manipulation may be present. Systemic symptoms are often present, such as fever, malaise, or dehydration. The disease occurs mostly in teen-agers and is associated with factors such as malnutrition, smoking, stress, or poor personal hygiene. Such factors favor the proliferation of fusiform and spirochete bacteria as responsible for the infection.

ANUG is treated by local mouth care, such as gentle debridement of lesions with a cotton-tipped swab soaked with hydrogen peroxide. Antibiotics are usually indicated (penicillin, clindamycin, or erythromycin), especially if fever or adenopathy is present. Pain medications should be administered and referral to a dental consultant arranged. Bony destruction can occur as a consequence of ANUG, so follow-up is important.

MOUTH LESIONS

There are a multitude of causes of lesions of the mouth, including ulcers. Some of the more common etiologies of ulcerations are described next. It should be noted, however, that many systemic diseases have dermatologic manifestations that can first make their appearance as lesions in the mouth. These diseases include pemphigus, erythema multiforme, lichen planus, Stevens-Johnson, Behçet, various hemorrhagic disorders, and neoplasms. If a lesion looks suspicious, the patient should be referred to a dental consultant for further evaluation and potential biopsy.

Aphthous Ulcers

These lesions are common, with about one-third of people manifesting one in their lifetime. Often, they are recurrent and characterized by a round, symmetrical, shallow lesion with a yellowish exudate. These ulcers are usually 0.5 to 1.0 cm in diameter and are painful. A burning sensation is often noted in the area just before eruption. The etiology is unknown. Treatment consists of general mouth care instructions and dyclonine hydrochloride topically for pain.

Acute Herpetic Gingivostomatitis

This is an acute infection, usually noted in children less than 6 months of age. It represents the first infection with herpes, and as such, presents with a classic prodrome of illness, followed by lymphadenopathy and fever. The oral lesions are usually multiple, shallow, round, and discrete ulcers with a red halo of inflammation. The gingiva are usually inflamed and painful as well. Acute treatment is symptomatic, ensuring control of fever and adequate hydration. A "swizzle" of equal parts viscous lidocaine, Maalox, and Benadryl can be given for symptomatic relief of oral pain.

Allergic Stomatitis

This condition causes localized or generalized swelling and inflammation of the gingiva, usually with no systemic symptoms. Burning is a predominant symptom. Diagnosis is by history, and treatment is avoidance, once the inciting allergen is identified.

Traumatic Ulcers

These can be caused by thermal injury, chemicals, or even bites, such as sustained during seizures. Aspirin is a common chemical burn, when applied topically on painful teeth or gums. As the burn resolves and the mucosa sloughs, a painful, red, bleeding surface often remains. Treatment for these ulcers is good general mouth cleansing and avoidance of the chemical or trauma.

COMMON PITFALLS

- A good general history, including susceptibility to allergies, is important. Failure to obtain a history potentially exposes patients to antibiotics and analgesics to which they may be allergic. In addition, procedures are often performed on those who should have antibiotic prophylaxis, and this may be neglected inadvertently.
- Failing to refer patients for routine dental care after noting poor oral hygiene and dental caries. Tooth loss is often preventable when follow-up dental care is made available and utilized.
- Failing to drain an abscess cavity when one is noted. Administration of antibiotics alone does not constitute adequate treatment in the presence of an abscess.

This chapter outlines postoperative complications from oral and maxillofacial surgery (OMFS) that may present to the emergency physician. OMFS procedures involve major facial surgery done in the hospital (e.g., osteotomies of facial bones) and minor procedures done in the office (e.g., removal of teeth). Patients may be referred to the emergency department directly from the surgeon's office after an intraoperative complication, or may have developed a problem several hours or days after hospital discharge or completion of office surgery.

OMFS postoperative complications are unique for two reasons: First, the airway may be compromised, and second, the patient may be in intermaxillary fixation (teeth wired together or secured with elastics). OMFS postoperative complications fall into the following general categories: ⁵

Intermaxillary fixation (teeth/jaws "wired" closed or secured with elastics):

- Airway concerns
- Emergency release of intermaxillary fixation for vomiting

Bleeding:

- After tooth extraction and alveolar bone surgery
- After periodontal surgery
- Postoperative midface osteotomy procedure

Swelling:

- Postextraction infection
- Surgical edema and hematoma
- Salivary gland obstruction
- Fracture of mandible during tooth extraction
- Sudden change in occlusion (bite)
- Office anesthesia complication
- Aspiration versus swallowed instrument, packing, or tooth

The three steps for initial evaluation are the following:

1. Ensure an adequate airway.
2. Control bleeding.
3. Obtain a history of the surgical procedure (what, when, and by whom).

After initial evaluation and stabilization, contact the treating OMF surgeon or the ear, nose, and throat (ENT) consultant.

INTERMAXILLARY FIXATION

Intermaxillary fixation (IMF) consists of tying the upper and lower teeth together with stainless steel wires or elastics. This is a common method of stabilizing the upper and lower jaws to allow for healing of jaw osteotomy procedures, jaw fractures, and jaw reconstruction procedures. Complications are rare, and the need to release the IMF on an emergency basis is infrequent. The critical reason to cut the fixation is vomiting. If release of IMF during the first 4 weeks after surgery is necessary, reoperation may be necessary or the surgical result will be compromised. The typical duration of this method of fixation is 4 to 8 weeks, during which time the patient must consume only liquids. Speech is usually difficult to understand, and most patients lose 10% to 20% of their weight while the jaws are wired together. If an acrylic surgical bite splint is interposed between the teeth, the oral airway can be greatly restricted. Edema can further restrict the oral airway. If, in addition to a restricted oral airway, the patient has a restricted nasal airway, then breathing becomes difficult. During the first 2 weeks after surgery when IMF is used and some surgical edema remains, some patients become anxious about breathing and adequate nutrition, and may present to the emergency department. Usually, reassurance and possibly a nasopharyngeal airway are all that are needed for treatment. Vomiting while in IMF is frightening to the patient but should not require release of IMF,

unless the emesis cannot be cleared.

Release of IMF can be done on an emergency basis when access to the airway is mandatory. Examples of such situations are trauma, significant airway restriction due to acute infection or surgical edema, and a severe medical emergency, such as status epilepticus, septic shock, or cardiac arrest.

Release of IMF is accomplished by using small wire cutters to cut all the wires that cross from one dental arch to the other (all wires traversing from the upper teeth to the lower teeth). There may be three to eight wire loops (six to 16 wires) to cut. Occasionally, rubber bands are used to hold the teeth together, and these can be cut with a scalpel or scissors. Release of IMF with wires may be time consuming to those untrained in placing IMF. Consider emergency blind nasotracheal intubation or cricothyroidostomy in extremely acute situations. If wires are cut and not removed, small loose wires will remain in the mouth. All patients with IMF should have wire cutters or scissors with them.

MANAGEMENT

Evaluation and treatment involve the following:

1. Analyze blood gas levels or capnometry.
2. Monitor with a pulse oximeter.
3. Assess the work of breathing and the possibility of fatigue.
4. Consider a nasopharyngeal airway.
5. Release IMF in extreme cases by cutting the vertical wires between dental arches with wire cutters or by cutting the elastic bands with a scalpel or scissors.
6. Consider cricothyroidostomy or nasotracheal intubation when immediate airway access is necessary and no experienced person is available to release the wire IMF.

DISPOSITION

If the IMF needs to be cut, the OMFS or ENT consultant should be called immediately. Otherwise, discharge or admission of the patient is totally dependent on the presenting complaint.

COMMON PITFALLS

- Failure to recognize that the IMF can result in aspiration if the patient is unable to clear the airway by expelling vomitus between the teeth
- Being too quick to cut the IMF when doing so may not be necessary
- Hesitancy to cut the IMF when doing so is necessary
- Discharging the patient or sending the patient to the floor without a wire cutter or scissors and instructions as to when to cut the IMF

BLEEDING

Bleeding (from the mouth or nose, or both) is one of the more common postoperative complications. Normally, a small amount of bleeding mixes with saliva during the first 12 hours after many intraoral procedures. Significant hemorrhage must be differentiated from this type of bleeding. Problematic hemorrhage is usually apparent during an office procedure or within the first 12 hours. It is important to obtain a history of aspirin or nonsteroidal antiinflammatory drug (NSAID) use.

Prolonged bleeding from a simple tooth extraction in the absence of a coagulopathy is usually minor and can be controlled with oral gauze packs. For removal of lower wisdom teeth, the incidence of problem bleeding is 0.5% to 1.1% intraoperatively and 0.5% to 0.8% postoperatively.⁶ Possible sources of bleeding include the extraction socket, inferior alveolar artery, posterior superior alveolar artery, long buccal artery, facial artery, palatine artery, lingual artery, and maxillary artery.

Bleeding after Tooth Extraction or Alveolar Bone Surgery

The most significant hemorrhage related to alveolar bone surgery in the mandible is from damage to the inferior alveolar neurovascular bundle that runs in a bony canal below the roots of the posterior teeth. Damage to this structure can occur during⁴ surgical removal of teeth, odontogenic tumors, and cysts and the placement of endosseous dental implants.⁴

MANAGEMENT

1. Reassure the patient.
2. Keep the patient's head elevated 45 degrees.
3. In the case of postextraction bleeding, simply biting on gauze may not be sufficient to stop the bleeding. The gingiva around the extraction site should be infiltrated with 1% or 2% lidocaine with 1:50,000 or 1:100,000 epinephrine. The anesthesia helps the patient to bite with more force. The vasoconstrictor helps to decrease capillary oozing. If bleeding persists, the socket should be packed with Gelfoam, Surgicel, or Avitene. The packing usually must be secured with a black silk suture. If bleeding persists, see the following item (item 4).
4. Decide whether the bleeding is caused by an anatomic problem or by a coagulopathy, including excessive aspirin use.
5. Consider a hematocrit and coagulation screen, type and crossmatch, and intravenous fluids.
6. Consider OMFS or ENT consultation for persistent or severe hemorrhage for possible suturing, electrocautery, or extraoral cutdown on facial, lingual, or external carotid arteries. Emergency ligation of the external carotid artery is seldom necessary; local control is preferred.

Persistent Bleeding from Palate Secondary to Palatine Artery Injury

MANAGEMENT

1. Apply pressure to the bleeding site with 4×4-in. gauze packs. An assistant or the patient holds the packing by hand. Administration of a local anesthetic with a vasoconstrictor is again useful (see previous [management](#) section).
2. If bleeding continues after 30 to 60 minutes of pressure, the OMFS or ENT consultant will need to ligate or cauterize the artery.

Delayed Bleeding after Midface Osteotomy

Delayed bleeding after midface osteotomy involves bleeding from the nose and nasopharynx, or acute swelling of the upper cheeks (unilaterally or bilaterally) within 2 weeks after surgery. Many patients have a small amount of bleeding from the nose after midface osteotomy procedures (e.g., segmental osteotomy and Le Fort I, II, III) due to disruption of the nasal mucosa and pooling of blood in the maxillary sinuses. This minor nasal bleeding must be differentiated from significant hemorrhage. The incidence of severe postoperative bleeding after Le Fort I osteotomy is 0.75%.^{1,3}

MANAGEMENT

1. Consider a balloon nasal pack as the first option in significant bleeding, because it simultaneously occludes the posterior, middle, and anterior nasal cavities.
2. Consider arteriography for significant bleeding to rule out an arteriovenous fistula or a pseudoaneurysm.
3. Hospital admission is probably necessary for observation, reoperation, or embolization.
4. Notify the OMFS or ENT surgeon immediately.

DISPOSITION

If bleeding can be controlled by the aforementioned measures, the patient can be safely discharged. In the case of postextraction bleeding, the patient needs to be instructed not to smoke, use straws, or spit. These actions all create a negative pressure in the mouth, which leads to clot dislodgment and rebleeding. Of course, the patient should be asked to refrain from aspirin- and NSAID-containing products. Persistent bleeding requires OMFS or ENT consultation.

COMMON PITFALLS

- Failure to follow a sequential approach to postoperative oral hemorrhage
- Failure to use local anesthesia and a vasoconstrictor for pain and hemorrhage control
- Ordering a coagulopathy workup before trying simple measures
- Failure to order a coagulopathy workup when simple measures fail
- Failure to obtain OMFS or ENT consultation when revision of the surgical area may be required for hemorrhage control

SWELLING

Patients may present with acute swelling after OMFS procedures because of concern over the airway or swallowing, or for an explanation. The swelling may be from a hematoma, surgical edema, acute cellulitis, or abscess.

Hematoma and Surgical Edema

Office procedures that may result in hematoma or surgical edema significant enough to warrant an emergency department visit are procedures in the floor of the mouth (e.g., excision of mandibular tori, excision of the sublingual gland, and removal of a stone from the salivary gland duct).

MANAGEMENT

1. The airway is the primary concern.
2. Have the patient sit up and lean forward.
3. Perform appropriate monitoring (e.g., pulse oximetry). Consider admission for observation.
4. With obvious airway compromise, consider the following interventions, in order of preference: insertion of a nasopharyngeal airway, oral or nasal endotracheal intubation, cricothyroidostomy, or tracheostomy.
5. Consider prophylactic antibiotics with both hematoma and surgical edema in the floor of the mouth to avoid development of a Ludwig's angina type of infection.

Postextraction Infection

A common reason for an emergency department visit is the rapid progression of an infection after removal of an impacted mandibular third molar (wisdom tooth). This can involve several tissue spaces, including the parapharyngeal space. Edema and infection in the masticator space cause trismus (limited mouth opening due to muscle spasm), making examination of the oropharynx difficult. The incidence of infection is 0.6% to 2.5%.²

MANAGEMENT

1. Obtain the patient's history: when and by whom the surgery was done, immunocompromise, preoperative infection and antibiotic use, current antibiotics.
2. Determine if there is significant limitation of mouth opening; examine the oropharynx for parapharyngeal swelling.
3. Check temperature and extent of swelling (e.g., whether it involves submandibular or submental spaces and extends across the midline). (See [Chapter 18](#).)
4. If the airway is compromised, consider inserting a nasopharyngeal airway. Cricothyroidostomy or tracheostomy is seldom necessary but must be considered for severe cases. If a definitive airway is necessary, a nasoendotracheal intubation is attempted first if trismus is present.
5. Consider admission for intravenous antibiotics and surgical incision and drainage in the operating room. Consult the OMF or ENT surgeon.
6. If trismus and swelling are minimal, oral antibiotics and daily outpatient follow-up for 3 or 4 days are essential.

DISPOSITION

Disposition in the case of postoperative swelling or infection is based on the severity of the condition. Mild postoperative swelling that is not compromising the airway, and should not compromise the airway, can be managed on an outpatient basis. If there is any doubt, the OMFS or ENT consultant should see the patient. Some with postoperative infections can be managed as outpatients. However, because fascial planes of the head and neck can be violated during surgery, a very high index of suspicion is necessary for the potential for infection to spread.

COMMON PITFALLS

- Failure to recognize the potential for airway compromise from swelling or postoperative infection
- Failure to recognize the potential for the spread of infection through the fascial planes of the head and neck

Swelling of Salivary Glands Due to Obstruction of Ducts

Acute swelling of the submandibular gland(s) and, occasionally, the parotid can occur. Surgical edema or a suture obstructing the opening can result from intraoral surgery or placement of intraoral acrylic surgical stents. Swelling typically is mildly tender, without signs of infection. The patient may present hours to 3 days postoperatively.

MANAGEMENT

1. Examine the salivary ducts for any obstruction that can be eliminated (e.g., sutures or acrylic stents) and consult the OMF surgeon. If edema is the only cause of the obstruction, the swelling will resolve in 3 to 4 days.
2. Antibiotics may be important, especially if the surgery was for removal of a salivary duct stone that was causing chronic partial obstruction.

DISPOSITION

Patients with swelling secondary to a salivary gland or salivary duct obstruction can generally be discharged for follow-up the next day. Analgesia and antibiotics are important. The patient should refrain from eating sour foods.

COMMON PITFALLS

- Failure to recognize mechanical obstruction of a duct that should be relieved.
- Failure to treat for infection due to the stasis of saliva.

Fracture of the Mandible from Extraction of Teeth

Fracture of the mandible typically results from removal of impacted lower wisdom teeth.

MANAGEMENT

1. Evaluation and treatment are the same as for any jaw fracture.
2. Application of a Barton's bandage to immobilize the jaw ([Fig. 16.1](#)) is seldom necessary, as prompt OMFS or ENT consultation is required.

Figure 16.1. Barton's bandage.

Sudden Change in Occlusion

A sudden change in occlusion (bite) during the postoperative period (after jaw osteotomy, fracture repair, or mandibular reconstruction in which rigid internal fixation was used without IMF) can occur due to failure of the internal fixation. Failure of external fixation devices (transcutaneous pins and bars) is readily apparent. The patient will present with a malocclusion (shifting of the bite) that occurred suddenly. There may be mild-to-moderate pain aggravated by jaw movement.

MANAGEMENT

1. Evaluation is the same as for fractures of the mandible. Treatment is usually reoperation, although emergency admission is typically unnecessary.
2. Notify the OMF surgeon: It may be desirable to stabilize the mandible immediately by IMF.

DISPOSITION

A fracture of the jaw secondary to an extraction or the disruption of occlusion is a major problem. The OMFS or ENT consultant should be notified immediately. Nondisplaced jaw fractures can be treated with antibiotics, analgesia, soft diet, and referral to the office the next day. Such fractures are normally treated with IMF that is placed in the office. Displaced fractures require immediate consultation and admission. Disruption of IMF and the occlusion may require reoperation.

COMMON PITFALLS

- Failure to consider jaw fracture as an etiology of postextraction pain
- Failure to place a patient with a jaw fracture on antibiotics
- Failure to recognize the clinical significance of a displaced occlusion
- Failure to consult the OMFS or ENT

Complications from Outpatient Sedation and Anesthesia

Drugs used for office sedation are narcotics, benzodiazepines, barbiturates, and occasionally ketamine. A patient may be transported to the emergency department from a doctor's office because of complications related to such sedation. The most frequent event is loss of an adequate airway, or prolonged hypoventilation, which leads to cardiovascular complications.

MANAGEMENT

Complications from outpatient office sedation are treated according to the patient's condition.

Aspiration or Swallowed Foreign Bodies

Teeth, dental restorations, bone, drill bit, packing, or dental instruments may all be swallowed or aspirated. Usually, the situation is not life-threatening. Evaluation includes the probable location of the object and whether arrangements need to be made to remove it. Packing aspiration is the most serious, as it can drape over the carina.

MANAGEMENT

1. Obtain a description of the object and the events surrounding the aspiration or swallowing.
2. Order a chest x-ray or abdominal radiograph to determine whether the object is in the lungs, stomach, or bowel.
3. Consider a pulmonary or gastrointestinal consult to remove the object by flexible fiberoptic endoscopy. Small, blunt objects may be allowed to pass, without intervention, through the gastrointestinal tract. Sharp or pointed objects in the gastrointestinal tract and objects in the lungs should be removed as quickly as possible.
4. Deeply aspirated packing at the level of the carina is devastating, because both bronchi may be obstructed.

DISPOSITION

Aspirated foreign bodies that appear to be in the gastrointestinal tract can generally be managed on an outpatient basis if there is no potential for perforation. If the potential for perforation exists, the gastrointestinal endoscopist should be called. Tracheobronchial aspiration requires immediate pulmonary consultation.

COMMON PITFALLS

- Failure to recognize tracheobronchial aspiration
- Failure to summon immediate assistance if deep aspiration of a pack below the cords and above the carina is suspected

ACKNOWLEDGMENT

The author gratefully acknowledges the contribution of R. Gregory Smith who wrote the previous version of this chapter.

Temporomandibular Joint Disease

Barry H. Hendler

[Temporomandibular Syndrome](#)
[Clinical Presentation](#)
[Radiographic Studies](#)
[Differential Diagnosis](#)
[Management and Disposition](#)
[Common Pitfalls](#)
[Temporomandibular Joint Dislocation](#)
[Bibliography](#)

TEMPOROMANDIBULAR SYNDROME

The temporomandibular joint (TMJ) consists of the mandibular condyle (the posterior extension of the mandible covered by the meniscus or articular disk) that articulates in the temporal fossa. The temporal fossa is bordered anteriorly by the articular eminence. When the mandible closes, the condyle moves posteriorly and superiorly in the temporal fossa. Therefore, on opening, the condyle moves anteriorly and inferiorly, guided by the articular eminence.

Temporomandibular myofascial pain dysfunction syndrome, or simply TMJ syndrome, is a complex neuromuscular disturbance, possibly resulting from and definitely aggravated by occlusal disturbances and the anatomy of the TMJ. Other entities, such as trauma, psychological tension, and neuromuscular habits (e.g., bruxism and clenching), contribute to the problem. Patients who present to the emergency department frequently complain of nonspecific unilateral facial pain generalized to the region of the TMJ. The pain is dull, and increases throughout the day with continued jaw motion. Clinical examination frequently reveals spasm of the masseter muscle externally and the internal pterygoid intraorally. There is usually limitation of opening, with deviation toward the affected side. TMJ x-rays are usually normal unless there is associated temporomandibular degenerative joint disease (osteoarthritis).

CLINICAL PRESENTATION

The term *internal derangement* of the TMJ alludes to any disturbance between the articular components within the joint. It implies a localized structural derangement that interferes with the smooth function of the joint. It has recently been applied primarily to changes in the disk–condyle relation, with the disk most commonly displaced in an anteromedial direction. Internal derangement also produces pain or functional disturbance in the masticatory system and is often a result of TMJ neuromuscular dysfunction. The patient should be questioned about the presence or history of joint noises. Patients with internal derangement almost always have or have had joint noises. The noise is usually described as either clicking or crepitus. Crepitus is considered to represent advanced disease and occurs as a result of movement across irregular surfaces. This may also indicate a perforation of the disk or its attachments. This is especially true when degenerative changes are observed on radiographs.

Typically, the patient with internal derangement reports a clicking TMJ followed by a period of no joint noise. When the disk is anteriorly displaced and does not reduce to a normal position during opening, the patient will have limited opening, or a “closed-lock” condition. This condition may be either intermittent or persistent. The emergency physician should measure the interincisal maximum opening, which is usually limited to 20 mm (normal, 35 to 50 mm).

Arthritic TMJ may present with pain and crepitation. There may be periods of pain exacerbation and remission. As in other arthritides, there is often morning stiffness that wears off with function during the day, as opposed to the TMJ syndrome, which worsens as the day progresses.

RADIOGRAPHIC STUDIES

Routine radiographic evaluation of the TMJ should include a panoramic view, which is the easiest to read and requires the least sophisticated technique. The emergency physician can also order a TMJ series or tomograms of the joints, taken in both open and closed positions. Tomograms avoid superimposition of other anatomic structures that make a regular TMJ series difficult to read. The panoramic survey and tomograms are necessary to distinguish arthritis, TMJ pain/dysfunction syndrome, or internal derangement. Degenerative joint disease (osteoarthritis) may involve one or both of the TMJs. Films may demonstrate flattening of the condylar head, erosions, or osteophyte formation. Rheumatoid arthritis should also be considered, but a good history should clarify the diagnosis. When any type of internal derangement is suspected, a computed tomography scan of the joints should be ordered to assess bony architecture (i.e., arthritis). Magnetic resonance imaging is essential to assess disk position; arthrography can be used to assess disk perforation.

DIFFERENTIAL DIAGNOSIS

When the diagnosis of TMJ dysfunction is considered, the emergency physician should rule out pain of odontogenic origin. Tooth pain or sore teeth, in the absence of odontogenic pathology, may indicate bruxism. Headaches are a common complaint of patients with a TMJ disorder. Patients with an internal derangement frequently complain of headaches on the affected side, but no specific diagnostic pattern has been documented. Because headaches are such a common complaint, one should not assume that an internal derangement is the cause unless more specific diagnostic evidence is present. Headaches associated with internal derangement frequently emanate from the TMJ and radiate to temporal-orbital-occipital areas. This frequently follows jaw function and may be relieved with an occlusal splint or other therapies directed toward internal derangement.

Earache is a common complaint. Tinnitus and occasional dizziness may also be noted. Ear pathology should be considered and ruled out before assuming that an earache is due to TMJ disease.

Neck ache and shoulder pain are often reported by patients with TMJ disorders. These complaints are not specifically diagnostic, but may reflect a more generalized muscle disorder. In general, all pain is exacerbated by chewing.

MANAGEMENT AND DISPOSITION

TMJ pain or dysfunction, regardless of cause, is treated initially by a combination of physiotherapy (moist heat for 15 minutes four times a day) and a soft diet for 2 weeks. Analgesics such as nonsteroidal antiinflammatory agents or aspirin–codeine combinations are effective in addition to muscle relaxants and tranquilizers such as diazepam. Bite plates (occlusal splints) are used to reposition the mandible to relieve spasm, correct oral habits, and “recapture” a displaced disk.

A documented internal derangement is usually referred to an oral and maxillofacial surgeon, who may perform arthroscopy or arthroplasty to correct disk position permanently or to reconstruct arthritic joints.

COMMON PITFALLS

- TMJ dysfunction is often called the “great impostor” because it mimics so many other facial pain syndromes.
- The physician who fails to understand disk displacement may confuse it with muscle spasm. A history of joint noise is critical in this regard.

TEMPOROMANDIBULAR JOINT DISLOCATION

In acute dislocation of the mandible, the condyle moves too far anteriorly in relation to the eminence and becomes locked. The mouth is in open position as opposed

to “closed-lock” position ([Fig. 17.1](#)). Subsequent muscular trismus prevents the condyles from moving back into the temporal fossa. The spasm of the external pterygoid, masseter, and internal pterygoid muscles, and associated edema, result in extreme discomfort and anxiety. Predisposing factors include anatomic disharmony between the fossa and the anterior articular eminence, weakness of the capsule forming the TMJ ligaments, and torn ligaments. Dislocation is likely to occur during maximum opening (yawning or laughing). Although the TMJ is a double joint, the dislocation may be bilateral or unilateral. Palpation of the TMJs may reveal them to be anterior to the articular eminence. Radiographs should be taken to rule out a fracture, as the clinical picture and occlusal disturbances of both fracture and dislocation are similar.

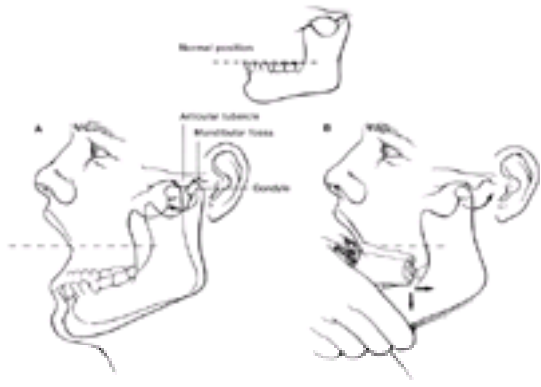

Figure 17.1. (A) Temporomandibular joint dislocation and (B) reduction.

An understanding of TMJ anatomy is important for proper manual reduction. It may be helpful to relieve the patient's anxiety and intense muscle spasm with intravenous diazepam, 5 to 10 mg, titrated by slow injection. When the patient is sufficiently relaxed, the physician should face the patient and grasp the mandible with both hands, one hand on each side, with the thumbs (wrapped with gauze) placed on the occlusal surfaces of the posterior teeth (see [Fig. 17.1](#)). The fingertips are placed around the inferior border of the mandible in the region of the angle. Downward pressure is applied to free the condyles from their position anterior to the eminence. The chin is then pressed backward after the jaw has been forced downward. The mouth closes and the condyle returns to its position in the fossa. Because of severe muscle spasm, the jaw may snap back quickly, so the physician must be aware.

Postreduction instructions include a soft diet for 1 to 2 weeks, avoidance of wide opening of the mandible, and the use of analgesics and muscle relaxants. Patients who chronically dislocate the TMJ and those who suffer acute recurrences may be helped by a Barton bandage (see [Chapter 16](#)) or elastic and Velcro jaw “bra” applied around the head to prevent maximum opening for 2 weeks, but this is seldom done. Severe cases may require intermaxillary wiring and fixation for added control. Patients who have suffered dislocation of the TMJ should be referred to an oral and maxillofacial surgeon for follow-up because surgical alteration of the eminence may be necessary.

CHAPTER 18

Dental, Oral, and Salivary Gland Infections

James T. Amsterdam

[Differential Diagnosis](#)
[Emergency Department Management](#)
[Disposition](#)
[Role of the Consultant](#)
[Indications for Admission](#)
[Transfer Considerations](#)
[Common Pitfalls](#)
[Acknowledgment](#)
[Chapter References](#)

The presentation of dental, oral, and salivary gland infections in the emergency department can vary from a patient with a simple complaint of pain or gingival swelling to a toxic patient with massive facial swelling and a compromised airway. Variable factors include the origin and location of the infection and the degree to which the infection has been contained or has spread to the deep spaces of the head and neck. The most common focus of infection is odontogenic, in addition to exposure to trauma or surgery that may violate the natural anatomic barriers of the fascial planes of the head and neck, resulting in deep-space infection. ^{2,3,10,11}

The key to diagnosis and management of dental infections and space infections of the head and neck is an understanding of the fascial planes of the head and neck (Fig. 18.1). Cellulitis of odontogenic origin usually involves the middle and lower part of the face and neck. Although such infections are generally well contained, in a debilitated host or in the case of a virulent organism, rapid spread of infection may be fatal. ^{1,3,4 and 5,7,8 and 9}

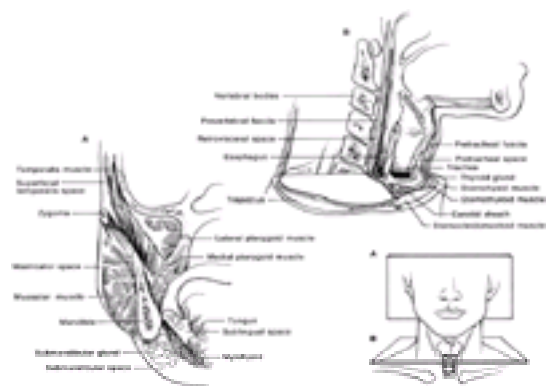

Figure 18.1. Fascial planes of the head and neck. **(A)** Coronal section of the head. **(B)** Cross section of the fascial planes of the neck.

The fascial spaces of the head and neck are potential spaces filled with loose areolar tissue that can rapidly break down when subjected to infection. In the case of oral infection, the deep cervical fascia is the most important. The deep cervical fascia consists of several layers that surround the neck, including the superficial and investing layer that attaches to the inferior border of the mandible and splits to form the masticator space. Other important spaces include the lateral pharyngeal space (lateral to the pharynx and medial to the masticator space), the retropharyngeal space (between the deep cervical and prevertebral fascia), and the pharyngomaxillary space (from the base of the skull to the hyoid bone), which communicates with all deep spaces (see Fig. 18.1). ^{1,3,13,14 and 15}

The mylohyoid muscle of the mandible divides the sublingual (superior) and submaxillary (inferior) spaces. The submental space is anterior to the sublingual space. Infection involving the submaxillary, sublingual, and submental spaces with elevation of the tongue is called *Ludwig's angina*, a serious infection with a potential for airway obstruction (Fig. 18.2). ^{1,3,10,12}

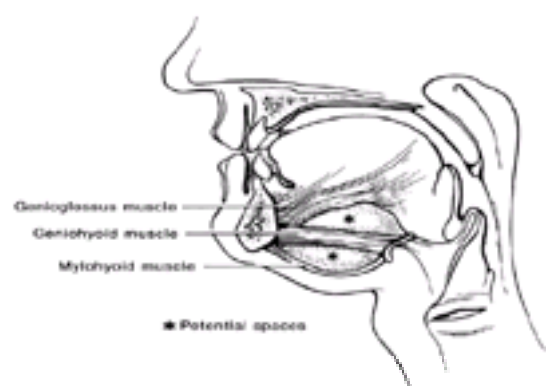

Figure 18.2. Ludwig's angina.

Infections that affect the midface involve the canine space, which is commonly infected by abscessed anterior maxillary teeth, and the buccal space, which is superficial to the buccinator and frequently infected by the molar teeth. Infections in these areas are especially important because of the possibility of cavernous sinus thrombosis due to the fascial venous system. ⁶

DIFFERENTIAL DIAGNOSISM

Before attributing any swelling of the face or the head and neck to dental infection, other entities should be considered. Tumors may present as nonspecific swellings and may be hard to distinguish from advanced primary infections if secondary infection is present. Viral infections, especially those that involve the salivary glands (e.g., mumps), can present as swellings. Less common infections are scrofula (tuberculous cervical lymphadenitis) and actinomycosis. Failure to respond to conventional therapy should lead the clinician to suspect some complication (tumor or uncommon infection). Certain fungal infections, although rare, are more common in the head and neck regions, such as mucormycosis. Fungal infections should be considered in immunocompromised patients, such as those with diabetes or the human immunodeficiency virus (HIV). ³

Submaxillary and parotid gland disease is not uncommon. These patients have a history of increasing pain when eating, and they are especially affected by sour foods. Submandibular gland infection is generally caused by *Streptococcus* secondary to stasis of saliva from obstruction caused by a stone. *Staphylococcus* is more commonly involved in parotid gland infections. Infectious parotitis is seen in the elderly and especially in diabetics. This entity is usually bilateral and associated with fever and toxicity. Autoimmune diseases, such as Sjögren syndrome and Mikulicz disease, can also cause facial swelling due to enlargement of the salivary glands (Fig. 18.3 and Fig. 18.4). ³

Figure 18.3. Normal anatomy of the parotid gland.

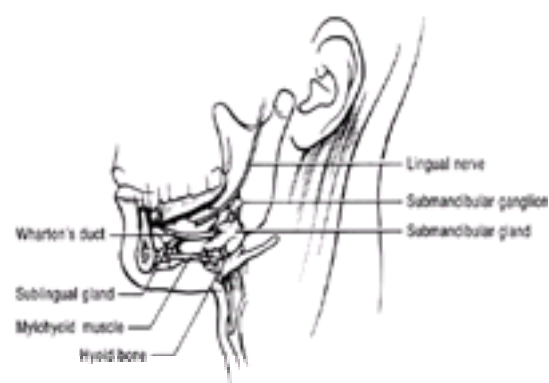

Figure 18.4. Normal anatomy of the submandibular gland.

EMERGENCY DEPARTMENT MANAGEMENT

Initial management of oral, dental, and salivary gland infections begins with localization of the infection. Most infections are of odontogenic origin and localized to a specific tooth. Patients with dental pain should be examined for the presence of infection. Pain to percussion with a tongue blade indicates involvement at the apex of the tooth (periapical abscess). Tender swelling over the gingiva adjacent to a tooth may indicate either a periodontal abscess or extension of a periapical abscess through the cortex of bone into the subperiosteal space. Differentiating these entities without a dental radiograph can be difficult. Management in either case would consist of a conservative incision, drainage, and antibiotic therapy (phenoxymethyl penicillin or erythromycin 250 mg four times a day).^{1,5}

A fluctuant abscess requires drainage, because antibiotics are no cure for pus. The gingiva should be anesthetized superficially with 2% lidocaine/1:100,000 epinephrine. A stab incision is made toward the alveolar bone and must extend through the periosteum if no pus is initially encountered; blunt dissection is performed with a mosquito hemostat. The area is irrigated, and, if there is room, a Penrose or iodoform drain can be placed. The drain should be secured with a black silk suture. In the case of these localized infections, there is no need to open the abscess beyond a stab incision. The drain will allow for continued drainage and the source of the infection will be eliminated with extraction of the tooth, root canal (endodontic) therapy, or periodontal therapy.⁴

The presence of cellulitis indicates that there has been spread of infection. The emergency physician must then determine the following: (1) the extent of involvement of contiguous spaces, (2) the potential for spread of infection to the fascial planes of the head and neck, and (3) potential for airway compromise. Once extensive involvement is recognized, it is the role of the oral and maxillofacial surgeon to compartmentalize the spread of infection and determine the site of the initial focus, so that pus can be evacuated under controlled conditions in the operating room.¹

[Table 18.1](#) summarizes the essential features of odontogenic and parapharyngeal space infections.

Infection	Location	Signs and Symptoms	Management
Parotid gland	Parotid gland	Swelling, pain, trismus	Antibiotics, drainage
Submandibular gland	Submandibular gland	Swelling, pain, trismus	Antibiotics, drainage
Sublingual gland	Sublingual gland	Swelling, pain, trismus	Antibiotics, drainage
Mylohyoid muscle	Mylohyoid muscle	Swelling, pain, trismus	Antibiotics, drainage
Hyoid bone	Hyoid bone	Swelling, pain, trismus	Antibiotics, drainage

TABLE 18.1. Essential Features of Odontogenic and Parapharyngeal Space Infections

The presence of more serious infections is determined by common physical signs and symptoms. After 3 to 5 days, clinical signs are usually apparent. Fever is present. Any involvement of the internal pterygoid or the masseter muscle will result in trismus (muscle spasm causing inability to open the mandible). The presence of trismus limits visibility of the oropharynx and makes the clinical diagnosis of retropharyngeal involvement difficult. If a toxic patient with trismus should vomit, the danger of aspiration is high because the emesis cannot be quickly evacuated. Therefore, patients with severe trismus need an aggressive workup (including a computed tomography scan of the retropharyngeal space) and admission for hydration and parenteral antibiotics. The oral cavity may be visualized under general anesthesia at the time of incision and drainage. The presence of Ludwig's angina requires aggressive attention to the airway. This may include nasotracheal intubation, tracheostomy, or observation in an intensive care environment where such procedures can be rapidly undertaken.^{1,3}

Odontogenic infections are caused by oral flora; in the absence of deeper spread, appropriate antibiotic coverage includes penicillin or clindamycin. Penicillin is the antibiotic of choice for the treatment of most orofacial infections, with the exception of some *Bacteroides* species. High-dose penicillin G (12 million U/d) is required for Ludwig's angina. Second- or third-generation cephalosporins are useful in cases that involve *Bacteroides* or penicillin allergy, although cross-over sensitivity must be considered. Ampicillin/sulbactam (Unasyn) also provides excellent anaerobic coverage. Clindamycin is a useful alternative, but potential side effects should be monitored, especially when oral therapy is initiated. Erythromycin is also a useful alternative to penicillin, but it is more difficult to administer intravenously. Chloramphenicol is reserved for extreme situations in which there is no alternative therapy.^{1,3,7}

Failure of an oral infection to respond within 24 hours of penicillin therapy suggests infection with an anaerobic bacteria (*Bacteroides fragilis*).

Parapharyngeal space infections (sublingual, submandibular, submaxillary, lateral pharyngeal, retropharyngeal, and pretracheal) are polymicrobial. Appropriate antibiotic therapy includes penicillin G (high-dose) and metronidazole or cefoxitin. Alternative therapy may include clindamycin or ticarcillin/clavulanate (Timentin).

DISPOSITION

Role of the Consultant

Patients with a simple periapical abscess can be managed with the institution of intraoral saline rinses, analgesia, and oral antibiotics. As discussed, a simple incision and drainage may be indicated. Follow-up should be arranged the next day with the oral and maxillofacial surgeon or the family dentist. ^{1,4}

Indications for Admission

All patients with suspicion of extension of infection to the fascial spaces of the head and neck should be admitted. Facial cellulitis with closure of the eye indicates potential spread of infection to the periorbital spaces and increased potential for cavernous sinus thrombosis. Patients with extensive trismus cannot be adequately evaluated by clinical examination. Patients with Ludwig's angina or impending Ludwig's angina (i.e., involvement of the three spaces without elevation of the tongue) are at risk for immediate airway obstruction and should be admitted. Such airway obstruction can occur precipitously and without warning, so anticipation is necessary. In most cases, the patient is admitted to the oral and maxillofacial surgeon. When the cause of the infection is unclear, the patient may be managed by an otorhinolaryngologist. Many cases are managed jointly by both services.

Transfer Considerations

If the initial receiving hospital has no surgical backup in the area of the head and neck, the patient should be transferred expeditiously to an appropriate facility. Blood cultures should be obtained and antibiotics instituted after consultation with the receiving physician. Special attention should be given to the airway. Advanced life-support personnel should be used. In the case of Ludwig's angina, it may be necessary to establish a definite airway before transfer in order to adequately stabilize the patient.

COMMON PITFALLS

- All patients with complaints of orofacial pain or swelling must be carefully examined for the presence of infection and extension of infection from the initial focus.
- The emergency physician should aggressively manage a patient in whom infection may be extending or has a high probability of extending. This is especially important if the infection has the potential to spread to the mediastinum or involve the airway, both of which can be fatal.
- Many patients fear dentists and, when sent home, return only when the situation is far advanced. Follow-up should always be recommended within 12 to 24 hours, and the patient should always be encouraged to return to the emergency department in the case of high fever, increasing swelling, inability to open the mouth, difficulty swallowing, or inability to open the eye.

The evaluation and management of epiglottitis requires clinical acumen, preplanning, teamwork, and therapeutic expertise to avert tragedy.

Scrutiny of the events surrounding the death of George Washington in 1799 suggests the diagnosis of epiglottitis, although, at the time, his death was attributed to quinsy. Clinical descriptions of epiglottitis appeared in the eighteenth century,¹³ and the condition was more accurately defined in the early part of the twentieth century.^{13,24} In the late 1930s and early 1940s, a precise clinicopathologic and bacteriologic definition was achieved, although subsequent clinical data implicated epiglottitis as a disease of childhood only. However, ample evidence currently supports an adult form of epiglottitis.^{13,16}

Available demographic data demonstrate that epiglottitis occurs in adults of all ages.^{3,15,16} It does not appear to have a predilection for season or race, but there is a preponderance of male patients.^{6,11,21} The true incidence of epiglottitis is difficult to ascertain because the index of suspicion for the diagnosis varies among clinicians.² The incidence is estimated to be in the vicinity of 1 to 4 per 100,000 adults per year.^{3,11,21} The causes of epiglottitis include infection, trauma, burns, and some medical disorders.

PATHOPHYSIOLOGY

Inflammatory disorders of the laryngeal region may affect either supraglottic structures (supraglottitis, epiglottitis) or infraglottic structures (laryngotracheitis). Strictly speaking, the term *supraglottitis* more appropriately defines the condition² because the pathologic changes involve not only the epiglottis, but also the aryepiglottic folds and false cords. However, tradition persists with the terminology of *epiglottitis*.

The larynx serves several purposes: It connects the hypopharynx with the trachea, maintaining airway patency; it serves as a valve to protect the airway during swallowing; and it allows for vocalization (Fig. 19.1). The supraglottic area is set obliquely down and back and is bounded anteriorly by the epiglottis, laterally by the aryepiglottic folds and posteriorly by the interarytenoid fold. The mucosa of the supraglottic area is continuous with that of the hypopharynx above and the larynx and trachea below (Fig. 19.2). The glossopharyngeal nerve provides sensory innervation on pharyngeal surfaces of the larynx. The laryngeal surface is supplied by the superior laryngeal branch of the vagus, which is also the major motor nerve to the intrinsic laryngeal musculature. Some authors believe that this functional relation explains laryngospasm and the exuberant autonomic activity associated with stimulation of the laryngeal surface of the epiglottis during laryngoscopy.

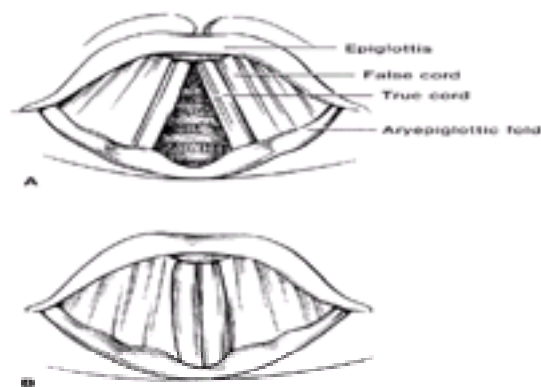

Figure 19.1. (A) Larynx in respiration. (B) Larynx during phonation.

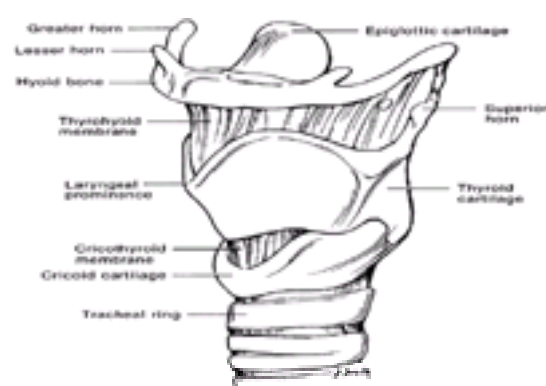

Figure 19.2. Normal anatomy of the larynx.

The pathologic picture varies according to the causative agent and the extent of the process. The gross findings vary from slight erythema and edema of an isolated portion of the supraglottis to global involvement with intense inflammation, edema, and airway obliteration.²¹ Microscopic examination reveals superficial and deep ulceration of the epithelium. Polymorphonuclear leukocyte infiltration is intense, and microabscess formation may be noted. Necrosis of vascular walls, smooth muscle, and apocrine glands is present. Edema on the lingual surface of the epiglottis may be minimal because the mucosa adheres to the cartilage. Elsewhere, no such limiting feature exists, and the mucosa is free to swell. Inferiorly, the limit of edema is the vocal cords, where the mucosa is tightly adherent.

The precise pathophysiology of total airway obstruction is not well defined, but numerous factors are involved: mucosal edema; aspiration of secretions, leading to laryngospasm of the inflamed, hyperesthetic larynx; inspissation of secretions; and fatigue. The patient's reluctance to lie flat suggests that mechanical factors related to the size of the swollen epiglottis are probably significant. It is highly unlikely, however, that an edematous, rigid epiglottis will fall or be aspirated into the glottis and cause obstruction. Abscess formation may occur, contributing to airway compromise. Respiratory distress correlates with the degree of narrowing of the airway and indicates increased resistance to airflow. Resistance is proportional to $1/r^4$ (r = radius). Thus, a 2-mm change in radius produces a 16-fold change in resistance.

BACTERIOLOGY

The identification of a responsible infectious agent in adult epiglottitis has proven difficult. In adults, the yield from blood cultures ranges from 10% to 30%.^{6,11} Surface

cultures of the epiglottis and pharynx have proven useful in some instances^{2,3}; however, in numerous cases, there is no growth or they are positive for commensals only.

This has led some investigators⁵ to suggest that epiglottitis exists in two forms: (1) as part of a bacteremic illness, or (2) as a local infection. Of the bacteremic illnesses, *Haemophilus influenzae* type B is the most common bacterium found in the blood cultures of adults. Cases with proven bacteremia run a more fulminant course. *Streptococcus pneumoniae* bacteremia is associated with the immunocompromised host (malignancy, steroid dependency, AIDS).¹⁹ The local infection may have a bacterial, viral, or fungal etiology; this form of the disease tends to run a more benign course. *H. influenzae* and beta-hemolytic streptococci are the most common causes of the local form. Herpes simplex is the only virus isolated in adults to date.¹⁰ However, influenza and parainfluenza viruses have been isolated in children. Fungi implicated are *Aspergillus* and *Candida*.⁴

Other bacteria isolated include *S. pneumoniae*, beta-hemolytic streptococci, staphylococci, *Haemophilus parainfluenzae*, *Streptococcus viridans*, and *Fusobacterium necrophorum*, *Klebsiella pneumoniae*,²¹ *E. coli*,²³ and *Neisseria* spp.⁸ Aspiration of gasoline, thermal and chemical burns, and trauma have all been cited as causes of noninfectious epiglottitis.^{12,14} Sarcoidosis has been reported to lead to chronic epiglottitis.

CLINICAL PRESENTATION

Any patient presenting with a possible diagnosis of epiglottitis or airway obstruction should be evaluated for urgent and rapid nonsurgical or surgical airway control in an acute care area with a high ratio of nursing support and equipment to patients. Personnel with expertise in airway intervention should be summoned if they are not available on site.

The presentation of epiglottitis in an adult is often less dramatic than in a child. Most children present in respiratory distress with impending airway obstruction. The clinical course of epiglottitis in the adult is variable. It can be mild and pose little threat to the patient, or it can be severe, resulting in total airway obstruction and death.^{6,11,15,16,21} Typically, adult epiglottitis presents as a sore throat out of proportion to physical findings, dysphagia, a muffled "hot potato" voice, and respiratory distress or dyspnea. Some authors include hoarseness, but others say that hoarseness is atypical.²⁰

For purposes of discussion, the clinical presentation may be categorized into a spectrum that varies from a fulminating course developing over hours to a subacute form smoldering for days to weeks:

Category 1: Severe respiratory distress, imminent or actual respiratory arrest. Patients in category 1 typically report a history of a brief but rapidly progressive illness. Blood culture often reveals *H. influenzae* type B.

Category 2: Intermediate condition with moderate-to-severe symptoms and signs of potential airway compromise. Patients in category 2 are at considerable risk. Their symptoms (inability to swallow or lie supine, dyspnea, and severe sore throat) and signs (muffled voice, stridor, and the use of accessory muscles) should alert the clinician to this risk. The emergency physician should prepare to intervene if the airway should suddenly deteriorate, and then undertake further evaluation of the airway.

Category 3: Mild-to-moderate illness without indications of potential airway compromise. Patients in category 3 may report a 3- to 14-day history of a sore throat and pain on swallowing, with minimal physical findings on examination. A patient can rapidly progress from category 3 to 2 or 1 with little warning.

DIFFERENTIAL DIAGNOSIS

Coexisting conditions can always complicate diagnosis and treatment, and extra care is required in potentially life-threatening situations. If epiglottitis is suspected, even if an associated condition has been diagnosed, definitive diagnostic maneuvers should be undertaken. Possible associated conditions include peritonsillar or retropharyngeal abscess, foreign body, angioedema, pharyngitis, inhalation or ingestion of a toxic substance, acute thyroiditis, epiglottic hematoma, and thermal injury.

EMERGENCY DEPARTMENT EVALUATION

Because the potential exists for rare sudden airway obstruction and death despite a "benign" presentation,^{11,15,16} the patient with possible epiglottitis should be evaluated in an acute resuscitation area with high-density nursing and should not be left alone, due to the risk of sudden airway obstruction without warning.

The diagnosis of epiglottitis depends first on its being considered. *Symptoms in excess of physical findings are the hallmark.* The patient may be tachypneic and tachycardic and have pharyngitis. Some patients describe exquisite tenderness on palpation of the thyroid cartilage.¹ Twenty percent to 30% of patients become moderately to severely ill, with signs of airway compromise, drooling, stridor, and cyanosis.

There is no typical time course for epiglottitis. The period from onset to presentation may be hours to days. Sore throat and odynophagia, with or without dysphagia, are consistent findings.^{15,21} Fever may or may not be present. There may be voice changes, chills, dyspnea, and pain on tongue protrusion.

A recent study found that dyspnea was the only intubation risk factor (n = 51) that predicted the need for aggressive airway management. Dyspnea had a positive predicted value of 62% and a negative predicted value of 100% as a symptom suggesting the need for intubation.¹¹

Patients in whom epiglottitis is suspected must undergo indirect (mirror) or direct (fiberoptic) laryngoscopy.¹⁷ In the past, there was controversy as to whether manipulation of the oropharynx could lead to airway compromise. This concern persists in children, but there is little evidence to support the concern in adults.^{1,13} Fiberoptic laryngoscopy is the diagnostic evaluation of choice. It is well tolerated and allows an excellent view of the supraglottis.^{7,16}

Soft-tissue lateral neck x-rays can also be helpful. Several abnormalities may be evident, including enlargement of the epiglottis (thumb sign) and aryepiglottic folds, and ballooning of the hypopharynx. One study²⁰ suggested that epiglottic and aryepiglottic widths greater than 8 mm and 7 mm, respectively, indicated acute epiglottitis. However, a 10% to 20% false-negative rate exists. Another study¹⁸ indexed both epiglottic and aryepiglottic width to third cervical vertebral body width and epiglottic width to epiglottic height and found that ratios greater than 0.5, 0.35, and 0.6, respectively, were 100% sensitive for epiglottitis. These results were derived from 33 patients, of which only six were adults. A more recent article described the qualitative evaluation of the presence or absence of a deep, well-defined vallecular air space running parallel to the pharyngotracheal air column that approaches the level of the hyoid bone in lateral soft-tissue neck radiographs. This well-defined space was absent in all 26 consecutive confirmed cases of adult epiglottitis in this study. Additionally, the investigators found a 98.2% sensitivity and 99.5% specificity in correctly identifying adult epiglottitis when random case controlled radiographs were examined by blinded participants. The authors suggest that this may be a useful diagnostic screen in patients who do not require immediate airway intervention.⁹

EMERGENCY DEPARTMENT MANAGEMENT

Emergency departments must be committed to preplanned, cooperative teamwork to prevent disaster for the patient with epiglottitis. The cooperative effort must involve the departments of emergency medicine, anesthesiology, and surgery (ear, nose, and throat in some centers), similar to a trauma team. Protocols for in-hospital management should draw on intensive care and infectious disease expertise. In community hospitals, preplanning must address optimal use of available resources, transfer agreements, and the exigencies of transport.

All emergency departments must be equipped to intervene in acute upper airway emergencies with endotracheal intubation or cricothyroidostomy. Additional emergency airway management equipment includes bag and mask devices with deflatable positive-pressure relief ("pop-off") valves and jet ventilators. Transcricoid jet ventilation via small-caliber catheters, while associated with barotrauma hazards, provides adequate ventilation and oxygenation until more definitive airway management can be achieved.

The issue of airway management is controversial and depends on available resources and personal skill. Sudden airway obstruction is rare, but always a possibility in

epiglottitis.^{11,15} Most adult patients (greater than 70%) present with no respiratory symptoms or signs (category 3) and can be safely observed for progression in an intensive care unit.¹⁴

Patients presenting in categories 1 and 2 must be judged individually. Patients in extremis or with totally obstructed airways must receive definitive airway management in the emergency department (Fig 19.3). Patients with mild dyspnea or respiratory complaints could be observed and monitored in the intensive care setting. The remainder should undergo definitive airway management in the controlled setting of the operating room, and subsequently be admitted to the intensive care unit.

Figure 19.3. Treatment algorithm for acute epiglottitis. (Modified from Hébert PC, Ducic Y, Boisvert D, et al. Adult epiglottitis in a Canadian setting. *Laryngoscope* 1998;108:64, with permission.)

Patients taken to the operating room should be accompanied by a physician skilled in airway management. Once in the operating room, a surgeon skilled in surgical airway management and rigid bronchoscopy should be scrubbed and ready in case orotracheal intubation is impossible or fails. An inhalation induction aided by the judicious use of intravenous sedation is the recommended anesthetic technique.^{6,16,23} The antibiotic of choice on empiric grounds is cefuroxime, cefotaxime (up to 2 g i.v. every 4 hours), or ceftriaxone (1 to 2 g per day i.v., given every 12 hours); alternative therapy includes ampicillin–sulbactam (Unasyn) 1.5 to 3.0 g every 6 hours i.v., or trimethoprim–sulfamethoxazole. These provide coverage for group A *S. pneumoniae*, *Staphylococcus pyogenes*, and *H. influenzae*.^{6,22}

Some authors have advocated the use of corticosteroids, but scientific evidence supporting their efficacy is lacking.¹¹ In the case of angioedema, however, steroids may be lifesaving. Aerosolized epinephrine and racemic epinephrine are not thought to be useful.

Helium–oxygen mixtures may buy time while preparing for definitive management. The density of helium is less than that of nitrogen and produces reduced airway resistance, improved gas flow, and decreased work of breathing. The emergency physician must be aware of the relative concentrations of helium and oxygen in the mixture, as various standard preparations exist.

DISPOSITION

All patients with epiglottitis, whether or not they are intubated, should be admitted to an intensive care unit.^{11,15} If they are to be observed, personnel and equipment necessary for emergency airway intervention must be immediately available.¹⁶ Resolution of the disease is monitored by fiberoptic laryngoscopy.¹ The ability of a patient to breathe around an occluded endotracheal tube with its cuff deflated is a good test for the suitability for extubation.^{1,11} This usually can occur 48 to 72 hours after intubation or admission to the hospital. Oral antibiotics may replace intravenous antibiotics at that time and should be continued for 14 days.

If *H. influenzae* type B is isolated, case contacts should receive rifampin. If there are children under age 4 in the household, all household contacts should be treated.

Transfer Considerations

Transfer may be necessary if the appropriate specialists and intensive care setting are unavailable. However, no patient in category 1 or 2 should be transferred unless airway control has been achieved. If patients in category 3 require transfer, they should be accompanied by personnel and equipment necessary to establish an airway.

COMMON PITFALLS

- The literature is replete with case histories documenting delays in the diagnosis of epiglottitis. Physicians are generally unaware of the adult form of the disease; thus, the most common pitfall is the failure to consider the diagnosis.
- Airway management for the patient with epiglottitis should be undertaken by an experienced physician.
- Elective blind nasal intubation is contraindicated.²⁵
- The possibility of sudden airway obstruction should always be considered.
- All patients with even mild dyspnea require close monitoring in an appropriate setting.

PHARYNGOTONSILLITIS

Sore throat affects patients of all ages and is one of the most common complaints in the outpatient setting. The term *sore throat* has become synonymous with acute pharyngotonsillitis because it is the most common cause of pain in the oropharynx. Tonsillitis and pharyngitis are somewhat difficult to separate because of the overlap of the infectious process. Many experienced physicians will arbitrarily label the recent onset of enlarged, erythematous painful tonsils *acute tonsillitis*, whereas a diffusely erythematous pharynx without obvious tonsillar enlargement or in a patient without tonsils is considered a pharyngitis. When both areas are involved, the term *pharyngotonsillitis* is used.

Transmission of most causes of pharyngitis is by person-to-person contact through droplets of saliva. The causes include multiple bacteria, viruses, and fungi. Acute streptococcal pharyngitis caused by group A beta-hemolytic streptococci (GABHS) has received the most attention, because it was demonstrated in the 1950s that rheumatic fever could be prevented by treating the preceding pharyngitis. Less than 1% of patients with untreated group A beta-hemolytic streptococcal throat infections will develop rheumatic fever; and of those, 1.8% will develop fourth-degree rheumatic heart disease.¹ Furthermore, whether treated or not, patients with group A beta-hemolytic streptococcal infections may develop poststreptococcal glomerulonephritis.

GABHS account for 10% to 15% of sore throats in adults.² Other groupable streptococci (C and G), as well as *Neisseria gonorrhoeae*, *Staphylococcus aureus*, *H. influenzae*, and *Corynebacterium diphtheriae*, also cause pharyngitis. Viral agents are probably the most common etiology, including enteroviruses, adenoviruses, rhinoviruses, apoinfluenza virus, and Epstein-Barr virus, the causative pathogen of infectious mononucleosis (IM). Candidiasis may be seen in the pharynx of the immunocompromised patient, or in the patient taking antibiotics or inhaled steroids. A sore throat does not always represent a pharyngotonsillitis, and thus the history and physical examination are necessary to exclude peritonsillar abscess, retropharyngeal abscess, and other potentially life-threatening processes.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Despite a multitude of studies and despite many clinicians' seemingly clear-cut algorithms, it remains an impossible task to differentiate bacterial from nonbacterial infections of the pharynx. Many primary care physicians with reliable patients tend to use throat cultures to determine which pharyngitides are due to GABHS. A classic study in children from 1971, however, showed that over 50% of children with sore throats and positive throat cultures had no significant rise in ASO or anti-DNAase B titers—meaning GABHS were not likely the source of the infection.³ Furthermore, a negative throat culture does not always mean that GABHS are not present in the pharynx.⁴

Other clinicians use the physical examination findings to help guide the diagnosis; however, the error rate among experienced physicians in differentiating GABHS from viral pharyngitis is 20% to 40%.^{3,4} There is a slight trend toward bacterial pharyngitis if the patient has fever, pharyngeal erythema, pharyngeal exudate, tender cervical adenopathy, headache, and absence of cough and rhinorrhea. Viral infections are typically accompanied by conjunctivitis, nasal congestion, hoarseness, cough, aphthous ulcers on the soft palate, and myalgias. It must be recognized, though, that these are trends that have poor statistical correlation with positive throat cultures and rises in ASO titers.

The pharyngitis that accompanies IM is exudative with grossly enlarged tonsils, especially in younger patients. Petechiae may be present on the soft palate. A concurrent lymphadenopathy may be present, with hepatomegaly and splenomegaly also possible. Fever is usually present.

Diphtheria is no longer a common cause of pharyngitis, but its presentation should still be recognized and considered, especially in the patient who has recently come from another country and has not received a full set of vaccinations. Usually anorexia, malaise, and a low-grade fever will be followed 1 to 2 days later by a gray or white membrane that adheres to the tonsils.

Patients with pharyngitis who present with severe pain on swallowing (odynophagia) may be dehydrated from lack of oral intake; they will also have increased insensible fluid loss from fever. Other complications from pharyngitis involve progression to peritonsillar cellulitis, abscess, or retropharyngeal abscess, and are addressed later.

EMERGENCY DEPARTMENT EVALUATION

Examination should begin with assessing the patency of the airway and surveying the presence and severity of tonsillar hypertrophy. If the patient does not have severely enlarged tonsils, and yet appears to have trouble breathing or swallowing, other etiologies, such as epiglottitis, must immediately be considered. In this circumstance, a soft-tissue lateral x-ray of the neck should be accomplished rapidly, with airway management equipment easily accessible.

Typically, erythema of the tonsils or pharyngeal mucosa is seen. Exudate or adherent membrane may be present on the tonsils. The neck and jaw angle should be palpated for the presence of enlarged nodes. A throat culture may be considered (see below).

Patients appearing dehydrated, with dry oral mucosa, may have an intravenous line placed and electrolytes drawn. A complete blood count will usually not add relevant information, but may be drawn. A Monospot heterophile agglutination test may be performed if IM is a diagnostic consideration.

EMERGENCY DEPARTMENT MANAGEMENT

Admission should be considered whenever a complication of pharyngotonsillitis is identified. The two most common reasons for admission are dehydration and the presence of peritonsillar cellulitis or abscess. A patient who cannot swallow cannot maintain adequate oral intake or take medication, and may deteriorate if managed as an outpatient. Intravenous hydration, antibiotic administration, and observation may be accomplished in the emergency department (ED); those patients who measurably improve may be discharged with 24-hour follow-up. Admission should always be considered for patients with unreliable follow-up or poor social circumstances.

When deciding to treat a pharyngitis in the ED, the clinician must weigh the benefits of decreasing the chance of the patient developing acute rheumatic fever and communicating the infection to others, against the chance of the patient developing an adverse reaction to the antibiotic prescribed. Treating a GABHS pharyngitis may decrease the severity of the symptoms 12 to 24 hours earlier, but this is of questionable significance. In addition, consistently overtreating patients theoretically may prompt GABHS resistance to penicillin.

There is no good strategy at this time to avoid all of the aforementioned complications. There are a few helpful algorithms that, with patient discussion and input, will allow the emergency physician to choose a logical course of action. One approach is to treat all patients and not culture. This approach recognizes the lack of reliable follow-up in the emergency setting, as well as the inaccuracy of throat culture results. It exposes many patients unnecessarily to penicillin, but will not miss a case of GABHS pharyngitis. It is probably the strategy that is most cost-effective, will relieve symptoms the soonest, and provide greatest patient satisfaction by expediting their disposition.⁴

Strategy 2 is to culture all patients and treat none (unless the culture returns positive). This strategy seeks to avoid overtreating patients with viral pharyngitis, as only around 10% to 15% of pharyngitis is due to GABHS. It can only be implemented in an ED with the resources in place for following up culture results and recontacting patients. Patients in an inner-city hospital setting may not have home telephones or may give inaccurate contact information, so this may not be a viable alternative. A variation in this strategy is to begin treatment in the ED and have the patient call back for culture results in 2 days. If the results are negative, the antibiotics are stopped.

DISPOSITION

Patients who appear toxic or have severe odynophagia who do not measurably improve after hydration and observation should be admitted.

Nontoxic-appearing patients who can tolerate oral fluids and medications may be discharged. If the patients are being treated for a presumed GABHS pharyngitis, a 10-day course of penicillin can be prescribed. While the traditional regimen has been 250 mg to 500 mg every 6 hours, 1000 mg every 12 hours has been shown to be just as effective.^{5,6} In addition, compliance with a b.i.d. regimen is significantly higher than a q.i.d. course.

Patients who are definitely not allergic to penicillin may be given the choice of a single injection of 1.2 million U of Benzathine penicillin. As the intramuscular may be painful, this should be done only after discussing the options with the patient. Alternatives include cephalexin 1 g b.i.d., or cefadroxil 500 mg b.i.d.

Patients with allergies to penicillin may be given erythromycin base 250 mg to 333 mg t.i.d. Azithromycin and clarithromycin have not been as well studied, but may be alternatives.

Patients diagnosed with infectious mononucleosis should be instructed to follow up with their primary physician in 7 days. They should be advised to avoid contact sports if there is the possibility of splenomegaly.

All discharged patients should have clear instructions to return for worsening odynophagia, worsening unilateral odynophagia, inability to tolerate oral fluid intake, or lack of improvement after 48 hours.

COMMON PITFALLS

- Consider acute epiglottitis or supraglottitis, especially in a patient who presents with sudden, severe pharyngitis, drooling (because it hurts to swallow), and respiratory distress. Adults usually have a more gradual onset over several days, and are less likely to develop sudden airway compromise unless they present later in the progression of the swelling.
- Do not give ampicillin to a patient with suspected mononucleosis. The resulting rash helps make the diagnosis and does not imply ampicillin allergy, but can be uncomfortable.
- Do not miss abscesses, which usually require hospitalization, intravenous penicillin, and drainage. Peritonsillar abscesses and cellulitis make the tonsillar pillar bulge toward the midline. Retropharyngeal abscesses and epiglottitis may require soft-tissue lateral neck films to visualize.
- Consider gonococcal pharyngitis in patients with a suggestive history. Patients will have a mild clinical syndrome and require special cultures on Thayer-Martin medium.

RETROPHARYNGEAL ABSCESS

The retropharyngeal space lies between the fascia, which is densely adherent to the paraspinal muscles, and the posterior pharyngeal mucosa, which can be seen directly through the open mouth. There are three fascial layers with intervening potential spaces, but the important point is that these potential spaces extend to the mediastinum and offer a direct, unimpeded path for the spread of infection.

Retropharyngeal abscess is primarily a disease of young children and occurs when lymph nodes in the retropharyngeal space become infected. These lymph nodes involute by puberty. In adults, retropharyngeal abscess is predominantly caused by ingested foreign bodies, such as fishbones that penetrate the posterior pharyngeal wall.^{5,7} Other causes include blunt and penetrating neck wounds, which have the potential to develop the delayed complication of an abscess, and iatrogenic injuries secondary to intubation or endoscopy. Uncommon causes include Pott disease (cervical tuberculosis), sinusitis, and otitis media. Retropharyngeal abscesses tend to be polymicrobial, with streptococcus, staphylococcus, and anaerobes most commonly recovered when cultured.

CLINICAL PRESENTATION

The patient presents with fever, neck pain, and sore throat out of proportion to the oropharyngeal findings. Other possible findings include odynophagia, neck swelling, drooling, torticollis, meningismus, cervical adenopathy, and stridor. If the abscess is high in the neck, nasal obstruction and a hyponasal voice result. The voice may sound muffled if the swelling is above the level of the larynx, or sound normal if the abscess is lower in the neck. As the swelling increases, difficult or noisy breathing may occur. Chest pain associated with these symptoms strongly suggests mediastinal extension.

On examination, patients appear toxic, dehydrated, and febrile. The head is held stiff; and passive or active motion of the head is painful. Inspection of the neck does not reveal any redness or swelling, although anterior displacement of the larynx may be appreciated. Palpation of the neck reveals deep tenderness only. Fluctuance is not always palpated because of the thickness of the intervening tissue. Unlike the presentation of a peritonsillar abscess, there is no trismus with uncomplicated retropharyngeal abscess, and direct visualization of the posterior wall should be possible. The area of the abscess may appear erythematous, boggy, and displaced forward toward the uvula if the abscess is located at this level ([Fig. 20.1](#)). A process more caudal in the neck may show no abnormalities on oral examination. Palpation of the posterior wall may confirm the diagnosis, but because of the risk of rupturing the abscess into an already compromised airway, *this maneuver is not recommended*.⁸

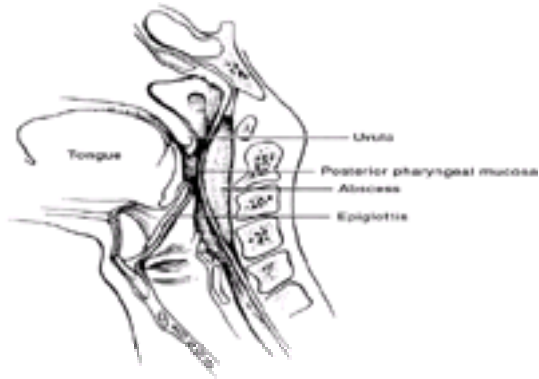

Figure 20.1. Retropharyngeal abscess.

Possible complications of a ruptured abscess are many and grave. The airway is at risk, either from obstruction of the airway by a growing abscess, or from sudden rupture of the abscess with subsequent aspiration or asphyxia. Direct extension inferiorly through the fascial planes can lead to mediastinitis. Extension laterally into the parapharyngeal space and carotid sheath can lead to jugular vein thrombosis (Lemierre disease), hemorrhage from the carotid artery or jugular vein, cranial nerve (IX, X, XII) deficits, or Horner syndrome. Overwhelming sepsis may occur, especially in immunocompromised patients.

DIFFERENTIAL DIAGNOSIS

Meningitis and other deep neck infections may present similarly, though examination and radiography will clarify the diagnosis. Bulges on the posterior wall are not necessarily of inflammatory etiology, and may occur from hematoma (e.g., in the anticoagulated patient), osteophyte of the cervical spine, neoplasm, or persistent lymph node. History will aid in differentiating these from an abscess.

EMERGENCY DEPARTMENT EVALUATION

Retropharyngeal abscess is a true medical emergency. Airway impingement or obstruction and abscess rupture can occur at any time; therefore, careful monitoring of the patient, as well as expedient evaluation and management, are essential in averting a potentially disastrous outcome. Equipment for emergency management of the airway, including a tracheostomy set, must be available, and the patient must be carefully monitored for respiratory distress. An intravenous line should be established and fluids started. A complete blood count, electrolytes, and blood cultures may be drawn, though these tests usually have little role in the patient's initial management. The lateral neck soft-tissue view is the most important initial diagnostic test in evaluating the retropharyngeal space and, along with a chest x-ray, should be undertaken immediately. Positive findings include air in the retropharyngeal space, an air–fluid level posterior to the pharynx or esophagus, and widening of the retropharyngeal soft tissues. Abnormal swelling of the retropharyngeal space is suggested when the posterior border of the air column is greater than 7 mm from the anterior border of the body of C2, or 20 mm from C6. Soft tissue wider than one-third the width of the body of C2, or the full width of the body of C6, also suggests abnormality. A normal lateral neck film effectively eliminates this diagnosis. A chest x-ray should be reviewed for mediastinitis.

A contrast-enhanced computed tomography (CT) scan of the neck and chest should be obtained in short order in patients suspected of having retropharyngeal abscess; in addition to establishing the diagnosis with certainty, it will define the extent of the lesion in the spectrum of cellulitis to abscess.

EMERGENCY DEPARTMENT MANAGEMENT

Advanced airway management equipment, including a tracheostomy set, should be stationed at the bedside. The patient should be monitored carefully. Intravenous fluids and intravenous antibiotics—high-dose penicillin (6 million U every 6 hours) and metronidazole (500 mg every 6 hours after a 1-g loading dose), or cefoxitin (2 g every 8 hours)—should be started immediately. An otolaryngology consult should be obtained early. Patients will likely be admitted to the intensive care unit or directly to the operating room. Definitive management includes incision and drainage under carefully controlled circumstances. The presence of mediastinitis mandates a significantly more extensive debridement by a thoracic surgeon.⁹ Incision and debridement for retropharyngeal cellulitis is at the discretion of the otolaryngologist.

While there are no case reports of patients exhibiting respiratory decompensation during CT scan, the physician is well advised to watch the patient closely and have advanced airway management equipment and personnel readily available.

COMMON PITFALLS

- Be prepared for airway obstruction and rupture of abscess.
- Palpation of the posterior pharyngeal wall risks rupture of the abscess.
- The lateral neck film is the most useful initial test for retropharyngeal disease.
- A contrast-enhanced CT of the neck is the preferred diagnostic test.

PERITONSILLAR CELLULITIS AND ABSCESS

Peritonsillar abscess is a complication of tonsillitis, whether from group A streptococcus or infectious mononucleosis.¹⁰ It occurs more frequently in teen-agers and younger adults, but it can present at any age, especially in immunocompromised or diabetic patients. The abscess forms in the potential space between the lateral aspect of the tonsillar capsule and the superior constrictor muscle of the pharynx. When tonsillitis spreads beyond the tonsil capsule, inflammation in this space results in cellulitis and then abscess if left untreated. Abscess cultures tend to be polymicrobial, with the frequent presence of group A beta-hemolytic streptococci and anaerobes such as *Bacteroides*.

CLINICAL PRESENTATION

Typically, a younger patient (though rarely under 10 years old) will present with worsening sore throat pain and fever of 2 days' duration or more. As the pain increases, it localizes to one side and radiates to the ipsilateral ear. It is accompanied by odynophagia and dysphagia, which eventually result in drooling and dehydration. The patient may tilt the head toward the painful side. Trismus may result, though, if severe, it suggests parapharyngeal abscess. The key in differentiating severe tonsillitis from peritonsillar abscess is the localization of the pain.

There is a continuum of illness from tonsillitis to peritonsillar abscess. The patient may present at any point, and symptoms and treatment vary accordingly. The early stage is inflammation without fluid collection, or peritonsillar cellulitis; there is absent or mild trismus, fullness on the side of the affected tonsil, and unilateral erythema extending onto the soft palate. The palate is not bulging, nor is the uvula displaced.

At the other extreme is abscess with trismus that makes examination of the oral cavity difficult. The ipsilateral soft palate is markedly erythematous and swollen. The tonsil is displaced downward and medially, and the uvula is pushed contralateral ([Fig. 20.2](#)). The breath is foul-smelling.

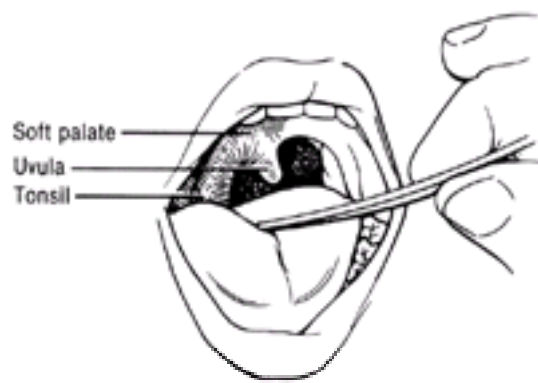

Figure 20.2. Peritonsillar abscess.

Local complications include extension into the contiguous deep neck spaces (e.g., parapharyngeal abscess), with the possible catastrophic consequences of erosion into the carotid artery, or thrombosis of the internal jugular vein (Lemierre disease). Airway obstruction, mediastinitis, sepsis, and descending necrotizing fasciitis are other infrequent complications. Most complications occur in diabetic or immunocompromised patients, or in patients who were neglected or noncompliant with an initial antibiotic regimen.

DIFFERENTIAL DIAGNOSIS

Unilateral enlargement of a tonsil may occur from squamous cell carcinoma, lymphoma, leukemia, vascular lesions, or neoplasms of the lateral pharyngeal space. Such an enlargement can usually be distinguished from abscess by history and presentation. Lateral neck abscess of dental origin may be confused with peritonsillar abscess, but a history of toothache should serve to differentiate the two.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

After examination, a complete blood count, serum electrolytes, Monospot, and throat culture should be obtained. Intravenous fluids should be started to correct the dehydration that is usually present, and intravenous antibiotics initiated. Penicillin (1 to 2 million U every 4 hours) or clindamycin (600 mg every 8 hours) are good choices.¹¹ Early cellulitis may be treated with hydration and antibiotics alone, though to differentiate abscess from inflammation may require needle aspiration. For abscesses, needle aspiration will provide significant relief.

The emergency physician may consult an otolaryngologist or, if experienced, can undertake diagnostic and therapeutic needle aspiration.¹² Great care must be taken regarding direction and depth of approach to avoid puncturing the carotid artery. A useful depth guide can be created by removing the plastic needle cap (or sheath) from an 18-gauge needle and cutting off the distal 2 cm with scissors. One then carefully replaces the modified needle cap over the needle. With patients in the sitting position, hunched slightly forward, apply topical anesthetic to the posterior pharynx. Instruct patients that although they will feel an initial puncture, the procedure will likely reduce their pain significantly. Aiming posterolaterally toward the medial aspect of the enlarged tonsil, insert the 18-gauge needle with 2-cm depth guide into the abscess and withdraw the plunger, aspirating any available fluid. Send the aspirate for culture and Gram stain.

Depending on the outcome of the aforementioned procedure or consultation with an otolaryngologist, disposition may vary. Uncomplicated, nonimmunocompromised patients who are able to tolerate oral antibiotics and fluids may be discharged with otolaryngology follow-up in 24 hours. Patients with more complex cases should be admitted to the hospital for intravenous hydration and antibiotics. If the previously described procedure does not relieve severe symptoms, or if there is any suspicion of spread of infection beyond the peritonsillar area, a contrast-enhanced CT should be ordered immediately. A small percentage of peritonsillar abscesses will not respond to needle aspiration, and will require incision and drainage.

COMMON PITFALLS

- Failure to recognize an impending abscess. This usually results in a repeat visit within a day or two when the patient fails to improve.
- Needle aspiration may be done by the emergency physician, but only with great care by those experienced in the procedure.
- Asymmetric swelling of the pharynx is always abnormal, even if asymptomatic; further evaluation is warranted.

LARYNGITIS

Laryngitis is manifested by hoarseness. When acute, the change in voice is secondary to vocal cord edema from inflammation or vocal cord trauma. Viral upper respiratory tract infection (URI) is the most common cause of acute laryngitis, and is usually accompanied by cough, sore throat, or rhinorrhea. Hoarseness may be exacerbated by thick secretions adhering to the vocal cords, or by the vigorous coughing that occurs with a URI. Acute hoarseness also may occur after prolonged shouting, or in opera singers or other vocalists with frequent or lengthy performances.

Typical agents causing URI with laryngeal involvement include parainfluenza viruses 1 and 2, adenoviruses, rhinoviruses, and coronaviruses. Bacterial superinfection may cause a more virulent illness. *Staphylococcus aureus* and *H. influenzae* have been implicated.

Hoarseness lasting longer than 4 weeks suggests a different and potentially more serious group of etiologies.

CLINICAL PRESENTATION

Hoarseness with other associated symptoms may be the presentation of life-threatening illness and should prompt immediate evaluation of the airway. A patient with impending airway obstruction complains of shortness of breath and may present with stridor, air hunger, drooling, and voice change. This is an emergency and not simple laryngitis.

Most commonly, acute laryngitis results from viral URI and is easily recognized when the patient presents with cough, sore throat, low-grade fever, and rhinitis. Hoarseness is due to inflammation of the vocal cords, edema from coughing, or tenacious secretions.

If the laryngitis is not from an obvious URI, the patient should be questioned about prolonged shouting, singing, or injury to the anterior neck. Sudden voice changes from overuse will be self-limited. Voice changes due to injury require further evaluation, as edema or hematoma can be progressive and impinge on the airway.

A change of voice that persists more than 3 weeks should be considered chronic; possible etiologies include vocal cord nodules, cysts, or granulomas; malignant laryngeal tumors; neurologic disorders; and gastroesophageal reflux.

EMERGENCY DEPARTMENT EVALUATION

Patients with a change of voice should be questioned about whether the change is acute or chronic, and if acute, rapid assessment of the airway should be accomplished. After patients relate the onset and duration of the laryngitis, they should be questioned about associated symptoms, underlying medical problems, and injuries to the anterior neck. Patients with a URI-associated laryngitis usually present a few days into their illness. Patients with sudden onset or rapid progression of symptoms are most vulnerable to airway obstruction and require careful, prompt evaluation. Patients should be examined for signs of impending airway obstruction, such as shortness of breath or stridor. They also should be checked for findings suggestive of URI, such as mild fever, pharyngeal erythema or edema, rhinitis, and cough. In viral URI, laboratory tests are not helpful.

A soft-tissue lateral x-ray of the neck should be obtained to exclude epiglottitis or to help evaluate neck trauma. If the patient appears toxic or if more than a URI is suspected, a complete blood count may be helpful. Arterial blood gas determination is not helpful, because relatively normal values are maintained until there is clinically obvious deterioration. Intravenous fluid may be considered if the patient is dehydrated and has more than a simple URI.

Flexible fiberoptic laryngoscopes can be used by experienced emergency physicians to evaluate cases of neck trauma with voice change. Laryngoscopy can also be used to evaluate causes of airway impingement.

EMERGENCY DEPARTMENT MANAGEMENT

Acute viral laryngitis requires simple symptomatic management. Mucolytics and expectorants such as guaifenesin and iodinated glycerol are useful and well tolerated. Decongestants also can be used. Antihistamines have no role in this setting. Antibiotics are reserved for patients with known immunocompromised states, or in patients with a course prolonged more than a week, in which bacterial superinfection is possible. Increased fluid intake as well as room air humidification are also helpful. Patients with signs of airway obstruction or a history of neck trauma require otolaryngology consultation.

Patients whose acute laryngitis is secondary to vocal cord overuse should be advised to rest their voice, which includes abstaining from whispering. For the special circumstance of vocalists with acute laryngitis who will need to sing within 48 hours, voice rest should be prescribed and an intramuscular injection of dexamethasone given if they have objective evidence of vocal cord edema. Singers should drink a lot of water, use a humidifier, and rest their voices, but they should do warm-up exercises prior to the performance. Severe laryngitis mandates canceling the concert. ^{2,13}

DISPOSITION

Patients with simple URI may be discharged and instructed to follow up with their primary physician as needed. A 10- to 14-day duration of symptoms may be expected. Patients who are hoarse from voice overuse should be instructed to completely rest their voices; these patients should be advised to follow up with an otolaryngologist if their voices have not normalized in 2 weeks. All patients with chronic laryngitis require otolaryngology referral for complete evaluation.

COMMON PITFALLS

- In the setting of acute hoarseness, a missed diagnosis of epiglottitis can be fatal. The physician must remain alert to the clinical picture that suggests more than simple laryngitis.
- All patients with chronic laryngitis must be referred to an otolaryngologist to rule out malignancy, neurologic disorders, and other etiologies. The importance of this follow-up must be stressed to the patient.

CHAPTER 21

Sinusitis

Eric T. Boie

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Upper respiratory complaints including sinusitis are among the most common disorders encountered by the emergency physician. It is estimated that 14% of the U.S. population, approximately 30 million people, are treated annually for diseases of the paranasal sinuses.¹¹ Billions of dollars are spent on physician visits, prescription and over-the-counter medications, and workdays lost secondary to sinus disease. Sinus disease is usually a harmless inconvenience; however, it occasionally presents as a fulminant, life-threatening entity in the emergency department (ED).

Sinusitis is an inflammatory disease of the paranasal sinuses resulting from infectious, allergic, or autoimmune processes.¹⁶ *Rhinosinusitis* has been proposed as a more precise definition, as inflammation frequently involves the nasal passages, and sinusitis without rhinitis is rare.¹⁰ Sinusitis can be further classified as acute, subacute, or chronic based on duration of symptoms. *Acute sinusitis* lasts 3 to 4 weeks, with complete resolution of symptoms either spontaneously or with treatment. *Chronic sinusitis* is defined by persistent symptoms for more than 3 months despite maximum therapy. In *subacute sinusitis*, symptoms last from 3 weeks to 3 months.¹

The exact incidence and prevalence of sinusitis is difficult to determine due to lack of rigid criteria defining sinus disease. Occurrence among men equals that among women. Children are more often affected than are adults; from 0.5% to 2.0% of upper respiratory infections (URIs) in adults and 5% to 10% of URIs in children are complicated by acute bacterial sinusitis.^{7,8} Sinus disease in the United States is more prevalent in the Midwest and South compared with the Northeast and West.¹⁰ Chronic sinusitis affects 5% to 15% of urban dwellers, and the prevalence of chronic sinusitis is increasing.¹

The human sinuses are composed of four paired, sterile cavities lined with ciliated epithelium. Maxillary and ethmoid sinuses are present at birth. Frontal and sphenoid sinuses develop in the seventh and tenth year of life, respectively.⁹ Individual sinus anatomy is highly variable, with frontal sinuses absent in 2% to 5% of the population.¹² The posterior ethmoid and sphenoid sinuses empty into the superior meatus. The frontal, anterior ethmoid, and maxillary sinuses empty into the ostiomeatal complex within the middle meatus. Obstruction of the ostiomeatal complex (OMC) due to inflammation, anatomic abnormality, or other pathology is the critical event in the development of acute sinusitis.⁹ Maxillary sinusitis is most common, followed by ethmoid, frontal, and sphenoid, in descending order of frequency.¹¹

Most cases of sinusitis follow a viral URI. Viruses injure the sinus epithelium, resulting in ciliary dysfunction and a massive inflammatory cascade. Ciliary dysfunction results in mucostasis, and the damaged epithelium is highly susceptible to secondary bacterial invasion from the contiguous nasal passages. Inflammation results in occlusion of the OMC, obstructing sinus drainage and creating a hypoxic, hypercarbic, acidic environment that is ideal for bacterial growth.⁷ Multiple factors contribute to the development of sinusitis that does not follow a URI, including dental infection, ciliary dysfunction, occlusion of the OMC, and immunodeficiency. Five percent to 10% of acute maxillary sinusitis occurs due to contiguous spread of dental infection.¹ Ciliary motility disorders, both congenital (Kartagener syndrome) and acquired, predispose to sinusitis. Inflammatory changes of allergic or infectious origin can result in OMC occlusion. Anatomic abnormalities such as polyps, enlarged adenoids, or malignancies can do likewise. Nasal foreign bodies also result in OMC obstruction and can lead to sinusitis: 95% of nasally intubated patients develop sinusitis.¹ Immunocompromised patients, including those with steroid dependence, cystic fibrosis, the human immunodeficiency virus (HIV), diabetes, neutropenia, cancer, chronic renal disease, and organ transplants, are all more susceptible to the development of sinusitis and are more likely to have severe disease.¹

Infectious sinusitis can be of viral, bacterial, or fungal origin. Viral rhinosinusitis is 20 to 200 times more common than bacterial sinusitis.² Over 200 viruses have been implicated in acute sinusitis, with subtypes of *rhinovirus*, *parainfluenza*, and *influenza* virus being the most common.⁵ *Streptococcus pneumoniae* (30%), nontypeable *Haemophilus influenzae* (20%), *Moraxella catarrhalis*, *Staphylococcus aureus*, other streptococcal species, and anaerobes of dental origin compose the primary pathogens in acute bacterial sinusitis.⁷ Antibiotic resistance is a growing concern. One-third of *Haemophilus* isolates and nearly all of *Moraxella* strains are beta-lactamase producing, and up to half of pneumococcal strains display penicillin resistance.¹¹ *Pseudomonas* is an important pathogen in patients with cystic fibrosis and HIV. The bacteriology of chronic sinusitis is not as well defined; however, anaerobes, gram negatives, and staphylococcal species are most frequently implicated.⁹ Fungal sinusitis presents either as an acute fulminant or a chronic indolent process. The former occurs in those who are significantly immunocompromised. Mucoraceae species, including *Rhizopus*, *Mucor*, and *Absidia*, cause necrotizing invasive disease most often in patients with diabetic ketoacidosis.⁴ *Aspergillus* species are becoming a more common pathogen, manifesting in one of three chronic forms in immunocompetent adults: indolent invasive, mycetoma ("fungus ball"), and allergic fungal sinusitis. The last is the most recently described and frequent form of fungal sinusitis in the United States.¹³

CLINICAL PRESENTATION

The clinical presentation of acute sinusitis is highly variable. Most of the presenting chief complaints are nonspecific and may include purulent nasal discharge, nasal congestion, facial pressure, dental pain, ear pain, fever, headache, cough, fatigue, halitosis, or diminished sense of smell. Such symptoms are almost indistinguishable from those of a viral URI, thus *duration* of symptoms becomes critical in diagnosis. A patient with cold symptoms that do not resolve after 7 to 10 days has a high likelihood of having acute bacterial sinusitis.² Criteria have been established to aid in the diagnosis of acute bacterial sinusitis, as outlined in [Table 21.1](#). In patients with more than 7 days of symptoms, acute bacterial sinusitis is probable if two major factors or one major and two minor factors are present.¹¹ The presentation of acute sinusitis in children differs from that of adults. Children with sinusitis most commonly present with rhinorrhea and cough, and there is often coexistent otitis.⁷ Children under the age of 5 are less likely to complain of facial pain, dental pain, and headache.⁸ Periorbital edema occasionally is the presenting sign in a child with ethmoid sinusitis.⁷ Unilateral sinus drainage in a child should alert the astute emergency physician to the possibility of a nasal foreign body.⁸ Chronic sinusitis in adults and children may present similarly to acute sinusitis, but symptoms tend to be more vague and less severe.⁹

Major ^a	Minor
Facial pain or pressure	Headache
Purulent nasal discharge	Cough
Fever	Fatigue
Nasal congestion	Halitosis
Nasal obstruction	Dental pain
Hyposmia or anosmia	Ear pain/pressure

^aDiagnosis requires two major or one major and two minor factors in a patient with symptoms for more than 7 days (from the Task Force on Rhinosinusitis).²

TABLE 21.1. Major and Minor Factors for Diagnosis of Acute Sinusitis

Systemic toxicity, mental status changes, severe headache, and fever are signs and symptoms indicative of more serious sinus disease or its complications.¹² The emergency physician needs to maintain a heightened awareness for these ominous markers, as early identification and treatment is critical in decreasing associated morbidity and mortality. Both acute and chronic sinusitis can present initially with complications. Complications occur most frequently in teen-age males.¹² The most

worrisome complications involve the orbit or intracranial cavity. Periorbital cellulitis is the most common complication of sinusitis, usually originating from the ethmoid sinuses.¹⁷ Periorbital cellulitis must be differentiated from orbital cellulitis, where rates of visual loss approach 10%.⁵ Intracranial complications of sinusitis include meningitis, osteomyelitis, cavernous sinus thrombosis, and intracranial abscesses (epidural, subdural, and intracerebral). Meningitis is the most common intracranial complication of sinusitis, as it is estimated that 15% of cases may be of paranasal sinus origin.¹² Extension of acute frontal sinusitis with suppurative inflammation of cortical bone results in the famed “Pott’s puffy tumor,” a condition requiring aggressive surgical and antimicrobial therapy.¹⁷ Cavernous sinus thrombosis classically presents with periorbital edema, exophthalmos, papilledema, and cranial nerve III, IV, and VI palsies. Intracranial abscesses will usually present with fever and acute neurologic signs. Fortunately, such severe complications of sinusitis are rare. However, long-term morbidity approaches 33%, with blindness, hemiparesis, seizure disorders, and cognitive impairment as some of the more common postmorbidity states.¹² A much less severe complication of sinus disease is asthma instability. Although no cause-and-effect relationship has been definitively established, it is widely believed that sinusitis exacerbates asthma.¹⁴

Special consideration must be given to the immunocompromised host with sinus complaints, as invasive fungal sinusitis is much more common in this population. Patients are typically toxic and may present with moldy-smelling, thick, brown or black nasal discharge. Nasal crusting is prominent, and perforation of the palate, nasal septum, or cribriform plate may be apparent.¹³ The invasive organisms cause ischemic necrosis of the bone and mucosa, with hematogenous invasion of the orbit, skin, and brain. Progression to coma and death can occur within hours. Interestingly, acute fungal sinusitis is relatively rare in acquired immune deficiency syndrome (AIDS) patients, presenting as a late-stage phenomenon when CD4+ counts drop below 50/μL.¹³ *Aspergillus* is the most common fungal pathogen in this group.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for sinusitis is broad, as the signs and symptoms of sinus disease are neither sensitive nor specific. Viral URI, nasal polyps, cocaine abuse, allergic rhinitis, vasomotor rhinitis, and rhinitis medicamentosa all may present with symptoms of nasal discharge and congestion. Cerebral spinal fluid rhinorrhea should be considered in a patient with a history of head trauma. Persistent unilateral nasal discharge with epistaxis is concerning for neoplasm or nasal foreign body.¹¹ Tension, cluster, and migraine headaches, as well as dental disease, are alternative diagnoses in the patient whose sinus disease manifests as cephalgia or facial pain. Patients with fever deserve particular attention, as pyrexia may be a manifestation of simple sinusitis or severe central nervous system (CNS) infection, such as meningitis or intracranial abscess.

EMERGENCY DEPARTMENT EVALUATION

Acute sinusitis is a diagnosis based primarily on clinical history and physical findings (see [Table 21.1](#)). Unfortunately, physical examination findings may not prove helpful, as none are specific for acute sinusitis.⁵ Findings in a patient with sinusitis may include mucosal hyperemia, purulent rhinorrhea, nasal airway congestion, crusting of the anterior nares, and facial pain. However, palpable facial tenderness is a poor indicator of underlying sinus infection, and “purulent” discharge is not a reliable indicator of bacterial sinusitis.⁷ Transillumination has been used as a diagnostic aid, as opacification to transillumination of frontal or maxillary sinuses was a marker of a fluid-filled, infected sinus. Transillumination actually has poor correlation with the presence of fluid, poor intraobserver consistency, and poor specificity. Thus, it is of little use in the diagnosis of acute sinus disease.^{5,7}

Radiographic imaging has little role in the diagnosis of acute sinus disease in the ED. The clinical significance of abnormal findings on imaging studies is debatable. Plain radiographs both underestimate and overestimate disease and have poor correlation with computed tomography (CT) findings.^{5,7} Abnormal findings are common in a large proportion of asymptomatic individuals, and findings of air–fluid levels, sinus opacification, or mucosal thickening rarely lead to a change in management.⁵ CT scan has become the modality of choice for sinus imaging, but also may be oversensitive in detecting “disease.”⁶ Eighty-seven percent of patients with viral URIs have abnormalities consistent with sinusitis on CT.¹ In a study of healthy, asymptomatic children aged 1 to 2, 69% had abnormal sinus CT scans.⁷ It is neither medically necessary nor economically feasible to CT scan every patient with symptoms of sinusitis. CT scans are most helpful after maximum medical therapy in patients undergoing consideration for surgical treatment, and thus should be reserved for the consulting specialist.⁵ Use of CT in the ED should be limited to those patients in which serious complications of sinusitis are suspected.⁶

Nasal cultures are not helpful in the diagnosis of acute sinusitis, as growth correlates poorly with cultures from sinus aspirates.¹ Sinus aspiration is neither practical nor routinely performed in the ED. Blood tests are necessary only in patients who show signs of systemic toxicity, show signs of CNS involvement, or have significant comorbid disease or immunosuppression.

The lack of a simple diagnostic test makes the diagnosis of sinusitis challenging, but also creates a tendency to label many common colds as sinusitis.¹¹ Duration and severity of symptoms may provide clues in the diagnosis. In acute bacterial sinusitis, symptoms generally worsen after 5 days, persist for at least 10 days, and are much more severe than those associated with a viral URI.²

EMERGENCY DEPARTMENT MANAGEMENT

The goal of therapeutic intervention in acute sinusitis is threefold: to relieve obstruction of the OMC, to restore mucociliary clearance, and to reestablish sinus sterility through eradication of infection.⁹ As acute sinusitis is not purely an infectious process, antimicrobial therapy alone will likely fail.¹¹ Combination treatment with antibiotics, topical steroids, nasal decongestants, mucosolvents, anticholinergics, antihistamines, and nonpharmacologic measures may provide the best symptomatic and therapeutic outcome.

Antibiotics have been the mainstay of treatment for acute sinusitis, but great controversy exists regarding indications for use, choice of antimicrobial agent, and duration of therapy. Mild cases of rhinosinusitis with symptoms lasting less than 7 days are most likely viral in etiology, and the temptation to prescribe antibiotics for these patients should be resisted.^{2,20} The natural course of untreated acute sinusitis is unknown, but it is estimated that 40% to 50% of cases would resolve spontaneously.^{7,16} Antimicrobial therapy is often cited as necessary to avoid development of complications of acute sinus disease; however, there is no prospective evidence to support this conclusion.

In patients meeting the diagnostic criteria for sinusitis with progressive or nonresolving symptoms for more than 7 days, use of a first-line antimicrobial agent is appropriate.² [Table 21.2](#) lists the commonly used first- and second-line antimicrobials for acute sinusitis. Amoxicillin is still highly effective and is the first-line agent of choice in acute sinusitis.^{7,20} Newer, more expensive antibiotics do not appear to be more effective than amoxicillin or trimethoprim plus sulfamethoxazole (TMP-SMX) in patients with uncomplicated sinusitis.^{3,20} Most studies suggest that almost any antibiotic results in clinical improvement greater than 85% of the time.¹⁶ Although no prospective study has established the optimum duration of therapy, a 10- to 14-day course is generally accepted as adequate.^{8,11} A small number of studies have shown 3 days of therapy as equally effective, but this is not yet an accepted practice.¹⁵ Second-line agents should be initiated if there is progression of symptoms after 2 to 3 days of initial therapy.^{2,7}

FIRST-LINE THERAPY
Amoxicillin
Trimethoprim and sulfamethoxazole (TMP/SMX)
Erythromycin-sulfamethoxazole
SECOND-LINE THERAPY
Amoxicillin-clavulanate
Cefixime
Cefepime proxetil
Cefprozil
Cefuroxime axetil
Levofloxacin
Trimethoprim
FIRST- OR SECOND-LINE THERAPY
Azithromycin
Clarithromycin

Second-line therapy is indicated when symptoms progress during the first 48 to 72 hours of first-line therapy.

TABLE 21.2. Antibiotic Therapy Alternatives in Acute Sinusitis ¹⁶

The use of topical steroids in acute sinusitis is attractive, as they are potent antiinflammatories with few side effects. Studies have demonstrated improved symptom relief, but the clinical efficacy of topical steroids is uncertain.^{1,5} Steroids are generally well tolerated, with local irritation and bleeding as the most common side effects.⁵

Topical alpha-adrenergic agonists, such as oxymetolazone, have been used to decrease mucosal edema, promoting sinus drainage and ventilation. These agents should not be used for more than 3 days, as this may elicit rhinitis medicamentosa due to rebound vasodilation. Oral systemic decongestants (ephedrine, pseudoephedrine, phenylephrine, phenylpropanolamine, etc.) also can be taken, but side effects, including nervousness, insomnia, hypertension, and tachycardia, may limit their use. Despite the extensive use of these agents, their efficacy remains unclear.¹⁰

The mucoevacuant guaifenesin can be used to increase mucous flow and decrease mucous viscosity.¹ Side effects are minimal but may include abdominal discomfort and emesis.⁵

Topical anticholinergics such as ipratropium bromide may reduce rhinorrhea, and thus can also be used as adjunctive therapy.¹ Antihistamine use in acute sinusitis remains controversial. While antihistamines may decrease rhinorrhea, some argue that their use is contraindicated, as they increase mucous viscosity, leading to inspissation and outflow obstruction.⁸ Nonpharmacologic therapy such as steam inhalation and saline douching provide symptomatic relief by softening crusts and moisturizing dry mucosa.

All of these adjunctive therapies are based largely on anecdote and personal preference, as there is little evidence that these additions make a great impact on clinical outcome.^{8,10} It is likely that the longer acute sinusitis is treated, the more the natural course of infection is seen; that is, spontaneous resolution occurs regardless of what is done.¹¹

Special consideration is needed for managing sinusitis in children, the elderly, and immunocompromised patients. Although debated, because children experience more URIs than do adults, the incidence of acute sinusitis in children may be higher. Sinusitis should be considered in any child with respiratory symptoms not improving after 10 days.⁸ Any child with recurrent acute sinusitis, or chronic sinusitis despite aggressive therapy, should be referred for evaluation for cystic fibrosis or underlying immune dysfunction.^{9,14} In elderly patients, the threshold to treat acute sinusitis should be lower, as aggressive medical intervention may be important in reducing morbidity in this group.⁵ In immunocompromised patients, increased alertness for fulminant sinusitis and its complications is necessary. Sinusitis is one of the most common problems affecting HIV-positive patients.¹⁸ The treatment of acute sinusitis is essentially the same regardless of HIV status, except for duration of antimicrobial therapy (21 days is standard).¹⁹ When CD4+ counts fall below 200, opportunistic sinus infections become more common and more resistant to standard therapy.¹⁸

DISPOSITION

Most patients with acute, uncomplicated sinusitis can be safely discharged with instructions to return to the ED or to follow up with their regular doctor if symptoms are worsening or not improving within 2 to 3 days. Patients should be educated on the signs of potential intracranial extension (severe headache, vomiting, confusion) and advised to return to the ED immediately for the same. Patients with sinus symptoms lasting longer than 1 month despite a complete course of therapy should be referred to an otolaryngologist for CT imaging and further evaluation.¹¹

Any patient with severe headache, altered mental status, systemic toxicity, meningeal signs, or visual complaints suggestive of intraorbital or intracranial extension requires aggressive management to prevent the significant morbidity and mortality associated with complicated sinus disease. Administration of broad-spectrum antibiotic therapy, most appropriately a third-generation cephalosporin plus vancomycin, should not be delayed by diagnostic procedures.¹⁶ Early antibiotics, followed by CT, lumbar puncture, and consultation of ear, nose, and throat; neurosurgery; and ophthalmology where appropriate, is critical.¹¹ The majority these patients will require admission to the intensive care unit.

Transfer to a referral center is necessary if specialist consultation is not readily available for patients with serious complications of sinus disease. Appropriate stabilization efforts and intravenous antibiotic therapy should be initiated prior to transfer. Advanced cardiac life support-capable transport by ground or air is necessary for patients with intracranial complications.

COMMON PITFALLS

- Obtaining radiographic imaging in the setting of acute, uncomplicated sinusitis adds little to the work-up except cost. There is rarely a role for imaging in acute sinusitis, unless complications are present.⁶
- Using antibiotics in patients with symptoms consistent with sinusitis of less than 7 days' duration should be avoided. Antibiotics are often inappropriately dispensed for viral rhinosinusitis, which is 20 to 200 times more common than acute bacterial sinusitis.²
- Patients with symptoms of sinusitis with marked headache and fever must be carefully evaluated to avoid missing early indicators of intracranial extension of acute sinus disease.
- Elderly, diabetic, HIV-positive, and other immune suppressed patients demand a keen awareness, as they are at greater risk for more severe sinusitis and its complications.
- Remember that despite its prevalence, the classifications, diagnostic criteria, clinical management, and ideal treatment options of acute sinusitis are largely anecdotal and without a prospective, evidence-based foundation.

CHAPTER 22

Rhinitis

Michael J. Foley and Gregory P. Moore

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Rhinitis and other nasal disorders are generally not life-threatening conditions, but they are responsible for frequent emergency department (ED) visits, restricted activities, loss of productivity, discomfort, and decreased quality of life. It is established that 40 million Americans will have a nasal disorder annually, resulting in millions of visits and significant health-care dollars spent on diagnosis and treatment.⁵ Allergic rhinitis alone affects approximately 20% of the U.S. population,¹² and the cost of medication for nasal obstruction is approximately 5 billion dollars annually.¹⁷

Rhinitis is the most frequent of the upper respiratory infections and can be broadly categorized into noninfectious and infectious types. Acute rhinitis is the usual manifestation of a common cold and, by definition, lasts less than 3 weeks. Chronic rhinitis lasts longer than 3 weeks and can occur in conditions characterized by granuloma formation (e.g., tuberculosis, syphilis, histoplasmosis). Simple viral infections (e.g., adenovirus) of the nasopharynx are the most common cause of rhinitis. Other infectious causes are bacterial or fungal. Allergic (seasonal or perennial) rhinitis is the largest cause of noninfectious rhinitis. Other noninfectious causes include vasomotor, atrophic, gustatory, hormonal, granulomatous, drug-induced, and idiopathic rhinitis.

Anatomic abnormalities associated with rhinitis may include septal deformities, nasal valvular collapse, septal hematomas, abscess, neoplasms, foreign bodies, and choanal atresia in children. These should be considered when evaluating this chief complaint. It is important to investigate patients presenting with clear, watery rhinorrhea for a possible cerebrospinal fluid (CSF) leak. CSF rhinorrhea is often unilateral and associated with surgery or trauma, but cases of spontaneous leaking have been described. There is no reliable method for distinguishing CSF from nasal mucus in the ED, despite the continued use of glucose indicator sticks and the formation of a halo effect on filter paper.

Allergic rhinitis is an immunologically based inflammatory condition triggered by exposure to an allergen. Antibodies (immunoglobulin M [IgM]) specific for the allergen are produced, and they subsequently attach to mast cells in the nasal mucosa. Later, when reexposure occurs, the allergen attaches to IgE on mast cells, causing the release of inflammatory mediators (the most important being histamine). *Seasonal allergic rhinitis*, by definition, has a seasonal variation in symptoms, with the common allergens being pollens (tree, grass, ragweed) and molds. *Perennial allergic rhinitis* can be more difficult to diagnose and occurs on the majority of days throughout the year. The most common allergen responsible for perennial allergic symptoms is the house dust mite.⁸ Animal dander (cats, dogs, horses) is another common nonseasonal allergen. A thorough history will help distinguish these two forms of rhinitis.

Nonspecific environmental triggers such as irritants (smoke, strong odors, fumes), temperature changes, humidity, and air conditioning are responsible for a condition known as *vasomotor rhinitis*. Rhinorrhea and nasal obstruction are the predominant symptoms, rather than sneezing or pruritis. Due to the rare nature of this entity, vasomotor rhinitis should be a diagnosis of exclusion.

Atrophic rhinitis occurs with atrophy of the nasal mucosa and commonly causes loss of smell and taste. Nasal and sinus surgery may result in cases of secondary atrophic rhinitis.

Certain medications affecting peripheral vascular tone have been associated with *drug-induced rhinitis*. Beta-blockers (systemic and topical ophthalmic), angiotensin converting enzyme inhibitors, birth control pills, chlorpromazine, aspirin, and other nonsteroidal antiinflammatory drugs have all been implicated. Prolonged use (greater than 5 days) of topical nasal vasoconstricting agents in the form of drops, sprays, or inhalers may result in a condition called *rhinitis medicamentosa*. Tachyphylaxis and rebound nasal congestion lead to a cycle of shorter duration of relief and, thus, more frequent use.

Gustatory rhinitis is a self-limiting form of rhinitis that occurs while eating spicy or hot foods and is a common condition of the elderly. *Hormonal rhinitis* may develop during puberty, pregnancy, thyroid conditions, or changes with age (e.g., in postmenopausal women).

Many drugs, such as cocaine, amphetamines, and amyl nitrate, are abused via the intranasal route. These patients have chronic rhinitis and inflammation of the nasal mucosa, and may develop bloody nasal drainage, mucosal ulcerations, or frank septal perforation.

CLINICAL PRESENTATION

Most patients with nasal disorders have symptoms of nasal obstruction and/or rhinorrhea. Other symptoms include postnasal drip, hyposmia (diminished sense of smell) or anosmia (absence of the sense of smell), congestion, and sneezing. A good question to initially ask of all rhinitis patients is, "What is your primary symptom?" This may identify the specific etiology and thus aid therapy (Table 22.1).

Symptom	Etiology	Discharge	Distinguishing Factors	Treatment
Unilateral or bilateral	Smells	Nasopurulent	Facial pain, fever	Antibiotic, decongestant
Unilateral	Foreign body	Nasopurulent	Foul odor	Removal
Unilateral	CSF leak	Clear	Surgery, trauma	Neurosurgical consult
Bilateral	Allergy	Clear	Pruritis	Antihistamines, corticosteroids, decongestants
Bilateral	Vasomotor	Clear/bloody	Loss of taste, smell	Supportive
Bilateral	Intranasal drug abuse	Bloody	Other signs of drug abuse	Cessation of drug abuse
Bilateral	Rhinitis medicamentosa	Clear	Use of nasal vasoconstrictors	Stop medication
Bilateral	Hormonal	Clear	During puberty or pregnancy	None
Bilateral	Gustatory	Clear	Associated with eating	Self-limited

TABLE 22.1. Common Causes of Rhinitis

Patients with infectious rhinitis have symptoms consistent with the common cold, with the exception of fungal infections, which have more chronic manifestations. Patients with allergic rhinitis describe profuse rhinorrhea, conjunctivitis, sneezing, and continuous or seasonal exacerbations. Eliciting a history of chronic nasal vasoconstricting agent use leads to the diagnosis of rhinitis medicamentosa. These patients usually have continuous nasal congestion and clear rhinorrhea.

It is essential to obtain a thorough medication history when evaluating a patient for drug-induced rhinitis. Hormonally induced rhinitis of pregnancy begins during the second month of gestation and terminates with delivery. Asking about a recent history of trauma helps in screening a patient for CSF rhinorrhea or septal hematoma. Investigate concomitant pulmonary symptoms, as rhinitis may be associated with asthma or other pulmonary disorders.

Compared with allergic rhinitis, patients with vasomotor rhinitis generally have less sneezing and pruritis. Patients with atrophic rhinitis commonly lose taste or smell and have recurrent epistaxis and a foul odor to the nasal discharge. Any bloody nasal discharge should alert the physician to a possible diagnosis of intranasal drug

abuse, intranasal foreign body, neoplasms, or angiofibroma (i.e., young males).

DIFFERENTIAL DIAGNOSIS

Specific clues in the history help narrow the differential diagnosis. Unilateral symptoms are associated with structural abnormalities. Allergic rhinitis should be suspected after a careful history of known exposure to allergens. The ED physician should suspect an intranasal foreign body in children with chronic, unilateral, purulent nasal drainage.

Nasal neoplasms are rare, but the emergency physician should consider the diagnosis in any patient with unilateral nasal obstruction, bleeding, or pain. Cystic fibrosis may present as rhinorrhea with nasal polyps in children. Rare disorders that cause rhinitis include Wegener's granulomatosis, sarcoidosis, CSF rhinorrhea, and nasal polyposis.

EMERGENCY DEPARTMENT EVALUATION

Following a thorough but directed history, the physical examination should focus on the head and neck. It is optimal to gather all the necessary equipment before examination of the nasal structures (similar to the approach to epistaxis). Palpate the nose for masses and tenderness. The nose and nasal mucosa should be examined with a head mirror or headlight. Rhinoscopy with a nasal speculum allows evaluation of only the anterior one-third to one-half of the nasal cavity. The remainder of the nasal cavity can be examined with a fiberoptic nasopharyngoscope, if available. Determining whether there is unilateral obstruction helps in the differential diagnosis. Evaluate the mucosal surface and look for foreign bodies or tumors. Caution must be exercised not to confuse large swollen turbinates with nasal polyps. Polyps are pale gray, lack sensation, and are mobile. Turbinates have a pink mucosal surface, are tender to palpation, and are relatively firm to palpation. Define the character of the nasal drainage as primarily clear and watery or thick and purulent. Palpate the maxillary and frontal sinuses and examine the oropharynx, ears, eyes, neck, and lungs to rule out conditions presenting with symptoms similar to those of rhinitis.

Ancillary laboratory tests are generally not helpful in the ED setting. To raise the suspicion for fungal rhinitis, cancer, or other rare nasal conditions, the ED physician should consider whether the patient may be immunocompromised in any way. These patients also need to be evaluated for sepsis syndromes with a complete blood count, blood culture, and chest x-ray. If sinusitis is suspected, plain films of the sinuses have been found to have low yield. Limited (5-mm slices) coronal computed tomography (CT) of the sinuses has become the standard radiographic study to evaluate the sinuses.

Non-ED testing, such as nasal mucociliary clearance, peak nasal inspiratory flow, olfactory nerve testing, swabs, smears, biopsies, allergy skin testing, IgE serologic testing, endoscopy, and nasal cytology, may be done in conjunction with an allergist or otolaryngologist in the outpatient setting. Outcomes of patients with rhinitis are much improved when the etiology is specifically identified.

EMERGENCY DEPARTMENT MANAGEMENT

Prevention of attacks by avoidance of precipitating factors should be recommended. Perennial allergic rhinitis may be controlled by reducing exposure to house dust mites and animal dander. This effort may completely relieve the symptoms of rhinitis without the need for medical management. Following avoidance, the next line of therapy is medical treatment to provide symptomatic relief. The three main medical therapies for symptomatic relief are antihistamines, decongestants, and corticosteroids.

Oral antihistamines are the cornerstone of medical therapy and are highly effective in controlling watery rhinorrhea, itching, and sneezing. Their main mechanism of action is via blocking of the H1 histamine receptors. First-generation antihistamines such as diphenhydramine (Benadryl) and chlorpheniramine (Chlor-Trimeton) easily penetrate the blood-brain barrier due to their high lipophilicity. They frequently cause sedation and altered motor skills and are therefore not recommended in school-aged children or in adults who will be driving or operating heavy machinery. Patients may also have urinary retention, constipation, dry eyes, and tachycardia due to the anticholinergic side effects. This side-effect profile led to the development of second-generation antihistamines such as astemizole (Hismanal), cetirizine (Zyrtec), fexofenadine (Allegra), loratadine (Claritin), and terfenadine (Seldane). The second-generation antihistamines are relatively nonsedating due to less lipophilicity and have improved patient tolerance but are considerably more expensive. The ED physician should be aware of potential drug interactions with all of the first-generation and most of the second-generation agents, as they are metabolized by the cytochrome P-450 system. Topical antihistamines such as azelastine (Astelin) also may be effective, but they are still under investigation for use in patients with rhinitis.

Decongestants reduce nasal congestion by decreasing vasodilation, resulting in less edema and blood flow to the nasal mucosa. Their mechanism of action is via stimulation of alpha-receptors. Topical agents include phenylephrine (Neo-Synephrine) HCl 0.5% and oxymetazoline (Afrin) HCl 0.05%. They should be used for only 3 to 5 days, as extended use may result in rebound vasodilation and increased nasal congestion. Systemic agents (alpha-adrenergic agonists) include pseudoephedrine (Sudafed) and phenylpropanolamine. These agents have been studied extensively and seem to be safe for use in patients with controlled hypertension.^{13,15} The use of decongestants in patients with uncontrolled hypertension may lead to stroke or severe hypertension. There are also a variety of medications with decongestant-antihistamine combinations.

Corticosteroids are the primary pharmacologic treatment for allergic rhinitis. Nasal steroids act on both the immediate- and the late-phase reactions. Examples include beclomethasone (Vancenase, Beconase), budesonide (Rhinocort), flunisolide (Nasalide, Nasarel), fluticasone (Flonase), and triamcinolone (Nasacort). These agents generally have a delayed clinical response, and patients should be advised to expect that nasal steroids will take at least 1 week to become efficacious. Minimal adverse effects include nasal irritation and epistaxis. Systemic steroid therapy is rarely indicated in cases of allergic rhinitis.

The primary advantage of cromolyn sodium is prophylactic use before allergen exposure, with the greatest benefit in patients with high IgE levels and considerable exposure to the offending allergen.⁴ Anticholinergics such as ipratropium (Atrovent) 0.3% nasal spray effectively control rhinorrhea by reducing the volume of nasal secretions by blocking parasympathetic nerve transmission.

Special considerations are the use of decongestants in patients with uncontrolled hypertension^{13,15} and the use of sedating medications in the elderly and school-aged children. The use of terfenadine or astemizole in conjunction with macrolide antibiotics (e.g., erythromycin or clarithromycin) or antifungal agents (e.g., ketoconazole) may result in life-threatening cardiac toxicity (QT interval prolongation and ventricular tachycardia).

Other treatment options that are unavailable in the ED include desensitization to allergens (e.g., pollens) and surgery. Surgical treatment may be necessary after failed medical management, especially for a deviated nasal septum or nasal polyps. By correcting these two conditions, topical medications may have better access to the nasal mucosa.

DISPOSITION

Almost all patients seen in the ED for rhinitis can be discharged home. All of the medications discussed are relatively simple to administer and are commonly used in the outpatient setting. Referral to a specialist (allergist or otolaryngologist) may be considered with progression of symptoms, complications, or the need for nasal endoscopy, CT scans, or allergy skin testing. This specialized evaluation allows a much clearer understanding of the pathophysiology in specific nasal disorders.

COMMON PITFALLS

- Failure to focus on the history and physical examination
- Not considering comorbid diseases in patients with rhinitis (e.g., hypertension, immunocompromised states, current use of macrolide antibiotics)
- Failure to obtain a good medication history (including over-the-counter medications)
- Failure to consider intranasal drug use as a cause of nasal congestion and rhinitis
- Missing an intranasal foreign body in young children with chronic nasal discharge
- Misidentification of turbinates as nasal polyps
- Avoid the use of terfenadine or astemizole in conjunction with macrolide antibiotics (e.g., erythromycin or clarithromycin) or antifungal agents (e.g., ketoconazole). This combination may result in life-threatening cardiac toxicity.

- Be aware that the use of decongestants in patients with uncontrolled hypertension may lead to stroke or severe hypertension.

CHAPTER 23

Mastoiditis

James A. Pfaff

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management And Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Before the advent of antibiotics, there was a 20% incidence of complications of otitis media, with mastoiditis being the most predominant. Since then, mastoiditis has become relatively rare, with a reported incidence as low as 0.004% of all patients who have had otitis media.¹⁷ While uncommon, mastoiditis can result in significant and even life-threatening complications. There have been reports of a recent increased resurgence of this disease.⁹

Mastoiditis is best defined as an inflammatory process of the pneumatic spaces of the temporal bone caused by middle ear suppuration; it is really a continuum of disease processes. It is classified into both acute and chronic forms. The mastoid air cells communicate with the middle ear cavity by way of the aditus ad antrum. These cells are lined with epithelium that is continuous with the epithelium lining the tympanic cavity and are inflamed during an episode of acute otitis media. When the aditus ad antrum is blocked, a closed space develops, causing stasis of secretions and the resultant inflammatory cascade. The inflammation may be confined to the periosteum or extend through it, with ultimate decalcification and resorption of the bony septum of the mastoid bone,⁴ a condition generally known as coalescent mastoiditis. According to Bluestone and Klerrie,¹ there are a number of directions to which the resulting inflammation can then spread: (1) back through the aditus ad antrum, with spontaneous resolution; (2) lateral to the surface of the mastoid process, resulting in a subperiosteal abscess (at present, the most common complication of mastoiditis); (3) anteriorly, forming an abscess below the auricle or behind the sternocleidomastoid, resulting in an abscess (known as Bezold's abscess); (4) medially to the petrous portion of the temporal bone (a rare condition known as petrositis); or (5) posteriorly to the occipital bone, resulting in osteomyelitis of the calvarium (a condition known as Citelli abscess).

The incidence of subperiosteal abscess has increased; nearly 50% of patients diagnosed with coalescent mastoiditis also have a subperiosteal abscess.²⁰ In addition to the aforementioned abscesses, additional complications of mastoiditis include lateral sinus thrombosis, brain abscess, epidural and subdural abscesses, meningitis, otic hydrocephalus, leptomeningitis, suppurative labyrinthitis, sigmoid sinus thrombosis, and facial nerve paralysis.⁶

Chronic mastoiditis is a complication of chronic otitis media, resulting in fibrosis of the mucoperiosteum, mucosal edema, granulation tissue, and bone abnormalities. It is usually characterized by chronic otorrhea through a patent ventilating tube or a perforation of the tympanic membrane (TM) that has been present for more than 2 months.¹⁴ Patients may or may not have an associated cholesteatoma, which is a cystlike mass formed by the ingrowth of squamous epithelium into the middle ear, either through the perforated TM or by retraction of the TM. Its presence will determine the type of therapy given in chronic disease. This disease should be considered in patients with long-standing ear disease, persistent aural discharge, pain, granulation tissue, or cholesteatoma that is refractive to medical therapy.⁸

There is an additional, well-described entity known as latent or masked mastoiditis. This usually results from resolution of overt middle ear disease without resolution of disease within the temporal bone. The patient often appears to have clinical resolution of symptoms when, in fact, there is subsequent subclinical disease that can result in bony destruction, until serious complications such as intracranial involvement occur.

Because acute mastoiditis is often a complication of acute otitis media, it has been reported that the organisms causing it are similar, yet this is not always the case.¹⁵ While *Streptococcus pneumoniae* is the most common organism isolated, *Streptococcus pyogenes*, *Staphylococcus aureus*, gram-negative organisms such as *Pseudomonas aeruginosa* and *Proteus*, and anaerobes have all been isolated in acute disease. This prevalence may be related to improved culture techniques for the organisms and not necessarily to a change in virulence.¹² *S. aureus*, *Pseudomonas*, and *Proteus* are the most common organisms involved in chronic disease, although there may be a high incidence of associated anaerobes.¹² Up to 20% to 30% of all cases may fail to yield an isolated organism.¹³ In immunocompromised patients, *Aspergillus*, *Mycobacterium tuberculosis*, other atypical *Mycobacterium* sp., and *Pneumocystis carini* have all been described, with the latter infection unique to acquired immunodeficiency disease (AIDS) patients.¹⁰ These infections have a slower and more indolent course than do acute diseases. Given the increasing prevalence of disease caused by *M. tuberculosis*, this pathogen should be considered in both the immunocompromised and the immunocompetent host in the presence of mastoiditis and otitis media that are not responding to traditional therapy.

Mastoiditis in children less than 1 year old was thought to be uncommon, given the lack of mastoid pneumatization, but there may be a relative increased incidence from the preantibiotic era. This may be related to the use of antibiotics and the difficulty in detecting the disease in younger age groups.⁷ As is the case in otitis media, there appears to be a predilection for the male gender. Mastoiditis has also been described as a complication of leukemia, mononucleosis, sarcoma of the temporal bone and Kawasaki disease.¹⁶

CLINICAL PRESENTATION

There is usually, but not always, a preceding otitis media, but in one series, 55% of patients with the diagnosis of acute mastoiditis did not have otitis media.⁶ The percentage of patients who have previously been on antibiotics ranges from 36% to 71%; their use does not have a protective effect.¹¹ Postauricular pain is the most common symptom (98%); headache and otalgia also are seen. The patient may have a toxic or lethargic appearance, with a history of decreased appetite or irritability. On examination, fever is present in 83% of patients; up to 76% of patients have postauricular tenderness, swelling, and erythema.²⁰ The auricle may be displaced forward and laterally, although in children less than 1 year old, the displacement may be downward and lateral due to the mastoid not being fully developed.⁵ There may be swelling of the posterior aspect of the external auditory canal, especially in the presence of a subperiosteal abscess.⁴ On otoscopic examination, the TM is abnormal in 88% of patients; it may be thickened, opaque, and bulging, with decreased mobility; the TM may be normal in 10%.¹⁶ The disease should be considered in the case of otitis media that is not resolving.

Increasing headache, otalgia, fever, postauricular pain, swelling, or change in the consistency of the otorrhea in patients with chronic otitis media should alert the emergency physician to the possibility of mastoiditis. Patients with chronic mastoiditis will have a perforated TM and otorrhea, and they may have a cholesteatoma. The cholesteatoma may appear to have white or yellow debris on the TM or an abnormality of the TM contour if it is confined to the middle ear.

Patients with masked or latent disease have a smoldering course, with recurrent or prolonged symptoms, little or no fever, and a variable pain picture preceded by a latent period after the apparent resolution of an acute otitis media.⁸ Patients may not have retroauricular swelling, and their TM may be intact or perforated. The first sign of this subclinical disease may manifest as serious complications, such as meningitis or an intracranial abscess.

DIFFERENTIAL DIAGNOSIS

Localized scalp infections, such as furuncles or due to trauma, will often present with postauricular swelling. Reactive lymphadenopathy from systemic infections of the head and neck region can also be easily mistaken for mastoiditis. Systemic lymph node disorders from viral infections or neoplastic disease can present with postauricular swelling. If there is swelling of this area in an adult with a history of tobacco use, a neoplastic source should be considered. Rhabdomyosarcoma, eosinophilic granuloma, and brachial cleft abnormalities mimic the findings of mastoiditis in infants.¹⁹

EMERGENCY DEPARTMENT EVALUATION

Mastoiditis should be considered in any patient with posterior auricular pain and swelling and in patients with a history of otitis media that is not resolving, particularly in the presence of fever and otalgia. Any patient with a history of chronic otitis media with posterior auricular swelling and pain should also have mastoiditis ruled out. Be particularly wary in the immunocompromised host or very young patient with persistent otitis media. The diagnosis of masked or latent mastoiditis should be

considered in any patient presenting with an intracranial infection without an obvious source.

Laboratory testing of the disease is not useful. While leukocytosis and an increased erythrocyte sedimentation rate are often present, they are neither sensitive nor specific for the disease. Blood cultures are generally not positive. Of course, a lumbar puncture should be performed in all patients manifesting signs and symptoms of meningitis.

In the past, radiographs were the main modality used in evaluation of the mastoid. Often, radiographs reveal clouding of the mastoid space and bony abnormalities, but they are generally unhelpful and at other times misleading.² Computed tomography (CT) is more useful in defining the extent of the disease, as well as intratemporal and intracranial complications. Contrast-enhanced CT may further define complications such as lateral sinus thrombosis. The usefulness of magnetic resonance imaging for this disease has not been extensively studied.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Treatment of mastoiditis depends on the probable etiology and the extent of the disease. All patients with the diagnosis of mastoiditis require otolaryngologic consultation and intravenous antibiotic therapy in the emergency department. Toxic-appearing patients or those with intracranial complications may require intensive care admission and probable neurosurgical referral. For the patient who requires admission, parenteral antibiotics are indicated for acute mastoiditis with only periosteal involvement. In general, decisions about admission, myringotomy, tympanostomy tubes, and mastoidectomy are made by the consulting physician.

The need for surgical treatment, such as myringotomy, tympanostomy tubes, and mastoidectomy may be required if acute disease does not resolve, or progresses. Risk factors for possible early surgical intervention include the presence of fever, leukocytosis, and proptosis of the auricle. A therapeutic mastoidectomy may be required.⁶

The antibiotics selected should be effective for *S. pneumoniae*, the most commonly isolated pathogen. They also should be able to penetrate the blood–brain barrier. Initial selections may include third-generation cephalosporins, such as ceftriaxone (1 g every 12 hours) or cefotaxime (1 g every 4 hours), or a combination of a semisynthetic penicillin and chloramphenicol.¹⁶ Concern for anaerobic bacteria may result in the addition of Flagyl.¹² Immunocompromised patients may require antifungal or antituberculous agents; the use of these should be made in conjunction with otolaryngologic and infectious disease specialists.

The use of daily parenteral antibiotics for ambulatory patients has been advocated if there is close follow-up by an otolaryngologist and an infectious disease specialist.³ Alternatively, for less severe disease, outpatient treatment includes the traditional regimens used for otitis media: amoxicillin, Bactrim, Augmentin, or the cephalosporins.

Patients who fail to improve within 24 to 72 hours and have evidence of coalescent disease, a subperiosteal abscess, or intracranial disease are candidates for mastoidectomy. The treatment of chronic mastoid disease is controversial, with some authors feeling that mastoiditis without cholesteatoma is a reversible process that can benefit from medical therapy and aural drainage.⁴ Mastoid surgery is required for those patients with chronic disease and a cholesteatoma. Antibiotic coverage should include agents specific against *Pseudomonas*, such as ticarcillin-clavulanate. The otolaryngologist is responsible for the decision regarding surgical intervention. Transfer arrangements should be made if no specialty consultation is available.

COMMON PITFALLS

- Failure to consider mastoiditis in a patient with otitis media that has not resolved in a timely manner
- Failure to consider the presence of latent or masked mastoid disease in toxic-appearing infants or immunosuppressed patients without other apparent sources of infection
- Failure to recognize the significant intracranial or intratemporal complications that can still occur in patients with middle ear disease
- Failure to consider a complication of middle ear disease as the cause of ear drainage

CHAPTER 24 *Nasal Hemorrhage*

Todd C. Rothenhaus and Ian D. Paul

- [Clinical Presentation](#)
- [Differential Diagnosis](#)
- [Emergency Department Evaluation](#)
- [Emergency Department Management](#)
- [Control of Posterior Epistaxis](#)
- [Disposition](#)
- [Common Pitfalls](#)
- [Chapter References](#)

Epistaxis is a frequent problem seen by the emergency physician. It is estimated that up to a seventh of the population will have at least one episode of epistaxis in their lifetime. The incidence is bimodal, with a peak from the ages of 2 to 10, and a broader peak between the ages of 50 and 80. ⁷ Nasal hemorrhage occurs most commonly in the dry, ²² and colder, ^{8,16} months. Most cases are minor; of patients presenting to the emergency department (ED), more than 90% can be definitively managed by the emergency physician. While most patients require follow-up with an otolaryngologist, only 5% to 10% of cases will require an ED consultation for management or admission.

CLINICAL PRESENTATION

Blood is supplied to the nasal mucosa from terminal branches of both the internal and external carotid arteries. ¹ The anterior and posterior ethmoidal arteries, branches of the internal carotid system, supply both the septum and lateral aspect of the nose superiorly. The sphenopalatine artery, also part of the internal carotid system, supplies the turbinates and meati posteriorly and the inferoposterior portion of the nasal septum. The superior labial artery, a branch of the external carotid artery, and the greater palatine artery, a branch of the internal carotid artery, supply the anterior portions of the septum and floor of the nasal cavity.

Nasal hemorrhage may present in a number of ways. Frequently, bleeding is minor and arrests in triage with properly performed compression of the nose. Although patients may attempt a number of unusual and unfounded techniques to arrest epistaxis, while in the ED, they should be instructed to firmly grasp and pinch the entire, soft, anterior portion of the nose and hold pressure for 10 to 15 minutes. If bleeding is not easily controlled, or there is any suspicion of airway compromise or hemodynamic instability, the patient should be brought directly to the treatment area.

Approximately 90% of nosebleeds are considered anterior, which means the bleeding can be visualized in the anterior portion of the nasopharynx. Anterior hemorrhage most frequently arises from Kiesselbach's plexus (also known as Little's area), an anastomotic network of vessels on the anterior portion of the nasal septum (Fig. 24.1). Posterior hemorrhage cannot be visualized directly, tends to be more severe, and is not amenable to simple outpatient therapy. Except in cases of trauma, epistaxis is typically localized to one side of the nose, and the source is frequently a single bleeding point.

Figure 24.1. Blood supply to Kiesselbach's plexus.

Occasionally, patients present with massive epistaxis that is initially confused with hemoptysis or hematemesis. If fresh blood is not clearly dripping out of the nose, examine the oropharynx under suitable light; blood dripping from the posterior nasopharynx confirms nasal hemorrhage.

DIFFERENTIAL DIAGNOSIS

Most cases of nasal hemorrhage are spontaneous and idiopathic. Other causes include facial trauma, ³ nose-picking (epistaxis digitorum), foreign bodies (especially in children, ⁷ the mentally retarded, and elderly institutionalized patients), and nasal or sinus infections. Iatrogenic causes include nasogastric and nasotracheal intubation, surgical complications, and overzealous treatment of self-limited hemorrhage. Hypertension has long been thought to be associated with epistaxis. However, whether hypertension predisposes to epistaxis remains unclear. ¹³ A deviated septum is a risk factor for recurrent epistaxis, as drying and cracking of the superficial nasal mucosa occurs at sites of turbulent airflow. Use of topical nasal steroid sprays may produce epistaxis through irritation of the nasal mucosa by the propellant.

Children nearly always present with anterior epistaxis associated with local irritation or recent respiratory infection. ⁷ Allergic rhinitis has been implicated as a common cause of recurrent epistaxis in children. ¹⁵

Posterior hemorrhage should raise suspicion for juvenile nasopharyngeal angiofibroma in young males, or squamous cell carcinoma in the Asian population. Osler-Weber-Rendu syndrome is characterized by a lack of contractile elements in the muscular wall of vessels, leading to arteriovenous malformations. Patients with acquired immunodeficiency syndrome (AIDS) may have thrombocytopenia from idiopathic thrombocytopenic purpura (ITP), splenomegaly, or drug use, or may present with a qualitative platelet disorder that may predispose to bleeding. ²⁰ Table 24.1 lists some of the many causes of epistaxis.

deformity precludes the use of Merocel.¹⁸

Epistaxis balloons (intranasal balloon catheters) are particularly useful in cases of intractable or posterior hemorrhage. Radiographic evidence has shown that these catheters work through multiple mechanisms, including direct tamponade of the bleeding vessel, tamponade of supplying vessels, occlusion of the posterior choana, and pressure on the inferior and middle turbinate arteries. Balloons are available in either anterior (single-balloon) or anterior–posterior (double-balloon) models. A valve affords access to each balloon. After checking the integrity of the balloons, the catheter is copiously covered with water-based lubricant or viscous lidocaine (petroleum-based materials may cause delayed rupture of the balloon¹⁷) and the catheter is inserted along the floor of the nose. The balloon should be inflated slowly to minimize pain. Air may be used initially, but saline or sterile water should be used in patients in whom the balloon will remain for more than a few hours.

Traditional anterior nasal packing is difficult for the novice, and should not be attempted until sufficient anesthesia is obtained. The nose should be packed with sterile petrolatum ribbon (0.5 to 1.0 in. wide) gauze, to which is added an antibacterial ointment to prevent the possibility of toxic shock syndrome. Soaking material used for prolonged packing in topical vasoconstrictors may lead to prolonged absorption and is contraindicated.¹⁹ Packing begins by grasping the ribbon about 6 in. from its end with the bayonet forceps. The ribbon is then placed in the nasal cavity as far back as possible, ensuring that the free end still protrudes from the nose. This first pass is then pressed onto the floor of the nasopharynx with the closed bayonets. The ribbon is then grasped about 4 to 5 in. from the nasal alae, the nasal speculum is repositioned so that the lower blade holds the ribbon against the lower border of the nasal alae, and a second strip is brought into the nose and pressed downward. This process is continued superiorly in a stair-step fashion until there is no room left in the nose. Both ends of the ribbon must protrude from the anterior end of the nose, and the ipsilateral nostril is covered with a piece of gauze and secured with tape.

Other alternatives to the traditional anterior nasal pack include calcium sodium alginate (Kaltostat), Oxycel, Avitene, and balloon tamponade. Topical thrombogenic agents such as gelatin sponge (Gelfoam) and microfibrillar collagen powder (Avitene) are useful in cases of epistaxis associated with coagulopathy when applied directly to the bleeding area. Packing with porcine fatty tissue is especially helpful in patients with thrombocytopenia or qualitative platelet disorders.

In the absence of either a suitable epistaxis balloon or a patient able to tolerate lengthy nasal packing, suitable nasal tampons can be constructed by cutting off the fingers of a sterile latex glove, packing them with rolled gauze or cotton balls, and securing the open ends with a silk suture. Two or three of these are then slathered in antibacterial ointment and placed in the nasal cavity, one above the other, until acceptable tamponade is achieved. If the ends of the silk sutures are left long, a dental roll may be secured outside the nasal alae to prevent the tampons from slipping into the nasal pharynx and causing obstruction.

Control of Posterior Epistaxis

Bleeding that begins with the sensation of blood in the posterior pharynx, bleeding that cannot be localized anteriorly, or bleeding that fails to arrest with anterior packing is considered posterior and will need to be managed in consultation with an otolaryngologist. However, bleeding should be controlled by the emergency physician using one of a number of available techniques.

The traditional method of posterior packing is cumbersome and should be replaced with the use of an epistaxis balloon or inflatable Foley catheter. Balloon catheters are easier to install, and equally efficacious, when compared with traditional posterior nasal packs.² Regardless of technique, posterior packing occludes the posterior choanae only, and requires some form of anterior pack. Once both the posterior choana and the anterior nares are occluded, the entire nasopharynx fills with blood. Hence, if the posterior pack dislodges, a large amount of blood can be aspirated.⁴ Posterior packs are uncomfortable and fraught with complications, including hypoxia, hypercarbia, exacerbation of obstructive sleep apnea, aspiration, hypertension, bradycardia, arrhythmias, myocardial infarction, and death.^{5,23} Inflatable balloon catheters designed with a central airway may limit or reduce hypoxia.

If an epistaxis balloon is used, the catheter is first placed as far into the nose as is possible. Next, the posterior balloon is inflated slowly with 4 to 5 mL of water or saline and the catheter is pulled gently forward to fit snugly in the posterior choana. Finally, the anterior balloon is filled with saline until the bleeding stops, the pain is too great, or bowing of the septum is noted. Pressure necrosis and adhesions may result from overinflation, and the amount of fluid placed in each balloon should be recorded.

If a Foley catheter is to be used, a 12F to 16F catheter with 30-cc balloon is placed into the nose along the floor of the nasopharynx until the tip is visible through the mouth in the posterior pharynx. It is then slowly inflated with 15 mL of saline, pulled anteriorly until it is firmly set against the posterior choanae, and secured into place with an umbilical clamp wrapped around dental roll or matted 4x4s to avoid direct pressure necrosis of the ala or columnella.

A traditional posterior pack is fashioned from 4x4-in. gauze rolled into a 1-in. roll and secured with three silk sutures or umbilical tapes. This pack is brought into position in the posterior choana by passing two small, red rubber catheters through each nostril and back out of the mouth, securing each of the two outer sutures to the catheters and pulling the catheters out of the nose again, drawing the pack through the mouth and into position. Each of the sutures is tied together over a gauze buttress to prevent pressure necrosis of the columnella. The third suture is brought out through the mouth and taped to the cheek to facilitate removal.

DISPOSITION

Because of the number of serious causes of epistaxis, including tumors in the elderly and foreign bodies in children, all patients who present to the ED with epistaxis should receive follow-up for a complete nasal examination. Patients should be instructed to avoid blowing the nose, straining, bending over, and participating in sports or other strenuous activity, and to sneeze with their mouth open. Home humidifiers and saline nasal sprays may be helpful in drier, colder months, and patients should avoid any manipulation of the nose. Discontinuation of offending drugs should be individualized and based on the particular indications for each. Patients with a grossly excoriated anterior mucosa should be instructed to gently apply topical antibiotic ointment to the site. Children with recurrent epistaxis and no known bleeding disorder should be referred for coagulation studies.

All patients with anterior packing should receive follow-up with an otolaryngologist in 48 to 72 hours. Anterior nasal packing prevents normal surgical drainage of the sinuses (and frequently the eustachian tubes), and patients should be placed on a penicillin or first-generation cephalosporin. Oral pain medications also should be provided.

All patients with posterior packing need to be admitted, and consideration should be made toward obtaining an arterial blood gas analysis. Clinicians should also strongly consider admitting frail, elderly, cardiac, or chronic obstructive pulmonary disease patients who require anterior packing. Many consulting otolaryngologists are opting for early management of posterior bleeds with endoscopic cautery under direct visualization in the operating suite, early surgical control using arterial ligation, or referral to invasive radiology for selective arterial embolization.^{9,14} If time permits and bleeding is not severe, early consultation may spare patients with posterior nasal hemorrhage the discomfort of posterior packing altogether.

COMMON PITFALLS

- Failure to prepare the necessary equipment for control of epistaxis leads to unnecessary inconvenience and delays.
- Epistaxis in young children is rare and should prompt a search for a foreign body.
- Failure to identify the source of bleeding or to place an anterior pack properly leads to rebleeding and necessitates a return to the ED for repacking.
- Failure to identify posterior epistaxis until after an anterior pack has been placed necessitates completely unpacking the nose so a posterior pack can be placed.

FOREIGN BODIES IN THE EAR

Complaints of aural foreign bodies occur routinely in the emergency department (ED), especially in children.^{4,21} A recent 5-year study of 191 patients presenting to an ED or referred to an ear, nose, and throat (ENT) clinic, identified 27 different objects inserted in the ears of patients ranging in age from 10 months to 17 years, with 74% of patients less than 8 years of age.² Heading the list of objects were beads, followed by plastic toys, pebbles, insects, and popcorn kernels.

Despite this documented frequency, there is a paucity of information regarding the treatment of aural foreign bodies. Perhaps this explains the high ENT referral rate following unsuccessful attempts at removal in the ED.⁶ Additionally, in pediatric-aged patients, the smaller size of the anatomic structures, coupled with their exquisite sensitivity, and the variable degree of patient cooperation impede object retrieval. Retained foreign bodies or trauma caused by repeated attempts at removal of objects from the external auditory canal (EAC) can lead to significant morbidity.

CLINICAL PRESENTATION

The presentation of a foreign body in the EAC differs depending on the patient's age. Adults typically complain that something is in the ear. Usually, this occurs after the patient has inserted an object into the EAC, which then becomes lodged, or when an insect crawls into the ear while the patient is asleep. What motivates children to stick stuff in their ears has not been well studied. It seems more associated to the presence of preexisting irritation than to etiologies of cognitive impairment, imitation of adult behavior, or playing make-believe.⁹ Diagnosing EAC foreign bodies in infants, preverbal children, or cognitively impaired adults can be much more difficult. The inability to communicate or fears of punishment often obscures the history. In this situation, common presenting signs and symptoms include otalgia, tugging at the ear, bleeding, otorrhea, tinnitus, or hearing deficits. Unusual symptoms, such as persistent coughing and hiccups, also have been reported.^{2,18}

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes otitis media, otitis externa, cerumen impaction, tympanic membrane perforation, cholesteatoma, and EAC trauma, including lacerations or hematomas.

EMERGENCY DEPARTMENT EVALUATION

A pertinent history regarding previous ear infection, disease, or trauma (including tympanic membrane perforation) is obtained prior to any instrumentation. The size and shape of the foreign body, along with the dynamics and duration of placement in the EAC, are ascertained. Associated symptoms, such as perception of foreign body movement, hearing loss, vertigo, or gait disturbances, are elicited. If a patient complains of severe ear pain due to object movement or sound within the ear, the presence of a live insect should be suspected. In this instance, most patients will be incapable of completing the usual history and physical examination prior to intervention. Various solutions have been instilled to kill or paralyze insects before removal. Microscope immersion oil has been shown *in vitro* to suffocate and still cockroaches most quickly.¹⁷ Anecdotally, mineral oil or 2% lidocaine has also been used successfully. Personal and home hygiene concerns should be discussed later in the patient encounter.

Most of the EAC has a very thin layer of epithelium that is exquisitely sensitive and highly vascular. Its cylindrical shape with two points of anatomic narrowing ([Fig. 25.1](#)) helps explain why objects easily inserted may not exit spontaneously. Removal becomes more difficult when the objects are located within the medial two-thirds of the EAC. Patients must be positioned comfortably and examined gently. Forewarning patient of the anticipated discomfort, and advising them to remain still during the examination, minimizes pain and prevents further advancement of the foreign body. Retracting the pinnae in a posterosuperior direction to straighten the canal, and using a hand-held halogen otoscope with a large-sized speculum, will optimize views of the EAC and tympanic membrane. Children usually require restraint, and possibly sedation, to receive a proper examination. It is best to have the child seated on the parent's lap, with the child's arms and torso held securely by the parent. Another adult should assist by holding the child's head immobile for the examination. Nitrous oxide has been suggested as a useful adjunct to the examination in children and adults.⁶

Figure 25.1. The anatomic narrowing of the external auditory canal.

EMERGENCY DEPARTMENT MANAGEMENT

There are several different tools and described techniques for foreign body removal. EDs should keep a prepared tray containing the instruments and equipment needed (Table 25.1). As in the examination, adequate patient cooperation is essential for successful removal and to reduce the risk of complications. Analgesia and sedation, with agents such as ketamine, are often required to achieve this cooperation and are preferred over physical restraint.

Foreign-body forceps (A)	Barnes tip suction (I)
Bayonet forceps (B)	Schuknecht foreign-body remover (J)
Alligator forceps (C)	Fogarty biliary catheter
Hartman forceps (D)	Cyanoacrylate glue
Nasal speculum (E)	Topical Lidocaine (4%)
Right-angle hook (F)	Topical vasoconstrictor
Ear curette (G)	Auralgan
Frazier suction tube (H)	

Letters in parentheses refer to Figure 25.2.

TABLE 25.1. Equipment Tray for Foreign Body Removal

Irrigation often removes aural foreign bodies expediently and is minimally invasive. As a prerequisite, tympanic membrane integrity must be confirmed by pneumatic otoscopy. Tap water or saline solutions are suitable irrigants and should be warmed to body temperature to prevent patient discomfort and dizziness during the procedure.¹⁰ Commercial irrigator systems used for cerumen removal are available for this purpose. Alternatively, a 14- or 16-gauge angiocatheter attached to a 60-mL syringe works effectively. Irrigation should be avoided in the treatment of hygroscopic substances, such as vegetables, beans, or rice. Given the potential for swelling worsening the impaction, direct instrumentation for removal is advised.

Irrigation is absolutely contraindicated in the removal of disk batteries. Moisture promotes the breakdown of the battery casing, which allows the concentrated alkali electrolyte contents to leak into the EAC. Tissue damage secondary to liquefaction necrosis and electrolysis can be severe.² Disk batteries need prompt removal under direct visualization. Repeated attempts at removal in the ED are also strongly discouraged, as bleeding will lead to similar complications.

Suction can also be used to remove impacted foreign bodies, especially those with smooth contours. The flange tip of flexible intravenous tubing can be inserted adjacent to smooth foreign bodies under direct visualization, and suction then applied.^{9,21} This technique is minimally invasive and presents little risk should an uncooperative patient move during the procedure. Alternatively, various suction tips, such as the Frazier or Barnes tip, and the Schuknecht foreign body remover are advocated for use in these situations² (Fig. 25.2). Unfortunately, the potential for complications is higher when rigid instruments are used within the EAC.

Figure 25.2. Selected instruments used for foreign-body removal. (A) Foreign body forceps. (B) Bayonet forceps. (C) Alligator forceps. (D) Hartman forceps. (E) Nasal speculum. (F) Right-angle hook. (G) Ear curette. (H) Frazier suction tube. (I) Barnes suction tube. (J) Schuknecht foreign-body remover.

Certain irregularly shaped objects, including insects, lend themselves to direct manipulation with alligator forceps under direct visualization via an otoscope. Microscopic inspection of the retrieved insect is advised to confirm that it has been removed completely. Organic material may be carefully crushed and brought out in sections if object dimensions prevent intact removal.

Alligator forceps should not be used with round, smooth objects or those with polished convex surfaces, such as disk batteries, due to the risk of medially advancing the object deeper into the EAC. In this instance, the right-angle hook can be used to reach beyond the object to coax it out.^{2,6} Cyanoacrylate glue can be used to adhere the object to an applicator (e.g., the end of a straightened paper clip, a swab stick, or bristles of a fine paint brush).²⁵

Once the object has been removed, the EAC and tympanic membrane are carefully reexamined for the presence of aural trauma, including abrasions, lacerations, or inflammation. Clinicians should complete a bilateral examination for detection of multiple or previously missed foreign bodies. Given the sensitive nature of the EAC, a topical anesthetic such as antipyrine–benzocaine (Auralgan) is recommended for a few days following a foreign body removal. Patients with an inflamed EAC can be treated with antibiotic otic drops and follow up with their doctor.

DISPOSITION

If the emergency physician cannot remove the aural foreign body easily or if more than minor canal trauma is sustained during the attempted removal, the patient is referred to an ENT clinic within 12 to 24 hours. Putty impaction is a problematic foreign body and also falls into this semiurgent follow-up category. Putty had been recommended to plug or waterproof the EAC in children with tympanostomy tubes. These products are difficult to extract, with piecemeal removal the norm.²⁶ Large impacted pieces usually require otomicroscopic removal to avoid EAC trauma.

Immediate ENT consultation in the ED is necessary for retained disk batteries, or sharp objects wedged against the EAC or tympanic membrane, when standard removal attempts have failed.

Indications for operative extraction usually involve sharp or wedged objects, especially in patients with existent injury to the EAC or tympanic membrane. Age at presentation has also been shown to be the most significant factor associated with the need for general anesthesia. In one study,² fully 88% of patients needing operative removal were children under 7 years of age at the time of presentation. These children would not tolerate repeat attempts at object removal.

COMMON PITFALLS

- The diagnosis of an aural foreign body is frequently missed because it is not suspected or is misdiagnosed in the setting of draining ear infections. All children under age 8 presenting to the ED should have both ears examined.

- Failure to recognize special circumstances involved in the management of foreign bodies such as disk batteries, putty, and insects, especially in young children
- Failure to consult ENT early for unsuccessful object removal in the ED. Persistence in removal attempts should be discouraged, as they cause decreased patient cooperation, increased risk of trauma, and increased likelihood of operative extraction.
- Failure to recheck the EAC after foreign body removal leads to missed or retained foreign bodies

FOREIGN BODIES IN THE NOSE

Nasal foreign bodies seem limited only by the dimensions of the patients' nares, and they occur predominantly in preschoolers. Food, followed by beads, paper, and parts of toys, are the common picks for insertion in the worst offenders, children aged 2 to 3 years old.^{4,7} Disk batteries remain the foreign bodies with the greatest potential for significant permanent morbidity.¹ Myiasis, or parasitic involvement, of the nose has been reported in the tropical regions of the United States, particularly among compromised hosts: diabetics, the elderly, and the chronically ventilator dependent. Fly maggots, ascarids, and worms are among the most commonly reported animate foreign bodies.²⁶

The nasal cavity has three turbinates along the lateral wall, which impair visualization and facilitate foreign-body entrapment. Differentiating between the child with a simple upper respiratory infection and the one with a purulent discharge due to a stashed gumball continues to challenge clinicians.

CLINICAL PRESENTATION

Patients presenting to the ED for this problem usually come in two varieties: the obvious patient, observed to have placed an object into the nose; and the obscure patient, classically presenting with foul pus copiously pouring out of a single nostril. Other presenting complaints include unilateral nasal obstruction, epistaxis, intermittent sneezing, or nasal pain with fever. Occasionally, nasal or facial cellulitis can be the only clue to a long-standing foreign body. Another rarely reported presentation is that of bad body odor, or bromhidrosis, without any nasal symptoms.²³ Harbored objects can go undetected in asymptomatic patients for extended periods, with incidental discovery on routine radiographs. Patients with parasitic involvement frequently report bilateral symptoms and elevated temperature.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of this entity includes simple sinusitis, tumor, and epistaxis unrelated to a foreign body. Nasal polyps also may mimic a foreign body.

EMERGENCY DEPARTMENT EVALUATION

A thorough, yet gentle physical examination is performed to minimize patient anxiety. Position the patient's head upright, for tilting the head backward (neck extended) limits the view obtained of the roof of the nasal cavity. Unlike for aural foreign bodies, sedation to aid examination or removal of nasal foreign bodies is rarely necessary, given the greater dimensions of the nasal vestibule and reduced mucosal sensitivity. Nasal obstruction can be confirmed visually by placing a mirror under the patient's nose and noting an absence of condensation moisture at the opening of the affected nostril during breathing. The sinuses are transilluminated for air-fluid levels or opacification and are percussed to assess for tenderness reflective of concurrent sinusitis.

To perform an adequate examination of the nasal cavity interior, a strong light source, preferably on a headlamp, and the largest nasal speculum the nostril can accommodate are best. For greatest visualization, insert the speculum until it is flush with the opening of the nostril and perpendicular to the nose. If a foreign body is not located on the initial direct examination, the nasal mucosa is prepared for further exploration by inserting cotton-tipped swabs soaked with either a 4% cocaine solution or a 1:1 mixture of a topical vasoconstrictor and anesthetic. Such nasal cavity preparation reduces mucosal inflammation, potential for bleeding, and patient discomfort.

Most foreign bodies are located immediately anterior to the middle turbinate or on the floor of the nasal cavity just below the inferior turbinate. Nasal radiographs may be helpful if a foreign body is strongly suspected but not seen on examination. Glass objects larger than 2 mm and gravel larger than 1 mm are radiopaque. Organic materials such as wood are best seen by computed tomography (CT) scan.¹³

EMERGENCY DEPARTMENT MANAGEMENT

Many techniques have evolved for noninvasive removal of nasal foreign bodies,⁷ and the emergency physician should be familiar with several options. Perhaps the simplest technique is to encourage the cooperative patient to blow his or her nose with the unaffected nostril occluded. For this maneuver to be successful, the nasal cavity must be adequately prepared with topical vasoconstrictors. For children too young to cooperate, a useful variation on this technique, the positive pressure method,³ may be all that is necessary for object expulsion. The key elements are to keep the patient's unaffected nostril occluded, while the parent blows a puff of air into the child's mouth. Alternatively, an Ambu bag and a tight-fitting mask can be used instead of the mouth-to-mouth technique. No studies have been undertaken to document the safety or efficacy of this method.

Long alligator forceps are the best instrument for removing irregularly shaped or compressible objects. The flange-tipped suction catheter connected to wall suction can be used to remove round or smooth-surfaced objects.^{7,9} Alternatively, a Fogarty biliary catheter can be passed beyond such round objects, inflated with 1 or 2 mL of fluid, and then pulled backward to bring the object within easy grasp.²¹

Other rigid devices, including the right-angle hook, can be positioned behind objects to retrieve them by withdrawing the instrument and object together. Removal of disk batteries is particularly amenable to this method.^{1,7} Recall, that disk battery retrieval is a considerably more delicate endeavor than removal of most other foreign bodies. Because these batteries are capable of producing rapid tissue destruction on contact with moisture present in the nasal cavity, care must be taken to avoid bleeding or crushing the battery casing. In the case of vegetable matter, minimal manipulation is advised, to reduce the potential for disintegration and possible retention.

When using these techniques, care must be taken to avoid aspiration of the foreign body. This complication occurs when the object is pushed further into the posterior nasopharynx during the removal attempt. If the foreign body is precariously perched, such that aspiration seems a significant risk, removal should occur in the operating room after the airway has been protected.

Removal of parasitic infestations is best left to ENT. Usually by the time the infestation is detected, serious tissue destruction has already occurred. Extensive irrigation and debridement, in combination with antiparasitic medications, are used to eradicate the infestation.²⁶

Once successful foreign body removal is achieved, the nasal cavity must be carefully reinspected. Evidence of multiple foreign bodies, trauma, pressure necrosis, or secondary infection is noted. If significant epistaxis has been induced during the removal procedure, 3 days of nasal packing is prudent. Patients leaving the ED with either nasal packs in place or evidence of sinusitis secondary to foreign-body impaction need oral antibiotics and close follow-up. Therapy should cover skin and upper respiratory flora. In the case of sinusitis, 14 days of therapy is recommended. Patients with nasal packs should receive prophylaxis until the packs are removed. Antibiotics prevent the increased likelihood of sinusitis and toxic shock observed with packing.

DISPOSITION

Urgent referral within 12 to 24 hours to an ENT clinic should be made when a nasal foreign body is strongly suspected but cannot be confirmed in the ED. Referral is also appropriate to follow up focal sinusitis or limited facial cellulitis treated with oral antibiotics and discharged from the ED.

Immediate ENT consultation is obtained in cases of (1) a disk battery that cannot be removed, (2) animate infestation with significant tissue destruction, (3) any case in which attempts at removal place the patient at risk for aspiration, and (4) extensive infection (e.g., spreading cellulitis).

COMMON PITFALLS

- Missed foreign body because the diagnosis was not considered or the examination was inadequate
- Aspiration of the foreign body because the object was pushed further into the nasopharynx during the removal attempt
- Missed or retained foreign body because reexamination was not performed after initial object removal
- Increased patient morbidity due to failure to consult ENT early for unsuccessful removal attempts or special circumstances such as disk batteries and parasitic infestations
- Failure to diagnose and treat sinusitis caused by foreign body impaction

FOREIGN BODIES IN THE THROAT

A foreign body in the throat is a common complaint in the ED, and it tends to occur at the extremes of age. Children often present with symptoms consistent with partial or complete airway obstruction due to foreign body aspiration. Tragically, aspiration is the cause of death in at least 300 children each year in the United States, with those under 2 years of age being the most commonly affected.²⁴ Overall, up to 80% of foreign bodies accidentally aspirated or ingested occur in the pediatric population. The foreign bodies children choose tend to be small objects such as peanuts, or objects not usually thought of as ingestible (e.g., coins, toys, screws, safety pins).

In adults with an intact swallowing mechanism, the upper airway is protected and throat foreign bodies tend to lodge in the posterior oropharynx. Elderly patients who wear dentures are at increased risk for throat foreign bodies because of the associated decrease in the palatal sensation and secondary impairment of swallowing. Other sources of functional, neuromuscular, and anatomic impairments of swallowing also increase in incidence with age. Likewise, the presence of structural cerebral dysfunction or altered sensorium, or desire for secondary gain may predispose patients to having a throat foreign body. In one prospective study of adults presenting to or referred to an ENT service for foreign body sensation, only 31% actually had a true foreign body, though most could associate the onset of symptoms to eating fish or chicken.¹⁴

CLINICAL PRESENTATION

Aspiration of a foreign body is the most common cause of acute airway obstruction. Symptoms of partial airway compromise include cough, choking, and dyspnea. Stridor places the foreign body in the laryngotracheal area, while wheezing and retractions indicate a bronchial location. Likewise, gastrointestinal impaction can occur at several levels. Odynophagia favors a pharyngeal foreign body, while dysphagia, drooling, and inability to eat suggest lower esophageal obstruction.

Children often present late, with vague histories and nonspecific symptoms, or may be asymptomatic following foreign body ingestion. Another pediatric presentation is that of partial airway compromise because of extrinsic compression from an intraesophageal foreign body pressing on the posterior aspect of the immature trachea.

Acute esophageal impactions in adults typically present within 12 hours of symptoms that began while eating either fish or chicken.^{12,14} Adults can reliably localize the position of the object. Patients who sense an object in the area under the mandibular angle often have impaction in the pharynx, including the base of the tongue, tonsils, vallecula, and pyriform recesses. Overall, these areas are the most common sites where sharp objects impale. If patients point lateral to the trachea and superior to the clavicle, the object is usually lodged in the cervical esophagus just below the cricopharyngeus muscle. Finally, patients with substernal chest pain often harbor an esophageal object at the level of the aortic arch or gastroesophageal junction. Symptoms that help predict an actual retained foreign body include severe pain at rest, inability to swallow secretions, otalgia, cough, dysphagia, hoarseness, and lateralizing pain that may progress.^{12,14}

DIFFERENTIAL DIAGNOSIS

In children, the differential diagnosis includes croup, epiglottitis, reactive airway disease, pneumonitis, neoplasm, and a foreign body in the lower esophagus.

In adults, the most common diagnosis after a true foreign body is residual oropharyngeal trauma, after a spontaneously relieved obstruction. Infection, abscess, neoplasm, and distal esophageal impaction also are possible etiologies.

EMERGENCY DEPARTMENT EVALUATION

Regardless of patient age, the foremost goal of the emergency physician is to differentiate the patient presenting with airway involvement from the one with pharyngoesophageal signs and symptoms. A foreign body causing partial obstruction of an airway can suddenly result in a complete obstruction. Total airway obstruction causes the patient to spiral rapidly through three stages: alert, awake, and apneic; then unconscious with a pulse; followed by cardiopulmonary arrest.

Children with partial airway compromise and symptoms of a throat foreign body require vigilant observation and readiness to intervene immediately to manage the airway. If possible, the emergency physician should examine the cooperative child's oropharynx to diagnose the foreign body. However, if the child is uncooperative, examination of the oropharynx and use of restraint or sedation should be avoided pending radiographic studies.

Radiographic investigation can be vital to diagnosing the presence of a foreign body. Anterior–posterior (AP) and lateral soft-tissue neck radiographs should be obtained to make the diagnosis of radiopaque laryngeal or esophageal foreign body and to exclude epiglottitis from the differential. Similarly, standard two-view chest radiographs are indicated to assess the substernal esophagus and airways for radiopaque objects. If these radiographs are obtained off-site, experienced personnel must accompany the patient to assess airway status constantly and be prepared to intubate immediately.

In general, an AP film will show an *esophageal* coin face-on, while the lateral film will depict a *tracheal* coin edge-on.^{12,21} Comparison radiographs, such as inspiratory and expiratory phase films and decubitus films, can aid in the diagnosis of aspirated foreign body. An expiratory view should demonstrate air-trapping and mediastinal shift in the setting of an endobronchial obstruction. Dependent positioning in a normal lung will force air out on expiration, allowing the hemidiaphragm to rise. However, with an endobronchial foreign body acting like a ball-valve, air-trapping occurs on expiration. This results in abnormal hyperaeration and failure of the hemidiaphragm to rise in dependency. Confirmed aspirated foreign bodies or suspicion of radiolucent objects in the lungs mandate immediate pulmonary consultation. Direct bronchoscopy, CT, and occasionally magnetic resonance imaging (MRI) can be useful adjunctive studies for certain radiolucent objects.¹⁶

In adults and cooperative children, there are several physical examination findings that suggest foreign-body presence. Specifically, pooling of oral secretions, presence of stridor or inspiratory wheeze, and subcutaneous emphysema of the neck due to esophageal perforation are found. A careful examination of the posterior oropharynx should be made, with special attention to the tonsillar fossae and posterior tongue, where objects are often missed.^{14,27} Dentition is assessed for missing teeth or dentures. If the initial examination is unrevealing, the lower portion of the pharynx is examined. A dental mirror and laryngoscope with a # 3 MacIntosh blade can be used to depress the tongue for better visualization. Obvious foreign bodies noted on the initial examination may be removed using bayonet or Magill forceps. A more extensive examination can be performed using fiberoptic nasolaryngoscopy. The area of the vallecula and the pyriform recesses should be scrutinized carefully. Any oropharyngeal lacerations or abrasions are noted, and can fully mimic the presence of a true foreign body.

Soft-tissue films of the adult neck are less valuable in the diagnosis of oropharyngeal foreign body due to their low sensitivity and specificity.¹⁴ Similarly, more than 30% of radiolucent masses are undetected on initial radiographs.¹² ENT consultation should be obtained promptly if the diagnosis of foreign body is confirmed in the ED or if a falsely negative initial examination is suspected. Often, an endoscopic evaluation, esophagram, or CT will be modalities for further patient assessment.

EMERGENCY DEPARTMENT MANAGEMENT

Apnea in the ED must trigger immediate action by the emergency physician. First, perform a jaw thrust maneuver to open the airway. Examine the pharynx for the presence of a foreign body. If present, remove it with a finger sweep, suction, or forceps. Proceed to direct laryngoscopy and one attempt to remove any deeper obstruction, if visualized. Persistent apnea strongly suggests a subglottic foreign body, requiring an open cricothyrotomy in patients over 12 years old, or needle cricothyrotomy in underaged children.⁸ Once an emergency airway is established, provide oxygen and ventilate.

The type of foreign body and its dimensional characteristics influence the likelihood of airway obstruction or esophageal impaction, which directly affect management.

For example, children ingest mostly inorganic foreign bodies (coins, pins, and toys) but tend to aspirate particulate organic material (peanuts, food, and seeds). Adults usually present with large food bolus obstructions within the esophagus and less commonly, the airway. Overall, when a foreign body is ingested, 80% to 90% will enter the gastrointestinal tract, with the remainder landing in the tracheobronchial tree. ²⁷

Ingested foreign bodies that are smooth, round, and smaller than a penny will pass uneventfully in most children and adults. ^{11,12,14,15} Disk batteries in the esophagus are an exception and constitute a true emergency. They should be promptly removed endoscopically to avoid well-described fatalities due to esophageal corrosion, necrosis, and perforation. ^{19,27} For other such impacted objects (coins, toys, etc.), extraction can occur using nonendoscopic methods (Foley catheter, magnetic tube) or endoscopic techniques. The interventional removal strategy chosen should take cost into consideration. The success rate for removal is 95% to 100%, and the complication rate is 0% to 2%, regardless of technique used. ^{19,22}

The standard Foley catheter method ^{22,27} is to insert a 12F to 16F Foley nasally or orally to below the level of the foreign body, with the patient in the Trendelenburg position on a fluoroscopy table. The balloon is inflated with barium contrast and the catheter is slowly withdrawn, backing the object out of the esophagus. Magnetic foreign bodies are extracted by magnetic tube also under fluoroscopy. ¹¹ After successful removal, an esophagram is performed to confirm the integrity of the esophagus.

Sharp objects are likely to perforate immediately; therefore, open safety pins, razor blades, toothpicks, and so forth, require immediate endoscopic retrieval, and that failing, surgical intervention. ^{5,15}

Another “time bomb” is the cocaine-packed condom, intentionally ingested by drug traffickers. Fatalities have been reported when these condoms rupture in the gastrointestinal tract. Large packets that become impacted in the esophagus can be confirmed on plain film. With this ingestion, endoscopic removal is contraindicated because of the associated risk of condom rupture. Emergency surgical intervention is considered as first-line therapy. ^{15,22,27}

Completely obstructing esophageal food (or meat) impactions are almost exclusively seen in adults, and should be urgently removed endoscopically. ^{22,27} However, a variety of chemical means had been reported in the literature previous to the advent of endoscopy for esophageal disimpaction. *Papain* was recommended to enzymatically dissolve a meat bolus. Unfortunately, its nonspecific action was also shown to weaken the esophageal wall and lead to perforation. ^{15,22} The use of *gas-forming* agents fell to similar complications. *Glucagon* may help with lower obstructions by decreasing tone at the gastroesophageal junction alone, to allow an object to pass. It has several unpleasant side effects, however, and is contraindicated in patients with pheochromocytoma, insulinoma, or hyperglycemia, or in those suspected of having a sharp foreign body. Anecdotal success with *atropine*, *benzodiazepines*, *calcium channel blockers*, and *nitroglycerin* has not been significantly better than with glucagon. ¹⁵ Basically, the risks associated with most of these agents—depressing the gag reflex and promoting aspiration or esophageal perforation due to vomiting—continue to prevent their widespread application.

DISPOSITION

ENT consultation should be obtained in all cases of retained laryngeal foreign body or when the possibility cannot be excluded. Flexible bronchoscopy with channel biopsy forceps may be used to remove objects not accessible with bayonet forceps. Patients found to have minor pharyngeal trauma as the basis of their symptoms may be safely discharged. The possibility of subsequent infection must always be discussed with the patient.

COMMON PITFALLS

- Significant morbidity and mortality have occurred in cases in which the airway was not aggressively managed in children with a laryngeal foreign body. Partial obstruction may become complete obstruction at any time.
- Laryngeal foreign body must be considered in children who present with croup, particularly those who do not respond well to conventional therapy.
- Deep-tissue abscess and mediastinitis are potential complications of missed laryngeal or pharyngeal foreign bodies.
- There is a high incidence of underlying esophageal pathology in cases of esophageal food bolus impaction. These patients should have a follow-up swallowing study to evaluate for this possibility once the acute problem is relieved.

Acute hearing loss has not been well defined. For the purposes of this chapter, however, it is defined as a loss of hearing that causes the patient to come to the emergency department.

The overall incidence of acute hearing loss is unknown because of the diversity of diseases involved. Sudden neurosensory hearing loss (NSHL) is estimated to occur in 5 to 20 patients per 100,000.^{1,5} It most commonly occurs in patients in their sixth decade.¹

There are two major groups of patients presenting with acute hearing loss. The first includes those whose hearing loss is due to conductive problems. Occasionally, a patient suffers acute hearing loss from both conductive and neurosensory problems. For example, a temporal bone fracture may damage the eighth nerve or the cochlea, as well as the tympanic membrane and the ossicles; it may also block conduction through the presence of a blood clot in the middle ear or external auditory canal. The second group includes those who suffer sudden NSHL (i.e., loss due to pathology in, or medial to, the cochlea). Sudden NSHL is defined as any hearing loss, ranging from instantaneous loss to that which occurs over a period of time (up to several days). Varying degrees of NSHL must be documented on an audiogram.^{1,6,11,17} Because audiometric testing equipment is unavailable in the emergency department, such definitions are of little use to the emergency physician.

PATHOPHYSIOLOGY

The pathophysiology depends on the underlying disease process. Sound is conducted through the external auditory canal and vibrates the eardrum, which in turn vibrates the ossicles and the fluids of the inner ear. Any disruption of the ossicles, the middle ear, or conduction of noise to the eardrum can cause a conductive hearing loss.¹² NSHL is caused by problems in the cochlea and central auditory pathway, which are generally problems with hair cell function or the acoustic nerve or brain stem.

ETIOLOGY

The etiology also depends on the disease process that has caused the hearing loss. In many cases of conductive loss, the cause can be determined and sometimes treated in the emergency department. Some causes of NSHL are well known and understood (ototoxic drugs, noise exposure, perilymph fistula, temporal bone trauma).^{1,2} In these cases, the cause frequently can be determined through the history, and the appropriate treatment begun. Idiopathic sudden NSHL is thought to have various causes, including viral infection,^{18,20} vascular problems, and autoimmune disease.^{1,3,4,6,9,20} The cause in an individual case, however, is often unknown.

OUTCOME

Most conductive hearing losses respond well to treatment or improve without treatment (e.g., cerumen impaction, acute otitis media). Ossicular problems and tympanic membrane perforations can usually be repaired with surgery. Recovery of acute NSHL depends on the underlying cause; most known causes, such as trauma or ototoxic drugs, have a fairly poor prognosis. In cases of sudden idiopathic hearing loss, patients with the least hearing loss tend to do better; those with more severe hearing loss generally do not do as well, even with treatment. Children and those over 40 years of age have a poorer prognosis.¹ Patients with vertigo have a poorer prognosis.^{1,6,13} If the patient truly has NSHL, particularly if it is profound, the physician should remember the poor prognosis and not be overly optimistic with the patient.

CLINICAL PRESENTATION

The typical presentation of a patient with sudden hearing loss is an ambulatory patient complaining of unilateral hearing loss, sometimes noted because of an inability to use the phone with that ear. There may be other complaints, such as vertigo, pain, aural drainage, facial nerve paralysis, or trauma. These associated problems may be so severe as to override the hearing problem; in some cases, the patient may not even complain of the hearing loss immediately. Occasionally, the patient will not know how long the hearing loss has been present; in such instances, it can usually be assumed to have been only a few days. Sudden hearing loss is usually not life-threatening; however, diabetic patients develop malignant external otitis, which, if untreated, has a mortality rate of 70% to 80%. Additional signs and symptoms depend on the underlying cause of the acute hearing loss.

DIFFERENTIAL DIAGNOSIS

Because acute hearing loss is a presenting complaint or a finding with multiple causes, it is more appropriate to consider possible causes rather than a differential diagnosis. Causes of conductive hearing loss, such as foreign body, acute infection, or cerumen impaction, can usually be determined and treated. In some cases, the cause of NSHL can be defined (e.g., ototoxic drugs), but in many cases it is idiopathic. [Table 26.1](#) and [Table 26.2](#) list common causes of acute hearing loss.

Cause	Signs/Symptoms	
Otitis media and externa	Acute otitis media	Rapid loss Pain on pulling or tugging Pain behind the eardrum Fever Tinnitus
	Acute external otitis	Itching/burning Pain on pulling pinna Pain on touch with drainage Swelling
Trauma	External otitis	Itching/burning Pain on pulling pinna Pain on touch with drainage Swelling
	Otitis media	Itching/burning Pain on pulling pinna Pain on touch with drainage Swelling
	Temporal bone fracture	History of pain/discomfort in cold water Hearing loss Tinnitus Vertigo Rapid loss behind the ear Redness behind the ear Pain
Tinnitus	Cholesteatoma	Chronic ear pain Other symptoms of infection
	Benign paroxysmal positional vertigo	Fluctuating hearing loss Vertigo Nausea
Impaction/Obstruction	Trauma to external auditory canal or tympanic membrane perforation	Loss of consciousness Chronic ear pain/discharge Blood in middle ear Tinnitus Vertigo
	Foreign body	History of sharp object injury Pain Fluctuating hearing loss Redness and discharge behind the ear Physical exam will confirm

TABLE 26.1. Differential Diagnosis of Conductive Hearing Loss

Category	Findings	Diagnosis
Conductive hearing loss	External auditory canal	Foreign body, cerumen impaction, otitis externa
	Tympanic membrane	Otitis media with effusion, otitis media with purulent discharge, perforation, ossicular chain disruption
	Middle ear	Ossicular chain disruption, ossicular fixation, ossicular discontinuity
	Inner ear	Meniere disease, vestibular neuritis, labyrinthitis
Sensorineural hearing loss	History	Acoustic neuroma, multiple sclerosis, stroke, meningitis, encephalitis, trauma, ototoxic drugs, aging
	Physical examination	Normal
	Investigations	Audiogram, CT scan, MRI, vestibular evoked myogenic potentials, otoacoustic emissions, brainstem auditory evoked potentials
	Management	Medical, surgical, hearing aids, cochlear implants

TABLE 26.2. Differential Diagnosis of Neurosensory Hearing Loss

EMERGENCY DEPARTMENT EVALUATION

History

The history is the most important element when evaluating acute hearing loss, particularly in the emergency department where auditory testing is unavailable. The physician should inquire about

1. Pain or drainage from the ear, which may indicate infection
2. A precipitating event, such as airplane travel or scuba diving (barotrauma)
3. Placement of a foreign body, which is usually, but not always, known
4. Exposure to ototoxic drugs or toxins²

The social history, including workplace, may indicate exposure to noise or toxic substances. The use of a cotton-tipped applicator can cause cerumen impaction or trauma to the tympanic membrane or middle ear, resulting in a blood clot in the ear canal, tympanic membrane damage, or ossicular disruption. Temporal bone fractures are associated with trauma and, usually, loss of consciousness. The history may reveal that hearing gradually worsened and was then completely lost (as with noise exposure). True episodic loss of hearing suggests Ménière disease, but the classic triad of episodic vertigo, fluctuating hearing loss, and tinnitus is necessary to make the diagnosis of Ménière disease. If this is the initial episode, Ménière disease may be suspected but not diagnosed.

Vertigo is an important complaint and is important prognostically in patients with NSHL. Its presence is associated with a worse prognosis. Vertigo is also a common complaint in patients with acoustic neuromas. Associated neurologic signs and symptoms may suggest multiple sclerosis. A history of vascular disease, such as stroke or myocardial infarction, may implicate vascular disease as the etiology of acute hearing loss. A history of human immunodeficiency virus (HIV) or HIV risk factors can help define the cause of hearing loss.^{1,14} Systemic illness, such as mumps, can cause hearing loss and should be explored. Tertiary syphilis can cause hearing loss; an FTA-ABS or equivalent testing must be done. Autoimmune disease (lupus, etc.) may precipitate an event of NSHL.

Possible reasons for secondary gain should be sought, which would lead to the diagnosis of pseudohypacusis (malingering).

Finally, the physician should ensure that any problems with hearing are not caused by language or mental status problems.

Physical Examination

The history should guide the physical examination. Vital signs may hint at a possible cause of the hearing loss. For example, fever may indicate meningitis or viral illnesses; an elevated blood pressure may suggest vascular disease.

The cranial nerves should be tested, with special emphasis on the facial nerve. When testing for facial nerve function, the physician should ensure that the movement is truly due to the seventh cranial nerve. For example, the eye can close by simply relaxing the third cranial nerve; eye closure must be forceful. The mouth can be moved by the masseter muscle, which is innervated by the fifth cranial nerve. Also, movement of the forehead on one side can cause apparent slight movement on the opposite side.

The ears should be examined with an otoscope. If temporal bone fracture or communication with the central nervous system (CNS) is suspected, sterile instruments should be used. Wax is not naturally present in the medial aspect of the ear canal (near the eardrum). If wax is present, it has been pushed in (by means of a cotton-tipped applicator or a shower), or it is not wax. A cholesteatoma should be suspected if there is a crusting on the eardrum, particularly on the superior aspect, over the pars flaccida.

Cerumen impactions may be removed by irrigation; however, the physician should ensure the eardrum is intact before irrigating the ear canal. Manipulation of the ear canal may stimulate the vagus nerve, especially in the elderly, causing mild cough or even cardiac arrest. In some cases, the wax may be too dry and impacted for removal by irrigation or under direct vision. Mineral oil drops, which are less toxic and less likely to cause a reaction than commercially available wax removal preparations, are an alternative (four drops four times a day for a week or two). Frequently, this will soften the wax, allowing it to drain on its own. If the wax does not drain on its own, suctioning under direct vision by an otolaryngologist or a primary care physician can remove the impaction.

Palpation of a tender mastoid tip may indicate mastoiditis. The temporomandibular joint should also be palpated.

Special Tests

Perilymph Fistulas

The physician instructs the patient to close his or her eyes and walk straight ahead; the physician then taps the patient on the shoulder and has him or her turn 180 degrees in the direction tapped. Turning in the direction of the fistula will cause unsteadiness.¹⁶

Tuning Fork Testing

The best frequency to use is 512 Hz; lower frequencies may cause the patient to *feel* the vibrations rather than actually *hear* the tuning fork.

The two tests most commonly performed are the Weber and the Rinne. The Weber test is traditionally performed by placing the base of the fork in the midline of the forehead. However, this test can also be done, and with better results, by testing the middle of the upper teeth, provided the patient does not have dentures. When doing the Weber test, the fork should be pressed firmly against the skull or teeth. A good contact between the base of the tuning fork and the skull is necessary to make the skull vibrate. If the sound is localized to one ear, there is either a conductive hearing loss in that ear or NSHL in the opposite ear.

The Rinne test should be done on each ear. It is “positive” if it is normal. Place the base of the tuning fork over the mastoid tip and press firmly; then, immediately take the tuning fork off and hold it next to the external ear canal. Ask the patient which is louder. Normally, air conduction is heard better (and therefore louder) than bone conduction. Louder bone conduction indicates a conductive hearing loss. Unfortunately, the Rinne test detects only large conductive losses (about 40 decibels). Thus, a lesser but significant conductive hearing loss yields a positive (i.e., normal) Rinne test.

Audiometry

Although it is best to test hearing with an audiometer operated by a qualified audiologist, it is usually possible in the emergency department to get some idea of the patient's ability to hear. Start speaking in a whisper and continue to speak louder and louder until the patient can hear. Note the distance and the approximate level of volume at which the patient can hear (i.e., whisper, soft conversation, normal conversation, loud voice, yelling). A noisemaker can be used to mask hearing in the normal ear. Malingerers and pseudohypacusis patients frequently respond to off-hand comments or requests spoken in a normal or soft voice when they believe they are not being tested.

Audiometric testing should be obtained if possible. However, if the patient has a readily identifiable cause of hearing loss, such as acute otitis media, serous otitis media, hemotympanum, external otitis, cerumen impaction, or foreign body, audiometric testing should probably be delayed until the underlying problem is treated.

Laboratory Evaluation and Special Studies

Laboratory evaluation in the emergency department depends on the suspected underlying cause. A patient with a cerumen impaction does not need a diagnostic work-up. If no clear cause for the sudden hearing loss is noted, the following tests may be indicated: HIV, antinuclear antibodies, sedimentation rate, complete blood count, renal profile, rheumatoid factor, immunoglobulin-E, thyroid function test (thyroid-stimulating hormone, T3, T4), prothrombin time, partial thromboplastin time, platelet count, serum electrolytes, glucose, VDRL, and FTA-ABS. Other tests may be indicated by history¹⁵ (e.g., lipid studies, rheumatoid factor, antinuclear antibody). Tests that may be ordered in consultation with a specialist include an audiogram, auditory brain stem response, electronystagmogram, magnetic resonance imaging and CT scanning of the temporal bones.⁸ A CT scan on a patient with simple acute otitis media may show fluid in the mastoid, and the radiologist will diagnose mastoiditis. This should not be treated any differently than acute otitis media unless there are clinical signs of mastoiditis, such as erythema, tenderness, protrusion of pinna, and, occasionally, fluctuance.

EMERGENCY DEPARTMENT MANAGEMENT

Simple causes of hearing loss, such as acute otitis media, external otitis, or cerumen impaction, can be treated in the emergency department. Foreign bodies can sometimes be removed, particularly in an older patient. Some problems, such as barotrauma and serous otitis media, require minimal treatment or close observation only. Ototoxic medications should be discontinued. Suspected malingering may require psychiatric evaluation; audiologic testing confirms malingering.

Generally accepted, recommended treatments for sudden hearing loss include observation, bed rest, and a low-salt diet. Treatment for a possible perilymph fistula includes these as well as sedation and absolute bed rest with the patient's head elevated. In some cases, if NSHL is confirmed, steroids may be given, particularly if HIV infection is not present.^{11,14,19} External otitis is frequently treated with ear drops containing neomycin and polymyxin B sulfates and hydrocortisone (Cortisporin). If an eardrum perforation is suspected, the suspension, not the solution, should be used; the suspension is less irritating and painful to the middle ear mucosa. Allergic reaction to neomycin is common. If the patient seems to be getting worse or not responding to Cortisporin drops, it may be due to an allergic reaction, necessitating a different medication.

Even in simple cases, it is probably wise to obtain an audiogram at some point in the patient's treatment. In all other cases, it is best to refer the patient to an otolaryngologist for treatment and further care.

DISPOSITION

Except for straightforward problems, consultation with an otolaryngologist should be obtained in most cases of sudden hearing loss. Ideally, the patient should be seen within 2 to 3 days; some studies have shown benefit if treatment is started within 7 days,¹⁰ 10 days,¹¹ or 16 days.⁷ The case can probably be discussed immediately with an otolaryngologist on the phone, and the timing of further consultation can be determined at that point.

Generally, patients with sudden hearing loss do not require admission to the hospital. The major exception is perilymph fistula. These patients require sedation and absolute bed rest. Depending on the social and home situation, it may be necessary to admit the patient to administer this treatment. For patients not admitted, close follow-up is indicated. After cleaning a cerumen impaction in an elderly patient, the patient may need evaluation for an underlying presbycusis, which may need further study and treatment. All follow-up can be accomplished by either a primary care physician or an otolaryngologist, depending on the severity and underlying problem.

If the patient must travel to consult a specialist, air travel is contraindicated in perilymph fistulas and in barotrauma cases, unless a specially pressurized plane is used.

COMMON PITFALLS

- Because acute hearing loss is a symptom or sign of multiple medical conditions, the disease that causes it may be either diagnosed and treated with relative simplicity, or of a nature that is undefinable and untreatable in the emergency department.
- History is frequently the key to diagnosis, and must include specific inquiry regarding recent infection; prior hearing or neurologic problems; occupational or recreational noise exposure; recent flying, diving, or high-altitude travel; and any self-instrumentation of the ear. Failure to elicit history in these areas may lead the emergency physician in the wrong direction.
- The emergency physician must methodically examine the ear and related structures (e.g., temporomandibular joint), perform a complete neurologic examination, remove cerumen from the external auditory canal to visualize the tympanic membrane, and, when appropriate, perform bedside hearing tests along with a fistula test. This will help avoid the error of diagnosing an "ear infection" with no objective findings to support the diagnosis.
- The emergency physician should take special care with respect to treatment in two situations. First, foreign body removal requires special techniques and should be performed with a clear strategy (see [Chapter 25](#)). Second, otitis externa should be treated with a drug in suspension in the case of tympanic membrane perforation or when the physician cannot visualize the tympanic membrane because of debris.
- A major pitfall is to offer a prognosis that is too optimistic. It may create or reinforce unreasonable expectations on the part of the patient, leading to dissatisfaction with the medical care received.

Just as dizziness is the complaint of abnormal orientation in space, vertigo is the abnormal feeling of motion, either of the person or of his or her environment. ¹⁷ Although the prevalence of dizziness in unselected emergency patients is unknown, data from the National Ambulatory Medical Care Survey show dizziness as a chief complaint in 2.6% of all patients, increasing to nearly 7% in patients by age 85 ([Table 27.1](#)).^{14,15} Distinguishing vertigo from lightheadedness, loss of balance, or nonspecific dizziness is important, because the patient with true vertigo is significantly more likely to have a labyrinthine disorder. ^{3,4,16} Labyrinthine disorders are not life-threatening, and specific treatment is unavailable. The challenge is to identify patients with serious causes of vertigo and dizziness. Regardless of cause, vertigo can be disabling, recurrent, and refractory to treatment. ^{3,16,17}

Etiology	Percentage
Peripheral vestibular disorder	43

TABLE 27.1. Etiology of Dizziness in 125 ED Patients

True vertigo is described as an illusion of movement. It is often accompanied by nystagmus and is due to a vestibular system lesion in the brain stem, eighth cranial nerve, or labyrinth. The most important step for the emergency physician is to determine whether the vertigo is due to a peripheral or central cause.

About 85% of patients with vertigo have *peripheral vertigo*, with dysfunction of the vestibular organs. The term *peripheral vestibular disorder* is applied to patients with rotational vertigo, nausea, or vomiting, with no sign of brain stem deficit. In addition to these labyrinthine symptoms, cochlear symptoms may be present as aural fullness, tinnitus, or hearing loss. Tinnitus can be described as a hissing sound, high-pitched ringing, bells, or machinery-like roaring. Peripheral vertigo has multiple etiologies, including infection (labyrinthitis), ototoxicity from chemotherapy, autoimmune/allergic (Ménière) or traumatic (benign paroxysmal positional vertigo [BPPV], temporal bone fracture). Episodes may recur and even be debilitating, or they may gradually decrease over time. In most cases, cure is unavailable, and treatment is targeted at rehabilitation. Causes of peripheral vertigo are listed in [Table 27.2](#).

TABLE 27.2. Causes of Peripheral Vertigo

Central vertigo has a more insidious onset and is frequently accompanied by neurologic symptoms, since the cause is a central nervous system (CNS) lesion. It may be due to ischemic changes from a cerebrovascular accident (CVA), multiple sclerosis, or intracranial tumor. Often the patient will describe a feeling of disorientation; however, true vertigo may also be present. This “lesion,” when induced by drugs or metabolic abnormalities, is considered “systemic” or “global” by some authors. ^{1,12} Common causes of central vertigo are listed in [Table 27.3](#).

TABLE 27.3. Causes of Central Vertigo

Table 27.4 summarizes the characteristics of peripheral and central vertigo. Miscellaneous causes of vertigo are listed in Table 27.5.

	Peripheral	Central
Intensity	Moderate to intense	Mild to moderate
Temporal pattern	Brief, episodic	Chronic, continuous
Onset	Abrupt	Gradual
Nystagmus	Rotatory/horizontal	Any kind, including bizarre vertical
Nausea/vomiting	Common	Uncommon
Hearing loss	Possible	Unlikely
Neurologic deficits	Otherwise none	Often present

From Edwards FL. Overcoming the diagnostic challenges of dizziness, vertigo, and syncope. *Emergency Medicine Reports*. Atlanta: American Health Consultants, Jan, 16, 1994.

TABLE 27.4. Characteristics of Peripheral and Central Vertigo

Hyperventilation syndrome: A noncentral and nonperipheral cause of vertigo reported in up to 23% of patients with dizziness.^{17,18} Vertigo follows hyperventilation, sometimes during a panic attack. Typically, the patient has perioral and extremity numbness and dizziness. While usually associated with lightheadedness, hyperventilation has been shown to precede true vertigo in some patients.¹⁹ An evaluation may be indicated based on clinical judgment, especially for the patient with true vertigo.

Motion sickness: A perceptual disorientation in healthy people due to rapid changes in position. A sensation of lightheadedness or impending faint without vertigo (often with dimming of vision) suggests a transient decrease of blood to the brain.

Impending faint: Caused by conditions that cause true syncope—vasovagal near-syncope, orthostatic hypotension, blood hyperviscosity syndromes, cardiac dysrhythmia, or cardiac valvular abnormality.

Nonvertiginous “dizziness”: May be due to stumbling or falling that is without any head sensation.²¹ The workup should be directed toward evaluating sensory neuropathy, or poor vision that causes falls.

TABLE 27.5. Miscellaneous Causes of Vertigo or Dizziness

CLINICAL PRESENTATION AND EMERGENCY DEPARTMENT EVALUATION

History

The history is critical to determination of the differential diagnosis. Identifying the length of duration, associations with head movement, inciting events, associated symptoms, and underlying medical conditions will guide the examiner in the appropriate direction.^{3,6} Most young patients with vertigo have some type of peripheral vestibular disorder.¹⁶ Serious causes of dizziness, although more common in older patients, do occur in the young and must be considered in all patients with vertigo. No single test is completely sensitive at detecting serious causes of dizziness, so the approach is a mixture of clinical judgment and ancillary testing. Underlying conditions that may be contributing to the problem include diabetes, certain medications (particularly antidepressants, beta-adrenergic blockers, and calcium channel blockers), migraine headaches, cardiovascular disease, or significant psychiatric history.

If the symptoms suggest central vertigo, consider a new or increased dose of medication, diabetes or hypoglycemia, hypo- or hyperthyroidism, anemia or polycythemia, atherosclerosis, neck injury or arthritis, CVAs of the brain stem, cerebellar infarction or hemorrhage, or vertebrobasilar insufficiency.⁸ A history of epilepsy suggests that partial complex (temporal lobe) seizure may be the cause of vertigo. A history of cancer or lymphoma might implicate a metastatic brain tumor. Fever and headache suggest that meningitis, encephalitis, or brain abscess should be evaluated. Peripheral vertigo may be present in coexistence with central vertigo, and any patient with neurologic signs should undergo further evaluation.^{4,12}

The duration of the vertiginous episodes greatly assists in the diagnosis. Vertigo lasting seconds and associated with head movement is often benign paroxysmal positional vertigo (BPPV) or vertebrobasilar insufficiency.⁸ Vertigo lasting minutes to hours may be Ménière disease, otosyphilis, Cogan syndrome, or recurrent vestibulopathy. Vertigo lasting days and associated with severe nausea and occasional hearing changes is most likely labyrinthitis (vestibular neuritis), although migraine vestibulopathy is also a possibility.^{3,6}

Physical Examination

Orthostatic hypotension, carotid sinus hypersensitivity, and dysrhythmia can cause vertigo.^{3,11} Lying and standing vital signs are desirable, but many patients either refuse to move or are too unsteady to stand. A directed physical examination should focus on the cranial nerves (especially hearing), cerebellar function, nystagmus, and positional testing. Vesicles on the auricle suggest Ramsay Hunt disease as a central cause of vertigo. The external auditory canal and tympanic membrane should be examined for any abnormality, as cholesteatoma, acute otitis media, and even cerumen impactions may cause vertigo.

Any cranial nerve abnormality strongly suggests a central process. Most commonly, a lesion of the seventh cranial nerve results in facial nerve paresis; a central seventh lesion is suggested by unilaterally decreased eye closing and smiling with intact forehead wrinkling due to crossover innervation.^{1,16} Loss of cranial nerves III, IV, and VI is revealed by a dysconjugate gaze in a particular direction; all directions should be tested (see Chapter 60).

Lesions of the eighth nerve may result in decreased hearing. Sensorineural hearing loss should be ruled out by testing hearing to whispered voice or to rubbing fingers, or with a portable hearing screener. Decreased hearing in one ear requires further evaluation, as it may be sensorineural and signify asymmetry of function of the eighth cranial nerve.^{9,10} Because most sensorineural loss reduces high-frequency tones, with tinnitus frequently present, a portable hearing screener that tests different frequencies is useful.²

Tuning fork tests may be helpful in identifying a unilateral sensorineural hearing loss or a conductive hearing loss. If the patient has bilateral sensorineural hearing losses, the tuning fork test will be equivocal. The base of a vibrating tuning fork placed on the midline of the forehead (the *Weber test*) relies on bone conduction; it is normally heard equally in both ears. Decreased sound in one ear implies either a sensorineural loss in that ear or a conductive hearing loss in the other ear. A vibrating tuning fork should be heard longer in air than through bone. In the *Rinne test*, the base of a vibrating tuning fork is applied on the mastoid bone. When the patient no longer feels it vibrating, it is quickly moved in front of the ear. Patients with normal conductive and sensorineural systems will still hear it vibrating. Sensorineural hearing loss is suspected if the hearing is equally reduced by both routes, but air conduction is still better than bone conduction.¹⁴ In contrast, in conductive hearing loss, the sound is felt longer by bone than through air.

Cerebellar function is tested by finger-to-nose testing, rapidly alternating hand movements, and the heel-to-shin test. Past pointing or poor coordination suggest multiple sclerosis, cerebellar hemorrhage, or infarction. Station and gait are usually abnormal during acute vertigo and have little discriminatory value. The Fakuda test involves marching in place with the eyes closed and is considered positive for a peripheral lesion when the patient leans or falls to the affected side.

The most helpful physical findings are nystagmus and positional testing. Nystagmus can be characterized as peripheral or central by observing it in a darkened room. Peripheral nystagmus is suppressed with fixation of gaze (opened eyes in a lit room) and is enhanced when the patient looks in the direction of the fast component. Peripheral nystagmus is typically horizontal or rotatory and is worsened with head movement.^{4,6} Central nystagmus may be of any type; however, nystagmus that is

vertical, dysconjugate, direction-changing, or not suppressed by visual fixation is *always* central^{4,6} (Table 27.6).

	Central	Peripheral
Direction	Any direction	Usually rotatory or horizontal
Laterality	May be one eye	Both eyes
Visual fixation	Enhances nystagmus	Suppresses nystagmus
Effect of gaze toward side of fast component	Does not enhance nystagmus	Enhances nystagmus

TABLE 27.6. Nystagmus from Central and Peripheral Lesions

If nystagmus is subtle or absent, the patient should undergo the Dix-Hallpike maneuver (Table 27.7). The patient is asked to sit near the top of the gurney in a room with the lights dimmed, with enough room to hang the head off the end of the gurney. He or she is brought rapidly from sitting to lying, with the head tilted backward 45 degrees below the horizontal and to the left 45 degrees from midline, with eyes open. A positive test is defined as either the onset of nystagmus, reproduction of the vertigo, or both. After 30 seconds, the patient is brought to the upright position and the test repeated with the patient's head turned to the right. Any positive test should be repeated after a few minutes to see if either the nystagmus or vertigo is less pronounced or "fatigable."

	Central	Peripheral
Negative test	Does not help localize the lesion	3–30 s
Latency	None	
Fatiguability	None	Yes
Duration	Sustained	Transient

TABLE 27.7. Dix-Hallpike Maneuver— Central vs. Peripheral Vertigo

Laboratory Testing

Significant electrolyte abnormalities are confined largely to patients taking diuretic medications or those who have a history of electrolyte abnormalities.^{3,4} Occult metabolic causes of central vertigo are unlikely, but routine glucose measurement should be done to screen for hypoglycemia. Unsuspected significant hypoglycemia is found in about 3% of patients. A complete blood count will identify patients with anemia or polycythemia and an elevated SED rate may point to rheumatoid arthritis or systemic lupus erythematosus. Orosyphilis will be identified with a positive FTA-ABS or MHA-TP.

Radiologic Imaging

If central vertigo is suspected, further evaluation is needed. Structural CNS lesions should be sought by either emergent head computed tomography (CT) or magnetic resonance imaging (MRI) with gadolinium scanning. These should be selected with regard to whether suspicion tilts toward intracranial tumor, cerebellar infarction or hemorrhage, acoustic neuroma, or multiple sclerosis.¹²

Other Studies

Electronystagmography (ENG) is a noninvasive means of detecting eye movements by recording corneoretinal potentials on a moving strip recorder; it may be useful acutely. ENG can often distinguish central from peripheral vertigo as well as identify which ear is the affected side.^{10,13} This test is usually performed by an audiologist. An audiogram should also be done to evaluate whether there is a hearing loss related to the disorder.

Routine electrocardiograms are abnormal in 20% of dizzy patients age 45 and older.⁸ Significant findings occur in 3%; these are mostly predicted by a history of cardiac disease.¹¹ The vestibular labyrinth is particularly vulnerable to ischemia and infarction in patients with a history of atherosclerosis (see Table 27.2).¹²

EMERGENCY DEPARTMENT MANAGEMENT

After the ABCs have been addressed, the patient older than age 45 should have an intravenous line, oxygen, and heart monitor until a cardiovascular cause of vertigo can be reasonably excluded. Symptomatic treatment should begin immediately. Intravenous boluses of isotonic crystalloid should be given to the orthostatic patient, unless a history of congestive heart failure requires a more judicious hydration regimen. Because many dehydrated patients do not manifest orthostatic changes, fluid should also be given to the patient who is vomiting or having prolonged nausea.

Drug overdose or drug toxicity should be managed according to the ingestant, time since ingestion, and overall condition of the patient.

Central vertigo should be managed as a priority. Acute onset of a structural CNS abnormality, manifested by an abnormal neurologic examination, requires that neurology or neurosurgery consultation be obtained. Head CT scanning is usually done, but its inability to see the posterior fossa often requires either clinical diagnosis or referral for MRI. The decision to obtain an MRI is best discussed with the specialist.

The patient with labyrinthitis will probably feel better with hydration and time. All unnecessary movement should be avoided. The patient who is vomiting might benefit from intravenous droperidol (2.5 to 5.0 mg). There is no evidence as to the superiority of any one antivertigo medication, but antihistaminic and anticholinergic medications seem to help. Choices include meclizine (Antivert, 25 mg orally three times a day), diazepam (Valium, 5 mg once per day orally), diphenhydramine (Benadryl, 25 mg orally four times a day), and transdermal scopolamine (0.5-mg disc every 3 days). Because the elderly are prone to become confused after using scopolamine, it should be avoided in these patients.^{3,15}

BPV or BPPV is easily managed with the Epley maneuver. This maneuver is similar to the Dix-Hallpike and begins with the patient sitting up, then laying him or her back, with the affected ear held at a 45-degree angle and the head extended until the vertigo resolves. The head is then turned to the opposite side and held at a 45-degree angle with extension. The patient is then rotated up on that side, with the head looking down at about 135 degrees; once the vertigo is resolved, the patient is seated upright, with the head sideways. The head is then turned forward. This procedure is repeated until there is no nystagmus or vertigo in any of the positions. The patient is then told to stay in an upright position for 24 to 48 hours. A soft cervical collar may be beneficial as well.^{5,7} (Fig. 27.1). This procedure should not be

performed in patients with cervical spine injuries or degenerated joint disease.

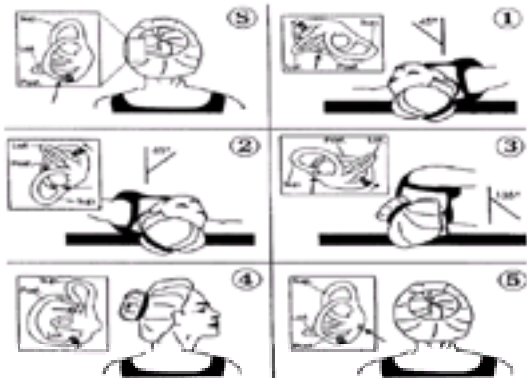

Figure 27.1. Epley Maneuver. Positioning sequence for left posterior semicircular canal as viewed by operator (behind patient). (Box) Exposed view of labyrinth, showing migration of particles (*large arrow*). (S) Start—patient seated (oscillator applied). (1) Place head over end of table, 45 degrees to left. (2) Keeping head downward, rotate to 45 degrees right. (3) Rotate head and body until facing downward 135 degrees from supine. (4) Keeping head turned right, bring patient to sitting position. (5) Turn head forward, chin down 20 degrees. Pause at each position until induced nystagmus approaches termination, or for T (latency + duration) seconds if no nystagmus. Keep repeating entire series (1–5) until no nystagmus in any position.

An acute attack of Ménière disease may be managed as a labyrinthitis, but the patient should be referred to an otolaryngologist for follow-up.

Perhaps as valuable as medication is performing Cawthorne's head exercises each morning and afternoon ([Table 27.8](#)). They worsen the vertigo while they are being performed, but they habituate the vestibular system, thereby allowing the vertigo to improve over time, often long enough to perform a required task.

Exercise	Description
1. Eye Exercises	Looking up, then down—at first slowly, then rapidly. 20 times. Then looking left, then right, then up, then down, then left, then right, then up, then down, then left, then right, then up, then down. 20 times.
2. Head Exercises	Head tilted backward, then forward, then to the right, then to the left. 20 times.
3. Sitting	Head tilted backward, then forward, then to the right, then to the left. 20 times.
4. Standing	Head tilted backward, then forward, then to the right, then to the left. 20 times.
5. Moving About	Walk, carrying a tray with a glass of water, then a book, then a bag of groceries, then a suitcase, then a briefcase, then a suitcase, then a bag of groceries, then a book, then a glass of water, then a tray. 20 times.

TABLE 27.8. Cawthorne's Balance Exercises

DISPOSITION

The patient with vertigo should be given time off from work or school. Patients should be cautioned, in writing, to avoid driving, working at heights, or operating heavy equipment until episodes have resolved completely.

Patients discharged with peripheral vertigo should be told that recurrence is likely, and that they should return for any symptoms of central dizziness. The symptoms appearing on the head injury checklist are useful, except that “dizziness or staggering while walking” is crossed off. Outpatient referral is indicated either to the primary provider for follow-up or to an otolaryngologist for further evaluation and management.

In the elderly, falls are especially dangerous, due to decreased strength and bone mass. Such patients should be discharged only if they are steady on their feet. Order a walker and encourage its use to prevent a fall if and when the dizziness recurs.¹⁵

Immediate consultation with a neurologist is indicated for the patient with signs of a new CNS abnormality. Immediate consultation with an otolaryngologist is indicated for the following: signs of otitis media in an immunocompromised patient, malignant external otitis, signs of perilymphatic fistula or cholesteatoma, or sudden sensorineural hearing loss with or without vertigo. Consultation with either a specialist or a neurologist should be considered in patients with vertigo of unknown etiology, in those with a history of cardiovascular disease, or those whose vertigo does not improve in the emergency department. Patients with a history of atherosclerosis and suspected labyrinthine ischemia should be seen by an otolaryngologist if attacks continue.^{6,8}

Admission is indicated for signs of central vertigo, vertigo caused by dysrhythmia, and vertigo that is disabling or associated with persistent vomiting, and for patients who cannot be safely discharged because they lack household help. Admission to a bed with continuous cardiac monitoring is indicated for patients with suspected vertigo from dysrhythmia.

Transfer is indicated for emergent neurologic or neurosurgical consultation or monitoring that is unavailable locally. In most cases, advanced cardiac life-support transport is indicated, owing to possible progression of a CNS lesion or need to treat a symptomatic dysrhythmia.

COMMON PITFALLS

- Most, but not all, young patients have a peripheral vestibular disorder.
- Medication-induced vertigo is common.
- A common error is to delay intravenous hydration in hopes that the nauseated patient will be able to drink or that the nonorthostatic patient is well hydrated.
- Orthostatic vital signs are often hard to define and interpret in vertiginous patients.
- Failure to recognize neurologic signs and symptoms in association with the vertigo
- Do not discharge a vertiginous patient who lives alone.
- Falls in the elderly may cause hip fractures. Consider admission for all elderly patients who are unsteady. Those discharged should be encouraged to use a walker.
- Provide return instructions and a referral to all discharged patients.

Acute otitis media (AOM) is a well-recognized disease, but there is disagreement over its definition and classification. International symposia have attempted to develop a uniform system of classification, but unanimity has not yet been achieved.^{1,11,15}

Figure 28.1 and Figure 28.2 present the anatomy of the middle ear. AOM has a rapid, short course of signs and symptoms of inflammation of the middle ear without reference to etiology or pathogenesis. An effusion is almost always present in the middle ear space. Acutely appearing effusions are usually assumed to be suppurative (generated by bacterial pathogens)—hence the use of terms such as *suppurative*, *purulent*, or *bacterial* otitis media. Terms such as *nonsuppurative*, *serous*, or *secretory* are used for effusions that do not appear to be suppurative. These effusions also can present acutely. Classically, nonsuppurative effusions are thought to be nonbacterial; however, bacteria and other pathogens have been isolated from these effusions. There is also frequent difficulty in differentiating suppurative from nonsuppurative effusions without invasive techniques.¹ Therefore, classification and nomenclature in this area remain perplexing.

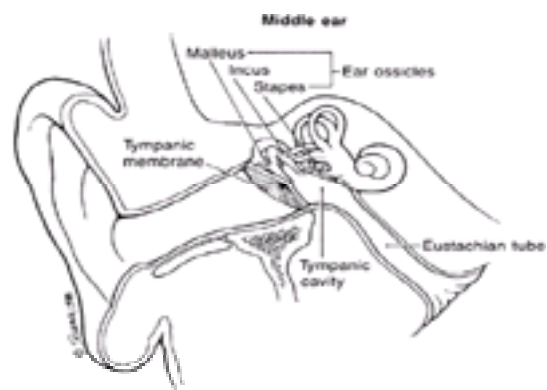

Figure 28.1. Anatomy of the middle ear.

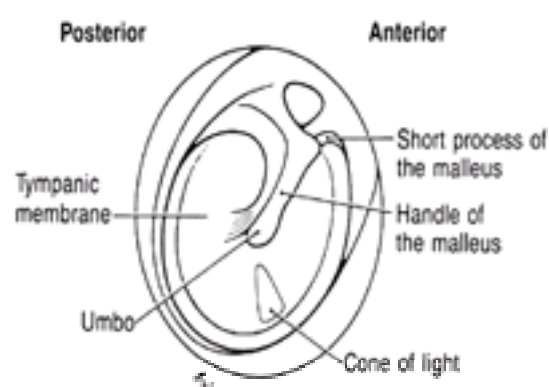

Figure 28.2. Anatomy of the tympanic membrane.

The term *acute* implies a rapid onset and brief presence of signs and symptoms, present for a period usually consisting of hours or days, and for all presentations of AOM, including nonsuppurative forms, no more than about 3 weeks.¹

EPIDEMIOLOGY

Although AOM is one of the most common and well-reported diseases of children,^{5,13,14,16,17,18} it is infrequently reported in adults.^{2,4,18} Textbooks usually mention adult disease in anecdotal or associative terms only. Surveys by government and private agencies often lump adult cases with pediatric cases or use a wide age range for grouping, which makes evaluation difficult. Various agencies, institutions, and governments have differing age divisions for pediatric and adult populations, which complicates statistical comparisons of available data. Often, no great effort is made to separate acute and chronic forms of otitis in adults. Therefore, quantifying AOM in adults is difficult at best with existing data.

However, in a 1980 survey by the U.S. National Center for Health Statistics, with 1869 primary care physicians sampled, 20% (2.4 million) of the 11.7 million reported visits for otitis media were in patients older than 15 years. Seventy-two percent (1.85 million) of these visits were associated with the acute form. A 1987 National Disease and Therapeutic Index survey of 2130 office-based physicians recorded 465,000 visits for AOM among patients age 10 or older, with 304,000 visits for those age 20 or older. The same study noted almost 3.9 million visits by patients 20 years or older for unspecified otitis media. A similar study in 1970 also noted about 4 million cases.

There is little other epidemiologic information on adults in the current literature. However, the epidemiology of pediatric disease has been studied intensively, and adult disease has been assumed to follow similar patterns.

ETIOLOGY

The etiology of AOM has been studied in large pediatric populations over many years. Adult etiologies have been assumed to be similar, although no such broad-based studies have been reported. The most frequent organism is *Streptococcus pneumoniae*, which is found in 30% to 39% of cases. The relative incidence of

pneumococcal infection is thought to rise with increasing age into adulthood. The second most common organism is *Haemophilus influenzae*, which occurs in about 20% to 30% of pediatric cases.⁴ *H. influenzae* is more common in, but not limited to, younger age groups. Some more recent studies of older children and one study of a small number of adults have identified *H. influenzae* in equally high proportions.⁴ *Moraxella* (formerly *Branhamella*) *catarrhalis* accounts for 3% to 15% of cases, and may be increasing in incidence.^{4,7,12,14}

Chlamydia and *Mycoplasma* species have been reported.¹⁰ Respiratory viruses are frequently associated with AOM.^{7,10} Viruses are being studied intensively in association with pediatric presentations of AOM, and these studies have suggested a greater role for viruses in the etiology of AOM.^{6,7,8} They predispose patients to subsequent bacterial infections, or may be the primary causative agent. Viruses in the middle ear may hinder the clinical response to antimicrobial therapy. Investigators report viral isolates either alone or in conjunction with bacteria in up to 30% of middle ear samples from pediatric AOM populations.^{7,8} The most common species are influenza virus, rhinovirus, respiratory syncytial virus, adenovirus, and parainfluenza virus.^{7,8} The relationship of viruses to adult cases of AOM is currently unknown, but is thought to be significant.

Adult microbiologic information is almost nonexistent compared with the wealth of pediatric information. Two prospective studies of adults cultured purulent middle ear effusions. In one study, involving 88 patients, the predominant organism was *S. pneumoniae* (62.5%), followed by *Staphylococcus aureus* (11.5%), *H. influenzae* (10.5%), *Streptococcus pyogenes* (7.3%), and other bacterial pathogens (8.8%). Some patients had multiple pathogens. The other study involved 34 patients; 26% grew *H. influenzae* and 21% grew *S. pneumoniae* from middle ear cultures.⁴ Only 9% of the cultured organisms were beta-lactamase producing. In 26% of patients there was no growth on the cultures.⁴

PATHOPHYSIOLOGY

The pathogenesis of AOM in adults is thought to be similar to that in children. The onset of symptoms nearly always follows an upper respiratory infection. Rarely, barotrauma is the inciting event. The major acute predisposing factor is obstruction or dysfunction of the eustachian tube.¹⁰ Hyperemia and edema of the mucosa at the pharyngeal portion of the eustachian tube is the typical obstructing event. This prevents normal ear ventilation and thus allows exudative and transudative fluid collections in the middle ear. Bacteria, viruses, and other pathogens are thought to be transferred to this fluid media by way of the eustachian tube. Some believe that isolation of fluid media in the closed space of the middle ear allows colonization by existing microbes, producing causative agents different from those that caused the primary infection. However, one recent adult study that simultaneously cultured purulent middle ear effusions and nasopharyngeal exudates demonstrated the same pathogens 97% of the time.

Colonizing microbes may proliferate within the middle ear space, thus activating the host's inflammatory defense system. Cytokines such as interleukin-1 and tumor necrosis factor are activated. Secondary mediators are, in turn, produced, including histamine, interferons, and leukotrienes. Circulating leukocytes then migrate to the site of infection and release proteolytic enzymes and free radicals, which, while attacking the targeted microbes, may also inadvertently damage host tissues. The local host damage may result in viscous effusions and chronic histologic changes, resulting in hearing impairment.⁸

Other predisposing factors include previous otitis infection; congenital, traumatic, or infectious damage to the eustachian tube; and damage to the tympanic membrane (TM). Other obstructive processes, such as nasopharyngeal tumors, can give rise to AOM. Researchers are exploring a possible link between exposure to cigarette smoke and AOM in children and adults.⁸

If no microbial pathogens can be identified in middle ear fluid collections, the pathophysiology is thought to result entirely from eustachian tube dysfunction or obstruction.

Barotrauma or aerotitis is a subset of eustachian tube dysfunction induced chiefly by technologic advances. Barotrauma is most common after air travel, although other causes include rapid elevator descents or descents into deep water such as with scuba diving, although it can occur even in a deep swimming pool. Cases can occur during travel over hills or mountains, especially if descent is rapid, such as in motor vehicles. Barotrauma is most commonly induced by a rapid descent, which produces a rapid increase in ambient atmospheric pressure that is significantly greater than middle ear pressure. Such rapid changes necessitate an active opening of the eustachian tube through contraction of the levator and tensor veli palatini muscles, allowing ambient air to be drawn into the middle ear space, thereby equalizing pressure. If the pressure change is too rapid for active middle ear air exchange, or dysfunction of the eustachian tube prevents this exchange, barotrauma results. Uncorrected negative pressure in the middle ear space causes retraction of the TM, immobility of the TM and ossicles, conductive hearing loss, and, if middle ear pressure is not equalized, transudation of serum and bleeding. If the ambient pressure change is rapid or great enough, TM rupture can also occur.

NATURAL HISTORY

Most cases of adult AOM resolve without sequelae. A few adults develop complications, but exact percentages are not known. The most common acute complication in adults is TM perforation and drainage of the effusion. Less common complications are secondary to local spread of infection and include mastoiditis, facial paralysis, subdural empyema, brain abscess, and meningitis. Adults with normal immunologic function seldom develop these complications. Pneumonic or meningococcal spread occurs most often in children; the incidence in adults is unknown. Chronic, untreated otitis media can lead to such local complications as nonhealing TM perforations, cholesteatomas, and chronic hearing loss. The effects of vaccines against various infective microbes implicated in AOM are being studied in pediatric populations. The potential impact of these interventions on the natural history of adult presentations of AOM is unclear.

CLINICAL PRESENTATION

In adults, the usual presenting complaint is ear pain or discomfort.⁴ Often, only one ear is affected, and the ear may have been the site of previous infection. There is usually a history of concurrent or recent upper respiratory tract infection.⁴ Other presenting complaints may include hearing difficulty, tinnitus, and vertigo. Fever is variable. In one prospective study, a symptomatic triad of otalgia, impaired hearing, and upper respiratory tract infection was present in almost 100% of patients, with elevated temperature in only 9%.⁴

Adults present more commonly than children with spontaneous TM rupture and serosanguineous or purulent discharge from the affected ear. Although the incidence of systemic spread from adult AOM is unknown, high fever and signs of systemic toxicity in the adult with ear pain should cause the examiner to consider a diffuse process and compromised immune system.

In one study in which adults delayed seeking initial evaluation, significant complications were present at the initial presentation. Therefore, the initial examination should include a search for potential complications.

There are two major categories of complications resulting from otitis media: otologic and intracranial.⁶ Otologic complications include TM perforation, mastoiditis, petrositis, facial nerve paralysis, and labyrinthitis. Intracranial complications include extradural abscess, subdural abscess, brain abscess, meningitis, lateral sinus thrombosis, and otic hydrocephalus. Many of these complications used to occur in untreated suppurative otitis media and have been significantly reduced in the era of antibiotic therapy, especially local otologic complications. Systemic complications from otitis media, such as bacteremia, pneumonia, and meningitis, are infrequent in adults.

Adults who present with symptoms of otitis media and high fever or signs of systemic toxicity or localized spread should receive a thorough examination. A white blood cell count, blood cultures, chest radiograph, and cerebral spinal fluid studies should be done, as indicated.

DIFFERENTIAL DIAGNOSIS

Almost any disease process of the head and neck can refer pain to the ear. Dental caries or abscesses commonly refer pain to the ear, as does sialoadenitis or temporomandibular joint syndrome. Sinusitis and pharyngitis can present as ear pain. Acute glaucoma and other optic diseases are occasionally referred to the ear. Otitis externa and soft-tissue infection in proximity to the auricle must be differentiated from otitis media. In most cases, a careful evaluation should produce the correct diagnosis.

EMERGENCY DEPARTMENT EVALUATION

Head and Neck

The evaluation of ear pain should include a thorough examination of the head and neck to rule out other causes. Teeth and gums are examined and percussed. The oral cavity and nasopharynx are inspected for inflammation, sinusitis, and other diseases. Parotid, submandibular, and submaxillary glands are palpated and the temporomandibular joints examined. The soft tissue around the auricle is inspected and palpated. The auricle and tragus are manipulated. The neck is inspected and palpated, and the carotids are auscultated for bruits. The eyes are briefly examined to rule out signs of glaucoma or other ocular pathology.

Middle Ear

The hallmark of the middle ear examination is otoscopic visualization of the TM: An examination for ear pain or other otitis media–related symptoms is incomplete without it. Wax, debris, and discharge that obstruct visualization must be removed. The TM is noted for appearance, landmarks, and light reflex. Signs suggestive of otitis media are loss of normal concavity of the membrane, bulging or retraction of the membrane, visual loss of the bony landmarks, and erythema or an opaque or bluish appearance of the membrane. A fluid level or bubbles behind the TM also may be seen. Findings from barotrauma-induced otitis media are usually the same as for other types of nonsuppurative AOM, although hemotympanum or membrane rupture can be seen.

Pneumatic otoscopy has classically been the most sensitive and simple bedside test for the presence of effusion behind the TM and should be part of the routine examination. Pneumatic otoscopy does not define whether the effusion is suppurative or nonsuppurative.

The hand-held acoustic otoscope reportedly is a reliable test for the presence of middle ear effusions.⁹ In one study, the acoustic otoscope was shown to detect effusions with equal facility in adults and children.⁹

Tympanocentesis and myringotomy of the middle ear are the most accurate invasive tests to evaluate middle ear effusions. These procedures not only detect the presence and nature of effusions (purulent vs. serous), but also provide material for culture and Gram stain. These procedures are normally reserved for the otolaryngologist.

EMERGENCY DEPARTMENT MANAGEMENT

Antimicrobial Therapy

Uncomplicated otitis media, presenting acutely with an effusion present, is usually assumed to be suppurative (bacterial). *S. pneumoniae*, *H. influenzae*, and, more recently, *M. catarrhalis* are the usual pathogens, with *S. pneumoniae* and *H. influenzae* thought to be the two most common organisms in adults.² The presence of beta-lactamase–producing strains has been increasing significantly in pediatric populations over the past decade, and is suspected to be likewise increasing in adults.^{2,8} Amoxicillin (500 mg orally three times a day for 10 days) and, more recently, trimethoprim-sulfamethoxazole (TMP-SMX) (double strength twice a day for 10 days) remain the first-line drugs of choice for adult populations, though resistance to these drugs is increasing.

Patients whose signs and symptoms continue after initial antibiotic therapy or those who are allergic to penicillins or TMP-SMX should receive alternative antibiotics. Alternative selections include one of the new macrolides (azithromycin or clarithromycin); one of the newer cephalosporins; the second-generation agents cefaclor, loracarbef, cefuroxime axetil, or cefprozil; and third-generation drugs such as cefpodoxime proxetil or cefixime; or alternative penicillins such as amoxicillin-potassium clavulanate.^{2,8} Fluoroquinolones, such as ciprofloxacin, are currently being studied as possible second-line antimicrobials for AOM, as is intramuscular injection of the third-generation cephalosporin ceftriaxone.⁸ Second-line, broader spectrum antibiotics should also be considered in patients at high risk for complications, such as those with diabetes or other types of relative or total immunocompromise. Choices in alternative antibiotic therapy must also take into account any allergic history, as well as the spectrum of activity of the chosen agent.

All presentations of AOM complicated by TM perforation should be treated with an antibiotic regimen.

Supportive Therapy

Supportive therapy includes fever control, relief of otalgia, and treatment of associated upper respiratory symptoms. Acetaminophen or ibuprofen is thought to be adequate to treat pyrexia and otalgia in most adults. Short-term narcotic analgesia may be appropriate for adults with severe otalgia. However, severe otalgia without significant TM bulging should prompt a search for other causes of the pain. Otalgia and other symptoms should improve significantly over the first 24 to 48 hours after appropriate antibiotic therapy begins; failure to respond is a cause for concern. Therefore, when prescribing outpatient narcotic analgesia, such prescriptions should cover only this initial period. Patients who experience continued otalgia or other symptoms should be instructed to return for further evaluation.

Myringotomy has been recommended for adults with severe otalgia and a bulging TM. This technique allows almost instantaneous pain relief and provides material for culture, and should be considered for adults with these symptoms.

Decongestants and antihistamines are effective in reducing the symptoms of an upper respiratory infection, and should be considered in adults. This is especially valuable for barotrauma-induced AOM.

TM perforations associated with AOM usually resolve spontaneously without sequelae. Purulent discharge through the perforation may result in an eczematoid external otitis. Topical ear drops consisting of a steroid–antibiotic mixture are often prescribed. However, if such drops enter the middle ear space through the perforation, they may cause a chemical ototoxicity.³ Therefore, there is no consensus concerning this therapy.

DISPOSITION

Role of the Consultant

Adults with uncomplicated AOM can be safely discharged on antibiotics and symptomatic therapy. Patients should be instructed to seek follow-up for worsening symptoms or for symptoms of systemic illness. Follow-up examination of the ear after completion of therapy has not been evaluated in adults. All patients with TM perforation secondary to AOM should receive a follow-up evaluation to confirm healing of the membrane.

Patients who return with continued symptoms despite therapy should be reevaluated for other causes. In their absence, a trial of an alternative antibiotic should be instituted. These patients should be told to return immediately for any worsening of symptoms. Follow-up at the completion of antibiotic therapy is mandatory.

Patients with persistent otorrhea secondary to TM rupture that continues after initial antibiotic therapy should be referred to an otolaryngologist.³ Patients whose symptoms persist after the second course of antibiotics also should be referred to an otolaryngologist.

Patients who return during or after therapy with any worsening of symptoms should receive consultation by an otolaryngologist. Myringotomy should be considered in patients with worsening symptoms, especially if the diagnosis is in question, severe pain is present, or infectious complications occur.

Patients with known immunocompromise or other disabling illness should have early referral. An otolaryngologist or primary physician must assess the results of therapy. Tympanocentesis or myringotomy may be necessary to determine the etiology.

Patients with signs of systemic toxicity or localized or intracranial infectious complications deserve an immediate and thorough examination. Immediate consultation is indicated. Hospital admission and parenteral antibiotics may be indicated.

Indications for Admission

Symptoms or signs of chronic or acute sequelae of AOM should be evaluated by an otolaryngologist. Subsequent treatment or hospitalization is based on the nature and severity of the symptoms. Most adults are successfully treated as outpatients, but the rare adult with systemic toxicity or severe localized spread should be admitted.

Transfer Considerations

Special consideration is necessary for patients who requires air transport. These patients must be transported at low altitudes, usually under 1000 feet, or in pressurized aircraft. Inability to equilibrate middle ear pressure and high altitudes can lead to TM rupture or localized spread of pathogens to adjacent tissues.

COMMON PITFALLS

- Failure to visualize the TM
- Failure to test the mobility of the TM
- Confusing a ruptured TM with drainage with otitis externa

Otitis externa (OE) is a general term encompassing all of the irritative and infective processes that involve the skin of the external auditory canal. ^{3,15,19} There are several systems for dividing the types of OE. One generally accepted system divides it into three major groups: *inflammatory OE*, in which the pathogenesis involves infectious pathogens, *eczematoid (allergic) OE*, and *seborrheic OE*.³ Inflammatory OE can be further subdivided into acute forms, in which the predominant pathogens are bacterial, and chronic forms, in which fungal organisms predominate.

Acute inflammatory otitis is by far the most common type of OE presenting to emergency physicians. It is defined as an inflammatory condition of the auricle, ear canal, or the outer surface of the tympanic membrane (TM).^{15,19} Acute inflammatory OE can be further subdivided into diffuse and localized forms. ^{3,12,15} Acute diffuse OE (“swimmer’s ear”) is the most common of all external ear infections.^{3,12,15,19} Acute localized OE is commonly an infection involving a hair follicle in the area of the ear canal.^{3,12} The initial presentations of these two processes are similar.

ACUTE DIFFUSE OTITIS EXTERNA

EPIDEMIOLOGY

Acute diffuse OE is found in all age groups, in all climates, and in all seasons. However, the incidence is greatly increased during the summer, especially among swimmers (hence the term *swimmer’s ear*).^{3,19,22,26} The spectrum of disease produced by this entity ranges from mild itching and irritation of the ear to excruciating pain, swelling, purulent discharge, and systemic illness. ^{19,24}

ETIOLOGY

Excessive wetness or dryness of the canal, trauma, or a change in the canal environment makes the ear canal epithelium vulnerable to infection by endogenous bacteria, virulent exogenous bacteria, or other microbial pathogens. ² Normal flora of the external canal include *Staphylococcus epidermidis*, *Corynebacterium* (diphtheroids), *Micrococcus* sp., and occasionally *Staphylococcus aureus*, *Streptococcus viridans*, and anaerobic bacteria such as *Propionibacterium acnes*.^{2,11,12,15,19} Common pathogenic exogenous bacterial organisms are *Pseudomonas aeruginosa*, *Enterobacter aerogenes*, *Proteus vulgaris*, *Klebsiella pneumoniae*, *S. aureus*, and non-group-A streptococci.^{2,7,10,12,16,19,20,26} *P. aeruginosa* is the most commonly isolated bacterium.^{2,8} Fungal organisms are rarely seen as the sole infecting organism in acute disease, but are most often found in hot, moist environments, or among those with immune compromise. ^{3,5,15,19} Commonly cultured fungal organisms are *Aspergillus niger*, *Candida* sp., *Actinomyces*, or yeasts.^{3,5,8,19} Herpesvirus hominis and varicella-zoster also may cause external otitis. ^{2,8}

ANATOMY

[Figure 29.1](#) shows the anatomy of the external ear. The adult external auditory canal is about 24 to 35 mm long and ends medially at the TM. ^{11,12,15,16} In the adult, the distal third of the canal is supported by the cartilaginous base of the auricle; the proximal two-thirds of the canal passes through the temporal bone. This ratio is reversed in infants and small children. ² A constriction, the isthmus, is present at the juncture of the cartilaginous and osseous portions of the canal and limits the entry of wax and foreign bodies to the area near the TM.^{12,15} The canal forms an S shape with a slight upward and backward orientation; this likewise discourages foreign-body entry.¹⁵ The epithelium of the canal originates on the outer surface of the three-layered TM and migrates outward at 1.5 to 2.0 mm a month. ^{1,15,16} The skin of the canal is thicker in the cartilaginous portion and includes a well-developed dermis and subcutaneous layer. The skin lining the osseous portion is thinner and firmly attached to the periosteum, lacking dermal papilla and subcutaneous tissue. ¹¹ Hair follicles are numerous in the outer third and sparse in the inner two-thirds of the canal. ¹²

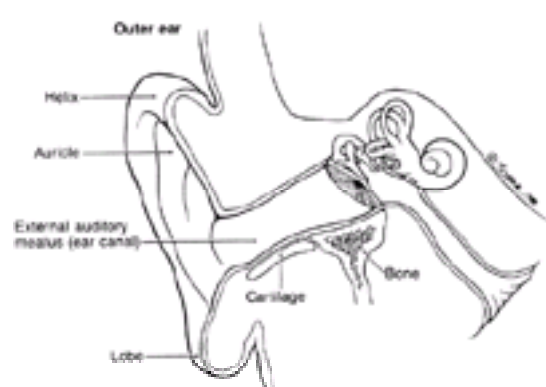

Figure 29.1. Anatomy of the external ear.

The external canal is equipped with barriers to prevent contamination of the canal and injury to the TM. ^{16,17} The outward movement of keratinized epithelium, along with the normal mandibular chewing motion, propels keratinized debris and cerumen outward. ^{5,15,16,24} The concentration of hair follicles and secretions of the numerous sebaceous and cerumen (apocrine-type) glands in the outer third of the canal, along with the S shape and isthmus of the canal, further prevent entry of foreign objects. ^{11,14,15} and ¹⁶ The waxy, water-repellent cerumen is a mixture of secretions from the sebaceous and apocrine glands in this area and the desquamated keratin layer from the stratum corneum. It protects by several mechanisms, including mechanical obstruction, stickiness, the water-repellent action of the lipids and

waxes, bacteriostatic and bactericidal effects, and the presence of lysozyme and immunoglobulins.^{11,14,15} and ^{16,23} Acidic pH plays a protective role, and possibly so does the presence of trace metals.^{15,16,23}

PATHOPHYSIOLOGY

The usual precipitating factor in acute OE is the introduction of infectious organisms into the epithelium of a previously traumatized ear canal in which protective defenses have been disrupted.^{2,16} Usual traumatic mechanisms are foreign bodies (cotton-tipped applicators, pencils), prolonged wetness (water sports, bathing, increased environmental humidity), or excessive dryness (previous infection, dermatoses, insufficient cerumen).² Various sequences of events have been proposed to explain the evolution of acute OE.^{5,16} In general, disruption of or interference with any of the protective mechanisms of the external canal can lead to OE. Predisposing factors include previous ear surgery or TM rupture,^{5,20} a narrow or abnormally angled canal,^{5,18} and excessive or decreased cerumen production.⁵ Even in the presence of predisposing factors, trauma and introduction of infectious agents into the canal are the immediate precipitating factors. In the most common scenario of infection, swimming pool water with an alkaline pH and commonly containing *Pseudomonas* organisms is introduced into a previously traumatized ear canal, often producing an episode of acute, diffuse OE.

NATURAL HISTORY

After the inciting event, symptoms develop over several hours or days. The spectrum of disease can range from mild to severe. Left untreated, the infection can resolve, persist as a chronic infection, or, with some organisms (usually *Pseudomonas*), progress over weeks or months to malignant (necrotizing, invasive) OE.^{9,17} This entity is seen almost exclusively in diabetics and other immunocompromised patients, although there are reports that it occasionally progresses from initially uncomplicated diffuse OE in nonimmunocompromised swimmers.⁹ Malignant OE can result in a high incidence of neurologic sequelae or death.^{4,6,7,9,18,25}

CLINICAL PRESENTATION

Patients presenting with mild-to-moderate acute OE may complain only of itching or irritation in the affected ear, often heightened by manipulation of the auricle or tragus.^{2,3,15,16,19} In more severe presentations, the severity of pain and tenderness may seem disproportionate to the degree of inflammation, probably due to compression of nerve fibers. Edema and erythema are present and the canal may be closed. There is usually a discharge described as yellowish, greenish, or watery. Fungal infections produce a dark or cheesy discharge. Frequently, the canal is so tender and swollen that the entire ear canal and TM cannot be adequately visualized. In such cases, complete otoscopic examination should be delayed until the acute swelling subsides.² If the canal is visualized, it often appears pale, soggy, and edematous, occluded by cerumen and desquamated epithelium.¹⁹ The TM, if visualized, may appear normal, opaque, or erythematous. It may have normal mobility or, if the drum is thickened, reduced response to insufflation.²

In more severe infections, there can be periauricular inflammation, cellulitis, lymphadenitis, and erythema.^{2,16,19} Fever is variably present^{2,19} and pain can be intensified by any manipulation of the jaw or the affected side of the face.¹⁹ Such presentations often result from combined infections with *Pseudomonas* sp. and *Streptococcus pyogenes* or from *S. aureus*.²

DIFFERENTIAL DIAGNOSIS

Many different diseases can produce ear pain. Locating the source of pain helps narrow the differential. The examiner usually can rule out otitis media by findings specific to the outer ear and canal. Pain on manipulation of the auricle and tragus is usually evidence against otitis media.¹⁹ If the TM can be visualized and mobility is normal, otitis media is not present. A serosanguineous discharge from the affected ear may represent a ruptured TM secondary to acute otitis media or penetrating trauma to the ear canal. Signs and symptoms of toxicity, facial nerve palsy, or meningeal signs are present in malignant OE.^{6,7}

Other diagnoses in the differential include adjacent disease processes with pain referred to the area of the ear canal: parotitis, periauricular adenitis, mastoiditis, dental abscess, temporomandibular joint pain, sinusitis, tonsillitis, or pharyngitis.^{2,15,16,19}

In cases of ear canal occlusion when severe pain and edema prevent adequate cleaning and visualization, excluding middle ear infection on the initial examination may be difficult.¹⁵

EMERGENCY DEPARTMENT EVALUATION

Emergency department evaluation includes manipulation of the auricle and tragus. The periauricular area is inspected for inflammation, cellulitis, folliculitis, or eczematous conditions. The canal is inspected and its condition noted. The TM is visualized, on initial examination if possible, and its mobility tested to rule out otitis media. Any exudate is cultured.¹⁶ Fungal cultures are included if the history is suggestive, the exudate is cheesy or black, or a candidal rash is present.

In elderly patients with diabetes and other immunocompromised patients with otorrhea and intense ear pain, the possibility of malignant OE must be considered. A white blood cell count (WBC) and erythrocyte sedimentation rate (ESR) are obtained in these patients.¹⁷ Signs of systemic toxicity, local extension of infection to periauricular areas, nuchal rigidity, or facial nerve palsy are sought.

If the WBC or ESR is more than mildly elevated, or any of the aforementioned signs are present, evaluation for malignant OE proceeds. This is especially true in patients who have had symptoms for weeks or months or in those who return with worsening or unresolved symptoms after previous evaluation and therapy.

Evaluation consists of proving spread of infection to the mastoid or base of the skull. Numerous radiologic techniques are used in this assessment. Plain films, including tomographic views, and computed tomography (CT) scanning can detect the bony erosions of advanced disease but are often of little help in early presentations.⁹ Technetium and gallium scanning are reported to be much more sensitive (than even CT scanning) in detecting early disease, and are preferred by many otolaryngologists.^{9,13,17} However, low specificity and decreased availability in emergency departments limit their usefulness. CT scanning is the current modality of choice for defining the anatomic extent of disease.^{13,17} However, significant destruction of trabecular bone is often necessary to define osteomyelitis by CT scanning.^{13,17} CT scans are generally more available to emergency physicians. The value of magnetic resonance imaging (MRI) is currently under investigation, but in small numbers of patients it has detected the presence of disease at least as well as CT scanning.^{9,17}

EMERGENCY DEPARTMENT MANAGEMENT

Basic management of acute OE includes aural hygiene, elimination of microbes, and analgesics. Hygiene involves cleansing of the ear canal and is considered by many to be the single most important part of therapy.^{3,15,16} For mild infections, dry-mopping with a small tuft of cotton attached to a wire applicator may be sufficient; sometimes it is even curative.¹⁵ In more severe infections, with an inflamed, edematous canal with cheesy secretions and debris, removal by suctioning is recommended.^{5,15,16} If appropriate suctioning devices are unavailable, one author suggests using a trimmed infant feeding tube attached to a De Lee suction device.¹⁵ Others suggest that in severe cases, suctioning should be done using the operating microscope. After all major debris and exudate are removed, careful irrigation with warm, sterile saline or a 2% acetic acid solution is recommended to complete the cleansing. Forceful irrigation is contraindicated, as it could traumatize further the macerated epithelium of the canal and actually promote suprainfection. After irrigation is complete, the canal must be dried. Several techniques have been used, including suction or instillation of a drying solution of dilute alcohol.² Some authors suggest using a hair dryer.^{15,16} In severe cases, this regimen must be repeated at regular intervals until inflammation has subsided.

Topical otic solutions are recommended by many for eliminating microbes and acidifying the canal in most cases of acute inflammatory OE. There is no consensus, however, on a solution of choice. Many are recommended and available, ranging from acetic acid preparation (2%) and half-strength Burow's solution (aluminum acetate, 1:20) to topical antibiotic preparations containing neomycin (active against gram-positive organisms and also against some gram-negative organisms, notably *Proteus* sp.) with either colistin or polymyxin (active against gram-negative bacilli, notably *Pseudomonas* sp.). Some of these commercially available solutions contain other ingredients, such as corticosteroids, to reduce inflammation.^{12,21,26} Most solutions seem to be effective if used in conjunction with the other recommended

treatment measures. There are anecdotal reports that neomycin-containing solutions produce a contact dermatitis, but the actual incidence in one trial was found to be 0.1%.⁹ Otic solutions are preferable to suspensions, except in TM perforation or the presence of a ventilation tube.

In canals that are severely inflamed and edematous, an ear wick may be necessary for the application of otic solutions.¹⁹ Expandable ear wicks of hydroxycellulose or similar materials are available and are reported by some to be preferable to cotton or gauze, although the latter are still recommended.^{15,24} The wick is placed about 10 to 12 mm into the outer third of the canal, and otic drops are placed directly on the wick.^{2,15} If wicks are required, steroid-containing solutions may have an advantage in hastening the reduction of inflammation. Ear wicks are usually used for 24 to 48 hours and then removed. Often they spontaneously fall out as inflammation subsides.

Otic solutions are applied to the affected canal three or four times daily, two to four drops per application. Seven to 10 days of therapy with resolution of symptoms is reasonable.^{5,11}

Pain from OE can be intense, and some patients may require narcotic analgesia during the initial evaluation, cleaning, and wick insertion and during the first 24 to 48 hours of treatment.^{2,3,11,15} Oral codeine or hydrocodone is effective.^{2,3} Continued severe pain after therapy begins should prompt reevaluation. Mild, locally applied dry heat often helps in pain management.^{2,3}

During treatment, introduction of water into the ear canal must be avoided. Swimming is prohibited. Showers should be brief and hair-washing infrequent and followed by instillation of otic drops.¹⁶ When bathing, shower caps, ear plugs, or other devices to prevent entry of water into the ear canal can be considered.²⁴

Oral antibiotics are generally unnecessary for mild-to-moderate cases of acute diffuse OE. In the vast majority of uncomplicated cases, these local measures should bring about resolution of symptoms. Oral antibiotics have been recommended in patients with more severe presentations, such as intense pain, fever, or lymphadenitis, or in patients who require ear wick insertion.^{2,5,12} Cultures of ear aspirates should be obtained in all such patients. Oral antibiotics are also recommended for patients with occluded ear canals who have symptoms, signs, or history suggestive of otitis media, such as upper respiratory infections, fever, or sore throat.²⁴

There are no firm guidelines for empiric oral antibiotic therapy for cases of acute OE presenting without complications. Penicillinase-resistant penicillins, trimethoprim-sulfamethoxazole, erythromycin, tetracycline, cephalosporins, and ciprofloxacin have all been advocated for initial empiric therapy.^{5,12,19} Culture results and evolution of the patient's condition should guide modifications to therapy. In the patient begun on an oral antibiotic who is improving, with cultures that indicate good sensitivity, continuation for a 10-day course with resolution of symptoms is reasonable. Almost all cases resolve with the aforementioned measures.

Parenteral antibiotics are occasionally required in the rare patient with symptoms of systemic toxicity,² or in the patient with a progressive or unresponsive infection. Cultures of ear aspirate should be done on all such patients and the possibility of malignant OE considered, especially in predisposed patients.

A combination of an aminoglycoside and an antipseudomonal penicillin should be started.^{12,15} If *S. aureus* infection is suspected, a cephalosporin or penicillinase-resistant penicillin is the initial therapy. Treatment is adjusted as culture results indicate. For patients with proven or suspected malignant OE, the infectious agent is almost invariably *P. aeruginosa*, and admission with parenteral antibiotic therapy is mandatory.³ Currently recommended initial parenteral treatment consists of an aminoglycoside in combination with an antipseudomonal penicillin, or an appropriate third-generation cephalosporin. Newer studies have reported good results with single agents such as ceftazidime or cefoperazone.^{9,11} The usual parenteral treatment period has been 4 to 6 weeks,^{3,11,12} with oral ciprofloxacin after about 1 week in responding cases.^{9,11}

DISPOSITION

Most patients with acute diffuse OE may be discharged home with instructions for good aural hygiene, topical antibiotic drops, and symptomatic therapy, including analgesia.²⁶ Discharge instructions should include avoiding water sports during therapy and for up to 2 to 4 weeks after resolution of symptoms. A 10-day follow-up is encouraged.

Elderly patients with diabetes or other immunocompromising diseases who are seen for OE should receive close follow-up and monitoring to prevent the rapid onset of malignant OE.²⁴

Patients with obstructed canals, with ear wicks inserted, or with severe pain (especially those whose initial otoscopic examination was limited due to pain and swelling), and patients on oral antibiotics or narcotic analgesics should be reevaluated in 12 to 24 hours to ensure that symptoms are resolving and to allow completion of a thorough otoscopic examination. As swelling subsides, polyps, neoplasms, foreign bodies, or otitis media not visible on the initial examination may be revealed.²⁴

Patients with severe edema, exudative discharge, and pain may require periodic, aggressive hygiene with irrigation, suctioning, and drying of the ear canal daily until symptoms regress. Otolaryngologic consultation should be considered in patients who require multiple daily visits for hygiene.

All patients with worsening of symptoms or failure to respond to initial management should be evaluated by an otolaryngologist. For patients with worsening symptoms, consultation should be immediate to consider possible hospitalization and parenteral antibiotic therapy.

Admission and parenteral antibiotic therapy are required for patients with systemic toxicity, meningeal signs, or facial palsy. A workup to rule out malignant OE is indicated, including lumbar puncture, CT scanning (possibly MRI), and bone scans.

ACUTE LOCALIZED OTITIS EXTERNA

Acute localized OE is usually caused by an infected hair follicle in the cartilaginous ear canal (aural furunculosis), which, in adults, consists of the outer third of the canal.^{2,3,12,16} More rarely, eczema, seborrhea, impetigo, warts, or herpetic eruptions can produce localized OE.¹⁵

The epidemiology and etiology are similar to those of acute diffuse OE, but in most cases the infecting organism is *S. aureus*.^{2,3} The pathophysiology is similar to that of acute diffuse otitis media: Most cases are caused by direct trauma to the ear canal, although occasionally they are secondary to a blocked sebaceous gland.³ The natural history of untreated acute OE is that of acute diffuse OE.

CLINICAL PRESENTATION

Itching and pain of the affected ear are the usual presenting symptoms. Physical findings are similar to those of diffuse otitis, except that a localized swelling or pustule (abscess) may be identified in the cartilaginous ear canal.¹ Local adenopathy is common. Often, the canal is swollen shut, impairing the differentiation of localized from diffuse OE. A discharge is not often present in localized otitis media until the abscess ruptures.³

DIFFERENTIAL DIAGNOSIS AND EMERGENCY DEPARTMENT EVALUATION

The differential diagnosis and evaluation of acute localized OE are the same as for acute diffuse OE.

EMERGENCY DEPARTMENT MANAGEMENT

Management of a localized otitis follows the same guidelines as for diffuse otitis. The vast majority of cases respond to good aural hygiene as described previously, topical otic solutions, and analgesia. If a discrete, painful lesion is identified, incision and drainage may be necessary, especially if pain is significant. If localized

cellulitis is present, an oral systemic antibiotic active against *S. aureus* (dicloxacillin or a cephalosporin) should be instituted for 10 days.

DISPOSITION

Symptoms of acute localized OE should resolve within a few days after initiation of treatment, especially with continued good hygiene. Cases that worsen or fail to respond should be referred to an otolaryngologist; worsening cases should receive immediate evaluation. Patients who have undergone incision and drainage and those receiving antibiotics for associated cellulitis should receive a mandatory follow-up in 12 to 24 hours.

COMMON PITFALLS

- Confusing OE with otitis media
- Misdiagnosis of a ruptured TM with purulent drainage as OE
- Underdiagnosing OE when symptoms of toxicity or malignant OE are present

The physician who faces an awake patient who is experiencing rapidly progressive airway obstruction knows the meaning of apprehension. Evaluation, differential diagnosis, and emergency intervention all must occur simultaneously. The window of time for effective intervention before irreversible injury occurs is so small that little margin for error exists. Progressive airway compromise exemplifies the need for anticipation, preparation, and practice to deal with the responsibility of emergency airway management.

Effective emergency management requires early recognition of a high-risk clinical situation and anticipation of further deterioration in the airway status. This approach allows intervention to occur at the proper time, before the situation becomes desperate. The necessary therapy is likely to be less traumatic to the patient if practiced early in a controlled manner. Preparation of equipment, drills of the emergency team, and practice of technique all contribute to lessen the margin for error and improve patient outcome.

This chapter presents an overview of nontraumatic conditions that affect upper airway patency. The focus here is on the development of the airway obstruction, its recognition, and early management.

CLINICAL PRESENTATION

Nontraumatic airway obstruction is often insidious in onset. Once begun, the process may further deteriorate gradually or decompensate suddenly without warning. Neither the person eating a large piece of steak nor the adult with epiglottitis expects that he or she will soon be suffocating when the event is in its early stages. Obstruction occurs abruptly in the first case; hours may pass during the obstructive process in the second. The emergency physician must understand the disease processes at work and be prepared to intervene quickly when necessary.

Several factors may affect the type of presentation manifest by a given patient. The site of the obstruction, the size of the obstructing agent, and associated spasm and edema are important determinants of the presentation.¹⁶ Historical factors may simplify the diagnosis. Physical findings may be nonspecific, or simply serve to separate patients into a category of obstruction.

Spectrum of Respiratory Distress

Airway obstruction proceeds from no clinical findings to obvious distress with a patient in an agonal state. The pattern of increasing obstruction is first manifest by some subjective findings of respiratory distress by the patient. The initial subjective finding may appear as “wheezing” with both an inspiratory and an expiratory component. Further obstruction alters the finding to stridor. Next, the airway obstructs completely and the patient struggles, loses consciousness, and will die without effective intervention to restore airway patency.

Apprehension, agitation, and struggling develop as obstruction increases. The fear in the eyes of a conscious patient experiencing airway obstruction is apparent. The patient's discomfort is transmitted to all who are present at the time. A nonproductive atmosphere of near hysteria can develop in the absence of an organized approach to relieve the obstruction. One of the benefits of public education on the choking victim has been to provide instruction that channels energies from useless activity into airway-clearing maneuvers. Deaths from choking numbered 3300 in the United States in 1997. Sixty-eight percent of those deaths occurred in individuals over age 65, and 54% in those over age 75. A smaller incidence peak occurs in the newborn to age 4 group.¹²

Although airway obstruction by a foreign body, such as food, occurs suddenly, obstruction by an expanding mass effect within the upper airway is more insidious. Abscesses may obstruct the airway by their location. Expanding hematomas behave similarly. Edema and soft-tissue swelling owing to infection or allergy behave slightly differently because of a more diffuse mass effect.

Signs to anticipate in the patient suspected of developing airway obstruction vary slightly, depending on the cause, but some generalization can be made. The habitus of the patient is important to note. An upright posture with the neck extended in the sniffing position is characteristic in the patient with supraglottic obstruction, such as epiglottitis. Forcing a supine position in such a patient for the convenience of the medical team is disastrous. Pursing of the lips is commonly noted in patients who are struggling for air. An asymmetrical mass may increase in size during the observation period.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of upper airway obstruction includes several causes for the obstruction. Foreign-body obstruction, infection, hypersensitivity, hemorrhagic disorders, extrinsic mass, and neoplasia all may result in the syndrome of upper airway obstruction. The patient's presentation may quickly narrow the diagnosis, or the diagnosis may remain a mystery until late in the patient's course.

Foreign-Body Obstruction

The classic example of upper airway obstruction by a foreign body is the “cafe coronary.” Food that causes an obstruction has often been poorly masticated. The victim may have painful or poorly fitting dentures or otherwise poor dentition that hampers chewing. Alcohol consumption is often implicated in the condition. This type of obstruction usually occurs in the supraglottic area and responds to the airway maneuvers prescribed by the American Heart Association.³

Aspirated toys or smaller pieces of food may pass the vocal cords and produce obstruction in the subglottic area. These obstructions may be intermittent and aggravated by the head-down position, which allows gravitational movement of the object to an obstructive position. Back blows and the head-down position may actually worsen these obstructions.^{12,16} The clinical presentation of a subglottic foreign body may be one of localized wheezing and atelectasis of obstructed

pulmonary segments as the foreign body becomes lodged in a bronchus.

Any object that can fit in the mouth may produce airway obstruction given proper circumstances. The broad range of possibilities is best approached by attempts to differentiate supraglottic and subglottic obstructions. The site of the obstruction affects management decisions. A supraglottic obstruction that is not removable may be bypassed by tracheal intubation or surgical airway placement. A subglottic obstruction may require a more difficult airway decision, depending on its location. Magill forceps may allow removal of foreign bodies under direct vision.²⁰ A recently described aspiration technique using a blunted endotracheal tube, wall suction, and a meconium aspirator or "Y" connector to the tube can greatly facilitate removal of subglottic foreign bodies such as balloons and steak.¹⁵

Infection

Cellulitis of oropharyngeal structures produces a treacherous setting in which airway compromise develops with little notice in a patient who has dysphonia and limited communication capacity. Ludwig's angina (cellulitis of the sublingual space) can quickly obstruct the airway. The condition is a true otolaryngologic emergency that requires airway maintenance and antibiotic therapy. Retropharyngeal or laryngeal abscess can cause gradual obstruction owing to expansion and catastrophic deterioration through sudden rupture into the airway.^{8,14} The natural history of these conditions needs to be kept clearly in mind when evaluating the emergency patient.

Hypersensitivity

Anaphylaxis can present suddenly after exposure to a known or unrecognized antigenic stimulus. When its representation is in the form of laryngeal edema, prompt intervention is needed to interrupt the obstructing process. A delay in the initiation of medical therapy may force surgical intervention in order to save the patient's life. Food, drug, and insect sting allergies are commonly encountered causes of anaphylactic airway emergencies. A history of exposure may depend on the patient's ability to communicate, which is directly related to the degree of airway compromise that is present.

Hereditary angioneurotic edema (HANE) is an autosomal dominant condition that is manifested by sudden edema of the face, hands, abdominal viscera, and airway.¹¹ Episodes may be triggered by minor trauma, emotional distress, and surgery. No race or sex predilection exists, and family history may be negative. HANE is most commonly characterized by a complement deficiency of C₁ esterase inhibitor (C₁ INH). The postulation is that the excess of a C₂ kinin develops because of the inhibitor deficiency, and the C₂ kinin is responsible for the increased capillary permeability seen in HANE.⁸ Management of the condition is discussed in a later section.

Angiotensin converting enzyme (ACE) inhibitor agents for control of hypertension have become a new cause of angioedema in patients previously free of the condition.^{9,13} Moderate-to-complete airway obstruction may occur. The drugs must be discontinued in patients experiencing this adverse reaction to prevent recurrence.

Hemorrhagic Disorders

The widespread use of anticoagulants for the treatment of cardiac and cerebrovascular disease has increased the population at risk for spontaneous hematoma formation. Spontaneous hematomas may develop throughout the body without any special predilection to one area. When the pharynx, the airway, or soft tissues surrounding these structures are involved, airway compromise is a predictable consequence.

Warfarin-predisposed patients have been reported with airway compromise owing to hematoma of the sublingual space, retropharynx, and hypopharynx.¹ The syndrome is marked by rapid, unexpected deterioration of a person who, in most cases, was previously healthy. Pain is often noted early, frequently preceding other symptoms. Signs of airway obstruction may develop before the examiner's eyes. Physical examination often reveals an area of swelling, frequently without ecchymosis. Soft-tissue radiography of the neck, computerized tomography, and indirect laryngoscopy are often useful. Close observation during the evaluation period is essential to avoid unrecognized abrupt deterioration with adverse outcome.

Extrinsic Mass

Unusual causes of airway obstruction owing to an extrinsic mass are occasionally seen. An example is the development of an obstruction in the esophagus caused by achalasia.¹⁸ The distended esophagus impinges on the airway in the neck and produces recurrent airway obstruction that disappears when the esophageal obstruction is cleared. Cystic lesions of various types may produce a similar syndrome that may require temporary airway support until the lesion is removed.⁶

Neoplasia

Direct or indirect airway obstruction may result from neoplastic disorders. Laryngeal carcinoma and intrinsic airway tumors produce a gradually developing obstruction that may be mistaken for bronchospastic disease. Bypass of the laryngeal lesion by intubation or cricothyrotomy reveals an abrupt decrease in airway resistance. The abrupt resistance change localizes the disease to a site above the distal end of the tracheal tube. Tumor masses extrinsic to the airway may impinge on its lumen in a manner similar to that described for cystic lesions.⁷ Bronchogenic carcinoma or lymphomas may produce a superior vena caval syndrome leading to airway obstruction.⁹

Congenital tumors of the oropharynx or neck may present immediate and unexpected airway emergencies at birth. Such a condition requires immediate availability of neonatal resuscitation capabilities and surgical readiness.¹⁷

Kaposi's sarcoma of the trachea has presented with airway obstruction. Death followed hemorrhage of the tumor when it was incised in an attempt to provide surgical airway support during obstruction.

EMERGENCY DEPARTMENT EVALUATION

Regardless of the cause of the obstruction, the emergency physician must first gauge its severity by quickly placing the patient in one of four categories: (1) stable, deterioration risk low; (2) stable, deterioration risk high; (3) compromised respiration; or (4) agonal state. Once this immediate classification has been made, the evaluation and therapy process can proceed with the appropriate degree of fervor.

A patient in the first category has been determined to be stable and at low risk of deterioration. This categorization is the most hazardous for the emergency physician to make. It implies that the patient can be evaluated at a leisurely pace with a minimal degree of observation. Such a patient will prove the physician wrong most often because the opportunity exists to do so. Airway-obstructing lesions notoriously deteriorate unexpectedly in patients who looked well minutes before the decompensation. Classification of a patient in the first category implies a certainty of diagnosis that is usually absent during initial evaluation. Although the patient may be placed in this category after an observation and data-collection period, it is seldom appropriate to place a patient with suspected airway compromise in this category early in the evaluation period.

The second category reflects the appropriate degree of concern during initial evaluation of any patient in whom airway obstruction is suspected. The risk of deterioration calls for constant observation, with equipment in readiness to intervene if necessary. Measures intended to arrest the underlying obstructive process should be instituted as soon as possible.

The third category, with established airway compromise, calls for immediate decision on airway implementation. The emergency physician must quickly assess the likelihood of success with a medical approach before airway establishment by intubation or surgical approach is required. The judgment must be made using clinical experience. An arterial blood gas analysis may help with the decision when it can be obtained immediately, but often such testing only delays needed therapy.

The last category, with the patient in an agonal state, represents the most straightforward, immediate evaluation and therapy situation. The airway must be established immediately. No other consideration takes precedence.

EMERGENCY DEPARTMENT MANAGEMENT

Airway management is the second part of the evaluation and therapeutic tightrope that must be walked when dealing with upper airway obstruction. The differential diagnosis coupled with the severity assessment will guide the therapeutic approach.

Modifying Factors

The patient who has been classified as stable and at high risk of deterioration is a candidate for attempts to improve status without physical airway intervention. Medical interventions are most effective when directed at a specific cause, but a few nonspecific interventions may be of benefit early. Oxygen supplementation should be initiated in all cases. Consideration needs to be given to nebulization therapy with racemic epinephrine or beta-2 agents and steroids to decrease edema in hypersensitivity or croup syndromes. If infection is a possibility, then appropriate antibiotic therapy should be considered. Bleeding disorders need supplementation of coagulation factors to arrest the process.

A mixture of 80% helium and 20% oxygen has been suggested as a temporizing measure in patients with airway obstruction caused by tumors.¹⁶ The density of the mixture is one-third that of air. The increased flow of gas allowed by the decreased density may improve oxygenation in selected patients with narrowed upper airways. Application of the gas mixture in other types of airway obstruction has been limited. Concern over use of the technique in patients with progressive obstructive disease centers around the possibility that the mixture will delay definitive management of the condition. Temporary cessation of the helium mixture might abruptly lead to complete obstruction while breathing room air in this scenario.

Treatment Directed at Cause

The likelihood that foreign-body obstruction exists should prompt airway-clearing maneuvers to be implemented according to widely accepted protocols described by the American Heart Association.³ Failure to clear the airway should lead to more aggressive airway-establishment maneuvers.

Mortality in children with epiglottitis seems to be reduced when a controlled, aggressive approach to airway intervention occurs. Those who undergo controlled airway establishment seem to have a lower mortality than those whose management is characterized by close observation with airway intervention as needed.⁵ Similar statistics are not available in the adult patient, but experience has shown that they, too, may deteriorate unexpectedly and need to be monitored constantly until the infection recedes. Preparation for surgical airway placement must be constant.

The patient with a hemorrhagic disorder with associated warfarin therapy requires some medical therapy to reverse the coagulopathy. Vitamin K enhances clotting factor synthesis in the liver. Levels of dependent factors II, VII, IX, and X begin to increase 2 hours after vitamin K administration, with significant elevation in 6 to 8 hours, and are frequently normal in 24 hours.¹⁷ The most rapid correction of the clotting abnormality is by administration of fresh-frozen plasma or prothrombin complex concentrates. Airway obstruction is an indication for rapid reversal, which means fresh-frozen plasma administration in most cases. Fewer side effects are seen with plasma than with the concentrates.¹⁷ Plasma is, therefore, the preferred emergency management.

Airway-Opening Maneuvers

Airway-opening maneuvers such as chin lift, head tilt, and oral and nasal airways are most useful in patients with a decreased level of consciousness.³ The situation is quite different if the comatose state is a result of hypoxia owing to airway obstruction. Patients who are suffering from an airway obstructive process need more than these devices provide. Specific medical therapy and more aggressive airway intervention therapy are usually indicated.

Nonsurgical Management

A patient with significant airway compromise who does not improve with medical intervention will often require tracheal intubation. Blind nasotracheal or orotracheal intubation will suffice in many cases in which the decision is made before the airway is completely obstructed. Rapid-sequence orotracheal intubation will facilitate intubation.¹⁹ Whether it will facilitate removal of the airway obstruction depends on its etiology and location. The physician must weigh the risks of paralysis against its potential benefit in each case. Inability to remove an obstructive agent or to secure the airway with tracheal intubation is an indication to pursue surgical approaches to the airway.²

Surgical Management

Transtacheal needle ventilation using a high-pressure oxygen source to supply intermittent ventilation provides adequate ventilation in cases in which exhalation can still occur through the upper airway. The presence of a ball-valve mechanism of the obstruction will allow exhalation to occur. The technique is a temporizing measure that allows time to secure the airway by other, more definitive means.

Cricothyrotomy is the emergency surgical airway of choice for most airway-obstructing lesions.¹⁴ If the offending lesion is subglottic, such as a laryngeal abscess, hematoma, or tumor, then tracheostomy is preferred over cricothyrotomy.

Providing details of the procedural approach to airway management is beyond the scope of this chapter. A more lengthy discussion of the procedures and the logic behind their use can be found elsewhere.^{3,8}

DISPOSITION

Role of the Consultant

The development of protocols for treatment of the wide variety of obstructive conditions needs to be begun by the emergency physician. A cooperative team effort needs to be organized by personnel from the emergency, anesthesia, otolaryngology, pediatric, and medicine departments who will be dealing with the patients, depending on the cause. Treatment of pediatric epiglottitis is an excellent example of the type of cooperative efforts that can optimize results. Communication and agreement on management should occur in advance for common, recurrent clinical problems, such as epiglottitis. The cooperative approach developed with these cases will carry over to optimize management of the more unusual causes of airway obstruction.

Indications for Admission

The patient with airway obstruction needs to be under constant observation in an intensive care unit until the risk of airway obstruction has passed. A good example of an attempt to separate high-risk from low-risk croup patients has been developed by Davis. A scoring system to assist with decision making in children with croup is based on clinical findings. A score of 0 to 15 is given based on the presence of stridor, retraction, air entry, skin color, and mental status. The patient is given a score of 0 to 3 for each of the five findings. The total score is then determined. Patients with a score of less than 5 may be treated at home with mist therapy. Those with a score higher than 5 should be admitted for at least a trial of racemic epinephrine, and possibly steroids, and close monitoring for deterioration that necessitates intubation. Similar scoring mechanisms might apply to other reversible causes of airway obstruction. Whenever doubt exists as to the immediate future course of a patient with airway obstruction, intensive care unit admission is mandatory.

COMMON PITFALLS

- The emergency physician should be aware of untoward events that might occur after relief of the obstruction. These include local trauma, infection, and other hazards of airway intubation. A prominent concern when dealing with airway obstruction is the sudden pulmonary edema after the obstruction has been relieved; the mechanism development is unclear but is presumably related to the sudden decrease in hydrostatic pressure. Treatment is supportive and may include diuresis.⁴
- The most common mistake when dealing with airway obstructive disease is to underestimate the potential for deterioration. A complacent attitude fosters poor

preparation, surprise deterioration, mismanagement, and tragic outcome. Upper airway obstruction is an emergency condition that requires maximal preparation.

- The second most common mistake is to relax monitoring to the point where deterioration goes unnoticed. All the time invested in preparation, drills, and skill maintenance is wasted if the disease process is not treated with the respect it deserves.

The neck mass is a complaint or finding that may accompany many disorders. It may be congenital or acquired, infectious or neoplastic, benign or malignant.⁴ In children, most neck masses are relatively common and minor, whereas the incidence of neoplastic lesions is high in adults. In neither group does the neck mass commonly present as an acutely emergent or life-threatening problem.

CLINICAL PRESENTATION

An accurate history and careful physical examination are critical in the evaluation of the neck mass. The primary goal is to determine the most likely site and cause. The history should address the seven cardinal symptoms of head and neck disease: dysphagia, odynophagia, referred pain with swallowing, hoarseness, stridor, speech disorder, and globus phenomenon.¹⁵ Dysphagia and odynophagia need not be present concomitantly but may allow the patient to localize the lesion to the upper aerodigestive tract. Referred pain is typically to the ear and has the same significance as odynophagia. A major concern suggested by neck pain is the presence of an infection or disease process extending to the deep spaces of the neck. Masses or space-occupying lesions can present as problems with speech or as airway obstruction, the latter the most likely emergency the physician may encounter with the neck mass. The globus phenomenon is the sensation of a lump in the throat that is present between meals and may be described as excessive postnasal drip, “worms” in the throat, trouble swallowing saliva, or excessive mucus. The globus phenomenon is not associated with difficulty swallowing food.¹⁵

Other important historical features include the use of tobacco in any form, the excessive use of alcohol,¹ previous radiation exposure of the neck, current or recent illnesses, current or recent injuries, infection of the head and neck, travel history, animal exposure, and other associated local or systemic symptoms. Specific questions about the mass include duration, changes or fluctuations in size, associated pain or inflammation, and sites of any drainage.

A good physical examination is critical and includes a thorough evaluation of the scalp, face, skin, nose, ears, oral cavity, dental structures, pharynx, nasopharynx, and the mass itself. Also included in this examination are indirect visualization of the nasopharynx and larynx with a mirror and headlight, and digital palpation of the nasopharynx and base of the tongue. The neck mass is examined and palpated for size, shape, consistency, mobility, and tenderness. When attempting to determine whether a neck mass may be a lymph node, it is important to recognize the location of the normal chain of cervical lymph nodes ([Fig. 31.1](#)). [Figure 31.2](#) shows the anterior and posterior cervical triangles in the neck formed by the sternocleidomastoid muscle medially and the midline of the neck anteriorly and posteriorly. The importance of these triangles and normal lymph node distribution will become apparent as one reviews the differential diagnosis of the neck mass.

Figure 31.1. Major cervical nodes and drainage patterns.

Figure 31.2. Anterior and posterior triangles of the neck.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a neck mass is extensive and depends on the patient's age. The “80% rule” states that 80% of isolated neck masses in children are benign¹⁵; in adults, 80% of nonthyroid neck masses are neoplastic and 80% of neoplastic masses are malignant. Furthermore, 80% of these malignant masses are metastatic and 80% of the primary tumors are located above the clavicle.^{4,12}

Infectious Neck Mass

The most common cause of a benign neck mass in children is cervical adenopathy secondary to an upper respiratory tract infection, usually of viral origin. Acute cervical lymphadenitis is most often caused by bacteria, with beta-hemolytic streptococci and *Staphylococcus aureus* the most common isolated organisms. Anaerobic bacterial infection should be considered if a dental infection is present. The child with acute cervical lymphadenitis is often febrile and tends to appear toxic. The

inflamed cervical mass is warm, erythematous, and tender.⁵ Cat-scratch disease is generally a self-limiting, benign, ipsilateral, lateral adenopathy⁵ that typically follows a scratch from a cat or, rarely, a dog or monkey bite. The etiologic organisms are *Bartonella quintana* and *Bartonella henselae*, fastidious gram-negative bacteria.¹¹ Although the adenopathy typically resolves in about 3 months,^{17,20} the clinical course may be shortened with antibiotic therapy (e.g., azithromycin for 5 days), and incision and drainage of the nodes is discouraged.

The most common viral cause of acute cervical lymphadenitis is mononucleosis. It is typically associated with fever, anorexia, malaise, pharyngitis, or an exudative tonsillitis. However, the very young child may demonstrate only cervical adenopathy and a mild upper respiratory tract infection.^{10,20}

Other potential but uncommon sources of infectious neck masses include *Haemophilus influenzae*, anaerobic bacteria, psittacosis, histiocytosis, toxoplasmosis, tuberculous adenitis (scrofula), actinomycosis, brucellosis, typhoid, and syphilis. Deep neck infection is a serious but uncommon problem that may lead to life-threatening complications such as airway obstruction, septicemia, erosion into the carotid artery, and extension into the mediastinum. Ninety percent of deep neck space abscesses occur in either the retropharyngeal, the lateral pharyngeal, or the submandibular space.^{4,13} *S. aureus* and hemolytic streptococci are the pathogens most frequently found in children. Anaerobic streptococci and *Bacteroides* may occur in adults, especially when dental infection is the primary underlying problem.¹⁹

With increasing numbers of geriatric patients, especially those from nursing homes and those who are victims of self-neglect, infections of the salivary glands and submandibular space are seen. These infections are associated with poor oral hygiene, dental disease, dehydration, and general debilitation. Parotid gland infection, cellulitis, and abscess of the floor of the mouth or submandibular space (Ludwig's angina) are common examples (Fig. 31.3).

Figure 31.3. Ludwig's angina.

As AIDS becomes more prevalent, it will probably assume greater importance in the differential diagnosis of the neck mass in both children and adults.

Congenital Neck Mass

About 6% of neck masses are congenital.³ The most common of these are thyroglossal duct cysts, dermoid cysts, branchial cleft cysts, and cystic hygromas (lymphangiomas). The first two present as midline neck masses; the latter two, typically as lateral neck masses.

Thyroglossal duct cyst is the most common benign congenital neck mass (Fig. 31.4).⁶ The thyroglossal duct is a microscopic thread of undifferentiated epithelial cells, a remnant of the embryogenic development of what becomes the pyramidal lobe of the thyroid gland. It descends from a position at the base of the tongue, through the hyoid bone to the inferior portion of the neck, where it fuses with the lateral aspects of the thyroid gland.^{16,18} For unknown reasons, the remnant of undifferentiated cells may become activated and differentiate into one of the epithelial cell forms or into glandular tissue (including thyroid tissue). It can be located anywhere from the base of the tongue to the thyroid gland, but it is commonly adjacent and inferior to the hyoid bone.⁹ The cyst tends to be fluctuant, smooth, rounded, well defined, and nontender. Although the size is usually 1 to 2 cm, it may fluctuate in size. It can also become infected. There is no significant sex prevalence, and although it may present at any age, the vast majority occur between 1 and 9 years of age, with a peak incidence between 3 and 5 years. The mass is typically discovered by a parent, who reports its intermittent presence. The mass becomes more visible with hyperextension of the neck. One study of midline cervical masses found that movement of the mass with swallowing or tongue protrusion was common but not pathognomonic of a thyroglossal duct cyst. However, an infrahyoid position and a history of inflammation and fluctuating size were helpful in differentiating between a thyroglossal duct cyst, an epidermoid cyst, and a midline enlarged lymph node.⁹ Serious complications or emergencies associated with thyroglossal cysts are rare, even though up to 30% develop an associated sinus that drains and serves as the route of recurrent infection.¹⁶ Surgical excision of the cyst and tract is necessary to prevent recurrent infection.

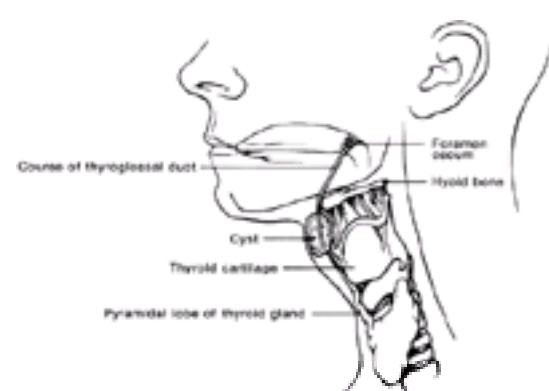

Figure 31.4. Thyroglossal duct cysts.

An epidermoid cyst is the most common of the dermoid cysts that occur in the head and neck.⁴ An estimated 27% of midline cervical masses are dermoid or epidermoid cysts.^{4,9} Typically, an epidermoid cyst is a nontender midline cervical mass that moves with the overlying skin and tends not to fluctuate in size or become inflamed. The submental and infrahyoid areas are the most common locations. Dermoid cysts are more common in children under 5 years of age, but may be acquired at any age as a result of a prior puncture wound. Again, serious complications or emergencies associated with dermoid cysts are rare, and the treatment is surgical excision.

Branchial anomalies may present as cysts, sinuses, or fistulas. The second branchial cleft is responsible for most anomalies, of which cysts are the most common (Fig. 31.5). The cysts are usually lined with squamous epithelium, less commonly with a columnar epithelium. They lie anterior to and in the middle third of the sternocleidomastoid muscle. There is no sex prevalence. They occur with equal frequency on either side of the neck. The cyst may develop at any age, although it may be more common in adults. When the cyst does develop in childhood, it occurs more often in the early school years.¹⁵ The cyst typically is rounded, nontender, slightly mobile, and of variable firmness. It may gradually increase in size, and may appear to enlarge with upper respiratory tract infections. Infections of the cyst are uncommon.

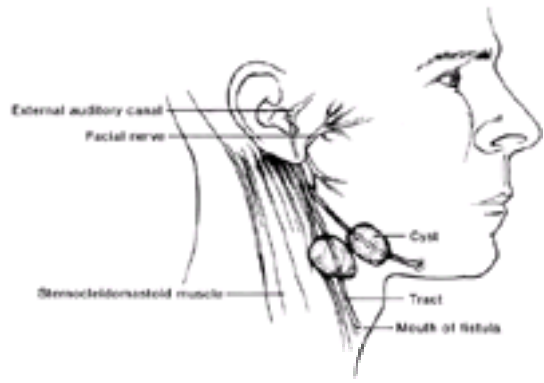

Figure 31.5. Branchial cleft cyst.

Branchial sinuses are relatively uncommon. They may open internally or externally. Almost all that open externally on the side of the neck result from the second branchial cleft or groove.¹⁶ Branchial sinuses are usually noted at birth, with the external sinus opening anterior to the lower third of the sternocleidomastoid muscle. The rare internal sinus opens into the tonsillar fossa. A fistula occurs when the tract has both an internal and an external opening. First branchial cleft anomalies with the external sinus opening in the external auditory canal require special precautions because of the proximity to the facial nerve and parotid gland. Acute, serious complications or emergencies arising from branchial cleft anomalies are uncommon. The treatment is elective surgical excision of the cyst, sinus, or fistula.

Cystic hygromas and lymphangiomas are congenital masses of lymphatic tissue thought to arise from lymphatic sacs. The cysts are thin-walled and lined with endothelial cells, and may be isolated or clustered. Eighty percent to 90% are located in the posterior triangle of the neck.^{8,18} Sixty-five percent present at birth, 80% are noted in the first year of life, and 90% are found before the end of the second year. There is no sex prevalence, and the masses occur with equal frequency on either side of the neck.^{4,7,18} The masses can be smooth, rounded or lobulated, soft, and compressible, and they can be transilluminated. An increase in size may occur with an upper respiratory tract infection. Although they tend to be asymptomatic, they may become large enough to cause difficulty with swallowing or breathing due to compression of the trachea. Emergencies are uncommon. The accepted treatment is surgical excision, although some surgeons prefer expectant observation in the asymptomatic mass in anticipation of a spontaneous regression.

Another congenital lateral neck mass is the hemangioma, a vascular anomaly present at birth that usually regresses spontaneously. The hemangioma is a bluish, nonpulsatile mass with a “bag of worms” texture located in the area of the parotid gland.¹⁵ Airway compromise can occur if the mass reaches sufficient size to encroach on the upper airway.

Other uncommon congenital neck masses include thyroid cysts, parotid gland cysts, and thymus remnants.

Neoplasms in Children

Benign neoplasms in children that present as neck masses include hemangiomas, lymphangiomas, fibromas, neurofibromas, and lipomas. Only 20% of neck masses in children are malignant. Of these, more than 50% are lymphomas in the Hodgkin disease and histiocytic lymphoma (lymphosarcoma) groups.

Malignant neck neoplasms in children tend to be single, nontender, and fast-growing, and are located in the posterior triangle of the neck. Age is a key element in the occurrence of the various malignant neck neoplasms. From ages 1 to 5, neuroblastoma, rhabdomyosarcoma, histiocytic lymphoma, and Hodgkin disease are more common. In the older child, histiocytic lymphoma and Hodgkin disease occur equally often. The adolescent most commonly acquires Hodgkin disease. Even though histiocytic lymphomas occur twice as often as the Hodgkin lymphomas in children, they present with nearly equal frequency in the head and neck. Eighty percent of Hodgkin disease and only 40% of histiocytic lymphomas present with a neck mass.^{14,20} Histiocytic lymphomas occur at any age, whereas Hodgkin disease is very uncommon before age 5, peaking between ages 5 and 9.^{4,19} Rhabdomyosarcoma is the most common solid tumor of the head and neck in childhood and is one of the most common tumors in children under age 6. It is less common in non-Whites. Rhabdomyosarcoma presents with rapid growth in the orbit, nasopharynx, ear, mastoid, face, or tongue. The neuroblastoma is the most common solid tumor in children overall, but it presents as a neck mass only about 5% of the time.¹⁹ Five percent of malignant neck neoplasms are thyroid cancer (medullary, papillary, mixed papillary, or follicular). There is a 2:1 female predominance. Roughly three-fourths of preadolescent children with a single thyroid nodule have a thyroid cancer.¹⁴ About 25% of neurofibromas and neurofibrosarcomas present in the neck and head, but they represent only 5% of malignant head and neck neoplasms. Unlike in the adult, metastatic squamous cell cancer that presents as a neck mass occurs in less than 1% of the total neck masses in children.

Adult Neoplasms

Benign neck neoplasms in the adult are of the same origin as those found in children but are significantly less common. Only 20% of adult neck masses are benign. Neck neoplasms account for 5% of all cancers. It is estimated that up to 90% of malignant neck masses in patients over age 50 are metastatic.^{5,15} Most often, squamous cell carcinoma from a primary site in the upper aerodigestive tract metastasizes to the lymph nodes of the upper, middle, and lower aspects of the neck. When a neoplasm below the clavicle metastasizes to the neck, it tends to involve the supraclavicular nodes. [Figure 31.1](#) shows the lymph node groups and the anatomic areas from which metastasis occurs.

In nine out of ten cases, the primary site for a metastatic node can be found with a careful history and physical examination. Of those with an occult primary lesion, roughly three-fourths have a primary lesion in the head and neck; the remainder have a primary lesion below the clavicle. Lymph node spread is an ominous development, reducing the chance of control of most head and neck cancers by at least 50%.²

Benign and malignant thyroid disease should always be in the differential diagnosis. This includes simple goiter, primary thyroid cancer, and metastatic thyroid cancer. Difficulty swallowing and voice change are especially suggestive of thyroid cancer in the presence of a thyroid mass or enlargement. Papillary and follicular carcinomas are the more common forms of thyroid cancer in the adult. Graves disease and autoimmune thyroiditis should also be considered when there is an enlarged or painful thyroid with associated weight loss, tachycardia, and tremors.

Three-fourths of salivary gland tumors are in the parotid gland, and one-sixth of these parotid tumors are malignant.⁴ A painful mass in the parotid gland that is adherent to the skin or deep tissues suggests a malignant neoplasm (see [Fig. 18.3](#) in Chapter 18).

Carotid body tumors are typically small, nontender, horizontally mobile masses that overlie the bifurcation of the common carotid artery. Their size increases slowly over years, and they may produce symptoms secondary to their size. Although surgical excision is the recommended therapy for small tumors in healthy patients, significant morbidity and mortality are associated with their removal.

EMERGENCY DEPARTMENT MANAGEMENT

A thorough history and examination of the head and neck are essential. The nasopharynx, base of the tongue, and larynx are examined both by digital palpation and by indirect mirror visualization. Critical complications or emergencies associated with neck masses are very uncommon, but when they occur they are almost always caused by airway compromise from tracheal displacement and compression or from upper airway obstruction by a mass. Infectious complications such as sepsis, deep neck space infection, and extension into the mediastinum are other life-threatening problems. A rare complication is erosion into the carotid sheath and subsequent rupture of the carotid artery. Appropriate blood tests include a complete blood count, Monospot, and thyroid function studies. Radiographic studies may include posteroanterior and lateral views of the chest, a sinus series, and a lateral view of the neck. Needle aspiration of a neck mass in the emergency department is not recommended. A neck mass of presumed inflammatory or infectious origin, including infected congenital cysts, can be treated with observation and antistaphylococcal antibiotics for up to 2 weeks. However, prolonged or repetitive courses of antibiotics are to be avoided. Endoscopic examination, sialography, ultrasound, computed tomography scan, magnetic resonance imaging, angiography, an upper gastrointestinal series, barium enema, and biopsies are usually

unnecessary in the emergency department, but may be completed by the consultant(s).

DISPOSITION

Role of the Consultant

Consultation in the emergency department with a surgeon skilled in head and neck surgery is required for any patient with signs or symptoms of airway compromise or if there is suspicion of a deep neck space infection. Any adult, especially one over age 40, with a history of tobacco or heavy alcohol use who presents with a neck mass of any size requires referral within a reasonably short time to a surgeon skilled in head and neck surgery. Children should be treated according to the most likely cause of the mass and referred to their primary physician within 2 weeks if the mass has not resolved or is changing shape. Children with a lymph node greater than 3 cm should be referred for evaluation regardless of their age. Children with an asymptomatic mass of presumed congenital origin should be referred for follow-up with their primary physician or a surgeon skilled in head and neck surgery.

Indications for Admission

The patient with a compromised airway or suspected deep neck space or mediastinal infection must be admitted. The toxic-appearing child or adult who cannot swallow or tolerate oral fluids adequately should also be admitted for intravenous antibiotic therapy and hydration.

Transfer Considerations

If the receiving hospital has no surgical backup, an emergent transfer to an appropriate hospital willing to accept the patient should be accomplished, because a tracheostomy or surgical exploration may be required in the presence of a compromised airway or deep neck space infection.

COMMON PITFALLS

- An incomplete or inadequate history and physical examination will result in the failure to find an apparent primary lesion in an adult. Do not focus on the neck mass or the lesion only. Ninety percent of the primary lesions can be determined from the history and physical examination.
- Failure to recognize the significant incidence of malignancy of neck masses in the adult results in delays in evaluation and definitive treatment.
- Failure to educate parents on the need for follow-up if their child has a suspicious cervical lymph node or mass also results in delays in definitive evaluation.

Chapter References

The stereotype of patients with head and neck neoplasms as 50- to 60-year-old men who smoke and drink to excess must not mislead the emergency physician. Neoplasms of the upper aerodigestive tract often occur in persons of all ages and both sexes who may neither smoke nor drink. Oral cancer is not uncommon in men and women who have used smokeless tobacco for more than 15 years. Major salivary gland tumors affect both sexes, are not related to smoking or drinking, and usually occur in people aged 40 to 60. The oral and pharyngeal mucosae are frequent sites of Kaposi's sarcoma in people with acquired immunodeficiency syndrome (AIDS).⁶

People who present to the emergency department with a neoplasm of the head and neck may be divided into two groups: (1) those whose tumors are symptomatic but who are unaware that they harbor a neoplasm and (2) those who know of their tumor. People in the first group are primarily diagnostic problems, whereas those in the second group are management problems.

UNDIAGNOSED NEOPLASMS

A neoplasm of the head or neck is normally symptomatic early in its course,² and symptoms are similar to or identical with symptoms of infection of the upper aerodigestive tract. Emergency physicians must not overlook neoplasm as a cause of these complaints:

1. A sore throat of more than 3 weeks' duration in a person over age 40 is cancer until proved otherwise.
2. Hoarseness or voice change that persists longer than 4 weeks in an adult over 40 is cancer until proved otherwise.
3. An otherwise unexplained unilateral serous effusion of the middle ear in an adult over 40 suggests cancer of the nasopharynx.
4. A nonhealing ulcer involving the mucous membrane of the upper aerodigestive tract for more than 2 weeks in an adult over 40 suggests cancer.
5. A solitary lump in the neck in an adult should be regarded as a neoplasm until proved otherwise.

Differentiating between infection and a tumor begins with a thorough history and a complete physical examination, with special attention to the upper aerodigestive tract (Fig. 32.1). With the aid of the fiberoptic endoscope, emergency physicians should be able to visualize the entire upper aerodigestive tract. Descriptions of standard techniques of the head and neck examination, including the use of fiberoptic endoscopes and rigid scopes, can be found in current otolaryngology textbooks.

Figure 32.1. Sagittal view of head and neck.

Head and neck squamous cell carcinomas are usually ulcerative, locally expansive, and invasive. Carcinomas of the nasopharynx and of the base of the tongue are exceptions to this generalization, as these tumors may initially be entirely submucosal.

Carcinoma of the Nasopharynx

Carcinoma of the nasopharynx most often makes its presence known by a unilateral enlargement of an upper jugular lymph node.¹⁰ Significant symptoms are epistaxis, nasal obstruction, congestion, and bloody sputum. Carcinoma of the nasopharynx also presents as a unilateral obstruction of the eustachian tube. This causes a sense of fullness or pressure and hearing loss in the affected ear. Otolaryngologic examination reveals either a retracted eardrum or fluid in the middle ear.

Visualization of the nasopharynx shows a tumor mass in the vicinity of the affected ear's eustachian tube cushion.

The differential diagnosis includes nasopharyngitis (viral or bacterial), lymphoma, and human immunodeficiency virus (HIV)-associated adenoid hypertrophy. Viral or bacterial nasopharyngitis is associated with diffuse inflammation of the entire nasopharynx and frequently a purulent exudate. Nasopharyngitis is often accompanied by pharyngitis. Lymphoma and HIV adenoidal hypertrophy both demonstrate a mass of lymphoid tissue which may obstruct the choana.

Emergency treatment includes control of any epistaxis, pain relief, and treatment of infection, if present. When a nasopharyngeal tumor is suspected, referral is indicated. No biopsy should be done in the emergency department. The patient should be referred to an otolaryngologist for follow-up, usually within 3 to 5 days.

COMMON PITFALLS

- Failure to associate an otherwise unexplained unilateral upper jugular cervical lymph node with carcinoma of the nasopharynx
- Failure to associate an otherwise unexplained unilateral middle ear effusion in an older adult with carcinoma of the nasopharynx
- Failure to visualize the nasopharynx

Neoplasms of the Nose and Paranasal Sinuses

Squamous cell carcinomas of the nose and maxillary sinus constitute the majority of tumors found in this area. These tumors often occur in older persons, predominantly male, with a median age of 60 years. Patients with squamous cell carcinoma of this area come to the emergency department because of epistaxis, nasal airway obstruction, and persistent nasal discharge. They may also present complaining of facial swelling or a palate mass. Good lighting and a nasal speculum are essential for adequate visualization of the nasal cavity. Fiberoptic endoscopes may be used if they are available. Examination reveals an ulcerative, exophytic tumor mass of varying size involving the lateral wall or the floor of the nose. Epistaxis associated with these tumors is rarely profuse.

The differential diagnosis includes mucosal melanoma, extramedullary plasmacytoma, juvenile nasopharyngeal angiofibroma, nasal foreign body, and septal hematoma. Melanomas may occur in the nose, particularly on the septum, as well as in the nasopharynx and oropharynx.⁸ They typically have a similar presentation as squamous cell carcinoma in the same location. Extramedullary plasmacytoma occurs in 40% of patients with a history of multiple myeloma and presents as an erythematous, friable nasal mass with frequent epistaxis. Juvenile nasopharyngeal angiofibromas occur in pubescent males and present with epistaxis (often unilateral) and nasal obstruction. Foreign bodies are usually accompanied by unilateral rhinorrhea that is often purulent. Septal hematomas may be due to trauma and demonstrate a widened septum, and associated ecchymosis.

If the emergency physician detects or strongly suspects an intranasal tumor, treatment should be directed toward achieving hemostasis by local tamponade using absorbable packing. Biopsies of the tumor should not be done, due to the risk of significant bleeding. The patient should be referred to an ear, nose, and throat (ENT) consultant for further evaluation.

COMMON PITFALLS

- Failure to visualize the site and cause of epistaxis
- Failure to consider cancer as the cause of the problem
- Inability to visualize the nasal cavity adequately

Carcinoma of the Mouth (Including Lips and Anterior Two-Thirds of the Tongue)

The person with carcinoma of the mouth usually comes to the emergency department because of a sore, nonhealing ulcer or oral bleeding. If the ulcer is on the anterior tongue, the person will also complain of exacerbation of the pain with tongue motion. Physical examination reveals a discrete mucous membrane ulceration and varying amounts of local induration.

The differential diagnosis includes herpetic ulcer, aphthous ulcer, lichen planus, pemphigus vulgaris, pemphigoid, and traumatic ulceration secondary to dentures.⁷ It is usually impossible to differentiate between these diseases by history and physical examination, except in an obvious case of carcinoma. If the ulcer has not healed in 2 weeks with application of various topical or systemic agents, or if it is associated with a neck mass, the emergency physician should arrange for the person to be seen by a consultant within 3 to 5 days. The emergency physician should not biopsy the ulcer, but should provide adequate analgesics, either systemic or topical, to relieve pain until the patient can be seen by the consultant. Diagnosis is usually made by biopsy of the lesion and the surrounding mucous membrane.

COMMON PITFALLS

Failure to consider cancer as the cause of the ulcer

Carcinoma of the Posterior Third of the Tongue

A patient with carcinoma of the posterior third of the tongue characteristically complains of a sore throat that persists longer than 2 weeks and some degree of dysphagia. The patient often notes that the sore throat did not improve with antibiotics, but worsened. Direct visualization may show an ulcerating lesion, but frequently there is no mucosal aberration. The base of the tongue and neck should be digitally palpated; this will reveal an area of induration or a discrete mass.

The differential diagnosis includes a lingual thyroid gland, lingual tonsillitis, and lymphoma. A lingual thyroid gland is usually situated in the midline directly beneath the cecal foramen, whereas an early carcinoma of the posterior tongue is usually a unilateral lesion. Lingual tonsillitis ordinarily occurs in an adult who has previously undergone palatine tonsillectomy, and is recognized by the presence of diffuse inflammation, fever, and an elevated white blood cell (WBC) count. Lingual tonsillitis improves with antibiotic therapy.

When carcinoma of the base of the tongue is diagnosed or strongly suspected, the emergency physician should evaluate the patient's airway, hydration, and ability to swallow. The results of that evaluation dictate the disposition. If the tumor is sufficiently large, the patient may have dyspnea, especially in the supine position. In this case, an otolaryngologist should be consulted for airway management. If the person cannot maintain hydration or swallow sufficiently to obtain pain relief with oral medication, the emergency physician must arrange admission, preferably to a head and neck surgical oncologist. If no specialist is available, arrangements should be made for transfer to a hospital that has appropriate personnel. If the person can swallow adequately to maintain hydration and obtain pain relief with oral medication, the emergency physician must arrange for the patient to be seen within 3 to 5 days by the oncologic surgeon.

COMMON PITFALLS

- Failure to visualize the base of the tongue
- Failure to palpate the base of the tongue digitally
- Failure to adequately assess the airway

Carcinoma of the Oropharynx

Carcinomas that arise in the oropharynx usually involve either the palatine tonsil or the soft palate. Often, the patient complains of a persistent sore throat, some degree of dysphagia, and fetid breath. Physical examination shows an ulcerative lesion that may contain impacted food debris.

The differential diagnosis for tonsillar lesions includes lymphoma and granulomatous infections. When the soft palate is the tumor's primary site, neoplasms of minor salivary gland origin must also be considered. The diagnosis is made through a biopsy of the lesion and the surrounding mucous membrane. The biopsy should be performed by an otolaryngologist.

Visualization of the tumor may be difficult due to trismus from invasion of the pterygoid muscles. This presentation may be similar to that of a retropharyngeal or parapharyngeal abscess. An elevated WBC and fever will be present in patients with an abscess; however, a computed tomography (CT) scan with contrast will clearly differentiate between tumor and abscess.

When carcinoma of the oropharynx is diagnosed or strongly suspected, hydration and ability to swallow should be assessed. If the patient can maintain hydration and obtain pain relief from oral medication, the emergency physician should arrange for follow-up care within 3 to 5 days with a head and neck oncologic surgeon. If the patient's swallowing function is compromised, the emergency physician must arrange admission to a head and neck surgical oncologist.

COMMON PITFALLS

Failure to consider cancer as the cause of the ulcerative lesion

Carcinoma of the Larynx

A patient with carcinoma of the larynx may present to the emergency department with a constellation of symptoms, ranging from persistent hoarseness to chronic sore throat, cough, and shortness of breath. Laryngeal neoplasms are readily visible to direct and indirect laryngoscopy. When visualizing the larynx, the examiner must note the location and size of the tumor, vocal cord function, and airway adequacy.

The differential diagnosis includes vocal cord nodule (singer's nodes), vocal cord polyp, Reinke's edema of the vocal cord, hemorrhage into the cord, granulomas of the cords, leukoplakia of the cords, juvenile papillomatosis, tuberculosis, sarcoid, syphilis, acute epiglottitis, and acute laryngitis.

When carcinoma of the larynx is diagnosed or strongly suspected, the emergency physician must evaluate the laryngeal competence (adequacy of the airway for respiration and the ability of the larynx to prevent tracheal aspiration). Suspected epiglottitis is not a contraindication to fiberoptic laryngoscopy. If laryngeal function is impaired, supportive measures, such as supplemental oxygen, endotracheal intubation, or emergency tracheostomy, are indicated. The greater the airway obstruction, the more cautious one should be in administering narcotics or relaxants to avoid precipitating respiratory obstruction. An otolaryngologist should be contacted for emergency consultation for probable hospitalization. If the larynx is competent, the emergency physician must arrange for follow-up care with an otolaryngologist. The urgency of this follow-up visit depends on the patient's status.

COMMON PITFALLS

- Failure to visualize the larynx
- Underestimating the degree of laryngeal obstruction

Major Salivary Gland Neoplasms

Tumors of the parotid gland are about four times more common than tumors of the submandibular gland. These neoplasms grow slowly and are essentially symptom-free; indeed, most are benign.⁹ Often, another person discovers the growth and points it out to the affected person. The sudden awareness of the tumor may prompt a visit to the emergency department. Other patients relate their tumor to a sore throat or some minor trauma. These patients usually do not seek attention until the tumor size alarms them.

The differential diagnosis includes acute parotitis, sialolithiasis with obstruction of the duct, Sjögren syndrome, and the benign lymphoepithelial lesion seen in HIV patients.

Physical examination may reveal a discrete tumor mass in a major salivary gland. The mass is usually firm, but a Warthin's tumor (benign cystadenoma) often feels cystic. If "stripped," the gland produces clear saliva. Acute parotitis usually has an abrupt onset. The gland is diffusely enlarged and very tender. "Stripping" the gland produces purulent saliva. Stones that obstruct the duct also become abruptly symptomatic; eating greatly exacerbates the pain and swelling, and stripping produces no saliva. Frequently, stones can be palpated along the course of the duct. The vast majority of stones are found in Wharton's duct (of the submandibular gland). Sjögren syndrome usually produces diffuse bilateral parotid enlargement. "Stripping" the gland produces thick mucoid saliva or none at all. Benign lymphoepithelial lesions are often multiple, bilateral cystic masses involving the parotid glands. Clear saliva is produced upon stripping the gland.

When a major salivary gland neoplasm is diagnosed, the emergency physician should arrange for follow-up care with an otolaryngologist. Because these tumors are slow-growing and most are benign, there is no urgency for the referral. No attempt should be made to incise and drain cystic salivary gland masses or to perform excisional or incisional biopsies in the emergency department. A CT scan or sialography may be useful in identifying duct occlusion from stones. A CT scan will also help in differentiating the type of tumor as well as its extent.

COMMON PITFALLS

Misdiagnosing intrinsic salivary gland tumors as inflamed lymph nodes

Unknown Primaries

Carcinoma of unknown primary will present with an enlarging neck mass, often accompanied by multiple enlarged lymph nodes.² The patient may complain of pain but often is brought in to the emergency department because of the mass' appearance. The patient may have systemic symptoms of fever, night sweats, and weight loss, and if the mass is sufficiently large, they may exhibit torticollis.

The differential diagnosis of a unilateral neck mass includes branchial cleft cyst, lymphadenitis, lymphoma, tuberculosis, sarcoid, cat-scratch fever, actinomycosis, carotid body tumor, metastatic cancer, and squamous cell carcinoma. Diagnosis is made by fine-needle aspiration (FNA), preferably by an otolaryngologist. Branchial cleft cysts are anterior to the sternocleidomastoid and feel cystic to palpation. Lymphadenitis is usually accompanied by fever and leukocytosis, whereas lymphoma often presents with multiple lymph nodes and systemic symptoms, including night sweats, fever, and weight loss. Sarcoid, acute mononucleosis and cat-scratch fever often involve multiple lymph nodes bilaterally. Tuberculosis and actinomycosis may present as a draining neck mass; actinomycosis is often associated with recent dental work or oral surgery. Carotid body tumors are pulsatile and occur in the upper third of the neck.

A contrasted CT scan of the neck is helpful for determining cystic from solid masses, and the presence of heterogeneity is more consistent with a malignant neoplasm. Open biopsy is to be discouraged; however, FNA is often extremely helpful. Unless the mass is compromising vital structures, arrangement can be made for follow-up with an otolaryngologist within 3 to 5 days. If there is a concern for airway compression, the head and neck surgeon should be contacted immediately.

COMMON PITFALLS

- Failure to evaluate the upper aerodigestive tract for evidence of the primary
- Failure to consider metastatic cancer
- Inadequate evaluation of vital structures

PREVIOUSLY DIAGNOSED NEOPLASMS

Patients with known head and neck neoplasms often seek emergency care because of complications associated with therapy or complications secondary to the neoplasm. Complications of therapy include dislodged feeding tubes, mucositis, dehydration, nausea, vomiting, a dislodged voice prosthesis, an obstructed tracheostomy tube, dysphagia, airway obstruction, and severe pain. Complications secondary to the neoplasm are hemorrhage, wound infection, salivary fistula,

esophageal obstruction, and airway obstruction.

COMPLICATIONS ASSOCIATED WITH THERAPY

Feeding Tubes

Feeding tubes (nasogastric [NG], gastrostomy, or feeding jejunostomy) are used to secure entry to the gastrointestinal tract for nutrition and hydration. Most often, this follows extensive primary resection, salvage surgery, and radiation therapy.

NG tubes are difficult to secure for long periods, so accidental removal is seen. It is usually possible to replace the NG tube, but the head and neck surgeon should be contacted for specific instructions, because he or she may prefer that no attempt be made to reintroduce the NG tube.

Gastrostomy tubes are less prone to accidental removal because they are anchored by a balloon-tipped catheter or via a mushroom-tipped tube. However, balloons may rupture and deflate, resulting in accidental removal. The stomach is often sutured in the vicinity of the gastrostomy ostia to the anterior abdominal wall to minimize the possibility of a gastric leak even if the tube comes out. This maneuver makes it easier to change the gastrostomy tube.³ When confronted with a dislodged gastrostomy tube, the emergency physician should contact the surgeon for instructions about which type and size tube to reinsert, if the patient has not brought the tube along. A gastrostomy fistula will contract quickly if the tube is left out for more than a few hours. If this has occurred, the fistula can be dilated to its original size by *gently* passing a series of catheters of increasing diameter. Excessive force can lead to a ruptured viscus, false passage into the peritoneal cavity, and hemorrhage. Once the tube has been replaced, its intragastric position should be checked by instilling and removing a small amount of sterile water or saline solution, or by aspiration of gastric contents.

Jejunostomy feeding tubes are seldom dislodged because they are sutured to the abdominal wall. If one comes out, the emergency physician should contact the attending surgeon.

Voice Prosthesis

After total laryngectomy, patients may elect to have a small tracheoesophageal (TE) fistula established so they can use a vocal prosthesis for speech. This prosthesis frequently dislodges. Although patients who use the prosthesis are taught how to insert the device, their attempts at insertion are not always successful. Occasionally, the prosthesis is lost. A TE fistula will close rapidly if patency is not maintained. If the emergency physician does not have experience in inserting a vocal prosthesis, the procedure should not be attempted. Patency of the TE fistula can be ensured by passing a 16F Foley or red rubber catheter through the tracheal puncture into the distal esophagus. The catheter can be secured to the neck or chest wall. Once patency of the TE fistula is ensured, the prosthesis may be reinserted by the surgeon or speech pathologist at a convenient time. A vocal prosthesis is small and can be aspirated into the distal tracheobronchial tree. The irritation of the prosthesis usually causes a chronic cough. If the prosthesis cannot be accounted for, a chest radiograph is indicated to rule out aspiration.

Radiation Therapy and Chemotherapy

Radiation therapy and chemotherapy are frequently associated with nausea, vomiting, mucositis, and dysphagia. The patient may seek emergency care for dehydration and inability to obtain pain relief from oral medications. Radiation therapy may produce significant laryngeal edema that causes airway obstruction. Emergency treatment for such patients depends on the severity of dehydration, dysphagia, and airway compromise.

Tracheostomy Tube

A tracheostomy tube obstructs for one of three reasons: (1) the tube is occluded by secretions, (2) the tube is lying outside the tracheal lumen, or (3) the tube is blocked by an overinflated cuff. The quickest solution is to remove the entire tracheostomy tube; this should result in immediate improvement in the airway. An obturator should always be used when reinstating the tracheostomy tube. Once the tube has been replaced, a sterile catheter should be passed into the trachea to confirm the intraluminal position of the tube. A tracheocutaneous (TC) fistula more than 72 hours old will not close immediately on removal of a tracheostomy tube. However, if the tracheostomy tube has been out for a number of hours before the person gets to the emergency department, it may not be possible to reinsert the tube until the TC fistula has been gently dilated using the graduated tube technique. The caveats for this technique are the same as those listed under the section for the gastrostomy tube.

Patients who have undergone total laryngectomy have a permanent stoma, which is the termination of the upper airway. The stoma may become occluded with thick secretions and crusts producing dyspnea. Removal of the crusts will immediately improve the airway. The patient may also present with bleeding from the stoma site. This is usually due to granulation tissue around the stoma. The bleeding is easily controlled by cauterization of the granulation with silver nitrate. Stomal stenosis may occur after radiation therapy and can produce dyspnea. In this case, the stoma can be gently dilated and a tracheostomy or laryngectomy tube inserted to ensure patency.

COMMON PITFALLS

- Using excessive force when replacing feeding tubes
- Failure to preserve the TE fistula after a vocal prosthesis becomes dislodged
- Failure to rule out aspiration of a voice prosthesis
- Failure to check the intraluminal position of a tracheostomy tube by passing a sterile catheter into the distal trachea
- Failure to recognize a laryngeal stoma obstruction

COMPLICATIONS SECONDARY TO NEOPLASM

HEMORRHAGE

Hemorrhage from a ruptured vessel is associated with an active enlarging tumor, prior irradiation, wound infection, or a salivary fistula.^{1,5} Of head and neck vessels, rupture of the carotid artery is most frequent, but rupture of the lingual artery is also seen. Catastrophic hemorrhage is often heralded by a “sentinel” bleeding episode, which may be manifested by coughing up a moderate amount of blood or bleeding from the neck. Often, the sentinel bleeding has ceased by the time the patient arrives in the emergency department. The emergency physician should be aware that a life-threatening situation may exist. If examination reveals a blood clot over the area of the carotid artery or the surface of the tongue, no attempt should be made to remove the clot. The quiet interval should be used to begin an intravenous infusion of saline solution and to draw a blood specimen for hemoglobin, hematocrit, and type and crossmatch. The patient needs constant observation, because bleeding may recur.

Catastrophic hemorrhage from the carotid artery may be external through the neck or internal into the hypopharynx. Internal hemorrhage is uniformly and rapidly fatal due to aspiration of large quantities of blood. External hemorrhage can be controlled by directly occluding the carotid artery. Definitive treatment of carotid artery rupture usually involves ligation of the artery, although, in selected cases, angiography and embolization of the carotid artery is successful.¹ Definitive surgery is best done in the operating room.

Massive bleeding from rupture of the lingual artery at the base of the tongue requires the emergency physician to simultaneously maintain the airway and occlude the ruptured vessel. The patient should be in an upright position. The blood should be removed with suction and then pressure applied to the base of the tongue with a tonsil sponge or 4×4-in. gauze pad on a curved hemostat. If the airway cannot be maintained while achieving hemostasis, an emergency cricothyrotomy may be required. The patient must be taken to the operating room for definitive surgical treatment as rapidly as possible.

Airway Obstruction

Airway obstruction secondary to an enlarging neoplasm will result in a visit to the emergency department. Obstruction can be mild or severe. Supplemental oxygen

should be given before and during laryngoscopy. Visualization of the larynx is critical in planning immediate treatment and allows the emergency physician to quantify the degree of obstruction and its location, and the feasibility of intubation directly or with the aid of a fiberoptic endoscope. Occasionally, the airway obstruction is severe enough that the patient must immediately be intubated, or else undergo a tracheostomy or cricothyrotomy. Rapid intubation with the guidance of a fiberoptic bronchoscope can often prevent the need for a tracheostomy. Tracheostomies are best performed in the operating room, but the emergency physician may need to perform a cricothyrotomy if the airway cannot be maintained.

Salivary Fistulas

Salivary fistulas may develop weeks or months postoperatively. They are more common in patients who received preoperative radiation therapy.⁵ The appearance of a salivary fistula is often frightening to the patient. Patients who have undergone a laryngectomy and develop a fistula may present with aspiration pneumonia. The emergency physician should suction and divert the salivary stream away from the trachea by opening and packing the wound lateral to the trachea. The surgeon should be consulted at this stage. The emergency physician may be asked to pass an NG tube. Once the saliva has been diverted or absorbed and an NG tube has provided a feeding bypass, the patient will require instruction on use of the NG tube for alimentation. The patient needs to follow-up with his or her otolaryngologist as soon as possible for management of the fistula.

Pain

Constant pain is a hallmark of the later stages of uncontrolled head and neck neoplasms. Although oral medication can often control such pain, the cancer patient may present to the emergency department because of inability to obtain pain relief. The attending surgeon should be made aware; the emergency physician should instruct the patient in alterations in the analgesic dosage, timing, or both, to achieve adequate pain control.

COMMON PITFALLS

- Failure to recognize a sentinel hemorrhage
- Underestimating the degree of airway obstruction
- Inability to establish an airway or perform a cricothyrotomy

Patients presenting to the emergency department with artificial conduits are commonplace. Complications of these devices range from minor inconveniences for the patient to life-threatening emergencies. Emergency physicians must be aware of the purpose, structure, and proper maintenance of these devices so they will be prepared for complications. In addition, physicians must recognize systemic pathology independent of the devices.

RESPIRATORY DEVICES

The tracheostomy tube is an airway appliance seen frequently in the emergency department. Patients receive tracheostomies because of underlying respiratory or neurologic conditions that require airway management. Complications include local infection, bleeding, obstruction, air leaks, and accidental or intentional removal.

Infection and Hemorrhage

Local wound infection is managed with regular cleaning and antibiotics as indicated. Hemorrhage early after placement of a tracheostomy is often local and superficial and can be managed conservatively. If hemorrhage persists, evaluation of the coagulation status is suggested. Acute, profuse bleeding around a well-established tracheostomy is most likely due to erosion into an artery, such as occurs in tracheoinnominate artery fistula. A sentinel bleed of small amounts may be the only warning sign prior to life-threatening hemorrhage. Fluid resuscitation and blood transfusion may be necessary if the patient is hypotensive. Bleeding may be controlled with hyperinflation of the tracheostomy tube cuff or by endotracheal intubation of the patient after removal of the tracheostomy tube to allow placing a finger in the stoma to compress the innominate artery against the sternum. All arterial bleeding requires surgical consultation.⁹

Obstruction of a Tracheostomy

Obstruction from mucus may be life-threatening. Suctioning can be attempted with an endotracheal suction catheter, but this may not be successful. Saline injected through the catheter loosens dried mucus. If suctioning does not improve ventilation, or if there is a mechanical problem with the tracheostomy tube (e.g., cuff air leak), the tube should be removed and replaced.

Replacement of Tracheostomy Cannula

Tracheostomy tubes may be cuffed or uncuffed and may come with an inner cannula that can be removed for cleaning. The patient's head should be extended to facilitate placement. A replacement tube should be the same type as the original. In an emergency, however, replacement with a smaller size is preferred if maintaining a patent airway depends on it. Removal and replacement of tracheostomy tubes should follow the curved path of the tube itself. When inserting a new tube, the obturator should be in place to facilitate insertion, then removed when completed. A well-positioned tube can be advanced gently with little resistance. If force is necessary to place the tube, efforts should cease because of the possibility of creating false passages, bleeding, and edema. The safest way to ensure proper placement of a tracheostomy tube is to use a thin red rubber catheter as a guide. The catheter can be placed through the existing tracheostomy before removal. If the tracheostomy tube has accidentally fallen out, the catheter may be placed directly through the stoma. Once the old tracheostomy tube is removed, the new tube without the obturator can be passed over the catheter into place. The red rubber catheter can then be removed.

If the tracheostomy tube cannot be replaced and the airway is in jeopardy, the physician should consider oral endotracheal intubation. The original indication for the tracheostomy, however, may hamper attempts at endotracheal intubation (e.g., laryngeal malignancy). If respiratory distress persists after adequate tube replacement, the physician must not overlook other causes (pneumothorax, pulmonary embolus, or cardiac pathology).

VASCULAR CONDUITS

Indwelling central venous access is essential in patients who require chronic therapy, such as chemotherapy, hyperalimentation, lengthy antimicrobial therapy, hemodialysis, and ambulatory heparin therapy. Most outpatients requiring these devices are immunocompromised. The most serious complications are line sepsis and central venous thrombosis. Artificial conduits of the vascular system include catheters for short-term use, catheters for long-term use, subcutaneous devices, large-bore catheters used for hemodialysis, and arteriovenous fistulas.

Short-term catheters are single- and triple-lumen catheters inserted percutaneously into the central circulation. They allow for phlebotomy and delivery of medications and blood products for up to 3 weeks. If a central line is used for phlebotomy, the port should be prepared with povidone-iodine. In a triple-lumen catheter, the longest port is prepared (the proximal lumen port). The catheter is flushed with normal saline and brisk blood return is ensured. Before phlebotomy, fluids or medications infusing through the other ports are held for 15 minutes. Five milliliters of blood are aspirated and discarded. Then the blood needed for phlebotomy is drawn. If giving medications, normal saline should be used to flush the catheter between medications. The final step after access is to flush with 5 mL heparin (100 U/mL).² To prevent air embolism, whenever the protective cap is removed from a port, the catheter arm should be clamped off until intravenous tubing or a syringe is attached.

Common *long-term catheters* include the Broviac and Hickman (Fig. 33.1).⁸ Access to the double-lumen Hickman catheter is gained in much the same way as with triple-lumen catheters. The catheters have a clamp that should be kept locked except during phlebotomy and administration of fluids and medications.

Figure 33.1. Hickman catheters are available with one, two, or three lumens. (Courtesy of Bard Access Systems, Inc.)

Subcutaneous devices (Port-A-Cath, Infus-A-Port) are surgically implanted and have subcutaneous infusion ports in continuity with a central Silastic catheter. The port chamber is visible and palpable on the chest wall ([Fig. 33.2](#)). Access to these devices is gained using aseptic technique, by inserting a 20- or 22-gauge, Huber-point, right-angled needle into the infusion port chamber. The relatively small gauge needle limits the speed of administration of fluid, blood, or medication. Heparin should be instilled after each use, but these catheters rarely undergo thrombosis.⁸

Figure 33.2. Infusion ports are subcutaneously placed and attached to a catheter placed in a central vein. (Courtesy of Bard Access Systems, Inc.)

Large-bore catheters used for hemodialysis ([Fig. 33.3](#)) are most often temporizing measures until permanent arteriovenous access sites mature. These Silastic, double-lumen, high-flow catheters are placed in a central vein and provide temporary access for hemodialysis for up to 8 weeks. After dialysis, each lumen is flushed with 2500 U of heparin. These catheters are used *solely* for dialysis; phlebotomy and medication and fluid administration should *not* be done—except in an emergency, when all other means of standard venous access have failed. Strict aseptic technique must be used. Blood must be aspirated before giving medications or fluids because of the heparin within the lumens.

Figure 33.3. Large-bore catheters for hemodialysis. (Courtesy of Bard Access Systems, Inc.)

Arteriovenous fistula (Cimino-Brescia fistula) is the preferred vascular access for long-term hemodialysis. A normal patent fistula should have a palpable thrill and an auscultatory bruit. The arteriovenous fistula should not be accessed in the emergency department except under urgent circumstances when attempts at standard methods of intravenous access have failed. To gain access to the fistula, the area is prepared with povidone-iodine and an intravenous catheter is placed in the usual fashion. When complete, the catheter is removed and gentle local pressure is applied to avoid hemorrhage.

Complications of Vascular Conduits

Thrombosis

Thrombosis is one of the most common complications of indwelling venous catheters. The risk increases with greater diameter, length, and rigidity of the catheter. The incidence of thrombotic complications can be reduced by changing the catheter frequently. Catheters must also be routinely flushed with 5 mL of heparin (100 U/mL) after use. Patients with a history of, or increased risk for, thrombosis can also be placed on low-dose warfarin therapy. In general, the implantable Port-A-Cath rarely develops thrombotic complications.⁸

Thrombosis is related to the formation of a fibrinous sheath around the catheter that begins almost immediately after placement. Thrombosis must be suspected if blood cannot be aspirated from the catheter. Urokinase 5000 IU (1 mL) is indicated, and the solution is injected slowly into each port of the catheter. After waiting 5 minutes, the syringe is removed aseptically, a 5-mL syringe is connected to the catheter, and aspiration is attempted. Aspiration attempts are repeated every 5 minutes. If the catheter is not open within 30 minutes, it is capped and the urokinase is allowed to remain in the catheter for 60 minutes before another attempt is made. A second injection may be necessary in resistant cases. When patency is restored, 5 mL of blood is aspirated to ensure removal of all drug and residual clot. If thrombolysis does not restore patency, the catheter must be replaced.

The complications of thrombus formation include extravasation and embolism. Thrombus formation around a venous catheter can lead to fixation of the catheter against the vessel wall, with subsequent perforation of the vessel. This can cause extravasation of the material being infused. Superior vena cava syndrome due to extravasation of 5-fluorouracil (5-FU) has been reported. Acute-onset vena cava syndrome produced by thrombosis of the superior vena cava in a patient receiving adjuvant chemotherapy through a Hickman catheter has been reported. After angiographic diagnosis, fibrinolytic therapy with streptokinase brought about complete resolution of the superior vena cava syndrome.¹⁹ Vessel wall perforation has occurred with infusion of 5-FU into the pericardium and into the lung parenchyma, causing chemical pericarditis and a necrotizing chemical pneumonitis. Thrombosis associated with false aneurysm formation and hemorrhage into the mediastinum, as well as perforation of the heart with cardiac tamponade, also has been reported.^{3,8,15}

Because of clot formation on the tips of venous catheters, there is the potential for pulmonary embolism during flushing, manipulation, and changing over a guidewire. However, the actual occurrence of a clinically significant pulmonary embolus is rare.⁶ An air embolism is possible if air is allowed to enter the venous circulation. If this is suspected, the patient is positioned in the left lateral decubitus position in Trendelenburg and stabilized with 100% oxygen and intravenous access. Supportive measures are instituted.

Care should be taken while manipulating catheters because of the risk of displacement, cardiac dysrhythmias, and perforation or rupture of the external catheter. A Hickman catheter repair kit is available that includes silicone adhesive, injection caps, and an external catheter segment with clamps.

Thrombosis is the most common complication of the arteriovenous fistula. If a patient states that the palpable thrill in the access is lost, a vascular surgeon should be consulted immediately for possible thrombectomy. The chance of successfully reopening a thrombosed access appears to be related to the time elapsed since thrombosis occurred.

Hemorrhage

Hemorrhage from an arteriovenous fistula, a life-threatening complication, can be from the dialysis puncture site, accidental trauma, infection, aneurysm, or pseudoaneurysm. Gentle pressure is applied to the area and the extremity is elevated. Care must be taken not to occlude and possibly thrombose the vessel by compressing too firmly. An auscultatory bruit should be present during compression to ensure the fistula is not occluded. Gelfoam soaked in topical thrombin can be applied to the wound to assist in hemostasis. If indicated, a complete blood count (CBC), platelet count, prothrombin time (PT), and partial thromboplastin time (PTT) are ordered. These patients must be observed in the emergency department or admitted for observation. Recurrent or prolonged bleeding requires surgical consultation because of its association with aneurysms, pseudoaneurysms, or infection.

Other complications of arteriovenous fistulas include carpal tunnel syndrome, distal venous stasis, and vascular insufficiency or "steal" syndrome.

Infections

Infections are common with indwelling catheters and arteriovenous fistulas. Local infections are usually manifested by fever, erythema, tenderness, and purulent drainage. Not all patients with local infections require catheter removal or admission; reliable patients with localized infection who are not febrile, toxic, or immunocompromised may be treated as outpatients. The decision to discharge a patient or to remove a catheter, and the choice of antibiotic, are made in conjunction with the patient's primary care physician, nephrologist, hematologist, or oncologist. Cultures from the catheter, blood cultures from a distant site, and cultures from the local wound site are obtained and the patient is treated with an oral semisynthetic penicillin or first-generation cephalosporin to cover both staphylococci and streptococci. If treated as an outpatient, a follow-up evaluation is needed in 24 hours.

Any febrile patient with a fistula or indwelling catheter without an obvious source of infection must be treated presumptively for an access infection. Patients with leukocytosis or neutropenia, tachycardia, and hypotension are admitted. These patients are treated with intravenous antibiotics effective against gram-positive and gram-negative organisms. Triple broad-spectrum antibiotics are needed for the neutropenic patient.

The decision to remove the indwelling catheter should be made in conjunction with the primary care physician. Most available data indicate that catheter removal does *not* usually influence the outcome of sepsis or local infection.¹² Septic shock, however, warrants catheter removal. Blood cultures should be drawn from the line before its removal, and the catheter tip should also be cultured.

Dialysis patients are at high risk for infectious complications involving the access device. Infections involving arteriovenous fistulas usually result from contamination at the time of puncture for dialysis and are usually caused by staphylococci. Superficial soft-tissue infections overlying arteriovenous fistulas can usually be treated on an outpatient basis with a single dose of intravenous vancomycin, because this medication is not dialyzable. If the patient is discharged, outpatient follow-up in 24 hours must be arranged with the nephrologist. An infection that involves the fistula itself can be serious, leading to thrombosis and hemorrhage. If this is suspected, or if the patient is febrile with signs of sepsis, admission is indicated. Special consideration can be made for the reliable hemodialysis patient who has a fever but otherwise feels well and has no tachycardia, leukocytosis, neutropenia, or signs of sepsis. This patient may be treated as an outpatient after a thorough search for infection is made, blood cultures are obtained, intravenous vancomycin is given, and the nephrologist is consulted. Some nephrologists, however, prefer to admit all febrile dialysis patients.

GASTROINTESTINAL CONDUITS

Artificial conduits of the gastrointestinal (GI) tract fall into two categories: (1) catheters to feed and administer liquids in the proximal GI tract and (2) ostomies of the distal GI tract for expulsion of stool and decompression. Both have similar complications secondary to involvement with the GI tract, but they also present with problems unique to the mechanics of the device.

The use of enteral feeding tubes has increased in recent years for patients who cannot feed themselves but have functional GI tracts. The emergency physician is most likely to encounter this in the institutionalized patient with a neurologic deficit. Gastrostomy, gastrojejunostomy, and jejunostomy tubes are the most common. Complications due to feeding, extraluminal migration, accidental removal of the tube, and tube blockage are encountered.

The physician must first rule out life-threatening conditions. Patients who are overfed or who have decreased gastric motility may easily aspirate stomach contents, resulting in pneumonia. Decreased gastric motility and large feeding residuals may be secondary to small bowel obstruction, systemic infection, or ischemic bowel.¹⁷ GI hemorrhage may occur from erosions of the device into the gastric mucosa.

If the physician suspects that a feeding tube is not in the lumen of the stomach or intestine, a radiologic study with contrast is obtained to confirm placement. Tubes must not be used for feeding if the location is in doubt, because of possible intraperitoneal contamination. Accidental injury to the device tract may cause contamination of the peritoneum by GI contents, resulting in peritonitis. Tubes that have migrated within the gut lumen may result in bowel obstruction caused by the internal anchor or balloon of a Foley catheter.

Patients with blocked feeding tubes are usually brought to the emergency department after standard attempts at irrigation have failed. Once there is obstructing material within the lumen of the tube, further irrigation is unlikely to relieve the obstruction. The practice of using wires or stylets to unblock tubes may be dangerous, because once beyond the visualized exterior portion of the tube there is always the chance of causing a tube puncture. A safe, effective method of unclogging jejunostomy tubes involves the use of a Fogarty arterial embolectomy catheter.⁴ The catheter is advanced into the feeding tube, monitoring the length of catheter advanced so as not to penetrate further than the length of the feeding tube itself. (This length can be measured by comparing it with stock feeding tubes of the same type as the indwelling tube.) If the catheter cannot pass easily, the distal balloon can be inflated, which helps dislodge the obstruction. With the balloon deflated, the catheter can be advanced further. Once the catheter has been passed almost to the end of the feeding tube, it is withdrawn while the balloon is intermittently inflated. The Fogarty catheter should *not* be withdrawn from the tube while the balloon is continually inflated: This may dislodge the feeding tube. This procedure can be repeated as many times as needed. A tube study with water-soluble contrast should be performed to confirm patency and position.⁴

A tube that cannot be unblocked, or a tube that has accidentally come out, must be replaced. In the rare instance of a jejunostomy tube that cannot be unclogged, attempts to change the tube with a guidewire should be referred to a surgeon. If a feeding tube is removed or has fallen out, the tract may begin to close unless it has been established for a long time. Even though clogged, the tube can act as a stent until adequate replacement can be arranged. A tube should not be electively removed unless it can be replaced in a timely manner.

A gastrostomy tube can easily be replaced with passage of a Foley catheter through the tract. Gentle, constant pressure with the tip lubricated is usually successful. Placement can be confirmed by auscultation over the stomach with air insufflation, as well as aspiration of stomach contents. If placement is in question, it can be confirmed with a radiologic study. Before inserting the gastrostomy tube, an anchor should be placed over the tube to prevent it from advancing further than desired. The anchor can be made from a latex catheter segment 3 cm long; holes are cut on either side and the feeding tube is placed through them, creating a crossbar-shaped apparatus. A clamp is inserted through the openings, and the feeding tube pulled through the anchor. Placement of the anchor can be adjusted to the proper depth before the catheter is inserted in the stoma. About 1 cm of feeding tube should show between the abdominal skin and the crosspiece.⁷

If a feeding tube must be removed, the physician must know what type of tube was placed. A Foley catheter replacement tube is the easiest to remove by deflating the balloon. Other types of tubes stabilized by small "mushroom" anchors may be removed with traction through the stoma. Other types may be sutured in place or have a large anchoring apparatus that cannot be pulled through. The external portion of the tube does not always indicate the type of anchoring apparatus. Cutting the tube at the skin and pushing the remaining stump of the tube back into the stomach should be avoided unless endoscopic removal is planned. Intestinal obstruction is possible, especially in children. Removal of certain catheter designs can be facilitated by passing a stylet through the tube; this distends and elongates the internal "mushroom," allowing easier removal.

Colostomies and ileostomies are conduits between the intestinal lumen and the abdominal wall. A colostomy from the distal colon expels relatively dry feces. Right-sided colostomies and ileostomies produce more liquid material, and the increased liquid output makes care more difficult and skin irritation more likely. Daily output of an ileostomy should be between 500 and 1000 mL, discharging frequently throughout the day. Ileostomies are usually covered by an open-ended pouch that can be emptied easily, because frequent removal of a close-ended pouch would promote skin breakdown. Colostomies usually have a closed pouch because of the

decreased frequency of emptying. All pouches should have no more than 1/16- to 1/8-in. clearance around the stoma, or skin breakdown will occur. Continent ileostomies consist of a pouch with a nipple that can be cannulated to remove intestinal products.

During the immediate postoperative period, the most dangerous complication of an ostomy is gangrene of the stoma. This is caused by a decreased blood supply to the artificially formed "anus." The visible mucosa should be pink and moist; dark or black mucosa suggests gangrene. It is impossible to tell how far the gangrene extends from an external examination; it may involve the intraperitoneal area and lead to peritonitis. These patients must be taken to the operating room and the wound opened to determine the extent of involvement and to resect the gangrenous segment.

Strictures and prolapse of the stoma are also seen; the latter is more common in ileostomies. A prolapsed stoma can be manually reduced but often recurs. Stoma retraction may occur and is usually secondary to increased tension on the bowel. Clinically, the stoma will appear to be level with the skin or below it.⁵ Skin breakdown is more common around ileostomies due to the more erosive material. Abscess formation can occur around colostomies or ileostomies. Peristomal fistula is seen in the setting of ileostomy performed for Crohn disease. Patients with ileostomies may also be prone to diarrhea and severe electrolyte disturbances. Food blockage of an ileostomy may result in complaints of abdominal pain, decreased output, or increased watery output. The patient may also provide a history of eating foods that are poorly digested.

Life-threatening complications and threatened integrity of the ostomy require surgical evaluation. Improved maintenance of appliances and prevention of skin breakdown are facilitated by skilled ostomy care nurses.

URINARY CONDUITS

Artificial conduits of the urologic system facilitate urine drainage. Indwelling urethral and suprapubic catheters are used for bladder management. Infection is the most common complication. The urinary tract of patients with indwelling catheters is usually colonized by organisms (bacteriuria). Urinary tract infection occurs when there is microbial invasion of the tissues of the urinary tract. Infection results from either bacteria ascending from the perineum along the catheter, or with blockage of prostatic and ejaculatory ducts. Patients with catheters in place longer than 10 days almost always develop an infection. Infection from the urethra and bladder may cause pyelonephritis and sepsis.

Bladder and renal calculi are important complications of urinary stasis and infection. Urethral strictures and, less commonly, urethral diverticula also occur. Both can lead to recurrent infection, hematuria, urinary extravasation, abscess formation, and urethrocutaneous fistulas.²¹ Fournier's gangrene is a life-threatening complication. Ischemic necrosis of the glans penis in a diabetic with an indwelling catheter has been reported, as has penile necrosis.²⁰ Other complications of urethral catheters include laceration, erosion, and hypospadias of the penile urethra.^{16,18}

A distinct disadvantage of urethral catheters, when compared with suprapubic catheters, is the potential trauma to the urethra if the catheters are pulled out without deflating the balloon. This usually occurs in demented or mentally ill patients. In most cases, a new catheter can be replaced easily without resistance. If this is not possible, a urologist must be consulted.

Occasionally, the balloon will not deflate for removal of the catheter. One technique for balloon deflation is to pierce the balloon with a sharp instrument. Although this can be done blindly, fluoroscopic or ultrasonographic guidance can be used. With gentle traction, the balloon is drawn against the bladder neck and is punctured with a 25-gauge spinal needle. In men, this can be done suprapubically. In women, it can be done through the anterior vaginal wall,¹³ or the needle can be introduced along the catheter transurethrally. These methods can lead to fragmentation of the balloon in the bladder; cystoscopy is necessary to remove the fragments and prevent a stone from forming around the foreign body.

The safest method is to cut off the adapter for the balloon channel. This alone may deflate the balloon if the problem is in the adapter. A well-lubricated, flexible angiographic guidewire or no. 26 orthopedic wire suture is inserted into the balloon channel and rotated. This should relieve the obstruction and allow the water to drain from the balloon.¹⁰

Regardless of which method is used, the balloon should always be inspected carefully after removal. If pieces are missing, a cystoscopy must be arranged to retrieve the balloon fragments from the bladder.

The external urine-collecting device, or condom catheter, can also cause complications: urinary tract infections, skin breakdown, and decubitus ulcers. Allergic reactions to the catheter material may also occur. Tight placement of the external catheter on the penis may cause pressure sores, erosion, and even partial gangrene or amputation of the penis.²¹ Severe edema and maceration of the penile skin can develop. Urethral constriction by the external catheter can cause proximal urethral dilatation, diverticulum formation, and, potentially, urinary extravasation, abscesses, and fistula formation.²¹

Patients who do not have a functional bladder may have a urinary diversion and wear a bag appliance to collect urine.¹¹ A cutaneous ureterostomy is a cutaneous stoma made from the ureter. Common complications include infection, necrosis of the stoma, and stomal stenosis. Infection can be treated with local wound care and oral antibiotics if the patient is not febrile, immunocompromised, or septic. If infection of the urinary tract is suspected, the patient may require admission and intravenous antibiotics. Stenosis and necrosis of the stoma require urologic consultation.

Urinary diversion by a bowel conduit consists of diverting the urine to a short bowel segment, usually the ileum, that is directed to the anterior abdominal wall. Complications include infection; intestinal obstruction; stoma necrosis, stenosis, and hemorrhage; parastomal hernia; and upper urinary tract deterioration secondary to infection or ureterointestinal obstruction. Infections can be local or involve the upper urinary tract. Upper tract infections are common secondary to chronic bacteriuria in association with a refluxing conduit. These patients may require hospitalization and intravenous antibiotics.

To obtain a clean urine specimen from a bowel conduit, a double-catheter specimen is taken. The tip of a 20F red rubber catheter is cut off. A smaller 12F or 14F red rubber catheter is inserted and held retracted inside the larger one. Both are inserted into the stoma so that a clean urine specimen can be obtained from the smaller catheter; the larger catheter is used to protect the smaller one from bacterial contamination.

Bowel conduits may have complications related to intestinal surgery (ileus or intestinal obstruction due to adhesions); consultation is necessary. Ureterointestinal obstruction can also occur, often secondary to malignancy. Gradual contraction of the stoma site occurs in most patients; if significant, this requires stomal revision. Bleeding can occur if there is superficial separation of the bowel mucosa from the stoma. The treatment is good stoma care. Stomal necrosis requires urgent consultation. Parastomal hernia formation is treated as any abdominal wall hernia.

Ureteral stents (Fig. 33.4) are used to ensure urine flow from the kidney. Common complications are obstruction, migration, and infection. All stents result in some morbidity (irritative voiding symptoms, hematuria, and flank pain during micturition). To some degree, all stents undergo encrustation by mineral deposition. This can be minimized by maintaining a dilute urine and preventing infection. In addition, acidification of the urine may help prevent encrustation.¹ If obstruction is suspected, an ultrasound, renal scan, or intravenous pyelogram is useful. Urologic consultation is necessary. Migration of the stent must also be ruled out in patients with persistent pain or significant bleeding. A kidney-ureter-bladder view is obtained, and the stent's position is checked. The proximal curl should be overlying the kidney, the distal curl overlying the bladder. There is an increased incidence of vesicoureteral reflux after stent placement, so urinary tract infections are common.

The Tenckhoff catheter (Fig. 33.5) is the most widely used catheter in patients on chronic ambulatory peritoneal dialysis. It is made of silicone rubber and has one or two cuffs made of Dacron velour. The cuff permits collagen tissue ingrowth between the fibers, which anchors the catheter. Complications occurring during long-term use of peritoneal catheters include local infections, peritonitis, catheter malfunction, cuff extrusion, and pericatheter hernias. Local infections are common at the skin exit site and are usually secondary to staphylococci. A culture should be taken, and antistaphylococcal antibiotic therapy started. Close follow-up and meticulous exit-site care are necessary. These superficial infections can progress to subcutaneous tunnel infections. The skin should be cleansed daily, and the catheter immobilized to prevent trauma and tension. If infection is suspected to involve the subcutaneous cuff or the catheter tunnel, or if the patient shows signs of peritonitis, the patient is admitted for intravenous antibiotics with surgical consultation. Cuff extrusion can occur following infection or can result from pressure necrosis of the skin at the catheter exit site. Catheter replacement is necessary.

Figure 33.5. Tenckhoff peritoneal catheter. This catheter is surgically implanted through the lower abdominal wall. (Courtesy of Bard Access Systems, Inc.)

Tenckhoff catheter malfunction usually involves obstruction of the catheter. Two-way obstruction is usually secondary to intraluminal occlusion by fibrin clots. These can be dislodged by forceful irrigation with a syringe or dissolved by fibrinolytic agents. One-way or outflow obstruction presents as reduction in drainage flow, complete failure to drain, or abdominal pain during drainage or infusion. This is caused by displacement of the catheter in the upper abdomen, encasement of the catheter by adhesions or omentum, or catheter obstruction by incarceration of tissue within the side holes. Catheter revision or replacement is usually necessary. Slow drainage from the catheter may be secondary to constipation and responds well to bowel stimulation by enema. This should be ruled out first before looking for a mechanical cause of catheter failure. Surgical consultation is necessary before catheter manipulation. Pericatheter hernias are managed as any abdominal wall hernia. The physician must be suspicious of peritonitis whenever there is leakage around the catheter.

NEUROSURGICAL CONDUITS

The ventriculoperitoneal (VP) shunt diverts cerebrospinal fluid (CSF) to the peritoneal cavity in hydrocephalus. Shunt malfunction and infection may be neurosurgical emergencies.

VP shunts comprise three parts: an intracranial ventricular catheter, a shunt device, and a distal catheter. The intracranial catheter is usually positioned with the distal tip in the front horn of a lateral ventricle. Most shunts have some type of one-way valve to prevent reflux. Shunts can have one or two chambers and can be dome-shaped or cylindrical. They can be tested by digital pressure on the pumping chamber to demonstrate shunt patency both distally and proximally. The emergency physician must know the type of shunt the patient has in order to test it properly. If it cannot be pumped easily, a distal obstruction is likely; if the chamber does not refill easily, there is probably a proximal obstruction. Shunts are labeled with radiopaque material to make radiologic study possible when evaluating for obstruction.

Mechanical obstruction of VP shunts is the most common complication. Obstruction can be caused by disconnection, kinking of tubing, valve and reservoir leakage, and blockage by CSF cellular elements. Clinically, the signs of obstruction are those of increased intracranial pressure. Patients have headache, decreased level of consciousness, nausea, and vomiting. Sudden obstruction may progress rapidly to herniation and death if untreated. By evaluating the function of the pumping chamber, it may be possible to tell whether the obstruction is distal or proximal, but leakage or disconnection cannot be ruled out. Plain radiographs of skull, chest, and abdomen will help determine what type of shunt is present and may demonstrate kinking or disconnection. Cranial computed tomography scanning determines the intracranial position and other pathology, such as hematoma. Puncture and drainage of the reservoir may relieve increased intracranial pressure if there is a distal obstruction, but most obstructions are proximal and this will not help. Ventricular puncture by the neurosurgeon may be life-saving.

Infection can be a serious complication; most infections are caused by *Staphylococcus epidermidis*. Ninety percent of infections occur within the first 4 months after insertion.¹⁴ The patient may have nonspecific symptoms such as nausea and vomiting, fever, and erythema over the device. All patients with suspected shunt infections are admitted for intravenous antibiotics. In addition to CSF infection, patients may have peritonitis from the distal tube eroding into abdominal organs or from contamination from a primary shunt infection. In the patient with a VP shunt and an acute abdomen, aspiration of the shunt may rule out shunt infection as the source of peritonitis.

COMMON PITFALLS

- Sepsis must be ruled out in febrile patients with an indwelling central venous catheter or an arteriovenous fistula.
- A central venous dialysis catheter or arteriovenous fistula should not be used for access in the emergency department unless standard attempts at intravenous access have failed and access is important.
- The patient with a stoma and fever or signs of sepsis should be examined for necrosis or gangrene of the stomal mucosa.
- The intracranial pressure should be assessed in patients with obstructed VP shunts; the intracranial pressure may rise rapidly, requiring immediate neurosurgical consultation.

[Common Pitfalls](#)
[Chapter References](#)

Acute abdominal pain accounts for approximately 5% to 10% of all presenting complaints in the emergency department (ED).⁵ The cause is nonspecific or unknown in most cases; in 14% to 40% of cases, the cause is surgical.^{5,6} The challenge for the emergency physician is significant because roughly one-third have an atypical presentation.¹⁹ In the ED, the disease is often in its least advanced stage, and the signs and symptoms are poorly defined. Efforts to reach a correct initial diagnosis are often vital. In the elderly patient, an ED misdiagnosis results in a mortality rate nearly 2.5 times higher than if the correct diagnosis is made and the patient is admitted.⁷

A complete and accurate history and physical examination are the keys to determining whether abdominal pain is surgical in nature. Diagnostic testing is often misleading or causes undue delay; it should never be a substitute for a complete history and physical examination.¹⁸ An understanding of the physiology and mechanisms of the three types of abdominal pain (visceral, somatic or parietal, and referred) is valuable to the clinician.

Visceral Pain

Visceral nerve fibers are found within the muscular walls of hollow organs and the capsules of solid organs. They are stimulated primarily by stretching, distention, and excessive contractions. Visceral pain is characteristically deep, dull, aching or cramping, and poorly localized. The afferent impulses reach the spinal cord through several midline nerve trunks. As a result, visceral pain is usually felt in the midline.^{8,9} Several viscera can share a common pathway and cause pain in the same area. For example, afferents of the stomach, gallbladder, and pancreas combine in the celiac plexus, and visceral pain from all three organs can be felt in the epigastrium. The visceral peritoneum and viscera are insensitive to touch, so pure visceral pain may be unaccompanied by tenderness, although the patient may typically move about or be restless.^{9,14}

Parietal (Somatic) Pain

The parietal peritoneum is sensitive to noxious stimuli because of somatic sensory innervation. Afferent fibers travel to a specific level of the spinal cord from T6 to L1, making this pain more localized.^{8,9} It is characteristically sharper and aggravated by stimulation of the parietal peritoneum with movement, coughing, or walking.²² The patient with parietal pain will generally lie still.⁵ Parietal pain in the surgical abdomen may develop acutely (ulcer perforation) or can follow visceral pain (appendicitis), in which visceral distention progresses to inflammation. The presence of true parietal pain usually indicates a surgical cause of abdominal pain.

Referred Pain

Pain felt at a site other than that of the primary noxious stimulus is called referred pain. Most visceral pain is of this type, but use of this term usually implies pain felt at a distant or extraabdominal location from the diseased organ. Referred pain occurs in an area supplied by the same neurosegment as the involved organ.⁸ The stimulus is usually intense and most often secondary to an inflammatory lesion.

CLINICAL PRESENTATION

Only through careful performance of the history and physical examination can the emergency physician avoid missing a subtle presentation of early surgical disease or ascribing a surgical cause to a nonabdominal or medical cause of abdominal pain.

History

Pain is a subjective experience, largely affected by psychological traits, ethnic and cultural background, and events surrounding its occurrence. Full patient cooperation should be sought and, if possible, sufficient time allowed for the patient to adequately describe what he or she is feeling. An ordered approach is helpful and should cover the following areas.

Time of Onset

Pain that awakens the patient from sleep is almost always significant.¹⁸ The length of time a pain has been present should be correlated with the expected findings for the diagnosis under consideration. For example, a high temperature would not be expected early in the course of an appendicitis. Some suggest that abdominal pain that has been present for 6 or more hours usually requires surgical intervention.¹⁸

Mode of Onset

A sudden, severe onset of pain, especially if coupled with weakness or fainting, implies a surgical condition of a serious nature. An abdominal vascular accident, perforation, or torsion of a viscus must be considered with this history. A ruptured or dissecting aneurysm, ulcer perforation, volvulus, or ruptured ectopic pregnancy may have such a presentation.^{1,18} Such a precipitous onset with relatively unimpressive findings on examination is characteristic of an abdominal vascular accident. The absence of a sudden onset does not rule out the aforementioned conditions, especially in the elderly. For example, less than half of the patients over the age of 70 with a perforated ulcer report the sudden onset of abdominal pain.⁷

A less acute but still abrupt onset is suspicious for surgical disease, often with visceral obstruction (cholecystitis and small bowel obstruction), but also includes nonsurgical entities (renal colic and pancreatitis). Pain that begins gradually and maximizes slowly is characteristic of an inflammatory process that may be surgical (appendicitis) or medical (salpingitis).²²

Progression Since Onset

Sustained improvement of an untreated pain is generally reassuring that the condition is nonsurgical. Progression can be diagnostic, as with appendicitis, in which a poorly described midline visceral pain becomes a localized parietal pain.²² It may also guide the rate of intervention, such as when the intermittent pain of a bowel obstruction becomes constant, raising the possibility of vascular compromise.

Location

When pain is parietal, basic anatomy usually indicates the involved organs. Visceral pain is poorly localized but can be expected to occur in a constant midline location. Upper tract lesions down to the duodenum will cause epigastric pain. Disease of the small intestine and proximal colon, including appendicitis, localizes periumbilically, whereas colonic and pelvic diseases are noted in the hypogastrium.⁹

Character

The severity of pain usually parallels the magnitude of the condition. Excruciating pain is typical of a perforated ulcer, mesenteric ischemia,¹⁵ or a dissecting or ruptured aneurysm. Compromise of visceral circulation by gastric or colonic volvulus also causes severe pain. However, severe pain is not always surgical (pancreatitis), and the individual pain threshold should be evaluated as well.

True colicky pain is intermittent, rhythmic, and the hallmark of small bowel obstruction, but it can also be seen with simple gastroenteritis. Biliary colic, although related to an obstructive process, is usually steady. In the elderly patient, altered pain perception or underreporting of pain severity can create significant diagnostic problems.³ Therefore, any abdominal pain in the elderly must be evaluated carefully.

Radiation and Referral

Referred pain patterns may be virtually diagnostic. Biliary tract disease typically causes upper abdominal pain that radiates to the ipsilateral shoulder or scapula. Pain of renal origin often radiates to the groin or testes¹⁶; diaphragmatic irritation may cause shoulder pain.

Influencing Factors

Pain aggravated by coughing, walking, or movement is typical of pain of parietal origin and usually indicates a surgical lesion.⁹ It is useful to ascertain the effects of transport to the ED. A patient with peritoneal irritation may indicate increased abdominal pain due to jarring of the vehicle on an uneven road surface. Pleuritic pain can indicate diaphragmatic irritation¹⁶ or be a clue to a nonabdominal cause.¹⁴ Relieving factors, particularly medication, should also be ascertained.

Previous Episodes

Recurrent episodes of a similar pain usually indicate a medical condition.¹⁴ Serious pathology, however, such as mesenteric ischemia, can present as recurrent pain. Efforts should be made to uncover the results of any previous investigation of the abdominal pain.

Associated Symptoms

Gastrointestinal symptoms are common with both surgical and nonsurgical conditions. In surgical diseases, however, the abdominal pain nearly always precedes vomiting, whereas the converse is true in 75% of cases of gastroenteritis or nonspecific causes.⁵ An important exception to this is Boerhaave syndrome, in which severe pain from esophageal rupture follows vomiting or retching. In other surgical conditions, vomiting ranges from nearly universal (small bowel obstruction) to uncommon (ulcer perforation).

The character and quality of the vomiting should be investigated. Violent retching with little vomitus and severe epigastric pain is characteristic of gastric volvulus. Vomiting that progresses from gastric contents to bilious to feculent is virtually diagnostic of small bowel obstruction.¹⁸

Anorexia is an important symptom; it is felt that the presence of hunger should raise doubts about the diagnosis of appendicitis.¹⁸ However, a pooled analysis of several studies on appendicitis indicated a sensitivity of only 68% for anorexia.²² Diarrhea does not rule out a surgical condition. For example, diarrhea is often reported by patients with appendicitis,²² mesenteric infarction,²¹ and even bowel obstruction.⁸

Associated weakness or fainting should raise suspicion for a serious condition. In one series, syncope was part of the presenting picture in 23% of patients with a ruptured abdominal aortic aneurysm.¹

Further History

A pertinent review of systems, medical history, and social history must not be forgotten. Genitourinary and cardiopulmonary symptoms may indicate a nonsurgical cause of pain. Gynecologic history is important in detecting ectopic pregnancy or distinguishing salpingitis from appendicitis. The presence of pregnancy may alter certain diagnostic tests. Pregnancy also may obscure the presentation, especially in appendicitis.²² A list of current medications should be obtained, paying particular attention to drugs that can cause pancreatitis and peptic ulcer disease. The social history, particularly in regard to alcohol use, must not be neglected.

Physical Examination

Patient cooperation should be established through reassurance and a careful explanation of what is to be done and why. The patient's clinical condition often limits the extent of the examination before intervention, but efforts for completeness are essential. The primary focus is on the vital signs, the abdominal examination, and the adjacent organs.

General Appearance and Attitude

Pallor and diaphoresis are strong indicators of a serious condition. Many patients may appear deceptively well.¹⁸ The patient with peritoneal irritation will lie immobile, reluctant to move, and may lie curled up to ease tension on the irritated peritoneum. Those with visceral pain tend to be restless in bed.^{9,18}

Vital Signs

A rectal temperature should be obtained. A high fever early in the course of a surgical cause of abdominal pain is uncommon, except in cholangitis. A normal temperature is often seen in appendicitis²² and in most patients with mesenteric infarction²¹; it should not lead the clinician astray. Tachycardia and hypotension associated with pain of recent onset suggest hemorrhage from a ruptured abdominal aneurysm or an ectopic pregnancy. Tachypnea may indicate a nonabdominal cause of the pain or metabolic acidosis.¹⁴

Abdominal Inspection and Auscultation

Distention is common with large bowel obstruction, including cecal and sigmoid volvulus. Auscultation is one of the least valuable and potentially misleading steps in the examination.¹⁸ Total silence is uncommon, and other, more reliable signs are usually present with peritonitis.

Palpation

Palpation is the most critical step. The goal is to define an anatomic area of maximal tenderness. This allows a narrowing of the diagnostic possibilities. Warm hands, verbal preparation, and a gentle manner yield the best results. Relaxing the abdominal muscles by thigh flexion also permits a better examination.¹⁸ Palpation should begin in the area farthest from the expected site of maximal tenderness.¹⁸ Gentle palpation usually suffices, and the use of one finger may aid localization. Pure visceral pain may be unaccompanied by tenderness.^{9,14} The presence of masses and organomegaly is determined and the size of the abdominal aorta ascertained in older patients.

Rebound tenderness is significant pain elicited by sudden release of a deeply palpating hand. This is distressing to the patient and, while sensitive for the presence of peritonitis, this test has an unacceptable false-positive rate (specificity of 50%).¹⁰ It is recommended that more reliable information may be obtained with light

percussion or gentle rocking of the pelvis.⁹ Rigidity is a significant sign of peritonitis. Voluntary guarding should be assessed with the thighs flexed and the patient taking a deep breath.

In the older patient, guarding or muscular rigidity may be absent despite serious intraabdominal pathology and peritoneal irritation.³ This may be partially attributed to the relatively thin musculature of the abdominal wall in older patients. For example, only 21% of those over the age of 70 with a perforated ulcer present with epigastric rigidity.⁷ Palpation of the elderly abdomen must be done carefully to detect subtle increases in muscle tone, as this may indicate a serious underlying condition.

Other Signs

Inflammation over the psoas muscle can be detected by passive thigh extension and may indicate appendicitis. Hypogastric pain on internal rotation of the flexed thigh may be due to an abscess overlying the obturator internus.²² Having the patient raise up on the toes and then drop on the heels, or striking of the heels, may indicate peritonitis. This is reportedly more accurate than rebound for appendicitis.^{10,11} The cough test, which involves having the patient cough and observing for flinching, grimacing, or moving of the hands toward the abdomen, has been reported to have a sensitivity of 78% and a specificity of 79% for peritonitis.⁴

Further Examination

All hernial orifices should be inspected, with care taken not to overlook the femoral canal. The pelvic examination yields information regarding salpingitis, ectopic pregnancy, and ovarian problems. The rectal examination is recommended for appendicitis but is not specific for appendicitis.²² In males, a testicular examination should be done to assess for epididymitis or torsion.

Femoral pulses are usually normal in a ruptured aneurysm, but a dissecting aneurysm may cause an inequity.¹⁸ Special attention to the lung, heart, and flanks and to skin lesions should assist in detecting nonsurgical causes of pain.

DIFFERENTIAL DIAGNOSIS

It is inevitable that a certain percentage of laparotomies reveal no surgical lesions. The emergency physician can decrease this percentage by ensuring that the initial history and physical examination are performed accurately and by being aware of the variety of conditions that can cause abdominal pain ([Table 34.1](#), [Fig. 34.1](#)).

Case	Percentage of Cases
Nonspecific abdominal pain	41-46
Appendicitis	4-24
Cholelithiasis	2.5-9
Gastroenteritis	7
Salpingitis	2-7
Urinary tract infection	3-5
Small bowel obstruction	2.5-4.0
Renal colic	1.5-4.0
Craniopain	2
Pancreatitis	1-2
Diverticulitis	1-2
Dysmenorrhea	1-2
Ectopic pregnancy	<1
Ovarian cyst	<1
Incomplete abortion	<1
Abdominal aneurysm	<1

Acute abdominal pain—an OMSB survey. *Scand J Gastroenterol* 1979;143(suppl129): and Wilson DM. *Practitioner* 1979;222:483.

TABLE 34.1. Causes of Acute Abdominal Pain in the Emergency Department

Figure 34.1. Surgical causes of abdominal pain.

In the patient with upper abdominal pain, myocardial infarction, pulmonary embolism, spontaneous pneumothorax, and pulmonary infections must be considered.¹⁴ Genitourinary disease, including testicular torsion, pyelonephritis, renal colic, and ovarian cysts, can cause significant abdominal pain.¹⁴ Salpingitis is one condition commonly mistaken for appendicitis.²²

Pancreatitis is an important medical cause of pain that leads to unnecessary surgery. Diabetic ketoacidosis, adrenal crisis, hypercalcemia, sickle cell anemia, black widow spider bites, and plumbism may cause an acute abdomen. Joint symptoms combined with a rash may indicate systemic lupus erythematosus or Henoch-Schönlein purpura, whereas a rash alone may establish the diagnosis of herpes zoster. Uncommon familial causes include acute intermittent porphyria, familial Mediterranean fever, and hereditary angioneurotic edema. The spinal nerves may be the source of pain with spinal tuberculosis, discitis, vertebral osteomyelitis, Paget disease, or malignancy.¹⁴

EMERGENCY DEPARTMENT EVALUATION

When the presentation is undifferentiated, the most important points to remember are to avoid overreliance on diagnostic tests and to perform sequential examinations until the disease process is clarified.¹⁸

Sensitive, rapid pregnancy tests are available and are routinely indicated in women of childbearing age. A urinalysis may indicate pyelonephritis or a kidney stone. A complete blood count is routinely ordered. However, one study found that only 71% of patients under age 65 and 37% of those age 65 or older who required surgery for acute abdominal pain had a white blood cell (WBC) count greater than 10,000.⁵ Ten percent of those with appendicitis have a normal WBC count.¹⁷ In elderly patients, 21% with appendicitis have a normal WBC count.¹⁶ A serum lipase or amylase may be useful if pancreatitis is a consideration. An elevated serum lactate may be seen in mesenteric ischemia.

The utility of plain abdominal radiographs is controversial. They are extremely helpful in small bowel obstruction. In ulcer perforation, up to 40% of patients may have no free air demonstrated on plain radiographs.¹² Computed tomography (CT) scanning can detect small amounts of free air and may be useful in suspected perforated ulcer when the plain radiographs are normal or equivocal. Ultrasound and CT scanning are valuable in the diagnosis of aneurysm, cholelithiasis, ectopic pregnancy, and ureterolithiasis.²⁰ The intravenous pyelogram, if normal on the 5-minute film, provides strong evidence against renal colic as the diagnosis. Other causes, particularly a ruptured aneurysm, should be considered.

The value of repeated examinations in nondifferentiated, acute abdominal pain cannot be overemphasized. Sustained improvement points to a nonsurgical cause; a worsening condition suggests surgical disease. An unexpected worsening may indicate the urgent need for laparotomy. The use of intensive observation and sequential examinations has successfully increased diagnostic accuracy in appendicitis. ²³

EMERGENCY DEPARTMENT MANAGEMENT

The specific therapy for each surgical cause of abdominal pain is covered in other chapters. Initial therapy includes intravenous volume replacement with isotonic fluid and gastrointestinal decompression by nasogastric suction.

The timing of narcotic analgesia is controversial. The surgeon's arrival may be delayed. The relief of severe pain is humane and may enable a more accurate history and physical examination. ^{2,19} Judicious doses of intravenous narcotics (titrated morphine sulfate, 2 to 5 mg i.v.) should be considered after the initial examination for patients in severe pain. If the surgeon is hostile to this approach, one must be immediately available for consultation. Naloxone, if deemed necessary, may be given to reverse the analgesic.

DISPOSITION

Urgent consultation with the appropriate surgical or gynecologic specialist is required in cases of hemodynamic compromise or suspicion of an acute vascular event. Peritonitis or the probable diagnosis of a surgical cause of pain should be quickly followed by consultation. Many cases, however, will be unclear initially, and consultation may be appropriately delayed.

A definitive or high-probability surgical cause of abdominal pain mandates admission to the hospital. If, after initial evaluation, the diagnosis is unclear, consultation may be obtained or a period of observation undertaken. If repeated evaluations over 4 hours have not clarified the situation, consultation or admission may be advisable. Elderly patients merit special consideration, as up to one-third with acute abdominal pain require surgery. ⁷

It may be impossible to rule out appendicitis within the first 12 hours of abdominal pain. The surgical conditions most likely to be discharged are appendicitis and small bowel obstruction. ⁹ A patient who is discharged after an evaluation of abdominal pain should be instructed to return if his or her condition worsens or if the pain or vomiting persists beyond 6 to 8 hours. Benign causes of vomiting are usually self-limited. Antiemetics or narcotic analgesics are seldom indicated on discharge.

Most surgical causes of abdominal pain are adequately handled by the general surgeon. Guidelines for transfer may be found for individual entities in the corresponding chapter.

COMMON PITFALLS

- Inadequate history and physical examination are the most common sources of error in diagnosing a surgical cause of abdominal pain.
- The rebound tenderness test lacks specificity and should be replaced by gentle percussion or indirect tests, such as the cough test.
- Pain perception and the muscular response to peritoneal irritation may be altered in the older patient.
- For most findings there is a definite percentage of exceptions. This is especially true with (1) the WBC count, anorexia, and appendicitis; (2) free air and perforated ulcers; and (3) bowel obstruction and diarrhea. Overreliance on diagnostic testing should be replaced by dependence on sequential evaluation.
- The patient should not be discharged on antiemetics or narcotic analgesics.

Patients with an abdominal mass present to the emergency department with various characteristics and consequences. An abdominal mass noticed initially by the patient may have been present for days, months, or years, or it may be discovered by the emergency physician as a new finding. The consequences of the process involved may have no influence on the patient's health, or they may cause significant disease or death. The extent of the emergency department evaluation may vary from a few minutes of discussion and physical examination to extensive laboratory and radiologic procedures leading to emergent surgery.

The incidence of patients presenting to emergency departments with abdominal masses is unknown. Often, abdominal masses as such are not coded in medical records departments; rather, they are coded as definitive diagnoses. Additionally, when discussed in medical records and literature reviews, it is not always clear whether the masses were palpable or discovered radiologically.

For the purposes of this chapter, an *abdominal mass* is defined as a palpable mass anterior to the paraspinous muscles, lying between the symphysis pubis and the costal margin. Masses palpable only on pelvic examination are discussed briefly here but are discussed in more detail in [Chapter 87](#).

The final diagnosis of an abdominal mass may include a normal abdominal organ, as palpated in a thin patient, or abnormal shapes of physiologically normal abdominal organs. Also included are organs affected by a pathologic process and abnormal fluid collections. Occasionally, organs not usually present in the abdomen may present as palpable masses in this location.¹⁶ Diffuse collections of air from a perforated viscus or bowel obstruction, ascitic fluid, and normal abdominal adipose tissue are not discussed in this chapter.

Normal organs often palpated in thin patients include the inferior margin of the liver, Riedel's lobe, kidney, cecum, sigmoid colon, aorta, and gravid uterus. Abnormal organs may be affected by various processes, including infection, neoplasm, metabolic disorders, mechanical factors, and external trauma ([Table 35.1](#)). Abnormal fluid collections, in addition to abscesses of the aforementioned organs, may include congenital cysts of the kidney, liver, spleen, and urachus. Infectious fluid collections may include any of these cysts secondarily infected, as well as loculated peritonitis, peritoneal abscess, and hydatid cysts.

INFECTIOUS	NONINFECTIOUS AND CONGENITAL
Liver	Pancreas
Hepatitis	Pancreatitis
Hepatic abscess	Pancreatic pseudocyst
Cholangitis	Liver and spleen
Parasitiform abscess	Cystitis
Pyelonephritis	Arteriovenous
Cholecystitis	Cystic abscesses
Cholangiocarcinoma	Cervix
Parasitic abscess	Uterus
Neoplasm	Spleen
Adenocarcinoma	Spleen
Squamous cell carcinoma	Pancreatic
Adenocarcinoma	Pancreatic
NEOPLASMS	ASCENDANT AND TRANSVERSE
Liver	Neoplasm
Hepaticoma	Arteriovenous
Adenocarcinoma	Cystitis

Leiomyosarcoma	Neoplasm
Adenocarcinoma	Neoplasm

TABLE 35.1. Differential Diagnosis of Abdominal Mass

CLINICAL PRESENTATION

The acuteness or chronicity of the development of signs or symptoms associated with an abdominal mass often determines the need for emergent therapy versus care delivered on an outpatient basis with appropriate follow-up. The development of sudden abdominal pain with a rapidly expanding abdomen suggests the presence of an abdominal aortic aneurysm, which requires emergent surgical therapy. Likewise, a child with progressive abdominal pain and development of an enlarging mass over a short period of time may exhibit findings suggestive of intussusception.²⁸ The intermittent presence of an abdominal mass may be due to a spigelian hernia.¹¹ Stable, nonemergent, chronic problems include palpable stool due to constipation or the large cirrhotic liver that, if accompanied by portal hypertension, may also include a palpable spleen.

The onset of new symptoms associated with chronic problems may require emergency therapy. The onset of pain and fever in a patient with palpable kidneys secondary to polycystic kidney disease may indicate the presence of either pyelonephritis or bleeding into the kidney. Similarly, nausea, vomiting, fever, and leukocytosis in a patient with a history of biliary colic may indicate cholecystitis complicating cholelithiasis.

Often, new symptoms associated with an abdominal mass may provide important clues to the diagnosis. Pain is probably the most common symptom associated with an abdominal mass (see [Chapter 34](#)). The presence of an abdominal mass in a patient with pain suggestive of pancreatitis may indicate a pancreatic pseudocyst.⁶ As always, the duration, severity, location, quality, and radiation of pain are important factors to consider in patients with pain and an abdominal mass.

Gastrointestinal symptoms are often useful in determining the cause. Nausea and vomiting suggest the presence of either hepatitis or obstruction of a hollow viscus. Constipation may be due to bowel obstruction secondary to tumor or localized inflammation, such as appendicitis or diverticulitis. Anorexia is often present in appendicitis, hepatitis, and malignancy. The presence of an abdominal mass and diarrhea suggests chronic pancreatitis with pseudocyst formation, an abscess associated with chronic colitis, or a secretive process associated with villous adenoma. Although upper gastrointestinal bleeding and a left upper quadrant mass may be due to bleeding esophageal varices (with associated portal hypertension and splenomegaly), such bleeding with a pulsatile abdominal mass and back pain suggests an aortoenteric fistula.¹⁴ Lower gastrointestinal bleeding and abdominal mass may be secondary to malignancy or to an inflammatory process with abscess formation, such as diverticular disease or colitis. Constipation, diarrhea, or a decrease in stool caliber is observed in colon cancer and tuberculous enteritis.

Genitourinary signs and symptoms may also help to determine the cause of an abdominal mass. Urinary hesitancy or urgency in the presence of a lower abdominal mass may suggest bladder distention secondary to urethral obstruction or urine retention caused by an anticholinergic medication such as a phenothiazine. The presence of hematuria suggests polycystic kidney disease, renal cell tumor, or, in the setting of an abdominal aortic aneurysm, aortocaval fistula.²⁵

Signs and symptoms of upper respiratory tract infection, such as sore throat and cough, along with a left upper quadrant mass could indicate splenomegaly secondary to mononucleosis.

Constitutional signs and symptoms such as fever, chills, and weight loss help to narrow the diagnostic probabilities in patients with abdominal masses. Those with hepatomegaly, fever, and anorexia may have hepatitis. If such patients also have night sweats and weight loss, the possibility of hepatic tuberculosis increases.¹⁰ Those with clinical pancreatitis who also have abdominal masses and fever are more likely to have pancreatic phlegmon.²⁷ Fever, in addition to an abdominal aortic aneurysm, greatly increases the likelihood of a mycotic aneurysm, with a much higher mortality rate.²² Fever may also be present in any abdominal abscess and is often present with lymphoma.

The importance of a complete history and physical examination cannot be overemphasized. This is well illustrated in a case report by McAuley and associates.²¹ A patient with precipitous high-output cardiac failure, a pulsatile abdominal mass, and unilateral lower extremity venous engorgement was found to have an abdominal arteriovenous fistula. The axiom of unifying all findings under one diagnosis is clearly useful in patients with abdominal masses.

DIFFERENTIAL DIAGNOSIS

The most important characteristic of an abdominal mass is its location. Size is also important, as illustrated by the fact that very large right upper quadrant masses are more likely to be neoplastic hepatic disease.⁵ Similarly, the consistency of a mass can lead to a diagnosis. A rock-hard or nodular mass suggests a neoplasm; tenderness, an acute inflammatory process. For example, a nontender, palpable gallbladder is likely to be neither acute nor inflamed, and may be due to obstruction caused by a neoplasm. Mobility of a mass indicates that it is not attached to the abdominal wall or retroperitoneal tissue. Pulsation of the mass indicates that it is vascular in origin and may be due to an aortic aneurysm.

In [Fig. 35.1](#), the abdomen is divided into nine overlapping areas: two upper and lower quadrants, three midline areas, and the bilateral flank regions. [Table 35.2](#) lists the normal contents of each region. With very large masses and organomegaly, displacement of organs and masses is common. The location of various abdominal masses is shown in [Fig. 35.2](#).

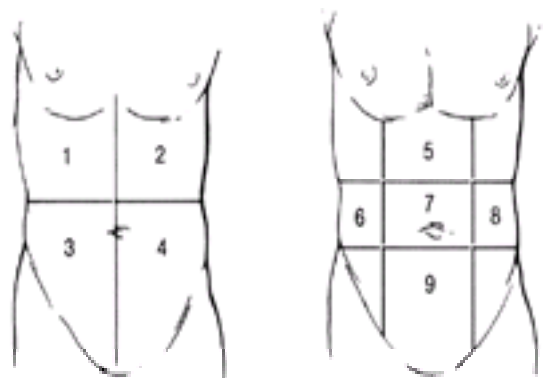

Figure 35.1. Regions of the abdomen. (1) Right upper quadrant. (2) Left upper quadrant. (3) Right lower quadrant. (4) Left lower quadrant. (5) Epigastric. (6) Right flank. (7) Umbilical. (8) Left flank. (9) Suprapubic.

Right upper quadrant	Umbilical
Liver	Stomach
Gallbladder	Duodenum
Colon	Other small bowel
Right kidney	Colon
Right adrenal gland	Aorta, vena cava
Epigastric	Lymph nodes
Gallbladder	Circumflex
Stomach	Left flank
Colon	Colon
Pancreas	Small bowel
Aorta	Kidney
Lymph nodes	Right lower quadrant
Left upper quadrant	Cecum
Spleen	Appendix
Stomach	Lymph nodes
Pancreas	Ovary
Left kidney	Suprapubic
Left adrenal gland	Distended bladder
Right flank	Small bowel
Liver	Sigmoid colon
Colon	Enlarged uterus
Small bowel	Left lower quadrant
Right kidney	Sigmoid colon
	Lymph nodes
	Ovary

TABLE 35.2. Normal Contents of the Abdomen

Figure 35.2. Abdominal mass.

Right Upper Quadrant

Masses in the right upper quadrant usually represent either the liver or the gallbladder. A rock-hard liver suggests malignancy or cirrhosis. Tender hepatomegaly in a patient who has jaundice, anorexia, nausea, and vomiting, but is otherwise hemodynamically stable, most likely indicates hepatitis. If the patient appears toxic with fever, leukocytosis, or left shift, the possibility exists of an intrahepatic abscess. A detailed history and thorough physical examination may delineate unusual causes of hepatomegaly. A travel history may suggest a possible amebic abscess or parasitic cyst. A patient with signs of right heart failure may have congestive hepatomegaly. Enlargement of one lobe of the liver may result from tumor, high bile duct obstruction,¹⁵ or hepatic vein occlusion.⁴

The gallbladder may be palpable in acute obstructive biliary colic without infection. Such a patient has intermittent pain without fever or leukocytosis. When accompanied by fever and leukocytosis, however, a tender right upper quadrant mass without a firm edge, suggesting a hepatic origin, should raise the possibility of cholecystitis. A nontender, palpable gallbladder with jaundice suggests a possible malignancy in the head of the pancreas or the ampulla of Vater.

Left Upper Quadrant

Left upper quadrant masses are generally due to splenic enlargement, and may involve pathology of gastric or pancreatic origin. Sudden, painful splenic enlargement may be due to a traumatic subcapsular hematoma. This can occur with minimal or no trauma when pathologic splenomegaly preexists, such as in patients with mononucleosis. Infections such as endocarditis and malaria may cause splenomegaly. Extremely large spleens in American adults are most often due to chronic myelocytic leukemia, portal hypertension, or myelofibrosis. A normal spleen may be displaced by a subphrenic process such as an abscess.²⁶ A left upper quadrant mass found in a patient presenting with abdominal distention, nausea, vomiting, and a succussion splash suggests a possible gastric malignancy or ulcer causing gastric outlet obstruction. Rarely, a left upper quadrant mass results from a foreign body in the stomach.

Epigastrium

A pulsatile mass in the epigastrium strongly suggests an abdominal aortic aneurysm. If such a mass is associated with pain, shock, or pulse disparity in the lower extremities, rupture or dissection of the aneurysm must be considered. Although pancreatic pseudocysts may be located anywhere in the abdomen, they are frequently found in the epigastrium. Such masses may be associated with shock if hemorrhage in the pseudocyst cavity occurs. Pancreatic cancer may result in a palpable mass, which is associated with aching pain, often in conjunction with wasting, anemia, and, occasionally, painless jaundice.

Periumbilical Region

Periumbilical masses may extend into other quadrants of the abdomen, epigastrium, or suprapubic region. Well-localized masses in the periumbilical region often include an umbilical hernia sac. This may be congenital, a result of surgery, or associated with blunt trauma to the abdomen.⁹ The contents of such a hernia can include stomach, omentum, bowel, or adipose tissue, and should be distinguished from abdominal wall masses such as lipoma or hematoma.²⁴ Lymph node masses in the paraaortic region of the retroperitoneum and mesentery are palpable as a deep mass. These lymph nodes, when enlarged because of malignancy or chronic infection, are often relatively nontender. A Sister Mary Joseph's nodule is a palpable lymph node in the abdominal wall suggestive of metastatic disease from a primary gastrointestinal malignancy.

Suprapubic Region

Masses in the suprapubic region are often pelvic organs, confirmed on pelvic examination (see [Chapter 87](#)). Occasionally, a distended bladder, which is normally midline, smooth, and moderately tender, is mistaken for a mass of other origin, such as the uterus. The distinction is often made after urinary catheterization.

Right Lower Quadrant

A mass palpated in the right lower quadrant in a healthy, thin adult is often a normal cecum. However, if it is associated with weight loss, occult blood in the stool, or a change in bowel habits, a malignancy or gastrointestinal tuberculosis should be considered. The patient with a mass and a classic history of appendicitis, but with symptoms present for more than 24 hours, possibly has an appendiceal abscess.

Left Lower Quadrant

Most left lower quadrant masses are related to the sigmoid colon. In a person who is otherwise healthy, a mass that changes shape or size may be normal stool in the sigmoid colon. A patient with diverticular disease, colitis, or malignancy may present with left lower quadrant mass and fever, suggesting a paracolic abscess.

Flank Region

Flank masses caused by kidney enlargement are often mistaken for other organs. If a mass is palpated in one flank, the other flank should also be examined for possible bilateral palpable kidneys, suggesting cystic disease. The presence of a varicocele and renal mass indicates a possible renal malignancy with renal vein thrombosis. In the right flank, a Riedel's lobe may be palpated and may occasionally be mistaken for the gallbladder or right kidney. However, close examination reveals that this mass is continuous with the liver. The sausage-shaped mass associated with intussusception is often felt in the right flank between the right upper and lower quadrants. This mass may move with time in a direction consistent with that of the colon. The additional findings of paroxysmal pain and currant-jelly stool provide further evidence for intussusception.

Finally, masses that involve abdominal organs need not be localized to the region in which the organ is usually found. Tumors of the small intestine and colon may be located in any of the abdominal regions rather than in the epigastrium.¹⁵ The spleen, when greatly enlarged, may be palpable in the right upper quadrant.³ When congenital failure or acquired laxity of splenic attachments occurs, the spleen may be found anywhere in the abdomen or pelvis.⁷ The variants of situs inversus viscerum, although rare, must be mentioned. This disorder is suggested in the patient with heart tones on the right side or a grossly abnormal electrocardiogram.

EMERGENCY DEPARTMENT EVALUATION

A patient who presents to the emergency department with an abdominal mass that has not been previously evaluated should undergo thoughtful evaluation. If the cause of the mass can be determined without question and found to be of a benign nature, laboratory evaluation may be unnecessary. If the cause is unknown, the patient should undergo testing for occult blood in the stool, electrolytes, a complete blood count with differential, and blood urea nitrogen and creatinine. If hepatocellular dysfunction or malnutrition is suspected, prothrombin time and liver function tests should be performed. If vomiting or diarrhea has been present, electrolytes should be measured. When metastatic disease is suspected, the blood count may reveal the presence of anemia or thrombocytopenia, and an SMA-23 may show hypercalcemia, hypomagnesemia, or elevated alkaline phosphatase (bone or liver). An unexpected abnormal laboratory value may be the only finding that steers the physician toward a correct diagnosis. For example, an elevated serum amylase level may lead to the diagnosis of pancreatic pseudocyst.⁶ Although many laboratory tests do not have high predictive values for any given pathologic process, they may become abnormal in the course of a disease process. An unexpected rise in the values of liver function tests, especially the alkaline phosphatase, may suggest that a neoplastic mass distant from the liver has metastasized to the liver.

Other aspects of the emergency department evaluation must also be individualized. For patients who cannot void or who have an undiagnosed lower abdominal mass, catheterization of the urinary bladder often helps rule out urinary retention. A nasogastric tube should be placed in patients with occult blood in the stool or persistent vomiting. Patients in shock, with signs of peritoneal inflammation, or those who appear toxic should have an arterial blood gas determination in addition to the laboratory evaluation, urinary catheterization, and nasogastric tube placement.

Radiologic studies provide the greatest diagnostic assistance in determining the cause of an abdominal mass. Although plain films of the abdomen seldom lead to a specific diagnosis, they are useful in determining the presence and, occasionally, the origin of abdominal masses. Both flat and upright films of the abdomen should be obtained in most cases. Occasionally, a nonpalpable mass is seen on plain films due to displacement of other organs, such as an abdominal aortic aneurysm displacing bowel on a cross-table lateral view of the abdomen. Plain abdominal films indicate the presence of an abdominal aortic aneurysm in 55% to 85% of cases, but a negative examination does not rule out the diagnosis. Accordingly, additional imaging with computed tomography (CT) scanning or ultrasound must be performed.^{13,20} A gas pattern in a mass displacing the bowel may suggest an abscess. Eighty-five percent of kidney stones and 15% of gallstones are visualized on plain abdominal films. An appendolith is thought by some to be diagnostic of appendicitis and may, after perforation, indicate an appendiceal abscess. Ingested foreign bodies can be seen on plain films and are most common in children and psychiatric patients. The presence of bowel gas outside the peritoneal cavity seen in inguinal and spigelian hernias is also useful.¹¹

Ultrasonography can be used to determine the nature of abdominal masses. Often, the presence of cholelithiasis and biliary obstruction is determined by ultrasonography, as are subcapsular splenic hematomas, hydronephrosis, and aneurysms. Ultrasonography can also help in differentiating abdominal wall hematomas from incisional hernias postoperatively,²⁴ in detecting intussusception,¹ and in determining the cause of colonic masses, such as stool.⁸ Ultrasound has been suggested as the best initial investigative tool to use in the emergency department evaluation of abdominal masses. It has positive and negative predictive values of 99% and 97%, respectively.² Advantages to using ultrasound include its noninvasive and portable nature, its accuracy in detecting the size of abdominal aortic aneurysms, and its usefulness in determining both intraperitoneal and intracapsular fluid accumulations. Unfortunately, ultrasound is operator-dependent and limited by obesity and gaseous distention of the bowel.¹⁷ Emergency physicians can become proficient in goal-directed ultrasound examinations.²³

CT scanning provides cross-sectional imaging of the entire abdominal, pelvic, and retroperitoneal structures with a high diagnostic accuracy. With the addition of

intravenous contrast, vascular structures are clearly delineated and the parenchyma of many organs are enhanced.¹⁸ Oral contrast allows for enhanced visualization of the bowel and the bowel wall. Although CT scanning and ultrasound sensitivities are both close to 100% in detecting abdominal aortic aneurysms, CT scanning has greater accuracy in determining size, detecting thrombus, defining cranial–caudal extent, demonstrating involvement with other vascular structures, and detecting a leak.¹² CT scanning is not limited by obesity and bowel gas but does require the patient to leave the department, thus creating management problems in the case of hemodynamic instability. Newer spiral CT scanners shorten scanning times considerably.

EMERGENCY DEPARTMENT MANAGEMENT

As always, life-saving measures should be instituted before evaluation. The ABCs should be attended to, and the treatment of shock should be initiated before other forms of evaluation and treatment are undertaken.

Certain emergencies require immediate recognition by the emergency physician. An abdominal aortic aneurysm (see [Chapter 52](#)), during rupture or dissection, often presents with severe pain and shock. Patients in shock are frequently “shot-gunned” with rapid volume expansion. However, the pulsatile, expanding abdominal mass is often overlooked because of guarding or obesity. Careful physical examination of the abdomen and a search for other physical findings must be performed in the initial stages of resuscitation. Early blood transfusion and immediate consultation with a vascular surgeon are key factors in determining the outcome in a ruptured aortic aneurysm.

A splenic subcapsular hematoma may also present as an abdominal mass. This possibility should be considered in all patients with tender, palpable spleens, even if a history of trauma is not present. Often the initial, normal hematocrit markedly decreases after volume resuscitation with crystalloid. Ultrasonography or CT scanning can often confirm the diagnosis.

Some abdominal masses may lead to bowel obstruction (see [Chapter 42](#)). The patient with severe vomiting should be considered to have a possible bowel obstruction and should be treated accordingly, with nasogastric suction and intravenous fluids.

Patients with rupture of, or hemorrhage into, a pancreatic pseudocyst may deteriorate rapidly due to third-space losses from peritonitis or hypovolemia from hemorrhage. In addition to a possible history of pancreatitis, such patients may have an elevated serum amylase or lipase level.

Gallbladder disease (see [Chapter 39](#)) may cause problems ranging from simple biliary colic to cholecystitis with severe toxicity. Patients in the latter group with palpable gallbladders may have an empyema of the gallbladder, which necessitates immediate surgical consultation and treatment.

DISPOSITION

All the problems noted in the preceding section necessitate consultation with either a general or a vascular surgeon as soon as the diagnosis is considered. The precise diagnosis of these problems need not be made before the initial consultation. Patients who present with fever, peritoneal signs, or intractable pain also require surgical consultation after completion of the initial evaluation. Admission to the hospital is the usual disposition of these patients.

Many patients with abdominal masses may be evaluated as outpatients. Determining the best method of evaluation depends somewhat on the preferences of the patient, physician, and institution, as well as consideration of relative costs. The availability and reliability of the patient also must be considered. Referral should be to a primary care provider who can assume responsibility for coordinating further studies.

COMMON PITFALLS

- The physician may initially fail to include a vital diagnosis in the early differential. Patients in shock require early evaluation for possible abdominal aortic aneurysm or pancreatic pseudocyst. Conversely, patients with huge lower abdominal masses often undergo extensive evaluation because urinary retention was not considered.
- Failure to do an adequate initial physical examination may result in a delayed or missed diagnosis.
- Inadequate documentation of findings may result in the failure of subsequent caregivers to recognize progression of disease.
- Inadequate resuscitation and failure to obtain timely surgical consultation may adversely affect the outcome.
- Failure to arrange for realistic, accomplishable follow-up plans for outpatient evaluation may result in patients being lost to follow-up. Many patients who are referred are not recognized as being unable to follow through with referrals because of alcoholism, transportation problems, language barriers, or financial concerns. These factors may dictate the need for admission.

People over the age of 65 are the fastest-growing segment of the population and currently account for 13% of the United States census.¹⁹ The impact of the elderly on the practice of emergency medicine is undeniable. The elderly make up 19% of emergency department visits; two-thirds of these patients are admitted, a clear indicator of the acuity of their presentation. The elderly account for 43% of all hospital emergency department admissions and 47% of admissions to critical care units. By the year 2030, 20% to 21% of the population will be over the age of 65, and the fastest growing subset of the population is people over the age of 85.

Conditions that cause abdominal pain in the elderly are usually more serious and more urgent than in younger patients ([Table 36.1](#)). Seventy-five percent of elderly patients who present to the emergency department with abdominal pain have a diagnosis made in the emergency department, and in contrast to younger patients, most will have a surgical disease. Even those who have no obvious cause found after evaluation in the emergency department may still have significant disease; 10% of these patients with “abdominal pain of unclear etiology” are diagnosed with cancer within 6 months of presentation.

Under 50 (6,317 cases)	%	Over 50 (2,436 cases)	%

TABLE 36.1. Acute Abdominal Pain in Patients Under and Over Age 50

Among patients hospitalized with abdominal pain, the diagnosis of a disease that requires surgical intervention occurs twice as often in the 65-and-older group, and mortality is increased tenfold ([Table 36.2](#)). The fact that 50% to 63% of elderly patients with abdominal pain are admitted to the hospital, 20% go directly from the emergency department to the operating room, and 13% die postoperatively¹⁴ shows that abdominal pain in the elderly is a potentially serious and potentially life-threatening problem.

Diagnostic Category	Cases		Mortality	
	n	%	n	%

TABLE 36.2. Abdominal Emergencies in the Elderly: Diagnosis and Mortality in Patients Above Age 70

Emergency physicians must be familiar with the differences in evaluating and treating elderly patients as compared with their younger counterparts.

Social Differences

The elderly differ from younger patients both socially and medically, making evaluation a challenge. The vast majority of the elderly live independently, often alone. Due to a fear of loss of independence, they may delay presentation to medical care when they develop symptoms and thus present much sicker than if they had been evaluated promptly. The elderly patient may have a complicated medical and surgical history and may be taking multiple medications. The elderly may have more than one process occurring, further compounding the difficulty of evaluation.

Physiologic Changes

The physiologic changes of the renal, immune, cardiac, pulmonary, and homeostatic systems decline with age. Changes that occur with aging alter the presentation of

abdominal pain, as well as the evaluation and natural history of the process. The elderly patient may have a delayed febrile response or delayed elevation in white blood cell count compared with a younger patient with the same medical condition. The omentum shrinks with age and is therefore less able to wall off intraabdominal processes, so the elderly patient may develop peritonitis earlier than a younger patient. Muscle mass, including abdominal musculature, decreases with age, and patients with significant intraabdominal processes may not manifest the guarding or rebound expected with peritoneal irritation.

Expanded Diagnoses

The number and type of diagnostic possibilities increase with age. In addition to the usual causes of abdominal pain seen in all age groups, vascular disease is more common in the elderly, with increased risk for vascular events such as myocardial infarction, mesenteric ischemia, and intraabdominal aneurysms. Cancer is more common in the elderly. The elderly are more likely to develop complications from other intraabdominal processes, such as appendicitis or cholecystitis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of abdominal pain in the elderly is extensive. The vast majority of the diagnosable causes of abdominal pain in the elderly patient are surgical problems requiring admission and possibly urgent or emergent surgery (see [Table 36.2](#)). In order of decreasing frequency, the diagnosable causes of abdominal pain in the elderly are as follows:

1. Biliary colic or cholecystitis (12% to 33%)
2. Nonspecific abdominal pain (15%)
3. Intestinal obstruction (hernias, adhesions, malignancies; 12% to 25%)
4. Appendicitis (5% to 14%)
5. Perforated viscus (7% to 10%)
6. Gastrointestinal bleeding (9%)
7. Pancreatitis (7%)
8. Diverticular disease (6%)
9. Vascular (mesenteric ischemia, aortic aneurysm; 2%)

Other important causes of abdominal pain include peptic ulcer disease (PUD) and nephrolithiasis. In addition, nonabdominal diseases can cause acute abdominal pain, including pneumonia, acute myocardial infarction, diabetic ketoacidosis, and drug toxicity. As mentioned, although 15% to 25% of elderly patients will have no discernible cause of their abdominal pain identified in the emergency department, up to 10% will be diagnosed with cancer within 6 months; the most common site is the colon.

Each of the following diseases is discussed in depth in a separate chapter in this text. The focus of the discussion here is to isolate features applicable to the elderly.

Biliary Tract Disease

Biliary tract disease is the most common diagnosable cause of abdominal pain in the elderly, accounting for 12% to 33% of all cases of abdominal pain. The incidence of gall bladder disease increases with age; almost 50% of those over age 70 have gallstones. The stereotype of female preponderance is eliminated once both sexes reach age 65; the ratio of females to males with stones decreases to 1:1 at this point. Most elderly patients present with typical symptoms, but up to 25% have no history of biliary tract disease. Up to 10% of the elderly have acalculous cholecystitis. On examination, up to 25% have no abdominal pain, and only 50% with cholecystitis will have peritoneal signs. Fever and leukocytosis are seen in 30% and 40%, respectively.⁵ Liver function tests may be nonspecific but typically show the usual pattern consistent with gallstone disease. Because elderly patients may lack fever, peritoneal signs, or elevation in the white count, it is prudent to obtain an imaging study of the biliary tree. HIDA scan and ultrasound are excellent tests to rule out cholecystitis and its complications.

Emergency department management includes intravenous hydration if indicated. Nasogastric suctioning is unnecessary unless the patient has severe nausea, vomiting, or ileus. Intravenous antibiotics to cover enteric gram-negative aerobes and anaerobes should be given. Ampicillin, gentamicin, and metronidazole provide effective initial coverage. Pain medication and urgent surgical consultation are also indicated.

Almost 80% of patients present with complications of biliary tract disease (cholecystitis, cholangitis, or pancreatitis); jaundice, high fever, and generalized peritonitis suggest severe complications from gallstones, and up to 43% of the elderly will present with jaundice.⁵ There is also a significantly higher incidence of emphysematous cholecystitis, gangrene, gallstone ileus, and perforation (8% to 10%). Perforation of the gallbladder has a mortality rate of 15% to 25%. Cholangitis may present with mental status changes and septic shock in up to 43% of patients.²⁰ Emphysematous cholecystitis is seen almost exclusively in the elderly. The diagnosis is suggested on plain films by gas in the gallbladder or biliary tree. The overall mortality of the elderly patient with cholecystitis is nearly 10%,⁵ and one study showed mortality rates were twice as high in men.¹⁷

Intestinal Obstruction

Bowel obstruction is the second most common cause of abdominal pain in the elderly that required surgery. The sites may be viewed as occurring in thirds: one-third of obstructions occur in the large bowel, and one-third in the small bowel, and one-third are due to hernias. The most common causes of small bowel obstruction are postsurgical adhesions and hernias. The most common cause of large bowel obstruction is malignancy; sigmoid volvulus and fecal impaction cause the remainder of large bowel obstructions. The elderly are predisposed to volvulus due to a sedentary lifestyle, chronic constipation, and medications that alter bowel motility. Sigmoid volvulus accounts for 70% of cases of volvulus in the elderly (– old). Cecal volvulus and other, rarer forms of volvulus, such as transverse colon or gastric volvulus, may occasionally be seen.

Most patients present with the acute or subacute onset of paroxysms of colicky abdominal pain in the umbilical or hypogastric region. Nausea, vomiting, and constipation are extremely common. Prior surgical procedures and changes in bowel habits are critical issues to determine.

On examination, the presence of fever may indicate peritonitis. Although the abdomen is frequently tender, tenderness may be minimal. Peritoneal signs suggest strangulation or perforation. A careful search for scars and hernias (particularly in the inguinal and femoral regions) is indicated. An examination of the genitalia and rectum may reveal cancer or impaction.

Laboratory studies are not usually helpful. Plain abdominal films are useful in making the diagnosis. If the obstruction is early, a nonspecific ileus pattern may be seen. Multiple air–fluid levels and distended loops of bowel on plain films are characteristic. In some cases, the films may demonstrate a volvulus, gallstone ileus, or bezoar. Sigmoid volvulus can be diagnosed by plain film most of the time. A “bird's beak” in the left lower quadrant and a single, dilated loop of large bowel suggest volvulus. Cecal volvulus may demonstrate a single, large, round, distended loop of bowel, usually in the lower quadrants.

Emergency department treatment includes nasogastric suctioning and intravenous fluids. Patients may “third space” large amounts of fluid into the bowel, so monitoring fluid status is critical. Close observation of the cardiopulmonary status is critical. A Foley catheter allows monitoring of urine output.

Urgent surgical consultation is indicated. Volvulus is a surgical emergency. Sigmoid volvulus may be initially treated with colonoscopy, barium enema, or a rectal tube. However, many patients ultimately require surgery, as there is a significant incidence of recurrence.

Pancreatitis

Pancreatitis is the most common nonsurgical cause of acute abdominal pain in the elderly. Its incidence increases with age, and it is usually secondary to biliary tract disease, peptic ulcer disease, or complications from therapeutic agents. The presentation is characterized by the gradual onset of severe and continuous epigastric pain accompanied by nausea and vomiting. Fever is uncommon unless the disease is secondary to another process. Although most patients complain of pain, severe tenderness on examination is uncommon. An elevated serum amylase and lipase level and leukocytosis are characteristic. Plain films of the abdomen may reveal localized ileus (sentinel loop) or a more generalized pattern of ileus.

Appendicitis

Appendicitis accounts for 5% to 7% of all acute abdominal emergencies in the elderly. Whereas 20% of younger patients are perforated at the time of surgery, 44% of elderly patients with appendicitis are perforated with gangrene or abscess at the time of laparotomy.¹⁰ This high rate of perforation is multifactorial and includes the more tenuous circulation to the appendix, other host factors, and delays in presentation, diagnosis, and treatment. In one study, only 15% of patients presented within 24 hours of the onset of pain. Up to 50% of elderly patients are misdiagnosed preoperatively.

Virtually all elderly patients with appendicitis present with abdominal pain, but only 35% will demonstrate the typical pattern of epigastric pain that moves to the periumbilical region and then to the right lower quadrant. Up to 17% of patients will have no right lower quadrant pain at all,² and, more often, elderly patients present with vague, poorly defined abdominal pain.

Fever is a poor indicator of appendicitis, although there may be some temperature elevation in up to 60% of patients. An important clue to diagnosis is right lower quadrant tenderness, present in 86% of the elderly patients with appendicitis. Approximately half of patients will have peritoneal signs in the emergency department.²

Emergency department evaluation includes a thorough history and physical examination. White blood cell counts are elevated in up to 80% of patients.² Plain abdominal radiographs are not helpful except to exclude other processes. The most suggestive finding on plain films is an appendicolith in the right lower quadrant. A persistent, abnormal gas collection suggests abscess formation. Abdominal ultrasound may be useful, but it has not been studied in the elderly.

Treatment includes keeping the patient NPO, administering antibiotics that cover abdominal flora, and obtaining surgical consultation. Complications include perforation, gangrenous appendicitis, and abscess formation. Mortality approaches 25% in patients over age 75.

Peptic Ulcer Disease

The incidence of PUD and its complications are increased in the elderly.⁹ This increase in incidence is multifactorial: an increase in the incidence of *Helicobacter pylori*, use of nonsteroidal antiinflammatory drugs (NSAIDs), an increase in the number of parietal cells, alterations in acid secretion and the gastric mucosal barrier, increased tobacco use, and decreased compliance with treatment.^{6,9,11} The proportion of duodenal to gastric ulcers decreases with age, dropping from 66% in those younger than 65 to 42% in those older than 65.⁹ Signs and symptoms depend on the stage of the disease and possible complications. Up to 94% of the elderly with bleeding secondary to PUD have been found to have no epigastric pain at all.⁹ Less severe symptomatic presentations include gnawing or burning pain localized to the epigastrium, substernal, or periumbilical area. Other initial manifestations include gastrointestinal bleeding, perforation, anemia, poor appetite, or weight loss. In people older than 65, one study reported that 65% of patients presented with atypical pain characterized by nausea, vomiting, loss of appetite or weight, melena, or no symptoms at all.⁹ Ten percent of patients present with an acute abdominal process.

The risk of gastrointestinal bleeding from PUD increases with age, as 50% of elderly patients are found to be bleeding at presentation.⁹

Examination of the elderly patient with PUD should focus on signs of perforation or bleeding. Abnormal vital signs may indicate acute bleeding. The skin, nail beds, and conjunctiva may be pale if the patient is anemic. The abdomen should be examined, particularly for tenderness. The elderly patient may not demonstrate peritoneal signs, even with a perforation. A rectal examination should be done to check for occult blood, melena, and masses.

Laboratory evaluation includes a complete blood count and electrolytes, as well as type and crossmatch for blood in patients in whom bleeding is suspected. Anemia may be noted.

All patients with epigastric pain should have an electrocardiogram to rule out an acute myocardial infarction.

An upright chest radiograph or left lateral decubitus film should be ordered if perforation is suspected. These films show free air in 50% to 90% of those who have perforated; instilling 500 mL of air through a nasogastric tube can increase the yield.

Initial treatment includes intravenous fluids and blood resuscitation in hypotensive patients in whom bleeding is suspected. Early endoscopy should be considered and has been shown to decrease mortality in one study.¹ Pharmacologic treatment of PUD in the elderly is controversial. Histamine H₂ receptor antagonists have not been found to affect risk of rebleeding, number of transfusions needed, or the need for surgery, but may decrease the mortality rate. The use of proton pump inhibitors is even more controversial, as one study found a decrease in the complication of PUD yet an increase in mortality in the elderly.⁷ Misoprostol, a prostaglandin inhibitor, is the most promising drug to prevent the development of 40% of ulcers in patients using NSAIDs.⁶ Patients with perforation should have a nasogastric tube placed and be kept NPO; urgent surgical consultation is required. Age and bleeding are independent risk factors for mortality from PUD, with a 13% mortality rate from bleeding in patients over age 74.⁹ Although perforation rates are not higher in the elderly, the mortality rate is higher because the elderly often present with minimal or atypical signs and symptoms, with consequent delays in diagnosis and treatment.

Diverticular Disease

Diverticular disease is common in the elderly, accounting for 9% of acute surgical admissions.³ Prevalence increases with increasing age, with at least 50% of patients over age 60 having the disease. The sigmoid colon is involved in up to 90% of cases. Diverticulitis represents an inflammatory response to a diverticulum that has ruptured into surrounding tissue. It is a common cause of abdominal pain in the elderly.

The most common complications of diverticular disease are lower gastrointestinal bleeding (15% will have at least one bleeding episode) and diverticulitis (30%). Diverticular bleeding is usually painless but can be massive. Patients with diverticulitis may have microperforations that cause mild symptoms or may develop macroperforations that cause the patient to become significantly ill.

The elderly patient with diverticular disease may present with bloating and constipation; diverticulitis may cause abdominal pain, more often on the left side and often worsened during bowel movements.

On examination, patients with significant macroperforation are often febrile. The abdomen is tender to palpation in the left lower quadrant, although suprapubic or generalized tenderness is also seen. Diffuse abdominal tenderness suggests frank perforation and peritonitis. Twenty percent have a palpable left lower quadrant mass. Evaluation should include a rectal examination.

Laboratory studies and radiographs are seldom useful, because the diagnosis is clinical. Abdominal films may demonstrate free air in the peritoneum if perforation of the diverticula has occurred. Computed tomography (CT) scanning can be useful, especially when an abscess is present. The white blood count may or may not be elevated in diverticulitis; patients may be anemic from diverticular bleeding.

Emergency department treatment of diverticulitis includes intravenous hydration and intravenous antibiotics to cover colonic flora. Diverticular bleeding should be treated with intravenous access and fluid and blood resuscitation as necessary. Surgical consultation is indicated in patients with symptomatic diverticular disease. Gastrointestinal bleeding in the elderly generally requires urgent localization of the site of hemorrhage and hospitalization.

Mesenteric Ischemia

Acute mesenteric ischemia or infarction (AMI) is a rare but grave cause of abdominal pain in the elderly, with a mortality rate of 85%. Predisposing factors include vascular disease, the use of vasoconstricting drugs as well as digitalis and diuretics, advanced age, prior thromboembolic events, hypotension or hypovolemia, and heart disease (particularly left ventricular aneurysms, atrial fibrillation, or valvular disease).

There are several variants of AMI, and the presentation varies depending on the location, degree of collateral circulation, and underlying disease. Thrombosis may be manifested by an insidious onset of pain, anorexia, and diarrhea with or without blood loss in the stool. An acute mesenteric occlusion from an embolus or thrombus

usually presents with catastrophic pain, minimal or no tenderness, and bloody diarrhea or Hemoccult-positive stool. If the process is advanced, cardiovascular collapse may be a prominent feature.

Mesenteric artery embolism accounts for 30% of cases; the source of emboli is most often the heart. These patients often present with the abrupt onset of severe abdominal pain. Mesenteric artery thrombosis tends to have a more gradual onset of abdominal pain; there may be a history of intestinal "angina." *The cardinal feature of AMI is pain out of proportion to the examination.* Patients with abdominal tenderness may have infarcted bowel causing peritoneal irritation. Bowel sounds are variable. Gastrointestinal bleeding is common and ranges from Hemoccult-positive stool to frank hematochezia.

The emergency department evaluation must be done quickly, for time is of the essence in AMI. Tests in patients with suspected AMI include electrolyte levels, blood urea nitrogen, creatinine, a complete blood count, an arterial blood gas, urinalysis, and type and screen for blood. The white count is elevated in up to 90% of patients; it often exceeds 15,000/ μ L, with a left shift of the differential. Prothrombin time (PT), partial thromboplastin time (PTT), liver function tests, and a serum phosphate may also be indicated. Abdominal films may show an ileus, "thumb-printing" of the bowel wall, air in the portal system, or air in the bowel wall. Nasogastric suctioning, intravenous fluids, and monitoring of the patient's cardiovascular status are critical. Vasopressors should be avoided or stopped. Antibiotics that cover bowel flora should be given. Emergent surgical and radiographic consultation should be obtained as soon as the diagnosis is suspected. Both ultrasound and CT scanning can be useful if the diagnosis is uncertain, but angiography is the diagnostic test of choice; it may also offer therapeutic options in some patients.

Constipation/Impaction

Slowing of gut motility, sedentary lifestyles, and medications may combine to produce constipation or fecal impaction. This is a common complaint, particularly among nursing home patients. Constipation that is of recent onset, however, should trigger an investigation, because it may be a symptom that indicates intestinal cancer. Paradoxical diarrhea is seen with the passage of loose, watery stools past an incompletely obstructing fecal mass.

The abdomen should be thoroughly observed for scars, hernias, and masses. The rectal examination may demonstrate a fecal mass; this should be digitally removed.

Miscellaneous Causes

Other causes of abdominal pain in the elderly include inflammatory bowel disease, intraabdominal abscess, prostatitis, aortic aneurysm, nephrolithiasis, pyelonephritis, and urinary retention. Acute myocardial infarction, congestive heart failure, pneumonia, thyroid disease, diabetic ketoacidosis, and drug toxicity can also cause abdominal pain.

EMERGENCY DEPARTMENT EVALUATION

History

An accurate history may be difficult to obtain; it may require patience and diligence. Elderly patients may be unable to give a cogent history due to dementia or residua of a stroke. They may not be able to hear the physician's questions. In addition to talking to the patient, consulting primary care physicians and family members and reviewing the patient's medical record may be necessary to evaluate the elderly patient fully. Information about the patient's medical and surgical history and a list of the patient's medications is of great value. Nonabdominal processes may also present as abdominal pain, so obtain a history of cardiac or pulmonary complaints (cough, shortness of breath, fever, or chest pain). Pneumonia, pulmonary embolism, and myocardial infarction may cause pain in the epigastrium and confuse the patient and the physician. A history of hypertension or heart disease may be a clue to the patient with mesenteric ischemia or abdominal aortic aneurysm.

Avoid making a premature diagnosis. The classic stereotype is the elderly patient with a history of nephrolithiasis who insists he is having a kidney stone; in fact, the pain may be due to a ruptured abdominal aneurysm.

The localization and progression of the pain can give clues as to the diagnosis. Although "typical" pain patterns are seen in elderly patients, the older patient may complain only of vague or poorly defined symptoms despite having a condition that may be life-threatening. The timing of the onset of the pain is important; pain of abrupt onset often signals a catastrophic event, such as rupture of an abdominal aortic aneurysm, perforation of a viscus, obstruction of a viscus, or mesenteric ischemia; nephrolithiasis may also present in this manner. Pain of rapid but not abrupt onset may also be caused by catastrophic events but is more characteristic of obstruction, infection, or inflammation. Pain that worsens over several hours to days is usually inflammatory or infectious. Pain out of proportion to physical findings suggests mesenteric ischemia or renal stone disease.

Physical Examination

In no group is it more important to examine the entire patient than it is in the elderly. The patient's general appearance often provides clues; his or her mental status and state of hydration and the color and moisture of the skin should be noted. Vital signs must be evaluated, but elderly patients may have normal vital signs despite significant disease. Elderly patients with infections may not develop fever; in fact, they may present afebrile or hypothermic. Tachycardia and tachypnea may be due to pain, early sepsis, intravascular volume depletion, hypoxia, acidosis, or hemorrhage. A normal or slightly decreased blood pressure in a normally hypertensive elderly patient may be a sign of sepsis, volume depletion, or hemorrhage.

A thorough cardiovascular and pulmonary examination is mandatory. It may reveal nonabdominal causes of the abdominal pain.

The abdomen should be observed for surgical scars, distension, and masses. Auscultation for bruits and bowel sounds should be done. Palpation of the abdomen for masses, tenderness, guarding, and rebound may be revealing, but the elderly patient may not guard or have rebound and may have only vague abdominal tenderness, even in the presence of significant intraabdominal disease. Special care should be made to evaluate the patient for ventral, incisional, inguinal, and femoral hernias. Femoral pulses should be assessed. The back should be inspected for deformity and assessed for bony or flank tenderness or masses.

All elderly patients should have a rectal examination, looking for tenderness, blood, and masses. A male patient with lower abdominal discomfort should have his prostate evaluated for tenderness or masses. A female patient should have a pelvic examination performed unless the pain is localized to the upper quadrants or she has had a hysterectomy and bilateral oophorectomy. Studies have shown that rectal and pelvic examinations are infrequently performed and often yield abnormal findings.¹³ In the latter situation, a visual inspection of the vulva is prudent.

Laboratory Studies

All elderly patients with upper abdominal pain, nausea, or vomiting should have an electrocardiogram to rule out myocardial infarction.

Once a differential diagnosis is formulated, appropriate laboratory examinations should be ordered. Although testing patterns should be adjusted to accommodate the higher return among elderly patients, normal laboratory values do not rule out surgical disease in the elderly.¹⁵ A urinalysis provides useful information regarding possible kidney stones or urinary tract infection. A complete blood count may be helpful if the patient is anemic (indicating acute or chronic bleeding) or if the patient's white blood count is elevated; however, *the white count is commonly normal in an elderly patient with significant infection and should not be used as a criterion of infection.*¹⁵ The white blood count differential should be checked, as elderly patients may have only a left shift to indicate infection, and a bandemia may be associated with a higher risk of mortality.¹³ Electrolytes may be helpful in patients taking diuretics, and an anion gap may indicate early sepsis or diabetic ketoacidosis. A digoxin level should be ordered in patients taking this drug. Liver function tests, amylase, and lipase are indicated in patients with suspected biliary tract or pancreatic disease. A blood gas should be obtained in patients with suspected mesenteric ischemia.

Radiographic Studies

Studies on the cost effectiveness of radiographs have greater application to younger patients with abdominal pain. It is important to have a low threshold for ordering tests on the elderly, particularly those for whom the diagnosis is unclear. A chest radiograph will provide information about intrathoracic processes that may be causing abdominal pain. Taken upright, it may reveal intraperitoneal air. In patients unable to tolerate an upright film, a left lateral decubitus film can be used to evaluate for the presence of free air, paying attention to the area above the liver as well as the region near the right iliac crest. Abdominal films should be inspected

for dilated loops of bowel, air–fluid levels, free air, ascites, calcifications, stones (less than 10% of gallstones are present on plain radiographs), air in the bowel wall or bowel wall thickening (“thumb-printing”) consistent with mesenteric ischemia, or air in the biliary tree or gallbladder.

Ultrasound evaluation may be helpful in a few selected abdominal conditions. In cholecystitis, both ultrasound and nuclear scintigraphy reach sensitivities and specificities of 95%. Ultrasound is the test of choice for detecting gallstones, while HIDA scan is slightly more sensitive in diagnosing cholecystitis.¹⁸ When arteriography is not readily available, intestinal ischemia secondary to arterial occlusions may be diagnosed by ultrasound. An absent Doppler signal from a visualized superior mesenteric artery or celiac artery (only feasible in about 60% of patients due to body habitus) has been found to be pathognomonic for total vessel occlusion. In appendicitis, ultrasound can be diagnostic, although it should never be ruled out by a negative study.

CT is the test of choice for many conditions. CT is especially useful if an intraabdominal abscess is suspected, as in diverticulitis (seen in one-third) or chronic appendicitis. In diverticulitis without abscess formation, CT may show bowel wall thickening, mesenteric inflammation, or air in the bladder or vagina secondary to fistula formation.⁸ One study found CT to be comparable to colonoscopy at picking up diverticular disease in patients over 70 years of age.¹² In appendicitis, CT may show circumferential appendiceal wall thickening (greater than 2 mm), and 25% will demonstrate an appendicolith. Mesenteric stranding, an inflammatory mass, or a “target sign” may also be seen.⁸ In mesenteric ischemia, CT can be helpful if the diagnosis is in question and the patient is stable. Findings may include gas in the bowel wall, nonenhancing bowel wall, or thrombotic mesenteric vessels. Depending on the diagnostic criteria, sensitivity has been found to range from 60% to 100% and specificity from 60% to 90%.^{4,8,21} Angiography and nuclear medicine studies also may be helpful when indicated.

EMERGENCY DEPARTMENT MANAGEMENT

Initial stabilization of the elderly patient is no different from that of any other patient. Attention to life-threatening problems must occur (ABCs). Fluid challenges should be given cautiously and their effect observed with frequent, if not continuous, monitoring of vital signs (including pulse, blood pressure, and pulse oximetry). Patients should receive no food or liquids by mouth until a diagnosis has been made. Vascular access should be established in most patients. Hydration with normal saline or blood products will depend on the volume status. Coexisting heart or lung disease must be considered. Nasogastric suctioning should be done in patients with suspected gastrointestinal bleeding, perforated viscus, mesenteric ischemia, or bowel obstruction. Antibiotics are indicated if infection is suspected. A Foley catheter is indicated in the ill patient.

DISPOSITION

Many elderly patients with abdominal pain have an underlying cause that requires hospitalization and possibly emergent surgery. *Surgical consultation and admission should be considered in most elderly patients with abdominal pain, particularly if the pain has persisted for more than 6 hours.* In patients with an unclear diagnosis, at a minimum emergency department observation is prudent for several hours, with frequent examinations. If the patient is to be discharged, a follow-up appointment within 12 to 24 hours must be arranged. The patient and family members should be instructed to return immediately for any worsening of pain or change in status. Family members and the patient's private physician should be involved in discharge arrangements.

COMMON PITFALLS

- The elderly underreport symptoms, delay seeking care, have comorbid diseases, and have altered immune and physiologic responses. The result is significantly greater morbidity and mortality for any given abdominal process in the elderly patient.
- The elderly are at least twice as likely to require surgery as their younger counterparts with abdominal pain.
- In general, the classic descriptions do not always apply to the elderly and should not be relied on for diagnosis.
- The elderly patient with abdominal pain may have a potentially lethal process despite a nonspecific or even relatively benign examination and normal laboratory studies.
- Information from family members, medical records, and treating physicians should be sought to obtain a complete medical history.
- Elderly patients with abdominal pain may benefit from emergency department observation, serial examinations, and radiographic testing.
- Exercise extreme caution when considering discharging elderly patients with abdominal pain. These patients should be reevaluated within 12 to 24 hours after discharge.
- Nonabdominal processes (myocardial infarction or pneumonia) may present as abdominal pain in the elderly.

- [Common Pitfalls](#)
- [Chapter References](#)

Effective emergency department evaluation of a breast mass depends on recognition of two major processes: cancer and infection. A breast abscess usually occurs in lactating women, but it may also represent inflammatory carcinoma in the elderly.^{8,11,14,16,17} Cancer, on the other hand, may present in a manner similar to fulminant mastitis.^{11,17} Experienced physicians can diagnose only 70% of breast cancers by examination alone.¹⁷ The initial evaluation of a breast mass may be difficult, challenging, and highly relevant to ultimate patient outcome.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for breast mass includes cancer, mastitis, Paget disease, benign neoplasms, lipoma, fat necrosis, Mondor disease, and abscess.

CLINICAL PRESENTATIONS

Cancer

One out of nine women in the United States develops breast cancer. This disease is diagnosed in 180,000 patients annually.¹ Risk factors for breast cancer are listed in [Table 37.1](#). In women under 25 years of age, fewer than 5% of breast masses are malignant. The incidence of breast cancer rises significantly during childbearing years, and by the age of 70 more than 75% of breast masses are malignant.^{2,10} Discussions of breast cancer histopathology and staging are beyond the scope of this chapter and are contained elsewhere.¹⁴

Risk Factor	Comparison Category	Risk Category	Relative Risk
Family history of breast cancer	No first-degree relatives affected	Diagnosed before age 50 or bilateral affected after age 50	2.0
Age at menarche	16 yr	17 yr or later	1.2
Age at birth of first child	None	1st child at age 15 or later	1.2
Age at menopause	50 yr	55 yr or later	1.2
Menopausal status	No therapy or oestrogen	Estrogen therapy or oestrogen/progestin therapy	1.2
Alcohol	No alcohol consumption	Alcohol consumption	1.2
Obesity	Not obese	Obese	1.2
Height	Not obese	Obese	1.2
First mammogram	None	Ever	1.2
Second mammogram	None	Ever	1.2
Third mammogram	None	Ever	1.2
Fourth mammogram	None	Ever	1.2
Fifth mammogram	None	Ever	1.2
Sixth mammogram	None	Ever	1.2
Seventh mammogram	None	Ever	1.2
Eighth mammogram	None	Ever	1.2
Ninth mammogram	None	Ever	1.2
Tenth mammogram	None	Ever	1.2

TABLE 37.1. Established and Probable Risk Factors for Breast Cancer

Masses that are smooth, movable, and firm with distinct margins are usually benign ([Table 37.2](#)).¹⁷ Seventy-five percent to 80% of cancerous lesions are hard and cartilaginous, with distinct edges that are serrated and irregular.¹⁴ However, 20% to 25% of cancerous nodules are less hard and less fibrotic in consistency, making accurate clinical diagnosis more difficult.¹⁴

Benign	Malignant
Soft or firm on palpation	Firm or hard on palpation
Discrete, regular margins	Indistinct margins
No attachments	Attached to skin or deep fascia
More likely to be tender	Less likely to be tender
No discharge	Bloody discharge
No skin changes	Dimpling of overlying skin or nipple retraction
Mobile	Less likely to be mobile

TABLE 37.2. Physical Findings Suggestive of Benign and Malignant Breast Masses

Cancerous nodules are usually located in the upper outer quadrant.^{14,17} Associated skin changes range from none to local edema or frank ulceration.^{14,17} Fibrosis may shorten Cooper's ligament and cause skin dimpling, a process also seen in fat necrosis.^{14,17} Bloody nipple discharge suggests ductal carcinoma, or it may reflect the presence of an intraductal papilloma.¹⁷

Lymph nodes involved in the spread of breast cancer are initially rubbery and shotty, but eventually they become hard and matted with progressive infiltration.¹⁴ Axillary glands are most commonly involved, although spread to the parasternal and supraclavicular regions may also occur.^{14,17}

Once in the lymphatic system, breast cancer cells disseminate to the lung, liver, and bony skeleton.¹⁴ Patients suspected of metastatic breast cancer should have a complete blood count, measurement of serum levels of calcium, electrolytes, and liver enzymes, and chest radiography.

Erythema, edema, tenderness, and induration are late skin changes in the setting of breast cancer, but they also may be seen in acute mastitis.^{5,16} Most breast infections occur 1 to 3 months postpartum,^{8,14,16,17} so mastitis or abscess in a nonlactating woman, as well as delayed resolution of a puerperal infection, is a warning sign of inflammatory cancer.¹²

Benign Neoplasms

Fibroadenomas are the most common benign neoplasms of the breast.¹⁴ They usually present during the third to fourth decade of life and are spherical, firm, mobile, and well defined.¹⁴ Fibroadenomas should be removed to rule out cancer and preclude continued enlargement.¹⁴ Fibrocystic disease causes cyclic pain and swelling of one or both breasts just before menses.¹¹ The nodules or cysts range from 2 or 3 mm to several centimeters in diameter.¹⁴ They are firm, round, distinct, and rubbery, and they transilluminate.¹⁴ Women with fibrocystic disease should be followed longitudinally because their risk of breast cancer is three to five times that of the general population.¹⁷ Conservative treatment includes a well-fitting brassiere, heat, and analgesics.¹¹ Danazol, an androgen derivative, may be effective if hormonal treatment is indicated.¹⁶

Fat Necrosis

Fat necrosis may present as a tender lump in the breast. This follows trauma in 50% of cases.^{11,14,17} The mass usually does not enlarge,^{8,10} but nipple retraction may be seen. Excision for definitive diagnosis is indicated.¹¹

Lipomas

Lipomas are superficial and occur in any quadrant of the breast. Mammography is usually diagnostic.

Mondor Disease

Mondor disease is thrombosis of the lateral thoracic or thoracoepigastric veins as they traverse the breast.¹¹ The inflamed vein is characteristically tubular and may cause retraction of the skin. Mondor disease is self-limited and usually diagnosed with ease.¹¹

Idiopathic Granulomatous Mastitis

Idiopathic granulomatous mastitis (IGM) is a rare *inflammatory* breast disease of unknown etiology. The clinical presentation is similar to that of mammary carcinoma, and IGM can be misdiagnosed as carcinoma. IGM is associated with women who have experienced childbirth and oral contraceptive use. Treatment consists of resection or corticosteroids. There is a 38% recurrence rate following treatment.⁷

Mastitis and Abscess

Most breast abscesses occur 1 to 3 months postpartum, but postmenopausal women may also develop mastitis.^{8,14,16,17} A postpartum breast abscess is caused by normal skin pathogens that invade through cracks in the nipple.¹⁵ Breast milk is an ideal culture medium. Unrecognized infection coalesces into abscesses, usually located away from the areola.¹⁷ Staphylococci are the most common causative agents^{5,14,16}; streptococci are cultured less often.⁸ Preventive measures include nipple hygiene (cleaning), hand washing, cleansing the infant's skin, and early recognition.^{5,14,17}

Postmenopausal breast abscesses are distinct from puerperal forms in cause and presentation. Causative bacteria include *Escherichia coli*,¹² group D streptococci,⁶ staphylococci,¹² and anaerobes, including *Bacteroides* sp.¹⁵ These abscesses are often found in the subareolar region in association with ductal ectasia, a chronic inflammation of major ducts below the nipple and areola. Recurrence rates after simple incision and drainage exceed 39%.³ Mamillary fistulas occasionally form between the areola and infected lactating glands.^{8,9}

Although most breast abscesses occur postpartum, cancer may mimic mastitis.¹⁷ Mastitis or abscess in a nonlactating woman and delayed resolution of a puerperal infection are warning signs of inflammatory cancer.

Tuberculosis remains the most common cause of persistent breast abscess.^{14,17}

Chronic infection also occurs after inadequate drainage of partitioned areas within an abscess.¹⁷ Untreated chronic infection may result in substantial morbidity and cosmetic deformity.¹⁷

Mastitis in the lactating breast causes pain, fever, erythema, edema, tenderness, and induration. Fluctuance in a centrifugal location is the hallmark of a superficial abscess. Intramammary and retromammary loculations occur deep in breast tissue and near the pectoralis musculature, respectively ([Fig. 37.1](#)).¹⁶ For this reason, fluctuance may not be readily apparent.¹⁶ The breast appears indurated, and the patient withdraws to palpation.¹⁴ Paradoxically, decreasing induration and diminished pain may reflect the need for wide incision and drainage.¹⁷

Figure 37.1. Breast abscesses. (A) Superficial abscess. (B) Intramammary abscess. (C) Retromammary abscess.

Postmenopausal breast abscesses are commonly subareolar. A mamillary fistula is identified by expressing pus from the nipple or areola.¹⁵ Nipple retraction and inversion are also observed.¹²

Chronic abscess presents as an indolent mass in a woman with history of tuberculosis or breast incision and drainage.^{14,17}

Paget disease of the nipple reflects carcinoma of the mammary ducts underlying the areola.^{14,17} The nipple initially appears dry, scaling, cracked, and eczematoid.^{14,17} The condition may progress to chronic skin inflammation and a surface crust. Subareolar fullness may or may not be palpable.¹⁴

EMERGENCY DEPARTMENT MANAGEMENT

Simple mastitis in the lactating woman, without abscess formation, is treated with antimicrobials that are effective against staphylococci and streptococci.^{5,8} Dicloxacillin (250 to 500 mg four times a day), or erythromycin (250 to 500 mg four times a day) in penicillin-allergic patients, is appropriate. Breast milk should be cultured for aerobes and anaerobes.⁵ Feedings may be discontinued for up to 48 hours if there is concern about infant diarrhea; however, drainage must be accomplished by continued feeding or pump.^{5,8,16} Local heat should be applied.¹⁷

Superficial abscesses may be drained and treated in the emergency department if there is no fever or toxicity. Incision and drainage may be performed by an emergency physician or a surgeon who is qualified to perform this procedure. Incision is performed in a curvilinear manner along skin lines¹⁴ or in a radial manner.¹⁶ A circumareolar approach may also be used.^{8,17} Care should be taken to ensure that there are no loculations that might result in a chronic abscess. In superficial abscesses, needle aspiration has been successful in a few patients (C.M. Magnant, *personal communication*, 1994). Culture (anaerobic and aerobic) and Gram stain of the drainage should be performed.⁸ The patient should be given antimicrobials and instructed in the same local measures as for simple mastitis. Patients should be educated about causal factors, symptoms, and how to avoid recurrent episodes of mastitis.⁴

DISPOSITION

Mastitis

Role of the Consultant

Patients with nontoxic mastitis or superficial abscess should be reevaluated in 24 hours. Mamillary fistulas should be referred to a surgeon for excision and definitive closure.^{8,9,12} Postmenopausal intramammary abscesses necessitate surgical consultation because of the high recurrence rate after simple drainage.^{11,15} Incision and drainage of superficial abscesses may be referred to a surgeon for cosmetic reasons if the emergency physician is not skilled in the procedure.

Indications for Admission

Women with marked temperature elevation or toxic appearance should be admitted and placed on intravenous antibiotics that are effective against staphylococci and streptococci. Women with simple infections that do not improve or that worsen after 24 hours should also be admitted. Patients with deep intramammary and retromammary abscesses are hospitalized for operative drainage.¹⁶

Transfer Considerations

Women transferred for operative care should be stable, without evidence of septic shock. Antimicrobials should be initiated by the referring hospital and pain controlled before transfer.

Suspected Breast Cancer

Role of the Consultant

Women suspected of having breast cancer should be referred immediately to a consultant who is experienced in the diagnosis and management of breast disorders. Mammography may be used to evaluate suspicious breast masses in women who are not pregnant and are at least age 20. Arrangements may be made for mammography to be performed on an outpatient basis. If mammography is performed, a subsequent visit to a specialist is important. About 18% of mammograms show a false-negative result for breast cancer,³ so patients should be counseled that a negative study does not necessarily mean the absence of disease.¹³

Indications for Admission

Patients with suspicious breast masses need not be admitted unless either breast cancer is advanced on presentation, with intractable pain or serious secondary infection, or family or socioeconomic factors place admission in the patient's best interest. In general, the initial evaluation of suspicious breast masses is done on an outpatient basis.

Transfer Considerations

Consider transfer or referral when no physician experienced in the management of breast disorders is available.

COMMON PITFALLS

- Inflammatory cancer may present with erythema, edema, and tenderness. Infection in a nonlactating breast and failure of a postpartum infection to abate in a timely manner should suggest the possibility of cancer.
- Inadequate drainage of a breast abscess may lead to chronic infection with substantial morbidity and cosmetic deformity.
- Subareolar abscesses in postmenopausal women are usually associated with ductal ectasia (chronic subareolar inflammation) and may recur, requiring removal of the involved duct system. These patients require surgical consultation.
- Subareolar abscesses may also present with mamillary fistula, demonstrated clinically by expressing pus from the nipple area. Surgical removal of the tract and definitive closure are indicated.

ESOPHAGEAL NEOPLASMS

The prognosis for esophageal cancer is grim and has remained unchanged in recent years. Long-term survivors are rare. Only 30% of patients present with nonmetastatic disease. Five-year survival rates range from 7% to 20% in reports of operable, small squamous cell carcinomas treated with surgery. Survival after diagnosis averages from 2 to 4 months if demonstrable metastases are present, to 8 to 14 months if “curative” surgery has been performed with chemotherapy added. Overall, 80% to 90% die within 2 years of diagnosis.

Prognosis depends on lymph node spread, metastases, and the depth of extension of the tumor ([Table 38.1](#)). When all of these are favorable (stages I or II), the 5-year survival rate is 50%. Unfortunately, one-third of patients have inoperable advanced cancer when first seen.

PRIMARY TUMOR (T)			
Tx	Adjuvant requirements to assess the primary tumor cannot be seen		
T0	No evidence of primary tumor		
Tis	Preinvasive carcinoma (carcinoma in situ)		
T1	Tumor invades into but not beyond the submucosa		
T2	Tumor invades into but not beyond the muscularis propria		
T3	Tumor invades into the adventitia		
T4	Tumor invades contiguous structures		
REGIONAL LYMPH NODES (N)			
Cervical esophagus (cervical and supraclavicular lymph nodes)			
Nx	Lymph nodes cannot be assessed		
N0	No demonstrable metastasis to regional lymph nodes		
N1	Regional lymph nodes contain metastatic tumor		
Thoracic esophagus (nodes in the thorax, not those of the cervical, supraclavicular, or abdominal areas)			
Nx	No nodal involvement		
N1	Nodal involvement		
DISTANT METASTASIS (M)			
Mx	Distant metastasis cannot be assessed		
M0	No evidence of distant metastasis		
M1	Distant metastasis present		
Stage I	Stage II	Stage III	Stage IV
T1N0M0	T2N0M0	T3N1M0	Any T, Any N1, M1
T2N1M0	T3N1M0	T4N1M0	

TABLE 38.1. TNM Staging for Esophageal Cancer

Squamous cell carcinomas and adenocarcinoma of the esophagus constitute the fifth most common cancer in men in the United States ([Fig. 38.1](#)). They account for an estimated 9,800 deaths per year in the United States, with an incidence of 2 to 5 per 100,000 in White men and a somewhat higher incidence in Blacks (17/100,000). The overall age-adjusted incidence in the United States in 1987 was 3.9 persons per 100,000, with an overall age-adjusted mortality of 3.4 per 100,000, reflecting the high mortality rate for this malignancy. There were 12,100 new cases diagnosed in the United States in 1995, with 12,500 new cases expected in 1997.

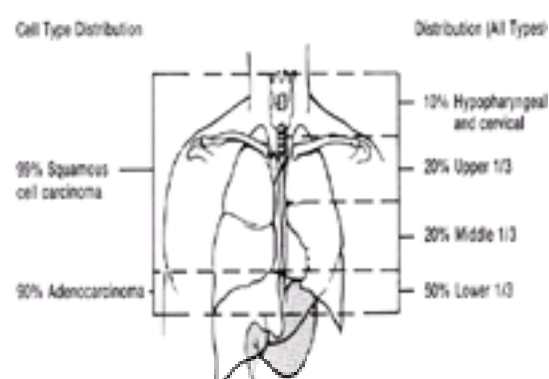

Figure 38.1. Locations of cancer of the esophagus. (From Schwartz SI, et al. *Principles of surgery*, 5th ed. New York: McGraw-Hill, 1989, with permission.)

Epidemiologic studies identify certain risk factors for the development of esophageal cancer. Heavy use of alcohol and tobacco, including tobacco swallowing, and nutritional deficiencies in vitamins A and C, riboflavin, zinc, and molybdenum have been implicated. Diets rich in fresh fruit and vegetables seem to be protective. Salicylate and nonsteroidal antiinflammatory medication use may also decrease risk of esophageal cancer. A disproportionate number of patients are of low socioeconomic status. Carcinoma of the esophagus has been associated with chronic iron deficiency and the Plummer-Vinson syndrome. It has been also associated with achalasia, reflux esophagitis, hiatal hernia, corrosive esophagitis and strictures from lye, and scleroderma. Occupational exposure to tetrachloroethylene, as for dry cleaners, and to toluene, as for shoemakers, paint mixers, and rubber cement mixers, appear to also be risks for the disease. A disproportionate number of patients with squamous cell carcinoma have had a partial gastrectomy.

Adenocarcinoma arising from Barrett's esophagus is thought by some to be gastric cancer. It accounts for as many as 60% of tumors confined to the lower esophagus and almost half of all esophageal cancers. Barrett's esophagus, or columnar cell-lined esophagus, is considered to be a premalignant lesion. It may present as adenocarcinoma in childhood, and attempts at control of Barrett's esophagus with agents such as omeprazole or with antireflux operations have met with mixed success.

Chronic ingestion of nitrosamines found in some salted foods, tannins in hot tea and other beverages, certain fungi that are contaminants of corn and produce fumonisins, betel nut chewing, opium, and thermal mucosal irritants have been cited as risk factors for esophageal cancer. Familial factors, such as tylosis, are rare.

Esophageal carcinomas may develop in association with other tumors of the upper aerodigestive tract, for example, cancers of the tonsil and palate, which may also arise after exposure to a carcinogen such as tobacco smoke.

Gastrointestinal involvement with Kaposi's sarcoma occurs in 50% to 70% of patients with Kaposi's sarcoma and the acquired immunodeficiency syndrome (AIDS). Lesions may appear as violaceous nodules on endoscopy or as dark red macules and may bleed, although they are generally asymptomatic. Primary lymphoma of the esophagus associated with AIDS has been reported. Malignant melanoma, mesenchymal tumors and small cell carcinomas are unusual primary malignancies of the esophagus; breast cancer is the most common tumor that metastasizes to the esophagus.

CLINICAL PRESENTATION

More than 90% of all esophageal neoplasms are malignant. Patients with benign tumors may present with bleeding or dysphagia but usually experience no symptoms. Benign tumors may be distinguishable from carcinoma only after surgical removal.

The earliest and most constant presenting symptom of esophageal cancer is dysphagia—initially of solids, later of liquids. One-half to two-thirds of the esophageal circumference must be involved with gross tumor to produce dysphagia, or when the diameter has been narrowed to approximately 13 mm. Total dysphagia occurs when the lumen is constricted to 4 mm in diameter. A vague retrosternal discomfort or a sensation of slow food passage may be perceived.

Weight loss, often of 9 to 10 kg over 2 or 3 months, may be due to dysphagia or to anorexia from widespread disease.

Pain may occur only on eating (odynophagia), reflecting mediastinal involvement, or it may be persistent. It is an ominous sign. Pain may be located in the epigastrium, substernally, or in the midback.

Excessive salivation may lead to aspiration, cough, and pulmonary infection. Patients may present with lung abscesses or pneumonia. Tracheoesophageal fistulas are quite common and may be due to the disease or to radiation therapy. Cough or hemoptysis may be a presenting sign. Regurgitation of undigested food may occur.

Other presenting signs depend on the extent of involvement of the tumor. Hoarseness, paralysis of the diaphragm, and gastric retention occur with invasion of the recurrent laryngeal, phrenic, and vagus nerves, respectively. Lymphadenopathy may be noted in the neck. Erosion into a bronchus may cause mediastinitis; erosion into the aorta may result in massive bleeding. Malignant pleural effusion or malignant ascites indicates unresectable disease.

Rarely, these tumors present with hormonal abnormalities. Hypercalcemia has been reported, sometimes with ectopic parathyroid hormone production from bony metastases. The syndrome of inappropriate secretion of antidiuretic hormone may result from pneumonia or from narcotic administration.

The emergency physician may see acute problems at any stage of this disease, as complications of both therapy and the disease itself.

The most common complication from radiation is esophageal stricture. Occasionally, patients may develop pericarditis, radiation pneumonitis, myocarditis, or spinal cord damage from radiation. Pneumonitis may not be due to aspiration, but to prior radiation therapy. Brain radionecrosis may result in increased intracranial pressure and herniation syndrome. Pneumopericardium with pericardial tamponade has occurred after surgical resection of esophageal cancer.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

In the emergency department, a chest film may show a pleural effusion, pneumonia, lung metastases, or an air–fluid level from total esophageal obstruction. Liver function studies, determination of serum electrolyte and calcium levels, and a complete blood cell count should be performed. Fecal occult blood testing over 3 consecutive days may be positive in as few as 20% of cases, and is an insensitive screen.

If esophageal neoplasm is suspected, it may be appropriate to obtain a barium swallow. The results of a barium swallow test are nearly always abnormal in symptomatic patients. In 90% of cases, the presence of stenosis, mass effect, or esophageal narrowing with a ragged mucosal pattern is diagnostic. Double-contrast esophagography obtained by coating the esophageal mucosa with barium and distending the lumen with air is especially useful in demonstrating early cancers or fistulas.

Esophagoscopy can define the site of the lesion, the extent of the circumferential involvement, and the length of involvement. Fiberoptic endoscopy also permits biopsy and cell scraping. Brushings combined with multiple biopsies can confirm a diagnosis of malignancy in over 95% of cases. Lugol's iodine or toluidine blue staining may differentiate normal tissue from neoplastic tissue or Barrett's epithelium.

Computed tomography (CT) is the best noninvasive method for assessing local spread of disease, but it is not accurate for detecting lymphatic spread. More invasive, but useful, studies for staging include bronchoscopy (to detect tracheal invasion) and mediastinoscopy. A bone scan should be obtained in patients with bone pain, as well as plain films of the area. Endoscopic ultrasonography (EUS) has been used to assess the extent of the circumferential involvement of tumor with the surrounding structures and may be the most accurate method for clinical staging. EUS is more accurate than CT for detecting involvement of regional lymph nodes. Magnetic resonance imaging (MRI) may be useful in assessing the relation of esophageal cancer to mediastinal structures, such as the aorta or trachea, as well as in detecting liver metastases.

Staging may also involve laparoscopy, thoracotomy, or thoracoscopy.

TREATMENT AND PROGNOSIS

Irradiation, surgical resection, or both, are the preferred modes of treatment. Surgical resection and irradiation provide a 2-year survival rate of 28% versus 11% for irradiation alone. Overall 5-year survival after surgery is cited at under 10%. Operative mortality from esophagectomy is approximately 8%. The surgical procedure may entail lymphadenectomy of varying degree or colon replacement of the esophagus. Often, treatment is palliative to relieve dysphagia and to allow enteral nutrition. Endoscopic mucosectomy for early esophageal cancer is an alternative, if the cancer is limited to the mucosa. Patients may undergo cervical esophagostomy, feeding gastrostomy, tracheostomy, or esophageal bypass. Bougie dilatation has been performed to facilitate passage of food. Laser opening of the occluded esophagus has a lower mortality rate and fewer complications than tube insertion and may be effective 80% of the time in palliating obstruction. Other methods for relieving tumor obstruction endoscopically include photodynamic therapy (PDT) utilizing light sensitizing agents and bipolar electrocoagulation (BTP or BICAP) to deliver thermal energy to the surface of the tumor. The emergency physician will need to be able to recognize various prosthetic devices, such as the Proctor-Livingstone or Celestin tube placed through the esophageal obstruction to facilitate passage of liquid or pureed diets. A Celestin tube has its own antimigration device detectable on film. A variety of self-expanding metal stents (SEMS) are commercially available.

Chemotherapy has an insignificant role in therapy for esophageal cancer. There are reports of remissions of 2 to 5 months in 5% to 50% of patients using a variety of agents, chiefly cisplatin, 5-fluorouracil, mitomycin-C, bleomycin, Taxol, vindesine, and vinblastine. Radiation therapy has been used alone or in combination with chemotherapy or surgery. Complications of radiation, such as esophagitis, stricture formation, transverse myelitis, the Brown-Sequard syndrome, pericardial effusion, or constrictive pericarditis, may cause presentation to the hospital.

COMMON PITFALLS

- The importance of early detection of esophageal carcinoma cannot be overstated. About 33% of patients have inoperable, advanced cancer when first seen.
- The earliest and most constant presenting symptom of esophageal cancer is dysphagia, initially with solids and later with liquids.
- Epigastric pain is an ominous symptom.
- The most common complication of radiation therapy is stricture of the esophagus.
- Pneumonitis may occur as the result of aspiration or from prior radiation therapy.
- In the emergency department, if esophageal cancer is suspected, it may be appropriate to obtain a barium swallow. In symptomatic patients, the barium swallow is nearly always abnormal.

GASTRIC NEOPLASMS

The incidence of gastric carcinoma has declined in the United States in the past 65 years, from approximately 50 per 100,000 in 1930 to 6 per 100,000 today—7.4 and 3.4 per 100,000 in males and females, respectively. However, it is still the sixth highest cause of cancer death in men in the United States, with 14,000 deaths annually and 22,400 new cases per year anticipated in 1997.

There is an increased incidence of the disease after age 50; it is unusual in persons younger than the age of 30. The mean age of diagnosis in the United States is 63. Neoplasm after partial gastric resection has been reported. The average delay in diagnosis is more than 10 months, due in part to patient denial and self-treatment with over-the-counter medications for "heartburn" and "gas" and to medical reluctance to work up common presenting complaints. The 5-year survival remains approximately 15% to 20%. The best hope for improving this figure lies in early diagnosis and possibly in screening asymptomatic patients, since 5-year survival for stage 0 gastric cancer may be over 95%, while it is 2% for stage IV disease. The latter has been effective in Japan, where gastric carcinoma is quite common (88 per 100,000) and surgical cure rates approach 50%. In the United States, approximately two-thirds of patients are at stage III or IV at the time of diagnosis.

Men are affected more frequently than are women. A genetic component may be involved, especially if first-degree relatives have had gastric carcinoma. Familial adenomatous polyposis and hereditary nonpolyposis colorectal cancer may be risk factors for gastric carcinoma. Diet has been implicated, especially a high intake of salted, pickled, or smoked foods, and, possibly, nitrates as precursors to carcinogenic nitrosamines. Mucosal changes associated with pernicious anemia may be premalignant, as are adenomatous gastric polyps. Smoking confers a slightly increased risk, as may the presence of type A blood. A role for *Helicobacter pylori* in causing atrophic gastritis that might be a precursor to gastric cancer has been suggested. This organism has been linked to mucosa-associated lymphoid tissue (MALT) lymphoma of the stomach as well. Pernicious anemia and the human immunodeficiency (HIV) virus have been linked to atrophic gastritis and to gastric lymphoma, respectively. Fresh vegetables, vitamin C, refrigeration of foods, wheat bran, and citrus fruits have all been proposed to be protective.

CLINICAL PRESENTATION

The patient may appear pale or cachectic with a low-grade fever. The most common symptom of gastric carcinoma is epigastric pain. This may be a mild ulcer-type pain, occurring after meals, or it may be continuous. Although the characteristics of the pain are nonspecific, the patient tends not to be symptom-free for more than 1 month at a time. There may be a vague postprandial fullness or burning. Dysphagia may be present, especially with tumors of the cardia. The average duration of symptoms before diagnosis is 6 to 10 months.

Weight loss of more than 3 kg is present in at least 40% of patients and suggests more advanced disease. Nausea and vomiting may be present, especially with pyloric tumors.

Unexplained anemia, melena, weakness, and hematemesis may also be presenting signs. Malaise, bloating, and anorexia are nonspecific symptoms of gastric cancer. There is some evidence of gastrointestinal bleeding in one-third of patients, but it is usually not severe.

Gastric obstruction with anorexia, upper abdominal fullness, and occasional vomiting of undigested food are less frequent presentations of a variety of gastric tumors. Rarely, a tumor may perforate and present with peritonitis, sepsis, or gastrocolic fistula.

Gastric cancer may spread through four separate mechanisms: (1) venous spread to the liver or more distant sites, such as the adrenals, bone, kidneys or lungs; (2) transperitoneal spread to the liver surface or ovary; (3) direct extension to the pancreas, mesocolon, or esophagus; and (4) lymphatic spread to the esophageal, paraaortic, and neck nodes.

Manifestations of advanced disease include a palpable abdominal mass, ascites, liver metastases, and palpable lymph nodes, especially a left supraclavicular node (Virchow), or left axillary (Irish's).

Jaundice may be due to either hepatic metastases or biliary obstruction at the hepatic portal. In women, metastases to the ovary may cause pelvic pain or mass, and an enlarged ovary (Krukenberg tumor) may be palpable on pelvic examination. Lung metastases with or without pleural effusion may cause shortness of breath. Cutaneous manifestations of gastric cancer include dermatomyositis, acanthosis nigricans, and multiple seborrheic keratoses. Infiltration of the umbilicus is called Sister Mary Joseph's nodule. Metastases to the prerectal pouch may be palpable as Blumer's shelf or present as mechanical bowel obstruction. There may be pain from bone involvement or neurologic symptoms from brain or meningeal metastases. Nephrotic syndrome, thrombophlebitis, and myopathy may occur.

If the tumor is detectable on physical examination, it is usually not curable. In fact, fewer than 10% of patients with symptoms have early gastric cancer (EGC) (cancer confined to the mucosa and submucosa).

Although 95% of gastric cancers are adenocarcinomas, approximately 5% of gastric malignancies are lymphomas. These will present as an abdominal mass, anemia, hematemesis, or perforation. Leiomyosarcomas are uncommon. Five-year survival with these rare types approaches 50% with surgical excision and radiation therapy.

Gastric carcinoids are rare and usually asymptomatic. If symptomatic, they present with bleeding, dyspepsia, or pain. Amine precursor uptake and decarboxylation (APUD) cells are diffused throughout the gastrointestinal tract. The carcinoid syndrome of flushing, diarrhea, asthma, cyanosis, and right-sided valvular heart disease is more frequently produced by intestinal tumors.

EMERGENCY DEPARTMENT EVALUATION

Diagnostic workup may be started in the emergency department and includes chest film, liver function studies, complete blood cell count, and abdominal ultrasonography or computed tomography (CT). The chest x-ray may demonstrate thickened and infiltrated gastric folds, or abnormal mass lesions. Liver scan or biopsy, endoscopy, lymph node biopsy, or evaluation of pleural or peritoneal effusions may reveal metastases.

Immunochemical fecal occult blood testing for 3 consecutive days will be positive in only 24% of gastric cancers, and is an insensitive test. Low pepsinogen I levels of a low pepsinogen I/II ratio may herald atrophic gastritis, but is of little screening value in the emergency department.

A routine upper gastrointestinal series is insensitive and without value in the diagnosis of EGC. Double-contrast upper gastrointestinal studies are more sensitive and the only type of barium meal examination that is capable of diagnosing EGC. Fiberoptic gastroscopy with biopsy and brush cytology is the *gold standard* for diagnosis. It can differentiate cancer from lymphoma and confirm the presence of carcinoma suspected by radiography. In combination with radiography it is 90% accurate in diagnosing gastric cancer. Endoscopic ultrasonography may be more accurate than CT in staging the depth of primary gastric tumors. CT scanning is useful in identifying liver metastases and in providing information about nodal involvement and extragastric tumor involvement, including peritoneal seeding and spread to the ovaries and rectal shelf. CT of the chest may reveal pulmonary metastases.

Serum carcinoembryonic antigen (CEA) is not sensitive or specific enough to have a role in the diagnosis of gastric cancer. Other tumor markers proposed, such as tumor necrosis factor-alpha and interleukin-6, seem not to be well correlated with tumor stage. Gene alterations may be detectable as mutation/deletion of *p53*, or mutations of APC, MCC, or DCC, but they do not have clinical significance as yet to the practice of emergency medicine.

EGC is curable in 90% of cases, regardless of lymph node involvement. The key is early diagnosis. History, physical examination, and radiographic studies cannot diagnose EGC.

The role of esophagogastroduodenoscopy (EGD) in the United States remains to be defined. Advocates of EGD note that complication rates are low (0.1%) and that it is often better tolerated than an upper gastrointestinal series. EGD is advisable if dyspepsia persists for more than 7 to 10 days or if improvement occurs but symptoms persist for 6 to 8 weeks. Some believe that gastroscopy is mandatory for all gastric ulcers; others believe that if radiographic findings are typically benign, with complete and sustained healing at 6 weeks, EGD is unnecessary.

TREATMENT AND PROGNOSIS

In the United States, the prognosis for patients with gastric carcinoma is bleak, with overall 5-year survival at 10% to 15%. Survival rates of EGC are 90% to 100%; unfortunately, only 6% with gastric cancer have EGC. The best predictor of survival after curative surgical resection is the presence or absence of serosal involvement. [Table 38.2](#) lists staging and TNM classification, with survival rates by stage.

PRIMARY TUMORS (T)		
T1	Tumor is limited to mucosa and submucosa regardless of its extent or location.	
T2	Tumor involves the mucosa and the submucosa (including the muscularis propria) and extends to or into the serosa. It is also not possible through the serosa.	
T3	Tumor extends through the serosa without involving contiguous structures.	
T4	Tumor penetrates through the serosa and involves the contiguous structures.	
REGIONS INVOLVED (R)		
R1	The stomach is regional lymph nodes.	
R2	Involvement of paragastric lymph nodes within 5 cm of the primary tumor along the lesser or greater curvature.	
R3	Involvement of the regional lymph nodes more than 5 cm from the primary tumor, which are resectable as separate, including nodes, celiac, and coeliac lymphatic nodes.	
R4	Involvement of other nonregional lymph nodes that are not resectable as separate, such as the paracardiac, retrocardiac, retroperitoneal, and aortic nodes.	
DISTANT METASTASES (M)		
M1	One distant site of metastasis	Stage I
M2	Two distant sites of metastasis	Stage II
M3	Three distant sites of metastasis	Stage III
M4	Four distant sites of metastasis	Stage IV
M5	Five distant sites of metastasis	Stage V

TABLE 38.2. TNM Classification of Gastric Cancer

Surgical resection provides the only opportunity for cure, but 10% to 20% of patients are not explored; approximately half of those who undergo surgery have nonresectable tumors. Of the remainder who are operated on with curative intent (50%), the 5-year survival is 26% to 33%. *Curative resection* is defined as removal of all gross disease with negative surgical margins. The median survival of “surgically cured” patients ranges from 33 to 47 months. Operative mortality averages 8%. Over 50 different reconstructive procedures have been described, and laser/electrocautery ablation may need to be repeated to provide temporary relief. Indications for surgery include diagnosis suggested on an upper gastrointestinal series or confirmed on biopsy, obstruction, perforation, and bleeding.

Some patients undergo palliative procedures only, such a gastrojejunostomy, yttrium-aluminum-garnet (YAG) laser to control bleeding or restore patency, or plication of the tumor to control perforation.

Chemotherapy produces no significant difference in survival rates but produces tumor regression in 10% to 25% of cases. Median survival for recurrent or inoperable gastric carcinoma can be improved from 3 to 6 months untreated to 9 to 11 months with chemotherapy. The most frequently used agents are 5-fluorouracil, mitomycin-C, cisplatin, etoposide, epirubicin, leucovorin, doxorubicin, and methotrexate. Taxotere, CPT-11, Taxol, and S-1 are newer agents. The emergency physician should watch for neutropenia, thrombocytopenia, anemia, nausea/ vomiting, diarrhea, infection, phlebitis/thrombosis, nephrotoxicity, neurotoxicity, and hepatotoxicity in patients on chemotherapy.

COMMON PITFALLS

Pathophysiology

- The average delay in diagnosis is more than 10 months and is due to patient denial and self-treatment with over-the-counter medications for “heartburn.”
- The most common symptom of gastric cancer is epigastric pain; most patients will not be symptom-free for more than a month at a time.
- Weight loss and dysphagia may be present, with the former suggestive of advanced disease.
- Diagnostic evaluation may begin in the emergency department if gastric cancer is suspected. A routine upper gastrointestinal tract series is without value. Double-contrast upper gastrointestinal study is the only type of barium study capable of diagnosing EGC.
- Fiberoptic gastroscopy is the gold standard for diagnosis.

[Common Pitfalls](#)
[Chapter References](#)

Gallbladder disease is a common problem presenting to emergency departments, primarily because of the high prevalence of gallstones. About 25% of women and 15% of men over age 50 have gallstones. In the United States, over 600,000 cholecystectomies are performed yearly, contributing to the \$5 billion annual cost of gallbladder disease.² Emergency physicians are confronted with a wide range of gallbladder pathology and should be familiar with the natural history of gallbladder disease to better understand the variable presentations of acute gallbladder disease and acute complications of chronic disease.

PATHOPHYSIOLOGY

The gallbladder acts as a reservoir off the common bile duct (CBD) that receives, concentrates, and secretes bile to assist in intestinal absorption of fat and fat-soluble vitamins. Gallstones form when cholesterol is supersaturated in the bile, leaves solution, and crystallizes on a matrix of calcium and other bile constituents. In the United States, about 90% of gallstones are cholesterol or mixed cholesterol stones. Once formed, gallstones may dissolve, remain unchanged, or grow larger.¹²

Risk factors for gallstone formation are those that predispose to increased concentrations of cholesterol in the bile and include increased age, obesity, female sex, family history, ethnicity, and hyperlipidemia. Crohn disease, ileal resection, and rapid weight loss are associated with decreased bile salts and are also risk factors for gallstone formation. About 10% of gallstones are formed of calcium bilirubinate (pigment stones); these are associated with hemolytic anemias, cirrhosis, biliary tract anomalies, and infections.²

Most gallbladder pathology is secondary to gallstones. However, about 10% of cases of acute cholecystitis are acalculous. Acalculous cholecystitis classically occurs in inpatients after major surgery, burns, trauma, or sepsis. After a major insult, bile stasis and low arterial inflow probably lead to gallbladder inflammation, infection, and, eventually, necrosis of the gallbladder wall. However, patients do present to the emergency department with acalculous cholecystitis. Over 70% of cases occur in outpatients, typically elderly men with significant atherosclerotic disease.¹¹ Acalculous cholecystitis must be considered in patients with acquired immunodeficiency syndrome (AIDS), who may present with cholecystitis and cholangitis secondary to cytomegalovirus and *Cryptosporidium* infection. Acute acalculous cholecystitis has a mortality rate that may be as high as 67%.⁶

CLINICAL PRESENTATION

It is helpful to view cholelithiasis (the presence of gallstones) in three stages: asymptomatic, symptomatic, and complicated. Complicated cholelithiasis includes such conditions as acute cholecystitis and its complications, choledocholithiasis (stones in the CBD), and the acute complications of chronic gallstones.¹²

Asymptomatic Cholelithiasis

Most people with asymptomatic gallstones remain asymptomatic. About 10% to 20% of people with asymptomatic gallstones develop complications over 20 years, or about 1% each year.⁷ When patients with previously asymptomatic gallstones become symptomatic, nearly all develop pain, rather than cholecystitis or other acute complications, so they can be managed expectantly. With some exceptions, prophylactic cholecystectomy is not indicated.^{7,12}

Symptomatic Cholelithiasis

Many people present to the emergency department with mildly symptomatic gallstones. Pain is caused by distention of the gallbladder as it contracts against stones obstructing the gallbladder neck or cystic duct. Typically, mild biliary pain is a vague midline discomfort, usually associated with nausea. The term *biliary colic* is a misnomer, as biliary pain is constant and lasts more than 1 hour and usually less than 5 hours. Pain typically occurs in the evening and is rarely postprandial. The vague nature and nonspecific location of the discomfort makes it often mistaken for gastritis, gastroenteritis, or other benign abdominal pathology. If the process continues, pain may become more severe, may become localized to the epigastrium or the right upper quadrant (RUQ), may radiate to the back or scapula, and may be associated with vomiting.⁴

Complicated Cholelithiasis

Complications of gallstones include acute cholecystitis and its complications, CBD stones, cholangitis, and complications of chronic gallstones. All are potentially life-threatening and require prompt recognition and treatment.

Acute Cholecystitis

In acute cholecystitis, the gallbladder neck or cystic duct is obstructed; the persistently increased intraluminal pressure, along with irritation from bile and stones, leads to mucosal damage, inflammation of the gallbladder wall, and, eventually, ischemia. In about 65% of cases, bacteria (usually enteric gram-negative bacteria and occasionally anaerobes) are cultured from bile. Bacterial suprainfection plays a role in some cases.¹² In acute cholecystitis, pain is typically sharp and more localized to the RUQ, with variable radiation to the epigastrium or back. Nausea and vomiting are common. Low-grade fever and tachycardia are usually present. Murphy's sign (respiratory arrest during deep inspiration while palpating the RUQ) or localized peritonitis may be elicited. In up to a third of cases, a swollen, tender gallbladder is palpated. Typically, a leukocytosis with left shift is present, and mild increases in liver function tests, alkaline phosphatase, and bilirubin are seen in 30% to 40% of patients.⁹ Laboratory tests can be normal and fever can be absent, especially in the diabetic or chronically debilitated patient, and must not be relied on to make the diagnosis.¹² Patients are rarely septic; if sepsis is present, consider more complicated conditions, especially ascending cholangitis.

Complications of Acute Cholecystitis

Gallbladder perforation usually occurs in the setting of an acute or chronic cholecystitis, typically in the elderly, debilitated, or diabetic patient. The gallbladder usually becomes gangrenous and then perforates. The perforation normally walls off to form an empyema, but occasionally a bile leak occurs and leads to bile peritonitis.⁹ Rarely, acute cholecystitis is complicated by infection with a gas-forming organism, leading to emphysematous cholecystitis. This typically occurs in diabetics and elderly men with vascular disease. Emphysematous cholecystitis is a serious condition with an overall mortality of 15%; mortality in uncomplicated acute cholecystitis is 4%.⁵

Common Duct Stones

Gallstones in the CBD are termed *choledocholithiasis*. Stones usually form in the gallbladder and migrate from the cystic duct, but they can form primarily in the biliary tree. Presentation is usually similar to that of acute cholecystitis but can be variable and sometimes more subtle. Patients may have jaundice if symptoms last more

than 24 hours.⁷ Choledocholithiasis usually causes an elevation in alkaline phosphatase and conjugated bilirubin, consistent with extrahepatic obstruction. Increases in amylase and lipase are variable. Four percent to 8% of patients with gallstones develop acute pancreatitis, which can vary from mild pain to severe pancreatitis, with massive fluid shifts and cardiovascular collapse.⁸ Biliary tract and pancreatic tumors can present with abdominal pain, pancreatitis, and jaundice, but the presentation is typically more indolent, and 50% of patients do not have pain.

Ascending Cholangitis

Ascending cholangitis must be considered in any septic patient who presents with signs and symptoms of acute biliary tract disease, especially if the patient is diabetic, elderly, or debilitated. Ascending cholangitis is a bacterial infection of the biliary system, most frequently associated with CBD stones and obstruction. Classically, it presents with Charcot's triad of RUQ pain, jaundice, and fever and chills; if mental status changes and shock occur, this is considered Reynold's pentad. Ascending cholangitis seldom presents classically, so it must be considered in any septic patient without a source. Mortality approaches 40%.³

Complications of Chronic Cholelithiasis

In chronic and occasionally in acute cholecystitis, gallbladder–enteric fistulas may form, causing pain, aerobilia, or infection. Rarely, a gallstone may pass through a fistula into the small bowel and lodge in the ileocecal valve, causing a small bowel obstruction (gallstone ileus). Fistulas have been described between the gallbladder and the duodenum, stomach, colon, pleura, and other organs. Chronically inflamed gallbladders can become calcified, leading to the radiographic finding of a “porcelain gallbladder.” These patients have a 25% risk of developing gallbladder cancer, which normally occurs in less than 1% of patients with chronic cholelithiasis.^{4,12}

DIFFERENTIAL DIAGNOSIS

When patients present with complaints attributable to gallbladder disease, a wide range of both intraabdominal and extraabdominal processes must be considered (Table 39.1). Elderly or debilitated patients are often difficult to assess and require ancillary studies to rule out life-threatening disease.

Complications of gallstones
Acute cholecystitis
Hepatitis
Pancreatitis
Peptic ulcer disease
Esophageal disease, with or without perforation
Appendicitis
Bowel obstruction
Colonic pathology
Pelvic inflammatory disease
Fitz-Hugh-Curtis syndrome/perihepatitis
Renal colic
Pyelonephritis
Pneumonia
Pulmonary embolism
Acute myocardial infarction
Aortic dissection
HELLP syndrome

TABLE 39.1. Differential Diagnosis of Acute Diseases of the Gallbladder

EMERGENCY DEPARTMENT EVALUATION

Despite the diversity in acute gallbladder pathology, evaluation should follow a relatively straightforward sequence based on the patient's clinical status (Table 39.2). The goal of the emergency physician is to rule out life-threatening problems and, if gallbladder pathology is suspected, to rule out acute cholecystitis and other complicated acute gallbladder disease. If the patient presents with pain or other symptoms attributable to gallstones and is well and not dehydrated or vomiting, referral for outpatient ultrasound and follow-up is appropriate. No further emergency department workup is necessary. In the sicker patient with severe pain or dehydration and possibly fever, further workup is indicated, including a complete blood count, electrolytes, liver function tests, bilirubin, amylase, lipase, and urinalysis.

Acute cholecystitis	Cholelithiasis	Cholangitis	Cholecystitis	Cholecystitis
RUQ pain	RUQ pain	RUQ pain	RUQ pain	RUQ pain
Jaundice	Jaundice	Jaundice	Jaundice	Jaundice
Fever	Fever	Fever	Fever	Fever
Leukocytosis	Leukocytosis	Leukocytosis	Leukocytosis	Leukocytosis
RUQ tenderness	RUQ tenderness	RUQ tenderness	RUQ tenderness	RUQ tenderness
Positive Murphy's sign	Positive Murphy's sign	Positive Murphy's sign	Positive Murphy's sign	Positive Murphy's sign
Positive ultrasound	Positive ultrasound	Positive ultrasound	Positive ultrasound	Positive ultrasound
Positive CT	Positive CT	Positive CT	Positive CT	Positive CT

Positive laparotomy	Positive laparotomy	Positive laparotomy	Positive laparotomy	Positive laparotomy

TABLE 39.2. Features That Differentiate Diseases of the Gallbladder

Radiographic Studies

The diagnosis of acute cholecystitis and its complications is primarily radiographic. Plain radiographs are most helpful for ruling out bowel obstruction or other causes of abdominal pain, although gallstones are visible on plain radiographs in about 10% of cases.

Because of its availability and low risk, ultrasound is the first-line method of evaluating the gallbladder and biliary tree. Gallstones alone do not make the diagnosis of acute cholecystitis. Other signs, such as a thickened gallbladder wall, sludge in the gallbladder, gallbladder distention, pericholecystic fluid, and focal tenderness are suggestive, with a sensitivity of more than 95% for acute cholecystitis.¹⁰ Ultrasound is also helpful in making the diagnosis of complications of acute cholecystitis. A dilated CBD or intraluminal stone is diagnostic of choledocholithiasis. Free fluid suggests gallbladder perforation. Ultrasound can also assess other extrabiliary causes of RUQ pain in the liver, kidney, or pancreas.^{10,12}

Cholescintigraphy with 99m-iminodiacetic compounds tests the patency of the cystic duct. Failure to visualize the gallbladder is highly sensitive for acute cholecystitis.

Hepatobiliary scanning is usually used when there is a high suspicion for acute cholecystitis, with an equivocal or negative ultrasound scan. However, some recommend it as the initial study for acute cholecystitis.¹²

Computed tomography (CT) scanning is reserved for patients with atypical presentations or possible concomitant intraabdominal pathology or complications.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Emergency department management of symptomatic cholelithiasis includes hydration, antiemetics, and analgesia. These patients can usually be sent home with

appropriate follow-up. If acute cholecystitis or another complicated presentation of gallbladder disease is considered, prompt consultation with a general surgeon is mandatory. Attention to the patient's volume and electrolyte status, antiemetics, and nasogastric tube placement is recommended. Analgesia, typically with intramuscular nonsteroidals or meperidine, is appropriate after surgical consultation. ¹

If the patient is febrile and acute cholecystitis is suspected, antibiotics are probably indicated, but this should be discussed with the consultant. The patient who is septic or is suspected of having ascending cholangitis, perforation, or emphysematous cholecystitis should be given antibiotics promptly after blood cultures. Typical biliary pathogens include enteric gram-negative bacteria or gram-positive species such as enterococcus or streptococci. Anaerobic species, particularly *Clostridium* and *Bacteroides fragilis*, occur in approximately 10% to 15% of cases, usually in the elderly or with obstructive disease. Appropriate coverage would include an intravenous antipseudomonal penicillin such as ticarcillin/clavulanate 3.1 g q6h or piperacillin/ tazobactam 3.75 g q6h. Alternative regimens, especially if anaerobes are suspected, include a cephalosporin or an aminoglycoside plus clindamycin or metronidazole. ³

Definitive treatment for symptomatic gallstones is usually surgical, with laparoscopic cholecystectomy standard treatment versus open cholecystectomy. ¹² Oral dissolution therapy is used to dissolve gallstones, occasionally in conjunction with extracorporeal shock-wave lithotripsy in patients who are substantial surgical risks or do not want surgery. ⁴

In patients who present with pain, fever, or jaundice after laparoscopic cholecystectomy, one must consider the increasingly recognized complications of the procedure, including biliary injury and fistulas, wound infections, and intraabdominal abscesses, which may present weeks to months after surgery. ¹²

Definitive treatment for acute cholecystitis and complicated gallstone disease is almost always surgical. Most surgeons prefer urgent cholecystectomy (open or laparoscopic) rather than delayed surgery. In patients with CBD duct stones, endoscopic sphincterotomy or dilatation to relieve obstruction followed by cholecystectomy, or open cholecystectomy with CBD exploration, is performed. ⁸ Most patients with ascending cholangitis need some type of urgent biliary decompression. All patients with gallbladder perforation, emphysematous cholecystitis, or gallbladder empyema need emergent surgery. ⁹

COMMON PITFALLS

- Acute complications of gallstone disease must be considered and recognized, particularly in the elderly and debilitated.
- Remember to consider cholecystitis or cholangitis in the elderly, diabetic, or debilitated patient who presents with fever of unknown origin, change in mental status, or other nonspecific complaints.
- Symptomatic gallstones should be considered in patients with mild or atypical presentations, such as nausea, dyspepsia, or vague abdominal pain.
- Always consider acute gallbladder disease in the pregnant woman with abdominal pain.
- Always obtain timely surgical consultation when complications of gallstone disease are considered.

[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Role of the Consultant](#)
[Indications for Admission](#)
[Transfer Considerations](#)
[Common Pitfalls](#)
[Chapter References](#)

Jaundice is a yellow discoloration of the skin, body fluids, and other viscera resulting from elevated levels of bilirubin in the serum. The numerous etiologies of jaundice are broadly categorized as either medical or surgical. Surgical jaundice is synonymous with extrahepatic biliary obstruction; medical jaundice encompasses all entities responsible for bilirubin overproduction, defective bilirubin metabolism, and impaired intrahepatic bilirubin excretion. This differentiation has practical importance in guiding patients to the appropriate specialist.

Extrahepatic obstruction can be distinguished from other causes of jaundice on the basis of the history, physical examination, and clinical laboratory findings in up to 90% of cases.^{2,7,10} Invasive and noninvasive testing is used selectively to confirm clinical suspicions and to further delineate the nature and extent of the pathologic process.

CLINICAL PRESENTATION

Patients presenting with extrahepatic obstruction often report that the jaundice was first noticed by a family member or friends. Typically, the patient is an older person who denies constitutional symptoms. Cholestasis, a term that describes impairment of either intrahepatic or extrahepatic bile flow, is characterized by pruritus, pale stools, and dark urine. Abdominal pain suggests the presence of gallstones or pancreatitis; weight loss implies a malignant process. The patient must be questioned about previous biliary surgery, exposure to infectious hepatitis, alcohol intake, travel history, the use of drugs such as chlorpromazine and oral contraceptives, and chronic medical conditions.

The general appearance of a patient presenting with extrahepatic obstruction is typically that of someone who is “more yellow than sick.”⁵ Evidence of sepsis, including fever and toxic appearance, is evident when the obstruction is complicated by bacterial cholangitis. Abdominal findings vary according to the cause of obstruction. Epigastric tenderness suggests a pancreatic process; right upper quadrant tenderness is more suggestive of choledocholithiasis. Hepatomegaly can be seen in both medical and surgical jaundice. A palpable, nontender gallbladder represents malignant common duct obstruction (Courvoisier’s law), especially if jaundice is painless.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the patient who presents to the emergency department with jaundice is listed in [Table 40.1](#). Despite the large number of potential etiologies, a careful history and physical examination can often narrow the differential diagnosis considerably. The selected use of laboratory tests guided by the clinical evaluation can rapidly pinpoint a definitive diagnosis.

PREHEPATIC	EXTRAHEPATIC
Hemolysis	Common duct stone
Sickle cell disease	Biliary stricture
Celiac disease	Bacterial cholangitis
Chronic myelomonocytic leukemia	Amplified carcinoma
Cryptosporidium parvum	Cholangiocarcinoma
Celiac sprue	Gallbladder carcinoma
Parasitic infection	Pancreatitis
Nonfatal pneumonia	Pancreatic carcinoma
Drugs	Perennial granulomatous cholangitis
Hepatocellular	Hemochromatosis
Hepatitis	Chronic duct ectasia
Alcoholic	Ascariasis
Autoimmune	Congenital choledochal cyst
Drugs	Congenital biliary atresia
Primary biliary cirrhosis	Recurrent pyogenic cholangitis
Primary sclerosing cholangitis	Postoperative cholecystitis
Hemochromatosis	Primary biliary cirrhosis
Intrahepatic cholestasis	Congenital biliary atresia
Cholestatic jaundice of pregnancy	Empysematous cholecystitis
Drugs	
Biliary obstruction	
Recurrent pyogenic cholangitis	
Familial cholestanolosis	

TABLE 40.1. Differential Diagnosis of Jaundice

EMERGENCY DEPARTMENT EVALUATION

Simple laboratory tests can be helpful in diagnosing surgical jaundice. In cases of extrahepatic obstruction, icterus typically results from elevated levels of conjugated bilirubin. Icterus resulting from hepatocellular disease may also be due primarily to conjugated bilirubin. Bilirubin fractionation is most useful in separating out diseases in which serum bilirubin levels are primarily unconjugated, such as hemolysis or ineffective erythropoiesis.⁶ The severity of hyperbilirubinemia may suggest the cause of obstruction. Malignancy causes the highest average levels, often in the range of 10 to 30 mg/dL. Choledocholithiasis typically results in a transient rise in the bilirubin level, rarely exceeding 15 mg/dL.¹¹ Hepatic parenchymal disease is characterized by elevation of both conjugated and unconjugated bilirubin levels.

Alkaline phosphatase is synthesized in the epithelial cells of hepatic cholangioles as well as in bone and intestine. In the presence of biliary tract obstruction, alkaline phosphatase of hepatic origin results in elevated serum levels. High serum alkaline phosphatase levels are not pathognomonic of extrahepatic biliary obstruction, but when accompanied by conjugated hyperbilirubinemia, this possibility should be strongly suspected.⁶

Liver function tests along with an amylase or lipase can differentiate hepatocellular from cholestatic or obstructive pictures.^{7,10} Transaminase levels are typically very high in hepatocellular disease but tend to be only moderately elevated in surgical jaundice.

Surgical jaundice may be accompanied by prolonged prothrombin times because of the inability of bile salts to reach the gut and assist in the absorption of vitamin K. This abnormality responds to parenteral injections of vitamin K over a 3-day period. Failure to respond implies the presence of hepatic parenchymal disease.⁶

Plain films of the abdomen are of limited value in the evaluation of jaundice. Only 20% of gallstones are radiopaque. Intrabiliary air may be visible, or an emphysematous gallbladder.⁶

The history of possible hepatitis exposure coupled with markedly elevated transaminase levels points to infectious hepatitis. Alcoholic liver disease is suggested by a history of alcohol abuse in combination with the physical stigmata of alcoholic liver disease. Exposure to hepatotoxins such as Amanita or carbon tetrachloride may suggest the diagnosis. Specific parenchymal disease may be diagnosed by liver biopsy in selected cases.¹

Perhaps the most difficult distinction to make is between intrahepatic cholestasis and extrahepatic obstruction, because both cause an elevation in conjugated

bilirubin levels. Currently, ultrasonography or computed tomography (CT) scanning can be used to demonstrate the dilated biliary ducts seen with obstruction. Both have similar sensitivities and positive predictive values, but ultrasonography is the diagnostic study of choice because of its lower cost and easier availability. CT scanning provides information about the level and nature of an obstruction and may be especially useful in identifying pancreatic masses. ^{8,9}

Once obstruction has been confirmed by one of these imaging techniques, prompt referral to a general surgeon is indicated. Management may include involvement by both a surgeon and a gastroenterologist. ⁴ The invasive techniques of transhepatic cholangiography (THC) or endoscopic retrograde cholangiopancreatography (ERCP) are reserved for equivocal cases or those in which corrective surgery is planned. These techniques may be used to bypass obstructions in a palliative or curative manner. THC is superior when a proximal lesion is suspected; ERCP is superior for distal lesions. ⁹

EMERGENCY DEPARTMENT MANAGEMENT

Patients presenting to the emergency department with obstructive jaundice are generally not toxic or in need of resuscitation. Rather, thorough evaluation to identify coexistent conditions that might delay or even preclude surgical decompression is required. In patients who have been vomiting or not eating, assessment of hydration status, electrolytes, and nutritional status is indicated.

One entity that requires prompt intervention is bacterial cholangitis. ¹² The potential for deterioration from sepsis is significant, and blood cultures must be obtained and parenteral antibiotics initiated. Bacteriologic organisms include *Enterobacter* sp. (68%), enterococci (14%), *Bacteroides* (10%), and *Clostridium* sp. (7%). Appropriate regimens include any of the following: antipseudomonal penicillin; ampicillin, gentamicin, and metronidazole; imipenem/cilastatin; ticarcillin/clavulanate; piperacillin/ tazobactam; ampicillin/sulbactam; ceftioxin plus an antipseudomonal aminoglycoside; a third-generation cephalosporin and metronidazole or clindamycin; and aztreonam and clindamycin. ^{3,7,12} Ceftriaxone should probably be avoided, because it has been associated with biliary sludging. ⁷ Patients who display signs of significant toxicity may require aggressive intervention with intravenous fluids, supplemental oxygen, cardiac monitoring, nasogastric suction, and bladder catheterization before expeditious disposition to a critical care unit or surgery.

DISPOSITION

Role of the Consultant

Because little can be done in the emergency department in the way of definitive therapy for patients with extrahepatic obstruction, surgical consultation should be obtained once the diagnosis is suspected. The surgeon should decide whether further evaluation is necessary or whether sufficient information is available to proceed to laparotomy.

Indications for Admission

Patients with bacterial cholangitis should be hospitalized for parenteral antimicrobial therapy. If there is no evidence of infection, most cases of obstruction can be further evaluated and treated in an outpatient setting. Intractable pain, intractable emesis, or evidence of associated pancreatitis should result in immediate consultation rather than a referral. Most such cases are appropriately managed in the hospital. ¹¹

Transfer Considerations

Most patients can be successfully evaluated at the local institution. Critically ill patients with obstruction and cholangitis should receive resuscitative fluids, intravenous antibiotics, and possibly cholecystectomy before transfer to a center with sophisticated imaging and critical care services.

COMMON PITFALLS

- Patients with simple biliary colic must be differentiated from those cases complicated by cholangitis or pancreatitis. Patients with cholangitis can deteriorate rapidly and develop septic shock and the multiple organ dysfunction syndrome. Likewise, patients with pancreatitis can develop the systemic inflammatory response syndrome. Accordingly, the clinical assessment should be accompanied by the appropriate laboratory assessment to avoid misdiagnosis.
- Critically ill patients with cholangitis require emergent drainage of the biliary tree. Those with pancreatitis require urgent surgical consultation to orchestrate the timing and type of decompressive intervention.

Acute appendicitis can mimic virtually any intraabdominal process; therefore, to know acute appendicitis is to know well the diagnosis of acute abdominal pain. ¹⁰

Appendicitis is an acute inflammatory process of the appendix resulting from obstruction of the lumen with subsequent bacterial invasion, distention, ischemia, and ultimate rupture. As traditionally taught, appendicitis presents with initial periumbilical pain, which later migrates to the right lower quadrant (RLQ). Anorexia, nausea, and vomiting are associated symptoms. Physical examination reveals a low-grade fever and RLQ tenderness, with guarding and rebound as the process progresses. Laboratory evaluation reveals a leukocytosis with neutrophilia. Unfortunately, this classic presentation occurs in only a minority of cases and the diagnosis may be difficult to make. In one large series, diagnostic accuracy averaged only 85%, with a 19% perforation rate. A percentage of the perforation rate is surely from delayed diagnosis. Incidence of perforation increases with the extremes of age, and perforation is associated with greater morbidity and mortality. ¹

The lifetime risk of appendicitis is 8.6% for males and 6.7% for females, with an annual incidence of 1.1:1,000. The male-to-female ratio for appendicitis is 1.4:1, although females have a higher rate of negative appendectomies. The peak incidence for males is between 10 and 14 years, and for females, between 14 and 19 years. Appendicitis rates are 1.5 times higher for Whites than for non-Whites, and are higher in summer. ¹ The etiology of these differences is unknown, but temporospatial clustering and outbreaks of appendicitis point to an infectious agent as a cause of some cases of appendicitis. ³

The normal, uninflamed appendix is a hollow visceral structure with a closed distal end arising from the cecum; on average, it is 9.5 to 10.0 cm in length. Although the density of immune cells in lymphoid follicles in the appendix suggests an immunologic role, the function of the appendix is unknown. ⁶ Its anatomic position can be anterior (postileal, preileal, and pelvic) or posterior (retrocecal and subcecal), and many appendices are mobile ([Fig. 41.1](#)).⁹ The traditional surface landmark for the location of the appendix is McBurney's point, which is located 1.5 to 2.0 in. from the inferior aspect of a line drawn from the anterior superior iliac spine point to the umbilicus. However, barium studies reveal that most appendices lie inferior to this point; therefore, making clinical decisions based on the presence or absence of pain or tenderness at exactly McBurney's point is unjustified. ²⁰

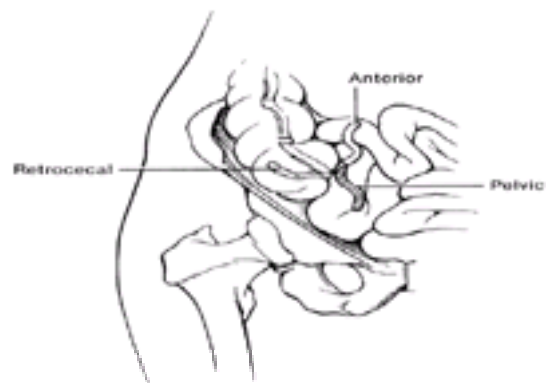

Figure 41.1. Anatomic position of the appendix.

PATHOPHYSIOLOGY

The common pathophysiologic event in appendicitis is obstruction of the lumen. Obstruction can be from lymphoid hyperplasia, intraluminal objects (fecaliths, foreign bodies, or parasites) or tumors (carcinoid, adenocarcinoma, or metastatic tumors). A variety of inflammatory conditions can result in hyperplasia of appendiceal lymphoid follicles that progresses until the appendiceal wall itself obstructs the lumen. Conditions noted for this process include respiratory infections, mumps, mononucleosis, amebiasis, and bacterial gastroenteritis.

Crohn disease can affect the appendix.³⁵ Patients with the acquired immunodeficiency syndrome can have other processes of the appendix, including Kaposi's sarcoma, lymphoma, or opportunistic infections (e.g., cytomegalovirus).³³

Once the appendiceal lumen is obstructed, mucus secretion within the appendix raises intraluminal pressures until lymphatic and venous return is impaired. Ischemic injury to the mucosa results, followed by bacterial invasion of the appendiceal mucosa and submucosa. Continued inflammation and bacterial proliferation result in perforation of the appendix and spillage of inflammatory cells and bacteria into the peritoneum, resulting in peritonitis. At times, the peritoneal infection is contained by the omentum and a periappendiceal abscess forms.³⁵

CLINICAL PRESENTATION

History

The characteristic clinical presentation of acute appendicitis is abdominal pain in association with anorexia, nausea, and vomiting ^{23,27} ([Table 41.1](#)). About 50% of patients present within 24 hours of the onset of symptoms, 33% between 24 and 48 hours and the rest thereafter. Abdominal pain occurs in nearly 100% of patients, is epigastric in onset in 74%, and migrates to the RLQ in 50%. Anorexia is present in 92% of patients, accompanied by nausea and vomiting in 78% and 54% of patients, respectively.

	Nonperforated (%)	Perforated (%)	All Cases (%)
SYMPTOMS			
Abdominal pain	99.6	99.3	99.6
Eggetic at onset	74.9	76.1	75.5
Constant RLQ	74.9	76.1	75.5
Nausea	79.6	79.8	79.7
Vomiting	17.8	14.2	16.2
Relaxation of pain	32.2	36.8	34.2
Fever	16.3	21.4	18.8
Diarrhea	0.5	0.2	0.4
Leukocytosis	93.3	94.2	93.8
Leukocytosis	93.3	94.2	93.8
SIGNS			
Abdominal tenderness	99.6	99.3	99.6
Right RLQ	26.3	28.6	27.5
Left RLQ	7.8	25.6	16.2
Generalized	9.6	25.6	17.9
Right-sided rectal tenderness	42.2	45.8	44.0
Local rigidity over RLQ	26.3	45.3	36.1
Generalized rectal tenderness	17.4	19.4	18.4
Rectal tenderness	4.8	4.3	4.5
Positive Rovsing test	4.8	3.7	4.2
Generalized rigidity	8.7	12.7	10.7
Palpable mass in RLQ	3.9	3.7	3.8

TABLE 41.1. Signs and Symptoms of Acute Appendicitis

Physical Examination

Although often regarded as a reliable clinical feature of appendicitis, fever is reported in only 21% of all cases and in only 16% of cases of appendicitis uncomplicated by perforation.

The most reliable sign of acute appendicitis is RLQ tenderness, present in nearly 100% of patients. Twenty-five percent of patients demonstrate referred RLQ tenderness under remote palpation (Rovsing's sign); rigidity in the RLQ is present in 30% of patients. Nearly 50% of patients demonstrate right-sided rectal tenderness.

The most significant complication of acute appendicitis is perforation, which either leads to generalized peritonitis and sepsis or is contained as an intraabdominal abscess. The mortality rate of perforated appendicitis is 1.66%, seven times greater than that of patients undergoing appendectomy for simple, acute appendicitis (0.24%) and 12 times greater than that of appendectomy of a normal appendix (0.14%).⁴⁰ Clearly, the clinician must try to diagnose cases of simple acute appendicitis before perforation occurs.

There are few reliable clinical features that distinguish nonperforated from perforated appendicitis (see [Table 41.1](#)). The duration of symptoms tends to be longer in patients with perforation (greater than 48 hours). Signs that suggest perforation include lower or generalized abdominal tenderness, local or generalized rigidity over the RLQ, the presence of a palpable RLQ mass, and generalized rectal tenderness.²⁷

Pediatric, geriatric, and pregnant patients deserve special mention. Because diagnosis often is more difficult in these groups, their morbidity and mortality is greater.

Pediatric Patients

Children's appendices have a much thinner wall than that in the adult, allowing more rapid mucosal penetration and subsequent perforation. Perforation rates average 37% to 59% in children under age 13. In children under age 3, the perforation rate increases to 67% to 79%. The inability of the very young to verbalize their symptoms contributes to the difficulty in diagnosis.^{11,15,29} Diarrhea is a presenting complaint in about a third of appendicitis patients under the age of 3^{11,19} (see [Chapter 260](#)).

Geriatric Patients

Only 20% of patients over age 60 who are diagnosed with appendicitis present with the classic nausea, vomiting, RLQ tenderness, and an elevated white count or shift. Consequently, the perforation rate is 67% to 90%. The mortality rate is 4.6%, 23 times greater than that of patients younger than age 60^{1,18} (see [Chapter 36](#)).

Pregnant Patients

The physiologic changes of pregnancy, especially during the second and third trimesters, impede the diagnosis and create a physiologic environment that suppresses the normal host response to inflammation. As the uterus enlarges, the appendix rotates in a counterclockwise direction out of the pelvis ([Fig. 41.2](#)). In addition, as the expanding uterus lifts the abdominal wall away from the appendix, the omentum is less available to wall off the infectious process following perforation. Diffuse peritonitis develops preferentially over a periappendiceal abscess. The increase in serum steroids during pregnancy diminishes the inflammatory response and facilitates a more rapid and overwhelming peritonitis.²⁶ These physiologic and anatomic processes result in a perforation rate of 43%.³⁷ The maternal mortality rate remains low at 0.7%, but fetal mortality may approach 8.5%.²⁶

Figure 41.2. Changes in appendiceal position during pregnancy.

DIFFERENTIAL DIAGNOSIS

A variety of conditions mimic appendiceal inflammation¹ ([Table 41.2](#)); the diagnostic accuracy of appendectomy for suspected acute appendicitis is only 85%. Disorders most commonly associated with removal of a normal appendix despite clinical suspicion of acute appendicitis include mesenteric lymphadenitis, other diseases of the appendix, and gynecologic ailments. The greatest diagnostic difficulties are encountered in women of childbearing age. The overall diagnostic accuracy for females is 77%; in contrast, males have a diagnostic accuracy of 91%.¹

Discharge Diagnoses Most Commonly Recorded After Negative Appendectomy	Percentage
Other diseases of the appendix (toxic, concretions, Atchek's diverticulum, fecalith, fistula, sinus/abscesses, mucocoele)	19.4
Other appendicitis (chronic, recurrent, relapsing, or subacute)	16.5
Meckel's diverticulitis	22.8
Abdominal pain	12.2
Gastroenteritis, noninfectious	9.4
Cholecystitis	4.1
Ovarian cyst	5.5
Uterine leiomyoma	4.3
Endometriosis	4.0
Lymphoid hyperplasia of the appendix	3.1
Cervicitis, endocervicitis	2.7
Other considerations in the differential diagnosis include regional enteritis, perforated gastric ulcer, diverticulitis, carcinoma of the bowel, ureteral calculus, pelvic inflammatory disease, mitral regurgitation.

TABLE 41.2. Differential Diagnosis of Acute Appendicitis

EMERGENCY DEPARTMENT EVALUATION

Appendicitis should be suspected based on the history and physical examination. The emergency clinician should be particularly aggressive in evaluating the very young, the elderly, and the pregnant patient, as the morbidity and mortality rates of acute appendicitis in these subpopulations far exceed those of others. No laboratory or radiographic study is completely sensitive for acute appendicitis, but several are commonly relied on for their supportive value.

Laboratory Studies

Acute appendicitis is classically associated with leukocytosis with a left shift. In one large study, 88% of adult patients with acute appendicitis had a white count of over 10,000 cells/ μ L, and 94% had a leukocytosis or a neutrophilia above 75%. Specificity was only 76% and 62%, respectively. Approximately 10% of patients with acute appendicitis have normal leukocyte and neutrophil counts.²² Unfortunately, the leukocyte count is nonspecific, being reported as low as 38%.² Further complicating matters, the normal range for the leukocyte count changes with age. By calculating likelihood ratios, one finds that the leukocyte count has minimal effect on the probability of disease, except for the extremes of the leukocyte count. However, only a small minority of patients will have such leukocyte values.³⁶ Some authors advocate serial leukocyte counts and progressive leukocytosis as suggestive of acute appendicitis. Studies regarding the clinical utility of sequential leukocyte counts are inconclusive, and it appears that utility, if any, is limited to a small percentage of the total patient population.^{13,25,38}

Urinalysis, often obtained in the evaluation of abdominal pain, cannot be relied on to distinguish disease of the urinary tract from that of the appendix. In one study of patients with histologically confirmed acute appendicitis, 30% had an abnormal urinalysis, regardless of the position of the appendix. In those with either a ruptured or inflamed appendix in the retrocecal or pelvic position, abnormal urinalysis was detected in 50%. Diagnostic decisions should *not* be based on the presence of pyuria or bacteriuria.³⁴

Imaging Studies

Radiologic studies should be reserved for those with equivocal symptoms and physical findings. In cases of strongly suspected appendicitis, time-consuming diagnostic procedures should not be used. One study demonstrated that patients who had a barium enema as part of their workup had significantly longer delays from presentation to surgery. Because the incidence of perforation is directly related to the interval between symptom onset and surgery, tests that may delay definitive therapy should be used with caution.²⁸

Plain radiographs are often obtained in suspected appendicitis; a variety of radiographic findings may be seen, including a fecalith, localized ileus, or obscuration of fat-tissue interfaces.¹⁷ These findings are nonspecific and the diagnostic yield is low.⁷ Plain radiographs should be obtained only when other diagnoses are high in the differential (e.g., bowel obstruction).

A barium enema can be used to evaluate potential appendicitis on the premise that a normal appendix can be filled with barium but an obstructed appendix will not allow the passage of barium. Generally, a barium enema is highly accurate in the diagnosis of appendicitis, although false-positive examinations occur and there is a relatively high incidence of technical failure.¹⁷

Labeled white blood cell scanning provides good sensitivity (90% to 97%) and specificity (89% to 97%). A major disadvantage of such nuclear medicine studies is that although early positive studies are possible, the procedure can take up to 4 hours to complete.^{5,32}

Abdominal ultrasonography is often used in the evaluation of appendicitis. When obstructed, the appendix appears as a blind-ended, immobile, noncompressible structure that cannot be displaced under direct pressure from the ultrasound probe. An appendix that is visualized on ultrasound examination is considered diagnostic of appendicitis. If the appendix cannot be seen, appendicitis is excluded. Unfortunately, ultrasonography is nondiagnostic in 3% to 11% of cases due to pain, guarding, obesity, or overlying gas. Sensitivity ranges from 75% to 89% and specificity from 86% to 100%. Poorer results are obtained in early appendicitis, perforation, and retrocecal appendicitis.¹⁷ Ultrasound is the preferred modality in pregnant patients and is highly sensitive in this population.²⁴

Helical computed tomography (CT) scanning of the abdomen is fast and highly accurate in the evaluation of acute appendicitis. The sensitivity of unenhanced helical CT is approximately 90%; with the addition of rectal or intravenous contrast, the sensitivity increases up to 97% to 98%.^{14,21,30} Specificity is equally high at 94% to 97%. Findings include a fecalith, an inflamed appendix, stranding in the surrounding fat or periappendiceal fluid, phlegmon, or abscess⁶ (Fig. 41.3). Helical CT in the evaluation of appendicitis appears to be cost effective, and its use may decrease the negative laparotomy and perforation rates.^{30,31} Furthermore, CT often provides an alternative diagnosis. In addition, it is useful in the assessment of cases of suspected perforated appendicitis with periappendiceal abscess formation, which may be treated conservatively or with percutaneous drainage and interval appendectomy.⁴¹

Figure 41.3. CT appearance of appendicitis.

Diagnostic laparoscopy, especially for women of childbearing age, has advocates. It is highly accurate and safe.⁸

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

The patient suspected of having acute appendicitis should be given nothing by mouth. Intravenous access is indicated to ensure hydration. Surgical consultation should be obtained promptly, as timely appendectomy of an inflamed but nonperforated appendix is of paramount importance. If acute appendicitis is suspected but in doubt, radiologic study, emergency department observation, or admission for inpatient observation with sequential examination is an alternative. Observation is a safe and effective way to distinguish patients with appendicitis from those without. ^{12,16}

Although traditional edict warns that analgesia will obscure the diagnosis in acute abdominal pain, the use of narcotics has not been shown to increase the number of delayed or missed diagnoses.⁴ The judicious use of short-acting narcotics is reasonable in patients with acute abdominal pain while evaluation is in progress, especially those in which a radiologic procedure is to be performed or surgical consultation is delayed.

COMMON PITFALLS

- Abdominal pain and tenderness are present in nearly 100% of patients with appendicitis; other clinical features are less reliable.
- Fever occurs in only 16% of patients with acute appendicitis; its presence is more suggestive of appendiceal perforation.
- Reliance on the leukocyte count is unwarranted and usually leads to false reassurance.
- Helical CT appears to be highly accurate in diagnosing appendicitis, although no test is fail-proof.
- Caution is advised in evaluating the young, the elderly, pregnant women, and women of childbearing age. The diagnosis is often elusive, and many patients proceed to perforation.
- When in doubt, admit the patient for observation to an emergency department observation area or surgical service for sequential physical examinations.
- The missed diagnosis of appendicitis remains one of the most frequent malpractice claims against emergency physicians. Document all examinations, laboratory results and their interpretations, and conversations with consultants, including their opinion, advice, and therapeutic plan. ³⁹
- For patients being discharged with indefinite diagnoses, provide clear, legible instructions explicitly detailing conditions meriting a return visit for further evaluation.

CHAPTER 42

Bowel Obstruction

Philip L. Henneman

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Evaluation](#)
[Disposition](#)
[Common Pitfalls](#)
[Bibliography](#)

Intestinal obstruction is a common disorder that has been recognized by physicians for centuries. It accounts for approximately 4% of patients presenting to an emergency department with nontraumatic abdominal pain of less than 7 days' duration. The challenge to the emergency physician is to promptly identify the patients with bowel obstruction from the many patients presenting to an emergency department with abdominal pain and vomiting, without doing multiple tests and without delaying treatment, admission, and surgical consultation.

Intestinal obstruction was associated with a 60% mortality in 1900. This has decreased to approximately 5% due to early recognition, aggressive stabilization with fluid resuscitation, simple nasogastric decompression, and, in most cases, surgical intervention. Mortality can still result from strangulation, bowel infarction, and resulting sepsis. Early recognition and initiation of treatment are the only way for the emergency physician to minimize major morbidity or mortality.

Intestinal obstruction accounts for about 20% of all acute surgical admissions. The obstruction most commonly affects the small intestine but involves the colon in up to 20% of patients. The vast majority of bowel obstructions are due to postoperative adhesions, accounting for 50% of small bowel obstructions. Other common causes include hernias and neoplasm in adults and intussusception, hernias, and congenital abnormalities in children. Feces, foreign bodies, strictures, abscesses, trauma, and volvulus are other less common causes.

The stomach, small bowel, biliary tract, and pancreas collectively secrete 8 to 10 L of fluid daily. Almost all of this volume is reabsorbed in the large bowel. Obstruction prevents the flow of fluid and other intraluminal contents to the colon, resulting in accumulation in the more proximal sections of the bowel. This causes a gradual distention of the bowel proximal to the obstruction, and increasing intraluminal pressure. As pressure increases within the bowel, hypersecretion of fluid into the bowel develops, and absorption from the bowel is retarded. Volume losses into the intraluminal space are variable but can be up to 9 L in 24 hours, causing significant depletion of intravascular volume. Further increases in intraluminal pressure result in capillary and lymphatic obstruction with resulting edema of the bowel wall. Retrograde peristalsis eventually develops, resulting in vomiting by the patient. If allowed to progress, venous and finally arterial obstruction will occur. Bacterial overgrowth occurs in the stagnant bowel contents. Hemorrhagic necrosis, gangrene of the bowel, and leakage of contaminated contents finally develop, resulting in bacterial peritonitis and sepsis. It is the goal of therapy to prevent these life-threatening complications.

CLINICAL PRESENTATION

Bowel obstruction should be considered in all patients with abdominal pain and vomiting, especially if they have a history of previous abdominal surgery or colorectal cancer. Pain is the initial and primary complaint, although it may be poorly appreciated or communicated in patients with altered or impaired mental status. The pain is usually intermittent and colicky, with cramps occurring every 3 to 10 minutes, depending on the location of obstruction. Vomiting generally follows the development of abdominal pain. The more proximal the obstruction, the earlier vomiting develops; in obstruction of the colon, vomiting may not develop for 24 to 48 hours. Although obstipation (i.e., no passage of feces or flatus) is the rule once obstruction is complete, the passage of stool and flatus may continue until the distal bowel is evacuated. Diarrhea may even occur when there is partial obstruction. Late in the course, abdominal distention may develop. This may be subtle to the physician, but the patient is often aware of this change.

The patient's vital signs usually reflect the degree of volume depletion and in general are only modestly altered until late in the disease process. Hypotension and tachycardia imply advanced disease. Gangrenous bowel, however, may be present without fever or tachycardia.

A helpful sign in diagnosing early small bowel obstruction is the auscultatory finding of crescendo–decrescendo rushes of high-pitched peristalsis sounds coincident with the patient's colic. Bowel sounds eventually decrease and disappear with overdistention and infarction of the bowel.

Abdominal tenderness is variable but usually present in most patients. The determination of rebound tenderness is often complicated by the presence of distended bowel, which may give a false-positive result of increased pain with rapid decompression of the abdominal wall. The absence of percussion tenderness (tapping on the abdomen) or pain with jostling of the patient's gurney or bed implies that peritoneal signs are not present. It is important to realize that the absence of local tenderness or rebound does not exclude the possibility of vascular compromise or infarction.

It is important to ask about and examine for the presence of an external hernia. An incarcerated hernia may be easily reducible with immediate relief of the intestinal obstruction.

In a recent, prospective study of 48 patients with bowel obstruction, the clinical variables most useful in diagnosing bowel obstruction were history of previous surgery, history of constipation, age over 50, vomiting, distended abdomen, and increased bowel sounds. Variables not classified as helpful in this study included sex, progress of complaint in relation to the onset of pain, nausea, history of similar complaints, guarding, and the severity of pain.

DIFFERENTIAL DIAGNOSIS

There are multiple reasons a patient may have abdominal pain and vomiting, including cholecystitis, hepatitis, pancreatitis, peptic ulcer disease, appendicitis, myocardial infarction, nonspecific abdominal pain, and pregnancy, to name a few. The presence of right upper quadrant tenderness should help to differentiate hepatobiliary disease. Elevated lipase or amylase will identify pancreatitis. Patients with peptic ulcer disease may have heme-positive stool. Appendicitis usually presents with right lower quadrant tenderness. The absence of abdominal tenderness may imply cardiac etiology in an elderly patient with risk factors. Patients with kidney stones may complain of abdominal pain but do not usually have abdominal tenderness. An electrocardiogram (ECG) may help diagnose myocardial ischemia, and patients with kidney stones usually have hematuria. A pelvic examination and pregnancy test will identify the pregnant patient. Colicky pain can be associated with appendicitis, cholelithiasis, kidney stones, or gastroenteritis. Diarrhea occurs in all patients with gastroenteritis but is an uncommon complaint in patients with bowel obstruction. Uremia and hepatitis can be associated with abdominal distention (ascites) and vomiting. Ascites and peripheral edema do not occur with bowel obstruction. The presence of jaundice should direct the emergency physician to the diagnosis of liver disease. Finally, air–fluid levels on abdominal x-rays are a common finding in patients with gastroenteritis, but frequent diarrhea, lack of distended loops of bowel, and fecal leukocytes or heme-positive stool will help in making the correct diagnosis.

EMERGENCY DEPARTMENT EVALUATION

The general appearance of the patient will help determine the overall status of the patient (i.e., sick or not sick). A complete history and physical examination are critical in making the diagnosis of bowel obstruction. Ill-appearing patients require supportive treatment (e.g., monitor, intravenous fluid, etc.) before a complete history can be obtained. Inspection of the patient's vital signs is critical to determine the patient's volume status and risk of infection. Tachycardia and hypotension should prompt the emergency physician to provide immediate fluid resuscitation. The presence of fever indicates an infectious etiology to the patient's symptoms and implies bowel infarction if bowel obstruction is diagnosed. Evaluation of the skin will help to identify jaundice in the patient with hepatobiliary disease or poor capillary refill in a patient in shock. Auscultation of the lungs may reveal a pulmonary cause of the patient's symptoms. Inspection of the abdomen may reveal distention or surgical scars. Auscultation of the abdomen may reveal crescendo–decrescendo, decreased, or absent bowel sounds. Gentle palpation of the abdomen demonstrates areas of tenderness, the presence of ascites or a mass, and the presence of guarding or rebound tenderness. Gentle tapping of the patient's costovertebral angle should be undertaken to determine the presence or absence of tenderness, which would imply renal disease. Pelvic examination is appropriate in all women with

abdominal pain, looking for discharge, cervical motion or adnexal tenderness, or masses—none of which are usually present in patients with bowel obstruction. Rectal examination and testing of stool for occult blood, although critical to the evaluation of all patients with abdominal pain, should be delayed until an upright abdominal x-ray is obtained in patients with a high clinical suspicion of bowel obstruction. Digital examination may introduce air into the rectum, confusing the determination of complete bowel obstruction. Inspection and examination for an external hernia may identify the cause of a patient's complaints and lead to early reduction and relief of an obstruction.

The most important diagnostic test for bowel obstruction is the upright abdominal x-ray. Patients who are too ill to stand can undergo a left lateral decubitus abdominal x-ray, which will reveal the same findings. X-ray findings in bowel obstruction include dilated loops of bowel, air–fluid levels, and strings of air pockets called the “string of beads” sign (Fig. 42.1 and Fig. 42.2). In approximately 5% of patients with bowel obstruction, the abdominal x-ray is normal; if the bowel lumen is completely full of fluid, it will not show the characteristic interface of air and fluid. Absence of air in the rectum may be a sign of obstruction unless the rectal examination was performed before the abdominal x-ray. Air within the distal portions of the bowel may occur if the obstruction is only partial.

Figure 42.1. “Stepladder” pattern of air–fluid levels on upright view in patient with small bowel obstruction.

Figure 42.2. “String of pearls” sign on upright view in patient with small bowel obstruction.

Patients with bowel obstruction may have metabolic abnormalities from profuse vomiting, third spacing of fluid into the lumen of the bowel, and resulting dehydration. Once the diagnosis of bowel obstruction is made, electrolytes, blood urea nitrogen, and creatinine results should be obtained and abnormalities corrected. A complete blood count may reveal an elevated white blood cell count in an elderly patient without other signs of early sepsis, but this finding is nonspecific. A hemoglobin or hematocrit may be elevated from hemoconcentration or decreased from hemorrhagic complications of bowel necrosis or chronic blood loss from a malignancy.

EMERGENCY DEPARTMENT EVALUATION

Patients with abdominal pain and vomiting should be brought promptly into the emergency department and evaluated. If appropriate because of abnormal vital signs or significant history, the patient should be placed on a cardiac monitor. The patient should be undressed and placed in a gown. An intravenous line should be started, and signs of hypovolemia should initiate prompt fluid resuscitation with normal saline. Blood samples can be drawn at the time of intravenous line placement and held until appropriate laboratory work is ordered. Patients who are vomiting or nauseated should be treated with an antiemetic (e.g., chlorpromazine) to make them more comfortable. After initial stabilization and treatment, a complete history and physical examination should be taken. Laboratory tests should be ordered based on the physician's differential diagnosis. If cardiac disease remains in the differential, an ECG should be performed. The patient should then undergo an upright or left lateral decubitus abdominal x-ray, depending on the patient's condition.

In general, the diagnosis of bowel obstruction is made with an abdominal x-ray. If plain radiographic findings are negative and clinical suspicion is high, abdominal computed tomography (CT) should be utilized, as it is superior to ultrasound and plain films in determining the level and cause of obstruction. In the vast majority of cases, abdominal CT is not necessary from the emergency physician's perspective, although it may help the surgeon decide the cause of the obstruction.

On confirmation of the diagnosis and after discussing the planned clinical course with the patient, a nasogastric tube should be inserted, after anesthetizing the nasal passage and posterior pharynx, and attached to intermittent suction. The gastric contents should be visualized to determine the presence or absence of blood. The patient should be given intravenous narcotic analgesics for relief of abdominal discomfort. Surgical consultation should be obtained and the patient admitted to the hospital. Febrile patients or those with evidence of peritonitis should also be given antibiotics as soon as possible to cover bowel flora.

DISPOSITION

Patients with bowel obstruction should be admitted to the hospital. Determining the appropriate hospital bed depends on the patient's condition and comorbid illnesses. Surgical consultation should be obtained promptly, with direct communication by the emergency physician. The challenge for the surgeon is to determine whether strangulation has occurred and whether the patient requires acute operative management or whether a trial of observation (12 to 24 hours) and bowel rest can be attempted.

Stable patients may be transferred if the patient requests it or consents to transfer. Unstable patients should not be transferred.

COMMON PITFALLS

- Delay in promptly and adequately treating a patient's hypovolemia
- Delay or failure to treat a patient's symptoms with antiemetics and narcotic analgesics
- Extensive laboratory and radiographic testing that delays the diagnosis and early consultation with a surgeon
- Delay or failure to place a nasogastric tube after making the diagnosis of obstruction
- Misinterpretation of abdominal x-rays in a patient with air–fluid levels due to gastroenteritis

CHAPTER 43

Hernias

Sharon Elizabeth Mace

[Classification](#)
[Definitions](#)
[Groin Hernias](#)
[Clinical Presentation and Evaluation](#)
[Differential Diagnosis](#)
[Emergency Department Management](#)
[Common Pitfalls](#)
[Bibliography](#)

A hernia is the protrusion of a part or structure or organ through the tissues that normally contain it. This all-inclusive definition would include abdominal wall hernias as well as other hernias, such as diaphragmatic hernias and internal hernias. Hernias of the abdomen are, by far, the most common type of hernia and are the focus of this chapter. Hernias are commonly encountered in clinical practice. It is estimated that 5% of the population has a hernia. Herniorrhaphy accounts for 10% to 15% of all the procedures in a general surgical practice, with about 500,000 such operations performed in the United States each year. Herniorrhaphy is the most common operation in general surgical practice.

CLASSIFICATION

Hernias can be classified as an external, internal, or interparietal hernia. An external hernia protrudes completely through the abdominal wall to the outside and, thus, can be seen and palpated. Examples of external hernias include incisional, umbilical, inguinal, and femoral hernias. An interparietal hernia is a rare hernia in which the hernial sac is contained within the abdominal wall. An internal hernia is a hernia in which the herniated part or organ occurs within the confines of a body cavity. Internal hernias include diaphragmatic hernias, hernias through a tear in the mesentery or omentum, and hernias through the foramen of Winslow into the lesser sac. Internal hernias are much less common than external hernias and can be very difficult to diagnose.

Hernias of the abdominal wall involve protrusion of part of the abdominal contents beyond the normal confines of the abdominal wall. Hernias can occur wherever there is a weakness in the abdominal wall. The weakness or defect allows protrusion of peritoneum and abdominal contents. The abdominal wall contains various fascial and muscular layers, which are designed to contain the contents of the abdomen. Hernias represent a failure of the abdominal wall (and its component parts) to contain the enclosed peritoneum and other abdominal structures or viscera. The intestines are the most common structure that undergoes herniation, but all intraperitoneal structures can herniate, from a tiny piece of omentum to part of or an entire organ, such as the bowel, bladder, kidney, or liver.

DEFINITIONS

A *reducible hernia* is a hernia in which the protruding or herniated structures can be returned through the abdominal wall defect back into the abdominal cavity. An irreducible hernia is one in which the protruding or herniated structures cannot be returned through the abdominal wall defect back into the abdominal cavity. Another term for irreducible hernia is *incarcerated hernia*, which is sometimes mistakenly used to imply that an irreducible hernia is about to become strangulated.

A *strangulated hernia* is one in which the blood supply to the herniated structures or viscus is compromised. Gangrene will occur in the strangulated viscus if the vascular compromise is not relieved. Strangulation of a hernia is a life-threatening situation with significant associated morbidity and mortality. Strangulation requires emergency treatment and surgical intervention. Hernias that have a small neck or opening and a fairly large sac have a tendency to strangulate. As the size of the hernial orifice increases, the likelihood of strangulation decreases. All strangulated hernias are irreducible or incarcerated, but not all irreducible or incarcerated hernias are strangulated.

Groin hernias, which include inguinal hernias (both direct and indirect; [Fig. 43.1](#) and [Fig. 43.2](#)) and femoral hernias ([Fig. 43.3](#)), are the most common, accounting for 85% of all hernias (80% groin, 5% femoral). If umbilical and incisional hernias were added to the category of groin hernias, they would comprise 95% to 98% of all hernias.

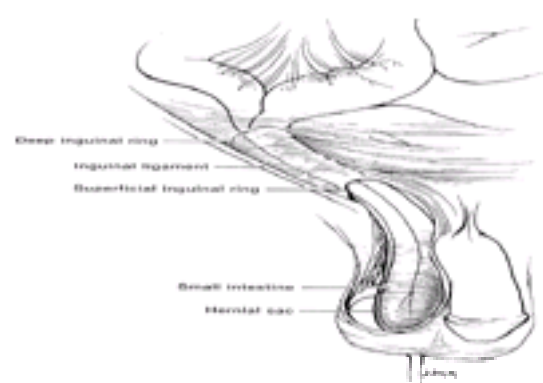

Figure 43.1. Indirect inguinal hernia.

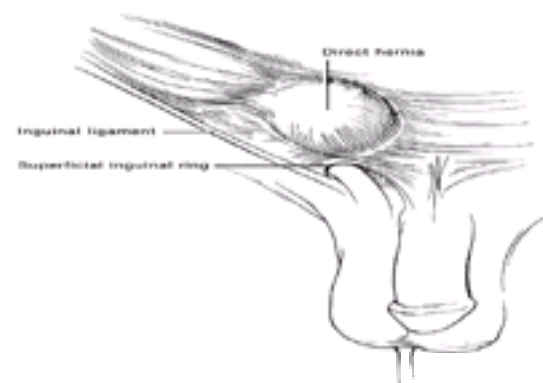

Figure 43.2. Direct inguinal hernia.

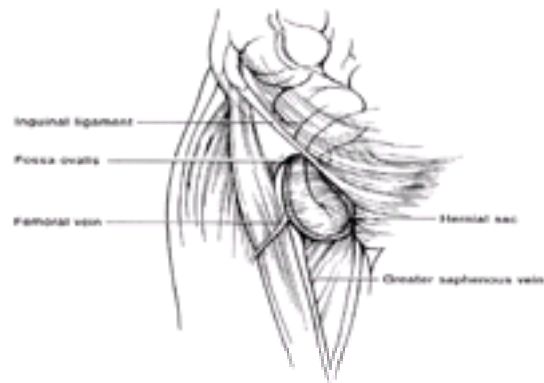

Figure 43.3. Femoral hernia.

Other, much rarer abdominal wall hernias include epigastric, pelvic, lumbar, and spigelian hernias. Epigastric hernias are ones that occur in the midline of the abdominal wall between the umbilicus and the xiphoid. Pelvic hernias are rare and involve the protrusion of abdominal contents through areas in the floor of the abdominal cavity. The obturator hernia, which is the most common of the pelvic hernias, involves herniation through the obturator foramen and generally occurs in elderly women. Lumbar hernias occur in the superior and inferior lumbar triangles, which are two naturally weak regions of the posterior abdominal wall. Spigelian hernias are protrusions of abdominal contents lateral to the rectus abdominis muscle through the external oblique fascia.

Ventral hernias include umbilical, epigastric, and spigelian hernias. Incisional hernias can be another type of ventral (anterior) hernia. Incisional hernias constitute about 10% of all hernias and result from postincisional weakness of the anterior abdominal wall.

Umbilical hernias are common in infants, occurring in up to 65% of African American infants versus 10% of Caucasian infants. The majority of umbilical hernias in infants close spontaneously, usually by age 2, and rarely incarcerate or strangulate. Conversely, umbilical hernias in adults often incarcerate, with strangulation occurring in 20% to 30%. Ulceration and perforation can also occur in adults with umbilical hernias, complications that are associated with high morbidity and mortality, especially in cirrhotic patients. Patients with increased intraabdominal pressure (such as ascites, pregnancy, or obesity) have a higher incidence of umbilical hernias, which occur in 20% of patients with cirrhosis and ascites.

Groin Hernias

The inguinal hernias (direct and indirect) and the femoral hernia are the three types of groin hernias. Anatomic location distinguishes the inguinal hernias from the femoral hernia. The inguinal hernias are above, or superior to, the inguinal ligament, while the femoral hernia is below, or inferior to, the inguinal ligament. The two types of inguinal hernias—direct and indirect—are also differentiated based on anatomy. With an indirect hernia, the protruding abdominal contents pass through the internal (or deep) inguinal ring and into the inguinal canal and lie lateral to the inferior epigastric vessels. With a direct hernia, the protruding abdominal contents lie medial to the inferior epigastric vessels and protrude through a weak area in the aponeurosis of the transversus abdominal muscle in Hesselbach's triangle (or the inguinal triangle). Hesselbach's triangle is an area bounded by the inferior epigastric artery (on the lateral aspect), the lateral border of the rectus abdominis muscle (on the medial aspect), and the inguinal ligament (on the inferior border). Of all inguinal hernias, about two-thirds are indirect inguinal hernias and one-third are direct inguinal hernias.

An indirect inguinal hernia transverses the deep inguinal ring into the inguinal canal and follows the path of a patent processus vaginalis. The processus vaginalis is formed during male fetal development to allow the descent of the testes from their original retroperitoneal site into the scrotum. If the processus vaginalis fails to close off after birth, an indirect hernia may occur that could allow abdominal contents to progress down the inguinal canal, even into the scrotum. In girls, the processus vaginalis follows the round ligament, while, in boys, the processus vaginalis follows the spermatic cord.

Inguinal hernias are much more frequent in boys than in girls because there is a much smaller aperture for the round ligament compared with the spermatic cord. Because of this embryology, childhood hernias are usually indirect hernias. Indirect inguinal hernias commonly incarcerate, while direct inguinal hernias almost never incarcerate.

A femoral hernia is the protrusion of abdominal contents between the femoral vessels (artery and vein) and the lacunar ligament in the femoral canal. Because of the narrow neck or opening, femoral hernias frequently incarcerate. Because of differences in the structure of the pelvis, femoral hernias occur almost exclusively in women. However, because of the rarity of femoral hernias, the most common hernia in a woman is an indirect inguinal hernia, not a femoral hernia.

CLINICAL PRESENTATION AND EVALUATION

Most hernias are asymptomatic and are usually found by chance, either by the patient or by the physician on a routine physical examination. The most common presenting complaints of a hernia are swelling and/or pain and discomfort.

If there is an acute incarceration, there may be the sudden onset of severe pain with nausea and vomiting. The pain occurring with an acute incarcerated hernia is caused by edema and inflammation of the herniated structures and the surrounding tissues. Incarcerated hernias are the second most common cause of bowel obstruction in the United States, with postoperative adhesions being the most common cause of bowel obstruction. If strangulation is present, the patient may present with signs and symptoms of bowel obstruction and/or perforation.

Occasionally, the initial symptoms may be somewhat misleading. In some patients, the pain from an incarcerated groin hernia may be located in the epigastrium because of traction on the abdominal contents from the hernia. In other patients, strangulation can occur without any symptoms and signs of bowel obstruction when only part of the bowel wall is herniated. This occurs with a Richter's hernia, one in which only one side of the intestinal wall is within the hernia sac.

Pain and/or hypesthesia located along the medial aspect of the thigh, radiating to the knee, due to irritation of the obturator nerve (Howship-Romberg sign) occurs in 50% of patients with an obturator hernia.

Physical examination should include inspection and gentle palpation for any bulges or masses. Cooperative patients may be asked to cough or strain, which increases intraabdominal pressure, in an attempt to demonstrate the hernia. Palpation of the external inguinal ring in a male patient may also be helpful in detecting an inguinal hernia.

In patients with an incarcerated hernia, the swelling is tender, and they may have a low-grade fever and tachycardia.

In patients with a strangulated hernia, signs and symptoms of bowel obstruction, peritonitis, perforation, abscess, and even septic shock may be present. Leukocytosis with a left shift is usually present, although this finding may not occur in geriatric patients. Dehydration with electrolyte abnormalities and an elevated blood urea nitrogen often occur. Acute abdominal series radiographs are indicated. The upright chest roentgenogram is necessary to rule out free air under the diaphragm resulting from perforation or dead bowel. The flat plate and upright abdominal films may demonstrate bowel obstruction and occasionally a hernia sac.

DIFFERENTIAL DIAGNOSIS

The most common diagnoses to consider in a patient presenting with a groin mass are inguinal hernia, enlarged inguinal lymph node(s), and hydrocele of the spermatic cord. Other less common etiologies include lipoma, saphenous vein varix, psoas abscess, and incarcerated ovary.

EMERGENCY DEPARTMENT MANAGEMENT

Patients with hernias can be grouped into three categories: (1) asymptomatic or minimal symptoms (swelling or mild discomfort), with a spontaneously reducible hernia; (2) irreducible but not strangulated hernia; and (3) strangulated hernia.

Patients in category 1 should be given discharge instructions, which include the warning signs of incarceration and strangulation, and told to avoid exercise and straining. They need referral to general surgery for evaluation for elective herniorrhaphy.

If the irreducible hernia is acute (and there is no evidence for strangulation), nonsurgical reduction should be done. Cool compresses may be placed over the hernia site to diminish local blood flow and decrease intraluminal gas pressure. Appropriate sedation is given. If the patient has a groin hernia, the patient is placed in approximately a 20-degree Trendelenburg position. The hernia may spontaneously reduce. If not, gentle manipulation may be attempted. Slow, steady compression ("gentletaxis") is used, not forceful attempts.

Once reduction is achieved, herniorrhaphy within a few days is ideal. This allows local edema to resolve. Because the incidence of recurrence is high, urgent surgery is recommended. If the hernia cannot be reduced, emergency surgery is done as soon as fluid and electrolyte abnormalities are corrected. Complications of nonsurgical or manual hernia reduction include partial reduction and hernia reduction in masse. Hernia reduction en masse is a rare complication in which the hernia sac is manipulated into the preperitoneal space. This gives the false impression that the hernia has been reduced, although it is still incarcerated and at risk for strangulation.

Surgical management is mandatory for all incarcerated hernias that cannot be reduced and for all strangulated hernias. Supportive care prior to surgery usually includes fluid resuscitation and antibiotics.

COMMON PITFALLS

- Failure to diagnose a small hernia
- Misdiagnosis of a hernia for other causes of a groin mass
- Failure to identify an incarcerated or strangulated hernia
- Failure to make an appropriate referral to a surgeon
- Failure to make a timely diagnosis and aggressively resuscitate a patient with a strangulated hernia

Bibliography

Colorectal cancer is the second most common cancer in the United States and in other developed countries, excluding skin cancer; it is exceeded in incidence and mortality only by lung cancer. Colorectal cancer accounts for 20% of all deaths from malignant disease in the United States and 14% of newly diagnosed cancer cases in both men and women. Most cancer cases occur in patients older than 40 years, with 90% of cases diagnosed after the age of 50. The peak incidence is in the seventh decade; the median age of colorectal cancer death is 68. However, 4% to 6% of cases occur in young adults aged 20 to 40 years. The mortality rate in the United States is 26 per 100,000 per year. The number of new cases in the United States is rising, with 145,000 new cases in 1987 and 152,000 new cases in 1993. Approximately 6% of the U.S. population develops cancer of the colon and rectum, and 6 million Americans alive today will die of the disease. The cure rate is 40% to 44%; the mortality for men is unchanged since 1960 and only slightly improved for women.

The American Cancer Society estimates that 75% of the 61,000 deaths in 1991 from colorectal cancer could have been prevented by early diagnosis and treatment. Other groups believe that modification of diet by decreasing animal fat intake, increasing fiber intake in the form of whole-grain cereals, fruit, and vegetables, and avoidance of specific chemicals such as cellulose, uronic acid, and carotene may lower the incidence of colorectal cancer. The role of the emergency physician in the detection and prevention of colorectal cancer may be significant. The process of change from normal mucosa to premalignant adenoma to frank invasion of surrounding tissues by carcinoma takes about 5 to 10 years. The natural history of the disease affords the physician a large window of opportunity for screening and detection. Predisposing factors may be elicited by history ([Table 44.1](#)).

<ul style="list-style-type: none">• Familial polyposis—nearly 100% chance of developing cancer by age 40 years• Gardner, Turcot, and Peutz-Jeghers syndromes (rare and inherited) correlate with development of adenomas in colon and subsequent cancer.• Patient history of colon cancer, adenomatous polyps, or breast, ovarian, or uterine cancer• Inflammatory bowel disease—up to one-third of ulcerative colitis deaths due to colon cancer. Crohn disease may be premalignant, especially when age at onset is younger than 25 years• Male homosexuality—risk factor for anorectal cancer, primary rectal lymphoma, Burkitt's-like lymphoma, and Hodgkin disease of rectum• Hereditary nonpolyposis colorectal carcinoma—homozygotes are being sought for this familial aggregation of colorectal cancer exhibiting mendelian segregation• There is an inverse correlation exists between dietary fiber intake and colorectal carcinoma; other implicated dietary factors may include red or processed meat, fat, and alcohol (high fiber intake possibly due to nitrosamines). Fruits, vegetables, and refined grains may be protective.• Chronic constipation• Job-related exposure to toluene, xylene (printers), other carbonaceous smokers in insulation, chemical plants, synthetic rubber manufacturing, oil refineries• Sedentary lifestyle• High body mass index (BMI), overweight• <i>Streptococcus faecalis</i>/endocarditis

TABLE 44.1. Predisposing Conditions for Colorectal Cancer

CLINICAL PRESENTATION

The most common presentations for colonic neoplasms include bleeding, weight loss, pain, obstruction, and change in bowel habits.

Bleeding

Bleeding from cancer is frequently self-limited and seldom presents as massive hemorrhage. Rectal bleeding may be occult or intermittent and is the most common sign of rectal cancer, particularly among patients older than age 40 years. Rectal bleeding should never be attributed to hemorrhoids without proper evaluation. Colorectal malignancy is present in 10% of patients older than age 40 years with new onset of rectal bleeding. Blood that coats the exterior of a formed stool is likely to have originated from the anal canal or rectum; if blood is admixed with feces, the bleeding source is usually higher in the colon.

Anemia

Although uncommon, severe anemia in colorectal cancer is usually caused by iron deficiency from chronic blood loss. However, liver dysfunction from metastatic disease or drug toxicity may cause a functional folate deficiency that results in anemia. In addition, microangiopathic hemolytic anemia has been reported with colonic malignancies. Fatigue, shortness of breath, and angina may all be secondary to anemia.

Obstruction

Rectal cancer often presents with tenesmus, but obstruction is uncommon. Left-sided colon tumors produce obstructive symptoms and changes in bowel habits. Right-sided colon tumors generally remain clinically silent because of the large-caliber and fluid stool, but a mass in the right side of the abdomen is the first sign of cancer in 10% of patients. Obstruction tends to occur at the sigmoid where stool is driest. The tumor may result in intussusception, or it may cause a volvulus due to fixation of the bowel wall by the tumor. In most patients, the ileocecal valve is incompetent, and both large and small bowel obstruction may occur simultaneously. For the 15% of patients in whom the ileocecal valve is competent, the vascular supply to the cecal wall is cut off, resulting in necrosis and perforation. Bowel obstruction and perforation have been associated with poor prognosis.

Constipation has been listed both as a frequent complaint and as a predisposing factor along with laxative abuse. Narrow-caliber stools, stool consistency changes, and a feeling of incomplete bowel emptying are all suggestive symptoms.

Perforation and Abscesses

Intestinal perforation may be localized and present with a tender mass or with generalized peritonitis. A psoas or a thigh abscess may occur. High emphysema and right hip pain, as well as Fournier's gangrene of the scrotum with perineal erythema, induration, and blistering, have been described after a perforated cecal carcinoma. Fistulas between the colon and pelvic organs are possible sequelae of perforation.

Metabolic Disturbances

Metabolic disturbances may develop from either the primary neoplasm or metastatic cancer. Hypokalemia and diarrhea are well-recognized features of villous adenomas, which have high potential for malignant change. Hypercalcemia may be caused by either bone metastases or, rarely, elaboration of a parathyroid hormone–like substance by the tumor. Adrenal insufficiency caused by metastases has been reported.

Hormonal Abnormalities

There are unusual cases of colon tumors that elaborate hormones. These arise from cells with the capacity for amine precursor uptake and decarboxylation (APUD) cell tumors. Carcinoid tumors, the best-known type, secrete serotonin, kallikrein, and certain tachykinins. Patients may present with flushing, diarrhea, abdominal pain, asthma, and right-sided valvular heart disease. Treatment consists of surgical removal of the tumor, administration of serotonin antagonists such as cyproheptadine for the diarrhea, and chemotherapy. Metastatic disease, especially to the liver, is usually widespread at the time of diagnosis. Colon cancer has also been found to elaborate adrenocorticotrophic hormone as well as an insulin-like hormone. Flushing attacks simulating the carcinoid syndrome may also occur with Verner-Morrison syndrome of hypersecretion of vasoactive intestinal peptide (VIPoma), although these tumors most often arise from the pancreas.

Metastatic Disease

Metastatic disease can have widely varying manifestations. Liver, lungs, bone, ovaries, adrenals, and the peritoneal cavity are most commonly involved. If the liver is invaded, coagulation defects may ensue. Thromboembolic events resulting from mucin-producing adenocarcinomas of the colon have been reported. Metastatic tumor to the lumbosacral spine may cause back pain and spinal cord compression. Approximately one-fourth of patients with colorectal cancer exhibit evidence of hematogenous spread on initial evaluation.

DIFFERENTIAL DIAGNOSIS

In the differential diagnosis, include any entity that may present with strictures, rectal bleeding, mass lesions, abdominal pain, or change in bowel habits. Diverticular disease, benign tumors, inflammatory bowel disease, ischemic bowel disease, tubercular and fungal infections, irritable bowel disease, infectious diarrhea, and medication-induced diarrhea all must be considered. Hemorrhoidal bleeding is generally benign and is a diagnosis of exclusion in the elderly.

EMERGENCY DEPARTMENT EVALUATION

Gastrointestinal complaints must be aggressively pursued; the average duration of symptoms of colonic neoplasms is 6.5 months before diagnosis. Only by shortening this period can mortality and morbidity be reduced. More aggressive screening may be warranted for high-risk groups such as first-degree relatives of individuals with familial adenomatous polyposis, members of hereditary colorectal cancer families, patients with colorectal adenomas or with previous colorectal cancer, and patients with inflammatory bowel disease.

The American Cancer Society recommendations for screenings are as follows:

- Men and women older than age 50 years should have a fecal Hemoccult test every year.
- Men and women older than age 50 years with none of the high-risk factors for colorectal cancer should have sigmoidoscopic examinations annually until two consecutive examinations are normal; thereafter, examinations should be every 3 to 5 years.
- Men and women older than age 40 years should have a digital rectal examination every year.

Several means of screening are available to the emergency physician, although many of them are not well tailored to emergency settings.

Digital Rectal Examination

Digital rectal examinations may detect 10% of colorectal cancers. This change from the 30% detection rate cited two decades ago reflects a proximal redistribution of colonic neoplasms. A shelflike deformity located anteriorly above the prostate (Blumer's shelf) may indicate metastatic tumor.

Occult Blood Testing

Stool should be tested for occult blood. The test can detect as little as 2 to 3 mL of blood in stool. A person may normally lose 0.62 mL of blood daily into the gastrointestinal tract. If two fecal occult blood smears are tested daily for 3 days, the clinical sensitivity for colon cancer approaches 80% to 93%. Emergency physicians do not have the opportunity to test multiple specimens, however; nor do they test patients who are on low-peroxidase diets. (Broccoli, turnips, cantaloupe, and radishes, among other foods, contain peroxidase.) The pseudoperoxidase activity of hemoglobin produces a blue color when hydrogen peroxide is applied to filter paper impregnated with guaiac. False-positive reactions may be produced by animal hemoglobin in meat or by nonhemoglobin peroxidases in stool from food and bacteria. Aspirin or other nonsteroidal antiinflammatory drug use may cause positive occult blood test result, while ingestion of ascorbic acid or other antioxidants may cause a false-negative test result. It has been estimated that annual fecal occult blood testing has the potential to cause a 15% to 33% reduction in colorectal cancer mortality.

Proctosigmoidoscopy

Proctosigmoidoscopy has been proposed as a diagnostic tool in the emergency department to evaluate colitis, sigmoid masses, or rectal bleeding. The rigid proctoscope is 25 cm long and, in theory, can detect 25% to 35% of colorectal cancers. Before undergoing this procedure, which is uncomfortable to the patient, the patient must use one or two Fleet enemas. Furthermore, most physicians do not routinely pass the scope beyond 17 cm of colon. The flexible fiberoptic 60-cm sigmoidoscope permits trained operators to reach those 50% to 64% of colorectal cancers that are in the lower half of the descending colon. Although the flexible sigmoidoscope is better tolerated by patients and can be advanced to 50 cm 75% of the time, its use in the emergency department may be impractical because patients are usually not adequately prepared and because most emergency physicians are unaccustomed to the procedure and to the biopsy technique. Patient flow and acuity often preclude performance of this procedure, which may have to be repeated by the gastroenterologist or surgeon.

Barium Enema and Colonoscopy

Barium enema and colonoscopy are excellent screening and diagnostic tests and should be undergone by high-risk patients in alternate years. Total colonoscopy detects synchronous cancers in 2% to 5% of cases and concurrent adenomas in 40% to 50% of colon cancers; it also enables biopsy and polypectomy of lesions. The major limitation of colonoscopy is that the cecum cannot be visualized in 10% to 36% of cases. Advanced or multiple distal polyps found on flexible sigmoidoscopy heralds the presence of an advanced proximal polyp—villous, malignant, or larger than 10 mm in diameter—in more than 5% of cases, making colonoscopy a valuable diagnostic tool, even after sigmoidoscopy.

Double-contrast barium study may detect 92% to 94% of cancers subsequently found within a 3-year period, but it is of little value in screening if only symptoms of benign disease are present. It is more sensitive than the single-contrast technique for detection of polyps, early inflammatory bowel disease, and lesions of the rectum.

Serum Carcinoembryonic Antigen

Serum carcinoembryonic antigen is seldom available in the emergency department and has low sensitivity and specificity for colorectal cancer, although it is of

preoperative value as a prognostic factor. It is most useful for early detection of metastatic cancer after curative resection of colorectal cancer. Positivity approaches 100% as dissemination occurs, and it suggests investigation for residual or metastatic disease. Healthy patients, patients with other malignancies, and patients with inflammatory bowel disease may test falsely positive. Its sensitivity for Dukes stage 1 and B tumors is 36%; for stage C, 74%; and for stage D colon cancers, 83%. It is the most cost-effective means of detecting potentially curable recurrent disease; a "low" cut-off of 3.0 ng/mL, or 2.5 ng/mL on two consecutive tests, has been suggested as the screening level for metastatic disease.

Magnetic Resonance Imaging, Computed Tomography, Ultrasonography, and Molecular Genetics

The role of magnetic resonance imaging (MRI), computed tomography (CT), and ultrasonography in the emergency setting is not well defined, although they have occasionally been useful in the diagnosis of colorectal cancer. MRI may be useful in preoperative staging of colorectal cancer, but it is no more sensitive than CT in diagnosing pericolic tumor extension and regional lymph node metastases. Angiographic CT and the use of T1-weighted spin echo images are the state-of-the-art imaging modalities for metastatic deposits in the liver. Endocavitary ultrasound is of some value in staging rectal cancer, being somewhat more sensitive than CT for detecting local tumor extension.

Tumor cells in the colon are characterized by phenotypic changes that are the result of qualitative alterations in gene expression. Genes altered in sporadic colorectal cancer include *ras* genes, APC, DCC, and *p53* tumor-suppressor genes, among others. Molecular genetics may have clinical uses in the future.

Monoclonal Antibody Imaging

Monoclonal antibody imaging is used for improved lesion detection. The monospecific antibody to a tumor-associated antigen is tagged with a radioactive moiety and administered either intraperitoneally or intravenously to detect tumor spread.

Surveillance and Recurrence

More than 500,000 people in the United States have surveillance to identify metastases, local recurrence, or a second primary cancer. A typical follow-up schedule may entail examinations every 3 months during the first postoperative year, every 4 months in year 2, and every 6 months thereafter through year 5. Monitoring of carcinoembryonic antigen and liver function tests are typical. Liver ultrasound is sensitive for detection of metastases greater than 1 to 2 cm in diameter; chest radiography has been suggested every 6 months to detect pulmonary spread. The yield of positron-emitted tomography and MRI for tumor surveillance is not better than less expensive studies.

TREATMENT AND SURVIVAL

Treatment of colorectal cancer is surgical. Once distant metastases have occurred, there is evidence that survival may be prolonged by surgery. Resection in appropriately selected patients with liver metastases can improve survival. As many as 25% to 32% of patients have been reported to be disease-free 5 years after resection of hepatic, pulmonary, or locally recurrent metastases. Sites for spread of tumor are typically liver, local recurrence, abdomen, lungs, retroperitoneum, ovary, and abdominal wall.

The mean 5-year survival of all patients with colorectal cancer is 40% to 45% ([Table 44.2](#) and [Table 44.3](#)). The cure rate has not changed substantially in three decades. Median survival is 3.5 years; this ranges from more than 10 years for *in situ* disease to a mean of 0.8 years for distant disease at the time of diagnosis. Five-year survival rate for localized colorectal cancer is 85% versus 55% for regional disease and 5% to 6% for distant disease.

STAGE I
Carcinoma in situ: Tis, N0, M0
Tumor invades submucosa: T1, N0, M0
Tumor invades muscularis propria: T2, N0, M0
STAGE II
Tumor invades through muscularis propria into subserosa or into mesoappendix: T3, N0, M0
Tumor perforates the visceral peritoneum or directly invades other organs or structures: T4, N0, M0
STAGE III
Any degree of bowel wall penetration with regional lymph node metastasis
N1: 1 to 3 pericolic or perirectal lymph nodes involved
N2: 4 or more pericolic or perirectal lymph nodes involved
N3: Metastasis to any lymph node along a named vascular trunk
Any T, N1, N2, N3, M0
STAGE IV
Any invasion of bowel wall with or without lymph node metastasis, but with evidence of distant metastasis
Any T, Any N, M1

TABLE 44.2. Colorectal Cancer Staging^a

Astler-Collier Classification ^a	5-Year Survival
A: Limited to mucosa	90%–100%
B ₁ : Extension into but not through muscularis propria. Negative nodes.	85%
B ₂ : Extension through muscularis propria. Negative nodes.	65%–85%
C ₁ : Extension into but not through muscularis propria. Positive regional nodes.	50%–60%
C ₂ : Extension through muscularis propria. Positive regional nodes.	25%–45%
D: Distant metastasis (liver, lung, bone, or adjacent organ invasion)	5%

TABLE 44.3. Survival Rates of Patients with Colorectal Cancer

For rectal cancer alone, 5-year survival rates approximate 88% to 93% for Dukes A node-negative rectal cancer, 71% to 85% for Dukes B cancer, and 29% to 41% for node-positive Dukes C cancer.

Patients with disseminated colon cancer merit limited palliative resection to abort bleeding and to manage obstruction.

Chemotherapy, although it cannot effect a cure or improve the survival rate, may cause temporary improvement in 15% to 25% of patients. Levamisole and 5-fluorouracil (5-FU) are used most frequently for Dukes C (Astler-Collier C1 and C2, TNM stage III), often with leukovorin (folinic acid). Fluorouracil has been given via direct intrahepatic arterial infusion or, investigational, via portal vein infusion, as well as via conventional systemic means. Fluorouracil may cause nausea, vomiting, diarrhea, oral ulcers, gastrointestinal ulceration, abnormal liver function studies, and bone marrow depression. Thrombocytopenia and mild leukopenia are the most common hematologic effects. Levamisole has caused arthralgias, nausea, fatigue, dermatitis, taste changes, and mild hematologic depression. Folinic acid has been used to enhance the inhibition of DNA synthesis; alfa-2a recombinant interferon may act synergistically with 5-FU. Dacarbazine (DTIC) has been used for malignant APUD tumors. The emergency physician may be called on to manage side effects or complications of these drugs. Hepatic artery catheter infusion of fluorouracil has been associated with local complications, including biliary sclerosis, cholecystitis, chemical hepatitis, and gastric ulceration. New, promising chemotherapeutic options not in common use include folate-based thymidylate synthase inhibitors such as raltitrexed, oral fluorinated pyrimidines such as capecitabine, topoisomerase I inhibitors such as topotecan and irinotecan, and platinum compounds such as oxaliplatin.

Radiation in colonic cancer is more problematic than in rectal cancer because of the natural tissue constraints in the abdomen. Adjuvant radiation therapy reduces the risk of pelvic recurrence in patients with rectal cancer; the role of radiation in the adjuvant treatment of colon cancer is investigational. Possible advantages of radiation therapy must be balanced against the risks of radiation proctitis and small bowel damage.

Immunotherapy using monoclonal antibodies has shown promise in isolated cases and is investigational at this time. Radiolabeled monoclonal antibodies that can be used in the detection of metastatic lesions from colorectal cancer may be linked to cytotoxic agents for immunotargeted therapy.

Acknowledgment

In the Western world, the increasing prevalence of diverticular disease parallels the advancing age of the population.¹ The prevalence of diverticular disease rises from 5% in persons younger than age 40, to 30% in those older than age 50, to 50% in those older than age 70, and to 66% in those older than age 85.³ Diverticulosis is equally common among men and women. The disease has widely differing prevalence rates in various geographic areas and ethnic groups. The lower rates of diverticular disease seen in people of Eastern ethnicity increase with Western migration. This is believed to be secondary to the adoption of a Western diet, which is typically lower in fiber than the traditional Eastern diet.¹

The common causative agent for the development of diverticulosis appears to be a reduction in dietary fiber content. The pathophysiology is related to a pressure gradient between the colonic lumen and the serosa and areas of relative weakness in the bowel wall. Very high intraluminal pressure can develop within short segments of the colon. According to Laplace's law of pressures within a cylinder, pressure equals tension divided by radius. Accordingly, the descending and sigmoid colons, which have narrow lumens, have the greatest intraluminal pressures. This pressure causes herniation of diverticula at the points where the intramural vessels penetrate the circular muscle layer, usually between the mesenteric and antimesenteric taenia. Increased fiber enlarges the lumen size, thereby decreasing the intraluminal pressure.

The sigmoid colon is involved in more than 90% of patients with the disease, and in approximately half of the patients it is the only segment of the bowel involved. The cecum is involved in 2%, the ascending colon and rectum in 4% each, and the transverse colon in 10% (Fig. 45.1).

Figure 45.1. Diverticulitis with abscess.

Most persons with diverticulosis remain asymptomatic throughout their lives.¹ In a large series of ambulatory patients with diverticulosis, followed for an average of 5.6 years, 17% eventually showed signs of diverticulitis.¹ The longer a patient has diverticulosis, the greater is the probability of complications, primarily diverticulitis and bleeding. There is no relationship, however, between the number and size of diverticula and the incidence of complications or probability of recurrent disease. The use of nonsteroidal antiinflammatory drugs is an etiologic factor in the development of diverticulitis.³

Diverticulitis results from inflammation of diverticula, resulting in microperforation or macroperforation (abscess, fistula, peritonitis, or obstruction). Diverticular bleeding results from an arterial lesion in the vasa recta, characterized by eccentric intimal thickening, altered internal elastic lamina, and focal medial thinning.⁶ A disproportionately high tendency exists for diverticula on the right side of the colon to hemorrhage. One theory holds that the wider necks and domes of right-sided diverticula cause greater exposure to injurious factors than for left-sided diverticula.⁶ Bleeding from diverticulosis is massive in about one-fourth of patients in whom it occurs and mandates transfusion in approximately one-third.¹² Fortunately, the vast majority of diverticular bleeding ceases spontaneously.

CLINICAL PRESENTATION

Patients with diverticulosis present to the emergency physician with three common patterns: (1) mild left lower quadrant pain; (2) acute left lower quadrant pain, tenderness, and fever; and (3) massive lower gastrointestinal (GI) bleeding.

Mild Left Lower Quadrant Pain (Painful Diverticular Disease)

Diverticulosis most frequently presents as left lower abdominal pain. The pain is usually dull, crampy, and intermittent and is often alleviated by the passage of flatus or stool. Signs of infection are absent.

Acute Left Lower Quadrant Pain, Tenderness, and Signs of Infection (Acute Diverticulitis)

Patients with acute diverticulitis classically present with abrupt-onset, severe, constant left lower quadrant pain; localized tenderness; and fever, leukocytosis, or other signs of systemic toxicity.

Occasionally, the pain and tenderness occur in the left upper quadrant. Patients may present with a picture of a ruptured viscus with diffuse tenderness, rebound, guarding, and diminished or absent bowel sounds. Rarely, diverticulitis may present with signs of fistulization, such as pneumaturia and draining infections of the lower abdomen or medial aspect of the upper thigh. Diverticulitis often presents atypically in immunocompromised patients, such as those with acquired immunodeficiency syndrome (AIDS), renal failure, or diabetes, and those receiving immunosuppressive therapy. In these patients, fever, abdominal pain, or

abdominal tenderness may be absent.⁸ Additionally, the incidence of free perforation, a rare complication in the immunocompetent, is much higher in immunocompromised patients.^{4,8,10}

Massive Lower Gastrointestinal Bleeding (Diverticulosis)

Patients may present with painless, massive rectal bleeding. Such bleeding is characteristically sudden, often profuse from the onset, and more frequent in older persons. The blood is usually bright or dark red, and although the patient may feel faint, initial hypotension is not common.

DIFFERENTIAL DIAGNOSIS

Diverticulosis

When diverticulosis presents as mild, sometimes colicky left lower quadrant pain, it must be differentiated from irritable bowel syndrome, Crohn disease, and colon cancer.

Acute Diverticulitis

Acute diverticulitis must be distinguished from more severe presentations of Crohn disease, ulcerative colitis, and ischemic colitis, although diverticulitis and inflammatory bowel disease may coexist. Vascular catastrophe, such as aortic rupture or dissection or mesenteric ischemia, is generally distinguished by pain out of proportion to physical findings. In women, diverticulitis that presents as a left lower quadrant mass has been misdiagnosed as a gynecologic mass.⁸ High fever, leukocytosis, and left lower quadrant mass should suggest a perforation and abscess. This may be due to inflammatory bowel disease, colon cancer, sigmoid volvulus, iatrogenic perforation of the rectosigmoid, or a tuboovarian abscess.⁷ Right-sided diverticulitis, a rare disease seen primarily in Asian populations, may mimic acute appendicitis.¹³

Diverticular Bleeding

Diverticular bleeding must be distinguished from other causes of profuse lower GI bleeding, such as angiodysplasia, ischemic colitis, and, occasionally, ulcerative colitis and colonic or rectal cancer. Upper GI hemorrhage occasionally presents as rectal bleeding and hemodynamic instability.

EMERGENCY DEPARTMENT EVALUATION

Left Lower Quadrant Pain

Historical information should focus on GI symptoms, previous similar attacks, prior diagnostic studies, and change in bowel habits. The duration of the attack, characteristics of the pain, and history of fever should also be elicited. With diverticulitis, the pain may be intermittent, crampy, and associated with nausea and vomiting. The attack may be associated with either constipation or diarrhea.

The physical examination should take careful note of the patient's temperature, pulse rate, and blood pressure. Complete abdominal, pelvic, and rectal examinations are essential. In rare cases, tenderness may be found only on rectal examination. Palpation may reveal the outline of the sigmoid colon as a ropelike mass. Minimal tenderness and mobility point to an irritable colon; a large, sausage-like, markedly tender fixed mass points to diverticulitis. Signs of peritonitis and the presence of a mass on pelvic and rectal examinations are important to note. Abdominal x-ray films (flat and upright) should be obtained to look for a mass in the left lower quadrant as well as for free air. A complete blood cell count should be requested with a differential white blood cell count. Leukocytosis with a left shift is compatible with the diagnosis of diverticulitis.

Lower Gastrointestinal Bleeding

The history should focus on the onset, color, amount, and frequency of bloody bowel movements. A history of previous attacks, bleeding tendencies, and bowel habits is important.

Hemodynamic instability should be assessed (blood pressure, pulse, and orthostatic changes). Abdominal and rectal examinations are particularly critical. The abdominal examination should focus on areas of tenderness and the presence or absence of a mass. The rectum should be palpated for masses, and the color of the blood in the rectal vault examined. If rectal bleeding is significant, nasogastric intubation can exclude active upper GI bleeding. If there is brisk, bright red bleeding, anoscopy can exclude anorectal causes such as internal hemorrhoids.

EMERGENCY DEPARTMENT MANAGEMENT

Painful Diverticular Disease

For the patient with left lower quadrant pain with no mass or signs of infection, institution of a high-fiber diet is effective in relieving pain. Anticholinergic agents have long been used, but their efficacy remains unproved. A follow-up flexible sigmoidoscopy should be done to rule out rectal cancer.

Diverticulitis

For the patient in whom the diagnosis of severe diverticulitis is highly probable, an intravenous line should be started, nasogastric tube inserted, specimens for blood and urine cultures collected and sent to the laboratory, and intravenous antibiotics begun. Acute diverticulitis can be diagnosed solely on clinical grounds. In cases in which the diagnosis is unclear, computed tomography, contrast enema, or ultrasonography can be performed. Controversy abounds as to which is the ideal initial study of choice. Such factors as patient stability, the diagnoses considered, body habitus, and the individual institution's relative expertise may influence a clinician's choice of diagnostic test.

Computed tomography offers the advantages of evaluating vascular structures, correctly estimating the extent of diverticulitis, and allowing possible percutaneous abscess drainage, and it is less invasive than contrast enema evaluation.⁵ Contrast enema is less expensive and has comparable or greater accuracy in diagnosing diverticulitis^{10,11} and is superior to computed tomography in diagnosing cancer.¹⁰ Though it has been stated that barium enema evaluation is contraindicated in patients with acute diverticulitis, several modern studies have confirmed the safety of water-soluble contrast enema.^{10,12} A few centers have reported high accuracy in diagnosing diverticulitis with ultrasonography.^{9,10,12} Sigmoidoscopy should be avoided in patients with acute diverticulitis.

For both complicated and uncomplicated diverticulitis, antibiotics should target gram-negative rods and anaerobic bacteria. Cefoxitin, a combination antibiotic such as ampicillin–sulbactam, and the combination of clindamycin and an aminoglycoside are good choices. Outpatient management for mild cases may include a combination of metronidazole and either trimethoprim–sulfamethoxazole or ciprofloxacin or monotherapy with amoxicillin/clavulanate.

Diverticular Bleeding

For the patient with massive lower GI bleeding, two large-bore intravenous lines (16-gauge or larger) should be inserted. A specimen should be drawn and sent for type and crossmatch for 4 to 6 U of blood. A Foley catheter should be placed. Lactated Ringer's solution should then be infused at a rate depending on the patient's vital signs and cardiac status. If the patient is not stabilized after 2 L of crystalloid infusion, a central venous line should be inserted and blood given. Fluid resuscitation should be aimed at restoring urine output to a rate of approximately 1 mL/kg/h.

DISPOSITION

A surgical consultation should be requested for patients in whom the diagnosis of acute diverticulitis is suspected and in all patients with rapid lower GI bleeding. Clearly, the patient with lower GI bleeding who is hemodynamically unstable should have an immediate surgical consultation.

Indications for Admission

Patients with diverticulitis complicated by abscess or fistula formation, obstruction, or free perforation should be admitted to a surgical service. Patients suspected of having severe acute diverticulitis and those with gross lower GI bleeding must be admitted. Obviously septic patients, those with severe concomitant diseases, and those with massive GI bleeding should be admitted to an intensive care unit.

Outpatient management should be limited to immunocompetent patients with mild uncomplicated diverticulitis. Severely immunocompromised patients with diverticulitis should be admitted, even those with benign-appearing presentations.

COMMON PITFALLS

- Although less frequently encountered in patients younger than age 40, diverticulosis is relatively more likely to be complicated and require surgery in younger patients than in older patients.²
- The classic signs and symptoms of diverticulitis are often absent in immunocompromised patients. These patients have a higher incidence of free perforation, failure of medical therapy, and postoperative morbidity and mortality.^{8,10}

The anorectal area is the site of few true emergencies but many uncomfortable conditions. The posterior quarters are so often a source of irritation that the idioms most frequently used to describe “irritations” refer to it. Hemorrhoids, abscesses, perirectal infection, functional disorders, and cancer are discussed in this chapter. The reader is referred elsewhere in this text for a discussion of proctitis.

ANATOMY

The anus is variously defined, but an accepted definition is the terminal large bowel from the dentate line distally to where the external margins of the anal canal meet. The anal opening is an elliptical orifice. The anatomy of the perianal soft tissue is easier to understand if one considers the region as made up of concentric layers. The central core is the anal canal; the first ring, the mucosa; the second, the internal sphincter; and the third, the levator and external sphincter. The inner visceral tube is composed of smooth muscle with autonomic innervation. The outer muscular group is funnel shaped, of skeletal muscle, with somatic innervation. Beyond this outer muscular layer, the fatty tissue of the buttocks extends to the dermis and epidermis of the skin surfaces.

The rectum is approximately 20 cm long and the most distal portion of the large bowel. It has no peritoneal covering; this distinguishes it from the sigmoid, which is completely invested with peritoneum. The primary purpose of the rectum is as a storage cavity for stool.

THE FUNCTION OF CONTINENCE

The rectum could not serve as a storage cavity for stool if there were no mechanism to keep the stool within it until the proper time for passage. The angulation of the anorectal system (60 degrees between the axis of the rectum and the anal canal) aids continence through the creation of a flap valve effect.^{1C} The angle is present except during defecation or when the hips are flexed more than 90 degrees. The anal canal generally has higher pressures than the rectum, a gradient vital to the preservation of continence. The gradient exists because the anorectal ring, comprising the internal and external sphincters and the puborectalis muscle, creates pressure through contraction. If the layers of the ring are cut completely, incontinence inevitably results.

ANORECTAL ABSCESSSES

Anorectal abscesses are serious because they may spread rapidly, dissecting into deep-tissue spaces. Perianal abscesses are located immediately adjacent to the anus; there is no induration noted on rectal examination. Ischiorectal abscesses are deeper, with diffuse and lateral perianal swelling; induration is present on rectal examination. Intersphincteric, intermuscular, and supralelevator abscesses generally do not have external signs, but swelling and tenderness at various depths are noted during rectal examination ([Fig. 46.1](#)).

Figure 46.1. Anorectal abscesses.

CLINICAL PRESENTATION

Ischiorectal and perianal abscesses normally present as severe perianal pain and a “boil.” Patients with deeper perirectal abscesses often present with fever, systemic toxicity, and a sensation of rectal fullness or heaviness. Although simple ischiorectal and perianal abscesses are the most common, an abscess may track into several tissue planes and have deep components in addition to superficial ones. On occasion, a perirectal abscess may extend intraabdominally and cause

systemic toxicity, peritonitis, and an abdominal or a pelvic mass.

Anorectal sepsis in severely neutropenic patients is common and deadly. Pyrexia and pain develop early, but because of the neutropenia, swelling and fluctuance develop late if at all. Therapy should include anaerobic coverage and a third-generation cephalosporin or broad-spectrum penicillin, possibly combined with an aminoglycoside. When fluctuance is present, or if cellulitis progresses despite antibiotics, surgery may be lifesaving. ³

DIFFERENTIAL DIAGNOSIS

Swelling and pus can be present owing to a local abscess or a sinus tract from a distant source. Pilonidal abscess, Bartholin gland abscess, deep perirectal abscess, and, rarely, intraabdominal abscess fistula (Crohn disease) can generate sinus tracts that may initially resemble a superficial buttocks abscess. Careful palpation is the most useful technique to differentiate a sinus tract from an abscess.

Coexisting and predisposing illnesses should also be sought. They include inflammatory bowel disease, tuberculosis, various blood dyscrasias, sepsis, diabetes, and corticosteroid therapy. Local trauma and local infectious processes (such as hidradenitis suppurativa, infected hair follicles, or a poorly healing episiotomy) also predispose toward abscess development.

An aneurysm in the rectal region may simulate an abscess. Abscess aspiration results in accurate diagnosis and prevents catastrophe.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The extent of a perirectal abscess and its anatomic location are usually determined with a careful digital examination. The emergency physician should drain only relatively superficial abscesses that can be drained through perianal skin (ischioanal and perianal abscesses). Adequate drainage is important.

Some authors recommend culture of the abscess by needle aspiration before drainage. Although *Escherichia coli*, *Staphylococcus aureus*, and fecal anaerobes are the most common organisms in perirectal abscesses, other organisms also cause abscesses. Antibiotic prophylaxis at least 1 hour but less than 2 hours prior to incision and drainage should be given to patients with clinically (as opposed to only echocardiographically) detectable valvular disease, with prosthetic valves, or with a history of endocarditis, rheumatic fever, or congenital heart disease. ¹ Antibiotic prophylaxis is reasonable in patients who are immunocompromised, but no standard guidelines exist. Amoxicillin-clavulanic acid or ampicillin-sulbactam is a good choice, and clindamycin is a good choice in penicillin-allergic patients. ¹ For penicillin-allergic patients unable to take oral antibiotics or patients who are known to carry methicillin-resistant *S. aureus*, vancomycin is the preferred drug.

Incision and drainage should be performed with the patient prone or in the jackknife position with the buttocks taped apart. Local anesthesia may be adequate, but many patients suffer less if given meperidine or morphine. The incision should be radial; removal of an ellipse of skin may be helpful in facilitating drainage. Loculations should be broken up with a hemostat, and the wound should be copiously irrigated. Loose packing with a single piece of gauze should be removed in 48 hours. Sitz baths encourage drainage. Routine abscesses usually heal without the patient needing antibiotics. Indications for antibiotic therapy include systemic toxicity, a large area of cellulitis, lymphangitis, and immunocompromise. Patients with these symptoms should be considered for admission.

Drainage of multiple abscesses may result in a residual fistula that will require further attention. The patient should be warned of this possibility and referred for follow-up surgery.

DISPOSITION

Deep abscesses with systemic symptoms necessitate urgent surgical consultation for drainage and admission to the hospital. Prompt therapy is important to prevent spread of the infection and septic shock. Poor outcomes have been associated with delay in therapy, inadequate treatment, and significant concomitant disease.

COMMON PITFALLS

- Failure to identify a deep abscess
- Failure to identify an abscess as complex or of pilonidal origin
- Treatment in the emergency department of an abscess that requires extensive surgical management
- Failure to identify conditions that warrant preincisional antibiotics

ANAL FISSURES

PATHOPHYSIOLOGY

Anal fissures begin as abrasions that cause anal sphincter spasm; this leads to a vicious cycle of spasm, inadequate drainage, and repeated injury to the anal opening during stool passage. The chronically inflamed tissue of the chronic fissure becomes resistant to healing.

CLINICAL PRESENTATION

The patient complains of pain and mild bleeding on stooling. The acute fissure appears as a slitlike radial cut on examination. The chronic fissure has the appearance of a midline ulcer with a skin tag and enlarged papilla. In both lesions, the skin surrounding the fissure appears normal. "Type A" patients seem to be more prone to develop fissures.

DIFFERENTIAL DIAGNOSIS

The appearance of an acute anal fissure is usually so clear that it is seldom misdiagnosed. A chancre may be mistaken for a fissure, but chancres are nontender. Tuberculosis, Crohn disease, ulcerative colitis, human immunodeficiency virus (HIV), leukemia, and syphilis predispose to anal fissures, and these fissures may be unusually severe, multiple, or not in the usual midline posterior anal location. ⁹ A careful examination of the perianal region is required to detect the ulceration of a chronic fissure behind the concealing skin tag.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Anal abrasions and acute and subacute fissures require good anal hygiene and a high-residue diet. A shower or brief sitz bath directly after stooling cleanses the area and reduces irritation. The goal is to permit early healing before the tissue is permanently altered by the irritation process. Traditional treatment for chronic fissures is surgery. Recently, medical treatments such as topical glyceril trinitrate or local injection of botulinum toxin have been demonstrated to be fairly effective in promoting healing. Any treatment plan requires referral. ^{4,6,8}

COMMON PITFALLS

- Failure to recognize an atypical fissure as a sign of more serious disease
- Failure to recognize and refer patients with chronic fissure

ANORECTAL FISTULAS

CLINICAL PRESENTATION AND EMERGENCY DEPARTMENT EVALUATION

An anorectal fistula is an abnormal communication between the anorectum (primary opening) and another site, usually after drainage of an anorectal abscess. The tract is usually single. A fistula or sinuses in the perianal area can also originate from nonanorectal sites, such as diverticulitis of the sigmoid colon, appendicitis, inflammatory bowel disease, periurethral infection, and presacral tumors.

EMERGENCY DEPARTMENT MANAGEMENT

Anorectal fistula is treated by uncapping the fistula and allowing it to heal outward from its base. The procedure should be performed by a surgeon and not in the emergency department.⁶ Treatment that necessitates incision through the anorectal ring can result in incontinence.

HEMORRHOIDS

CLINICAL PRESENTATION AND EMERGENCY DEPARTMENT EVALUATION

Hemorrhoids are varicose veins at the rectal outlet and are the most frequent cause of rectal bleeding. Increased pressure in the hemorrhoidal veins is thought to be the major predisposing factor. Conditions believed to cause rectal venous outflow obstruction include pregnancy and bearing down when stooling (increased abdominal pressure), repeated storage of firm stool in the rectal ampulla (local obstruction of venous return), and hepatic fibrosis (shunting of venous return).

Internal hemorrhoids occur above the anorectal line. They are covered by mucosa and are insensitive to painful stimuli. These features differentiate them from external hemorrhoids. When thrombosis is present, hemorrhoids may be painful and a hard clot is palpable in the hemorrhoidal vessels. Hemorrhoids may itch but are usually not painful unless thrombosis is present. When pain is the chief complaint and hemorrhoidal disease is not extreme, another source for the pain should be carefully sought.

EMERGENCY DEPARTMENT MANAGEMENT

Acute exacerbations of hemorrhoidal disease characterized by prolapse of part of the anal canal and thrombophlebitis of the hemorrhoidal plexus require conservative treatment with stool softeners, sitz baths, pain-relieving ointment or suppository, and analgesics. Topical hydrocortisone is of value only if there is itching. With the exception of chronic or constantly prolapsed internal hemorrhoids, most episodes of hemorrhoidal disease are self-limited. A thrombosed external hemorrhoid can be treated conservatively or surgically. After local anesthesia, the clot can be evacuated through a short incision made over the clot. Sitz baths and a pad to absorb the oozing are helpful after treatment. If bleeding is heavy, packing with Surgicel for a few hours or overnight reliably produces hemostasis. A thrombosed internal hemorrhoid should be managed by a surgeon.

RECTAL PROLAPSE

Rectal prolapse is a full-thickness protrusion of a portion of the distal rectum through the anal opening. The protrusion has a tubular appearance with concentric folds on the end. Mucosal prolapse occurs when the rectal mucosa loses its connection to the underlying muscle and protrudes out the anal opening; it differs from rectal prolapse in that there is no protrusion of muscle and the protruding tissue forms a circle with radial grooves. Internal rectal prolapse occurs when the upper rectum and sigmoid prolapse into the rectal ampulla but not through the anal orifice. Internal rectal prolapse is found primarily in women.³ They may complain of incontinence of flatus or feces, tenesmus, rectal pressure, pelvic fullness or pain, lower back pain, or a sensation of incomplete evacuation.

EMERGENCY DEPARTMENT EVALUATION AND DIFFERENTIAL DIAGNOSIS

A patulous anus is commonly found when repeated rectal prolapse is the presenting complaint. If the lesion has reduced at the time of examination, the most effective way to provoke prolapse is to have the patient strain. Rectal pain from rectal prolapse is uncommon and should suggest a secondary lesion or incarceration. Occasionally, a polyp or rectal tumor may protrude through the anus and simulate prolapse. Examination after reduction helps to differentiate the conditions. Mental illness, multiple sclerosis, tabes dorsalis, and cauda equina syndrome are associated with rectal prolapse, although they are responsible for only a small percentage of cases.

EMERGENCY DEPARTMENT MANAGEMENT

Reduction of most prolapses can easily be accomplished in the emergency department, but such reduction is usually short-lived. Incarceration of a rectal prolapse necessitates emergency operative therapy. It can progress to strangulation, bleeding secondary to ulceration, and rupture. Adults eventually require surgery for recurrent rectal prolapse. Most authorities recommend early surgery, because once incontinence develops from weakening of the sphincter, surgery to correct the prolapse may not restore continence.⁶

IMPACTION

Impaction is generally the result of inadequate regulation of stool consistency, although anatomic factors, such as denervation and stricture, also may play an important role in selected cases. The maintenance of a lumen of normal caliber for the rectal outlet depends on the regular passage of a formed stool and explains why chronic diarrhea predisposes to impaction. Constipation, the most common cause of impaction, can itself be caused by many conditions. Diabetes, lead poisoning, uremia, opiates, sedatives, iron supplements, and immobilization all can cause constipation. Insufficient fluid intake prevents bulk from exerting a softening effect and can even cause bulk to be the impacting agent. Pain or partial obstruction can delay the passage of stool, as can poor bowel habits or psychological factors, leading to a more inspissated stool.

Most fecal impactions occur in the rectum.¹⁰ If impaction is located in the rectum on digital examination, it is still important to assess for other masses on abdominal examination. Impaction may result in diarrhea, with only liquid stool able to make its way past the impaction. The impaction often weakens sphincter tone, resulting in chronic passage of watery stool.

Most impactions necessitate urgent treatment. Mineral oil enemas may be effective, if used several times a day, in softening and lubricating the impaction. When digital disimpaction is required, the disruption of the impaction should be gentle to avoid trauma to the rectal wall. Injury may cause a subsequent abscess. Nonrectal impactions, obstructive symptoms, fever, and dehydration warrant consultation and admission.

MISCELLANEOUS CONDITIONS

ANAL PRURITUS

Pruritus ani results from mucus secretion from internal rectal prolapse, pinworm eggs, pubic lice, or scabies. Idiopathic anal pruritus usually presents as a nocturnal itch in a tense person. Thickened, lichenified perianal skin is characteristic. Ice alleviates the itch, as may sitz baths and good anal hygiene. A shower directly after stooling may be helpful.

VENEREAL DISEASE AND WARTS

Condylomata acuminata is caused by the human papillomavirus. The warts may be pedunculated or sessile. Patients with even modestly compromised cellular immunity are more vulnerable to wart infection, but the warts are also very contagious among nonimmunocompromised persons. Most human papillomavirus infections, including most that predispose toward malignant transformation, do not result in visible warts.¹¹ Condylomata acuminata are four to 13 times more prevalent in the population of patients seen in sexually transmitted disease clinics than in the general population.⁷ No therapy totally eradicates the human

papillomavirus, but various locally destructive therapies can temporarily destroy visible warts. ⁵

Condylomata lata are wartlike lesions caused by syphilis. They are smoother than anogenital warts and are nearly always moist. Syphilis should be recognized and treated by the emergency physician. Treatment includes benzathine penicillin G, 2.4 million U i.m., or a 10-day course of tetracycline or erythromycin. Venereal diseases such as herpes simplex, lymphogranuloma venereum, and gonorrhea can also manifest as rectal diseases.

RECTAL ULCERS

Rectal ulcers, which occur particularly in acquired immunodeficiency syndrome (AIDS) patients, are very painful and often hard to treat. Many are idiopathic, probably of viral origin. The differential diagnosis includes syphilis, chancroid, tuberculosis, herpes, lymphoma, sarcoma, carcinoma, mycobacterium avium, intracellulare, *Cryptococcus neoformans*, and chlamydia.³

CARCINOMA

The symptoms of anal cancer are often indistinguishable from those of benign lesions. The most common symptoms are pain and bleeding. A palpable mass is present in 25% of cases; pruritus is present in about 15% of cases. In about 25% of cases, patients are asymptomatic and cancer is detected by routine rectal examination. The predictive value in older persons of a positive guaiac test result for colorectal carcinoma is 5% to 10%. In addition, adenomas are found in 30% to 40% of patients with positive guaiac test results. Squamous cell tumors account for 80% to 95% of anal tumors. ⁵ Adenocarcinomas are common in the rectum. Risk factors for colorectal carcinoma include prior adenoma, family history of large bowel cancer, personal history of breast or uterine carcinoma, exposure of pelvis to radiation, and presence of ureterosigmoidostomy. Familial polyposis, ulcerative colitis, and Crohn disease of the colon are more severe risk factors. Leukemic infiltration into the anal area can result in severe anal pain but in minimal physical findings, except for superficial induration. The patient may appear quite ill. The white blood cell count is usually diagnostic. Persistent coccygeal pain suggests a tumor of neural origin in the coccyx and lower back. Spasmodic pain is more characteristic of benign conditions such as coccygodynia, a syndrome (secondary to trauma) of sharp pains precipitated by movement of the coccyx.

PILONIDAL DISEASE AND HIDRADENITIS SUPPURATIVA

Pilonidal disease is a syndrome of infection in the presacral midline that causes sinus tracts, abscesses, and pits. Hidradenitis suppurativa is a chronic inflammatory disease that originates in areas of apocrine sweat glands and results in superficial, often multiple, and interconnected abscesses. Treatment of both conditions involves incision and drainage of abscess cavities, moist heat or soaks, and antibiotics. Both conditions necessitate more extensive surgical procedures by a surgeon for definitive treatment; otherwise, recurrence is inevitable.

[Reversible Ischemic Neurologic Deficits and Strokes](#)

[Acute Carotid Artery Dissection](#)
[Pathogenesis](#)

[Clinical Presentation](#)

[Arteriographic Findings](#)

[Treatment](#)

[Chapter References](#)

There are essentially two major conditions relating to the carotid artery that demand urgent evaluation and treatment if a patient is to achieve maximal recovery: (1) acute cervical thromboembolic disease and (2) spontaneous carotid dissection. Although less common than some peripheral vascular problems, these two entities are widely prevalent etiologies to stroke, the third leading cause of death in the United States, occurring in over one-half million people annually. Historic data indicate that approximately 35% to 40% of strokes are lethal and over 70% of those recovering will have some permanent neurologic deficit.¹⁰ This morbidity extracts a high socioeconomic cost as productive, contributing individuals are often transformed into assistance-dependent members of society. Rapid diagnosis and initiation of treatment help to minimize the potential devastating loss of neurologic function and maximize the chances of returning a patient to an independent lifestyle.

ACUTE THROMBOEMBOLIC DISEASE OF THE CAROTID ARTERY

Over the years, several manifestations of acute thromboembolic events involving the cervical carotid artery have been identified and given various descriptive terms. These include transient ischemic attack (TIA), crescendo TIAs, reversible ischemic neurologic deficit (RIND), fluctuating stroke (stuttering hemiplegia), progressing stroke (stroke in evolution), and established stroke. TIA and RIND are addressed in this chapter.

TRANSIENT ISCHEMIC ATTACK

A TIA is defined as any focal neurologic deficit lasting less than 24 hours (usually less than 1 hour) with complete resolution. Crescendo TIAs represent a succession of TIAs in which each succeeding event is more severe than the previous TIA or the time interval is shortening between attacks. Amaurosis fugax is a unique type of TIA that is defined as temporary, monocular loss of vision, often appearing as a curtain coming down or across the visual field. The natural history of a TIA resulting from carotid artery occlusive disease has been documented in a review of several nonoperative series.²⁰ Untreated patients have a permanent stroke risk of approximately 7% annually for the first 5 years (or about one-third overall), which can be reduced to about one-half of that with antiplatelet agents.¹³ Crescendo TIAs represent a more ominous picture, although the exact risk in these patients is poorly defined because most are treated surgically on an urgent basis.¹¹

Of utmost importance, any patient presenting with these symptoms mandates immediate evaluation to determine the cause of the TIAs. Etiologies other than carotid artery disease include cardiac emboli, migraine headaches, intracerebral aneurysms or space-occupying lesions, nerve palsies, inflammatory arteriopathies (Takayasu disease) and intraocular abnormalities, usually of the retina. A good physical examination often reveals evidence of the source. Along with a meticulous neurologic examination, particular attention should be paid to the presenting blood pressure, the heart auscultation, the cervical auscultation, and the funduscopic examination.

In most instances, a carotid duplex ultrasound (US) is the best means by which to rule in or out the presence of significant vascular disease. The accuracy of these noninvasive examinations approach 95% in experienced hands and is the deciding factor if further intervention, either arteriogram or surgery, is warranted.⁵ If the US clearly shows a high-grade stenosis (75% to 80%), many surgeons will perform a carotid endarterectomy on that basis alone¹⁶ (Fig. 47.1). Less severe lesions or those examinations demonstrating ulcerative plaques usually require arteriography, which more clearly shows the anatomy, to determine whether this represents the probable etiology of the TIA. The value of a computed tomography (CT) scan in these circumstances is debatable. Although it does rule out intracranial lesions, studies have shown CT findings to be both predictive and unproductive of the outcome following surgery.¹⁵ Those with a normal US should undergo a CT scan and echocardiogram on an urgent basis. Anticoagulation with intravenous heparin is not usually needed unless there appears to be a delay in the evaluation and treatment.

Figure 47.1. Arteriogram of an internal carotid artery high-grade stenosis at the typical location just past the carotid bifurcation. Atherosclerotic lesions similar to this are often the etiology of TIAs and strokes.

REVERSIBLE ISCHEMIC NEUROLOGIC DEFICITS AND STROKES

RINDs are defined as acute focal neurologic deficits that last longer than 24 hours but completely resolve. Fluctuating strokes demonstrate a waxing and waning of the severity of the neurologic deficit, progressing strokes show a continual gradual worsening over several days, and established strokes have stable, fixed deficits. Although it is impossible to determine if and when a fixed neurologic deficit will resolve, these patients should all be treated in a similar manner. A prompt, yet thorough physical examination should be done and a CT scan obtained to rule out intracranial hemorrhage. Until recently, little more than supportive care could be given to individuals presenting with acute strokes. Studies have now demonstrated a better long-term clinical outcome if the deficit is less than a few hours old and the patient can be started on thrombolytic agents. Several protocols are being used. A large multicenter, prospective, randomized study utilizing intravenous tissue plasminogen activator (TPA) within 3 hours of a stroke resulted in a 30% increase in the number of patients having little or no disability at 3 months.¹² This improvement comes with a price, however, as the risk of symptomatic intracranial hemorrhage increased from 0.6% to 6.4% with this treatment. A more recent study showed a similar benefit in patients up to 7 hours following the onset of their stroke.¹⁸ Another technique uses urokinase through an intraarterial catheter placed in the carotid artery within 4 to 6 hours of a stroke.⁸ If the internal carotid artery can be recanalized, the prognosis is significantly better than that for permanent occlusions. The latter arteriographic technique also allows good visualization of the carotid anatomy and avoids the need for US. These more aggressive approaches require that a dedicated team of neurologists, interventional radiologists, and vascular surgeons be available at all times. These factors limit the applicability of these approaches in smaller, nonteaching hospitals. Low-molecular-weight heparin has also been used acutely, with significant improvement in neurologic recovery at 6 months over placebo.⁹

Patients presenting more than 6 to 7 hours after a stroke began should generally undergo a CT scan of the head and US of the carotid arteries unless another obvious source of the stroke is identified. Very high grade stenoses or intraluminal thrombus will usually require anticoagulation with intravenous heparin and earlier than normal surgical intervention.⁷ If these tests are negative, the patient should be admitted for monitoring, further workup as to the etiology of the stroke and hypertension control as needed.

ACUTE CAROTID ARTERY DISSECTION

Dissection of the carotid artery is a less common but equally devastating cause of acute cerebrovascular insufficiency. Although well described in the trauma literature, carotid dissections can occur spontaneously with common, everyday neck movements, or with no inciting event at all. Similar to TIAs, the early, accurate diagnosis and initiation of treatment of dissections can often determine the severity of the long-term neurologic deficit resulting from these lesions.

PATHOGENESIS

Underlying etiologies of spontaneous carotid dissection are varied. They include congenital anomalies, infections of the pharynx, syphilis, and arterial wall defects such as Marfan syndrome, cystic medial necrosis, fibromuscular dysplasia, arteritis, and atherosclerosis.^{1,6} The initiating event appears to be a tear in the intima of the internal carotid artery or intramural hemorrhage, which may result from any of the aforementioned factors. Also, it is thought that stretching of the vessel over the lateral articular processes of the first two cervical vertebrae may play a role in some instances.¹⁶ This hyperextension of the neck may go unrecognized or may result from everyday movements such as coughing or even washing hair.

In most instances, the dissection begins 2 to 3 cm beyond the carotid bifurcation or, less commonly, slightly more distal in the midcervical internal carotid artery. It usually extends up to the point where the internal carotid artery enters the petrous canal. As blood progresses up the false channel within the medial layer of the arterial wall, the true lumen becomes compressed and either narrowed or occluded. At other times, microemboli may travel to the distal cerebral circulation, the false lumen may reenter into the true lumen, or, rarely, pseudoaneurysms may develop in the thinned-out arterial wall.

CLINICAL PRESENTATION

Carotid dissection can occur in all ages, from very young children to the elderly, with the majority occurring in middle age. In a large series of 30 patients at one institution, the most common symptoms were TIAs (56%), completed stroke (30%), amaurosis fugax (17%), severe headache (20%), neck pain (13%), tinnitus (7%), and incomplete Horner syndrome (3%).¹⁴ There is often a delay between the inciting event and the development of the clinical symptoms; this delay may range from hours to days. A thorough history and physical examination, along with a high index of suspicion, are needed to identify these problems early in their course. A carotid duplex US represents the quickest means by which to detect an abnormality in the internal carotid artery and should be done as soon as possible.¹⁷ This will often indicate a severe stenosis or occlusion, which should lead to an urgent arteriogram.

ARTERIOGRAPHIC FINDINGS

Two types of arteriographic pictures of carotid dissections are seen. The most common type is that of a very narrowed segment of the internal carotid artery a few centimeters from the bifurcation to the base of the skull (Fig. 47.2). This is known as the “carotid string sign” and is quite characteristic of a dissection. This type of narrowing may also be seen in the more distal internal carotid artery, depending on where the intimal tear or medial hemorrhage begins. The second commonly seen pattern is that of a tapered occlusion of the internal carotid artery several centimeters after the bifurcation (Fig. 47.3). This is called a “dunce’s cap.” If some time has passed since the occlusion occurred, the internal carotid may be thrombosed back to the bifurcation, making it difficult to distinguish from atherosclerotic occlusive disease that had progressed to thrombosis. Other findings often seen on an arteriogram include delay in the column of contrast reaching the brain; a small filling defect at the base of the dissection, representing an intimal flap (with or without thrombus); and distal middle cerebral artery emboli.

Figure 47.2. Arteriogram showing the most common finding seen in acute carotid dissection. The long, irregular, narrowed segment of the internal carotid artery is known as the “carotid string sign.” (Reprinted with permission from Okuhn SP, Stoney RJ. In: Bergan JJ, Yao JST, eds. *Vascular surgical emergencies*. Orlando: Grune & Stratton, 1987:125–137.)

Figure 47.3. Arteriogram demonstrating the “dunce’s cap,” which represents an acute occlusion of the internal carotid artery following dissection. This may later disappear as the thrombus propagates proximally to the bifurcation. (Reprinted with permission from Okuhn SP, Stoney RJ. In: Bergan JJ, Yao JST, eds. *Vascular surgical emergencies*. Orlando: Grune & Stratton, 1987:125–137.)

TREATMENT

Once the diagnosis of carotid dissection has been established, the best results are generally obtained by anticoagulation with intravenous heparin, followed by oral anticoagulants for up to a year.^{14,17} Care must first be taken to ensure that no intracerebral hemorrhage exists or that no carotid pseudoaneurysm has developed. Anticoagulation helps maintain patency of the narrowed lumen and prevents emboli from occurring. In most cases, the true lumen will normalize within a few months, with recurrence a very rare event. This medical management has been shown to be superior to the direct surgical intervention that was initially attempted in the 1960 and 1970s.⁴

In some instances, surgery may be beneficial if the diseased segment of artery is surgically accessible. This would include patients with recurrent emboli despite anticoagulation, those with pseudoaneurysms, and those with documented progressive stenoses. In these cases, resection of the diseased artery and interposition grafting is most commonly done. If the distal end of the dissection cannot be approached and the back pressure is measured at 70 mm Hg or more, the carotid can be ligated with little risk of stroke.³ More recently, placement of internal carotid stents have been reported to be moderately successful in some acute carotid dissections.² The long-term durability and safety of these endovascular techniques is yet to be determined.

CHAPTER 48

Emergency Aspects of Peripheral Vascular Insufficiency

Henry C. Veldenz

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

The presentation of a patient with an ischemic limb to the emergency department represents both a challenge and an opportunity in assessment and management. Guided by history and physical examination skills, this encounter can be readily directed to the appropriate outcome for the patient. Once the acuity and severity of the ischemic limb has been elucidated, disposition, ranging from outpatient follow-up to emergency surgery, can be selected.

Lower extremity peripheral vascular occlusive disease (LEPVOD) occurs in the patient population at risk for cardiovascular disease.^{1,3,5} It is merely a regional manifestation of the underlying systemic disease of atherosclerosis. Thus, hypertension, hypercholesterolemia, tobacco abuse, diabetes mellitus, end-stage renal disease, and inactivity are prevalent among these patients.

The incidence of LEPVOD has been stable over the past decade. Hypercoagulable states, however, are recognized with an increasing frequency.⁴ When LEPVOD becomes clinically apparent, the *levels* of occlusive disease that may affect a patient also have a corresponding *collateral bed* that carries circulation in times of need. However, unlike the named arterial level involved in the occlusive process, the collateral circulation is a high-resistance vascular system, explaining diminished flow in states of increased flow demand. This state plays a role in both occlusive and embolic situations.

Important to the management of the ischemic limb are the *timing* and the *severity* of the ischemia. Presentations that represent chronic disease of minimal severity, such as intermittent claudication, are handled differently from the acute, profound ischemia of an acute aortic embolic occlusion. The timing and severity of presentation *are* related to the patient's underlying anatomy and pathophysiology.

CLINICAL PRESENTATION

The presentation of vascular insufficiency is heavily dependent on the underlying pathology. A person with a macrovascular embolus will potentially manifest all six of the P's of acute ischemia: pain, pallor, pulselessness, poikilothermia, paresthesias, and paralysis. The most important symptom will be pain, with the sensory and motor changes occurring early in the course.

The patient with chronic occlusive disease will also complain of pain, but unlike that of a patient with an acute embolic occlusion, the pain will have been present for a period of days to weeks. The acute sensory and motor deficits are absent; instead, patients exhibit a spectrum of chronic changes. Typical chronic trophic changes are also seen in chronic occlusive disease; if the LEPVOD is severe enough for long enough, the patient may also have frank tissue loss demonstrated by ischemic ulceration or actual gangrene.

The patient with intermittent claudication will give a history of pain in a leg or legs with walking a set, short distance. This distance is almost always reproducible. The leg is symptomatic *distal* to the level of occlusive involvement. The degree of disability is related to the presence of collateral development. An anatomic level of LEPVOD is usually present, such as a superficial femoral artery occlusion producing *calf* claudication or an external iliac artery occlusion producing *calf and thigh* claudication.

Ischemic rest pain occurs in the forefoot or the toes. It can also be described by the term *metatarsalgia*. In the very elderly, pain may not be the chief complaint; instead, the patient may complain of symptoms of sleep deprivation from untreated pain. It takes two anatomic levels of occlusion, requiring flow through two high-resistance collateral beds in series, to produce ischemic rest pain. Ischemic rest pain does not occur in the calves, nor is it cramping of the calves at rest. The patient with ischemic ulceration or gangrene also has two or more levels of occlusion. Rest pain is present if the neural changes have not progressed too far. Also, a history of a prior trivial trauma may have incited the tissue loss.

To illustrate these concepts, consider the following scenarios: the presence of one-block right calf claudication combined with normal pulses, except absent right popliteal and tibial pulses, indicates a right superficial femoral artery occlusion. The profunda femoris collaterals provide limb viability. However, the presence of rest pain in the right foot, perhaps with a beginning ischemic toe ulcer, would also have calf and thigh claudication with minimal ambulation and absent pedal, popliteal, and femoral pulses. In this scenario, the collateral beds of the hypogastric and profunda arteries cannot provide enough nutritive flow at rest. Symptoms and findings are distal to the right iliac and femoral artery occlusions in this situation.

DIFFERENTIAL DIAGNOSIS

Knowledge of common syndromes with similar presenting complaints is essential. Claudication can be confused with other musculoskeletal or neurologic conditions, such as fibromyalgia, osteoarthritis, sciatica, lumbar back syndromes, or spinal stenosis. However, vascular claudication is consistently reproducible by the same degree of exertion and is relieved by the same degree of rest. The other conditions can produce discomfort at rest, have different inciting factors, and are inconsistently related to variable exertion.

Ischemic rest pain also can be mimicked by other neurogenic, muscular, or skeletal conditions. Diabetic neuropathy is the most common condition; it can also coexist with rest pain. The presence in the contralateral foot of the "stocking and glove" distribution and associated numbness may aid in the distinction. In addition, "burning" attributed to diabetic neuropathy is different from the usual gnawing, aching, "pins and needles," or "on fire" descriptions of the foot in ischemic rest pain. In both claudication and rest pain, the diagnosis of LEPVOD can be strongly suggested by physical examination. The patient with signs of actual tissue loss *may* have a similar differential diagnosis. (Trauma and infection are also considered, but are usually apparent from the history or physical.)

EMERGENCY DEPARTMENT EVALUATION

The timing of the pain helps determine acuity. The degree of secondary skin, sensory, and motor changes suggests the severity. Location of the pain helps determine the location of the process. Additional history of comorbid diseases is important to obtain.

The examination is the most cost-effective tool for the assessment of LEPVOD. While physician extenders, students, and junior residents can and should participate in patient care and evaluation, the accuracy of the vascular examination is an experience-dependent process.²

Initial inspection of all extremities provides the traditional starting point, with uninvolved limbs providing key "normal" references for changes. Skin quality, color, and tissue loss are inspected. The stethoscope can detect bruits (signifying noise from turbulent flow) in the carotid, femoral, and, possibly, the popliteal systems. The carotid, brachial, radial, ulnar, femoral, popliteal, dorsal pedal, and posterior tibial pulses should be palpated bilaterally. Each should be charted in a manner that another examiner can tell whether the initial pulses were normal, diminished, or absent. A given pulse will be *diminished* below a stenosis, while a given pulse is *absent* distal to an occlusion. Excellent collateral development can transmit enough flow to create a diminished pulse, but this event is unusual.

Additional maneuvers can be noninvasive yet provocative for ischemic changes that confirm a diagnostic impression. Elevation pallor is induced when an affected extremity is raised 2 to 3 ft above the heart. A normal or mildly ischemic leg will still have capillary refill against the gradient created. An extremity with two or more levels of occlusive disease will pale with this maneuver. This pallor should be evident even in dim fluorescent lights. A follow-up maneuver is to try to induce dependent rubor. The pale foot is dangled over the edge of a bed or chair, rendered dependent to gravity. It will become a plethoric red or purple over 60 to 90

seconds, demonstrating the pooling of blood into chronically vasodilated distal circulatory beds.

Diagnostic studies before consultation or disposition are probably rare if vascular surgical support is available. Laboratory profiles of renal function and coagulation help facilitate possible arteriography. Correction of other concomitant cardiovascular, pulmonary, or metabolic abnormalities is appropriate. Plain radiography of an affected foot with gangrene or signs of infection can be helpful. Foreign bodies, soft-tissue gas, and osteomyelitis can change aspects of management.

Noninvasive vascular laboratory examination, such as the continuous-wave Doppler instrument or duplex ultrasound, serves only to confirm impressions to which a solid history and physical should give rise. A common troublesome situation is that of a patient with a limb threatened by ischemia, but with good "Dopplerable" pulses.

The Doppler units have exquisite sensitivity for any moving column of blood. The presence of a strong signal can lull the emergency physician into a false sense of security. *In sum, the absence of a pulse is better evidence of ischemia than the Doppler signal is evidence of adequate perfusion.*

EMERGENCY DEPARTMENT MANAGEMENT

Initial management is based on the severity of the ischemic process. Claudication does not require urgent management. Ischemic rest pain is serious and may result in major limb loss if untreated.

Intravenous hydration is appropriate if either angiographic or operative treatment is indicated. Anticoagulation with heparin should be coordinated in consultation with a vascular specialist. The presence of tissue loss requires the additional assessment for the possibility of infection. Erythema secondary to cellulitis, and not dependent rubor, may require institution of antibiotics. Antibiotics should cover for the diabetic foot, with its typical gram-negative and anaerobic organisms. Moreover, if wet gangrene or soft-tissue air is identified, urgent intervention is necessary.

DISPOSITION

In most if not all presentations for LEPVOD, the patient can benefit from a vascular consultation. The patient with claudication can usually be referred for outpatient care. It is a chronic condition that can be electively managed outside of the emergency department. A patient with an acute embolus needs urgent vascular consultation. Frequently, this presentation will result in emergency thromboembolectomy. However, the surgeon involved with this decision needs to see the patient as soon as possible in order that the correct operative or percutaneous approach for revascularization can be instituted.

The presence of rest pain implies two levels of occlusive disease and significant potential for limb loss. While the need and timing for revascularization are typically urgent, the eventual treating vascular consultant should make this decision. Emergency department consultation is appropriate for this patient. Signs of limb loss, such as ischemic ulcers, dry or wet gangrene, or infections, are also appropriate reasons for emergency vascular consultation. Many times, the consultant will request an arteriogram, but this decision should be made by the vascular surgeon, because the arteriogram might delay the time to operative revascularization. In the more severe and urgent situations, the consulting surgeon will decide on admission or direct transfer to the operating room.

In smaller facilities, the availability of vascular surgery consultation may have bearing on some decisions. The absence of surgeons or arteriographic capability may mandate patient transfer. Patients with the urgent situation of rest pain can transfer via ground services. Acute embolic ischemia, profound rest pain with neurologic deterioration, or ascending infections may require rapid transfer to a receiving hospital with vascular surgery services. Aeromedical transport is appropriate if available.

COMMON PITFALLS

- A common troublesome situation is one in which the patient with a threatened limb from ischemia "has good Dopplerable pulses." The Doppler units have exquisite sensitivity for any moving column of blood, and the presence of a strong signal can lull the emergency physician into a false sense of security. *Remember, the absence of a pulse is better evidence of ischemia than the Doppler signal is evidence of adequate perfusion.*
- Many times, the consultant will request an arteriogram, but this decision should be made by the vascular surgeon, because the arteriogram might delay the time to operative revascularization
- The presence of rest pain implies two levels of occlusive disease and significant potential for limb loss. While the need and timing for revascularization are typically urgent, the eventual treating vascular consultant should make this decision in the emergency department.
- The examination is the most cost-effective tool for the assessment of LEPVOD. While physician extenders, students, and junior residents can and should participate in patient care and evaluation, the accuracy of the vascular examination is an experience-dependent process.

CHAPTER 49

Septic Thrombophlebitis

Timothy C. Flynn

[Clinical Presentation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Role of the Consultant](#)
[Indications for Admission](#)
[Transfer Considerations](#)
[Common Pitfalls](#)
[Chapter References](#)

Although venous thrombosis is an entity commonly seen in the emergency department, septic thrombophlebitis is relatively rare. The most common cause of septic thrombophlebitis is the introduction of an intravenous catheter used for therapeutic infusions. Up to 30% of catheters cause thrombosis of the veins into which they are inserted, but fewer than 1% to 2% cause bacteremia.² Immunocompromised patients and burn patients are at highest risk for developing this potentially lethal complication.^{8,9}

Insertion of a catheter into a vein provides ready access and a favorable environment for the multiplication of microorganisms. A catheter in the lumen of a vein destroys the vascular endothelium. The resultant exposure of the media then promotes fibrin deposition and thrombosis. If a sufficient volume of clot develops, local defense mechanisms may be overwhelmed, because there is no chance for macrophages and other cells of bacterial defense to be deposited in the clot itself. Even if meticulous care is taken in the insertion of the catheter and maintenance of the catheter site, blood-borne microorganisms may be introduced into the thrombus from remote septic sources, especially in the burn patient, whose wound is a repository for bacteria.

Intravenous drug abuse is an increasingly important cause of septic thrombophlebitis and probably the most common cause seen by the emergency physician.¹ Substances injected by addicts are extremely toxic to the endothelium and are likely to promote thrombosis. This toxicity, combined with the usual lack of sterility of the injectate, injection site, and injection apparatus, predisposes this group of patients to a septic thrombus. A drug abuser may present with any accessible vein affected, including veins in the head and neck, deep veins (femoral or subclavian), and even the penile veins.

Local inflammatory processes may also lead to septic thrombophlebitis, and patients with this condition may be encountered in the emergency department. Although less frequently seen in this era of aggressive antibiotic therapy, in the past this was a common and almost universally fatal problem, particularly in the postpartum or postabortal patient.^{3,4} Septic sites in the pelvis or neck region provide a ready source of bacteria that invade the local venous drainage system.¹⁰ Thrombosis is induced as a result of the inflammatory process, and the clots become a culture medium for the growth of microorganisms, thereby further promoting clot in the local region and then dissemination into the bloodstream, resulting in sepsis.

Once established, a septic vein can give rise to septic emboli.⁵ Clot contaminated with microorganisms dispersed into the pulmonary vasculature can result in multiple areas of infarction and abscess formation. Bacteremia from septic veins also can result in endocarditis or infections of previously placed prosthetic material, such as heart valves and arterial prostheses.

CLINICAL PRESENTATION

Superficial septic thrombophlebitis usually presents as an erythematous, tender cord proximal to the site of a previous venous cannulation or injection site.² Although the patient is usually febrile, there may be minimal physical findings in peripheral veins, especially in infected deep veins. The patient may appear septic, with all the classic signs of pulmonary and cardiovascular collapse, or there may be few signs of sepsis, except persistent fever.⁴

DIFFERENTIAL DIAGNOSIS

A diagnosis of septic thrombophlebitis should be considered in any patient with a peripheral or central venous line who has a fever that persists after removal of the catheter. One must also consider this entity in patients who have pelvic inflammatory disease and fail to respond to usual treatment. In the burn patient, the fever workup should include a careful inspection of all current and previous cannulation sites, because this process is so common in this patient population. The same careful inspection of venous sites should be done for the immunocompromised patient and the intravenous drug user. The diagnosis is frequently one of exclusion and is often overlooked in patients with multiple problems or other sources of sepsis.

EMERGENCY DEPARTMENT EVALUATION

Examination of all catheter or injection sites is critical and may be especially challenging in the drug addict. Once a peripheral vein has been identified as a potential site of sepsis, every effort should be made to obtain a culture, either of the clot or of pus expressed from the vein. It may be necessary to make a small incision over the vein to express the clot, although removing the catheter and milking the clot back through the catheter site is usually enough. Aspiration of the clot or instillation of sterile nonbacteriostatic saline solution into the region, followed by aspiration, can be attempted, but these maneuvers seldom yield positive results. Cutdown sites should be opened, the tie on the vein removed, and the vein milked. All clot and suppurative material should be cultured for both aerobic and anaerobic organisms.¹¹ A Gram stain may be helpful in directing initial therapy.

Deep veins and central veins are not amenable to direct physical examination, but B-mode ultrasonography and computed tomography are useful in establishing whether there is clot present in these veins. The presence of clot does not necessarily indicate invasion by microorganisms; however, suspicion must be raised if there is clot identified in the septic patient.

Septic thrombophlebitis in the pelvic or cervical region is almost invariably associated with other inflammatory processes in the region. It is an uncommon but serious postpartum complication, occurring in roughly one in 2,000 deliveries.⁷ Examination of the pelvis may show tenderness or induration in the pelvic side wall, and there may be a cervical discharge. However, particularly in postpartum patients, physical signs may be lacking and only certain clinical features will suggest infected pelvic veins. These patients often have high-spiking fevers and mild ileus and respond poorly to broad-spectrum antibiotics. They may or may not have positive blood cultures. A positive blood culture without frank abscess suggests septic thrombophlebitis. In the cervical region, suppurative thrombophlebitis is often associated with undrained abscesses in the peritonsillar and deep cervical tissue. Computed tomography may be useful in identifying undrained abscesses as a source of bacteria that can invade clots. Any therapeutic modality directed toward the vein needs to be done after adequate treatment of the local abscess.

EMERGENCY DEPARTMENT MANAGEMENT

Clearly the most difficult task is to identify a vein as the possible source of sepsis in patients who have a variety of other possible septic foci. In the patient with a classic presentation (fever, a cord extending proximally from an intravenous site, erythema, and pain), the first line of therapy is usually removal of the catheter, elevation of the extremity, and local application of heat. These patients should receive broad-spectrum antibiotics (vancomycin). The most common offending organisms are gram positive, especially *Staphylococcus aureus*. In hospitalized patients or immunocompromised patients, a variety of gram-positive or gram-negative organisms may be the cause of sepsis. If the patient fails to defervesce within 24 to 36 hours, complete surgical excision of the vein is necessary. Although this procedure can be done under local anesthesia at bedside, it is preferable to take the patient to the operating room for complete removal of the vein and tributaries that have clot in them.

In patients who have central or deep vein clot or suspected pelvic or cervical septic thrombophlebitis, attempts at resection are fraught with hazard. Therapy includes

administration of broad-spectrum antibiotics and systemic anticoagulation. The addition of anticoagulation to the regimen has improved patient outcome. ^{2,6} Anticoagulation prevents further accumulation of thrombus and allows the body's thrombolytic processes to clear the thrombus as the source of bacterial infection. Fibrinolytic therapy may be considered, although there is no literature regarding its use, and one must be concerned about the creation of septic emboli as the clot breaks up.

DISPOSITION

Role of the Consultant

Patients with suspected septic thrombophlebitis from an indwelling central catheter should be followed by their primary physicians. In some patients, this catheter may be the only site of venous access; removal of the catheter may present a major problem. The catheter should not be removed until it is demonstrated that clot is present and infected; catheter-related sepsis may be treated solely by changing the catheter over a wire, allowing continued access to the venous system. Patients with suspected pelvic or cervical abscesses and suppurative thrombophlebitis should be seen by a gynecologic and an ear, nose, and throat surgeon, respectively. Many of these patients may have areas of undrained pus that require further surgical procedures. Infectious disease consultants are quite helpful in antibiotic therapy selection pertinent to the microflora prevalent in the community. General surgery consultation may be necessary for those patients who require peripheral vein excision.

Indications for Admission

All patients suspected of having a septic vein should be admitted for intravenous antibiotic therapy. The degree of systemic toxicity dictates whether the patient requires monitoring in the intensive care setting. Outpatient management is not appropriate.

Transfer Considerations

Few of these patients require transfer emergently. Patients with either central lines or peripheral lines should be returned to their primary physicians for follow-up.

COMMON PITFALLS

- The most common pitfall is the failure to consider this entity in patients who present with fever. This is especially true in the addict population or in the patient with pelvic septic thrombophlebitis. A delay in diagnosis may result in septic pulmonary emboli, endocarditis, or seeding of a previously uninfected prosthesis.
- Primary prevention by the emergency physician relies on recognition that any intravenous line is a portal of entry for bacteria and a potential site of thrombosis.
- Many patients require emergency intravenous access; breaks in sterile technique are common. This may be unavoidable in the emergency department, but the intravenous lines or cutdowns should be removed as soon as possible once a stable situation is achieved. Most hospitals have policies that require rotation of intravenous sites every 72 hours to prevent contamination and subsequent suppuration. Careful attention to catheter insertion technique and the proper care of catheter sites by a dedicated team of nurses are the first line of defense against this potentially lethal complication.

Because vascular surgeons operate on patients with progressive, multisystem disease, complications are common and tend to be either life- or limb-threatening. The diagnosis and management of these complications are difficult, and the outcome is often not good. Because patients with vascular disease are frequent users of the health-care system, clinicians seeing the patient should be aware of the common procedures performed and the possible complications likely to occur.

In general, vascular procedures are done for either aneurysmal or occlusive disease. The most commonly performed *carotid* procedure is an endarterectomy, which involves opening the artery, scraping out the diseased intima and media, and then closing the arteriotomy either primarily or with a patch. *Aortic* procedures for either occlusive or aneurysmal disease almost always involve the implantation of a synthetic graft in the abdomen or chest. *Infrainguinal* procedures call for the implantation of a graft to bypass occluded segments of the femoral, popliteal, or tibial vessels that cause limb-threatening ischemia. Autogenous vein is the preferred conduit for these procedures, although some surgeons still use synthetic grafts for bypasses to the above-knee popliteal segment. For a variety of reasons, surgeons may perform *extraanatomic* procedures, most commonly axillobifemoral or femoral–femoral bypasses. These are usually reserved for high-risk patients or when infection is present in the usual site of graft insertion. Although autogenous materials have been tried in these positions, synthetic grafts seem to have a better patency and are preferred. *Vascular access* procedures for patients on dialysis are either arteriovenous fistulas or synthetic arterial-to-venous grafts.

The ideal graft material has yet to be developed. All currently available arterial substitutes have some major drawback. *Synthetic* grafts are all either Dacron or polytetrafluoroethylene (PTFE). Neither material allows for the development of an endothelial-lined intima in the human, and thus grafts are prone to thrombosis, anastomotic stenosis, and infection. Due to modern manufacturing techniques, structural failure in the graft itself is rare and grafts of these materials are successfully used with acceptable rates of complication, especially in vascular reconstructions of the aorta and its major branches. *Autogenous* grafts are those in which the patient's own tissue is used. Saphenous vein is the most readily accessible and easiest to use autogenous conduit. It can be harvested and reversed or used *in situ* after valve disruption. When saphenous vein is not available, arm veins may be used with a very reasonable patency. Autogenous grafts maintain some degree of thrombosis resistance and are less likely to become infected. Because of the exposure of these venous structures to arterial pressures, intimal hyperplasia and fibrosis can occur, resulting in graft failure. *Homografts* are conduits made from veins from other humans. The most common of these is the human umbilical vein graft. These grafts were thought to be superior to synthetic grafts in the infrapopliteal position but were found to be prone to the development of pseudoaneurysms over time and are rarely used today. Cryopreserved saphenous veins have also been tried but have an unacceptable patency.

Vascular grafts are subject to a variety of significant complications. The most common problems likely to be encountered in the emergency department are

1. Progressive stenosis and occlusion
2. Infection
3. Erosion into contiguous structures
4. Disruption of the suture line, resulting in false aneurysm

PROGRESSIVE STENOSIS AND OCCLUSION

Depending on the size of graft insertion, as many as 15% to 80% of grafts will fail within 5 years. The combination of thrombogenicity and progress of atherosclerotic disease in the inflow and outflow tracts can lead to graft thrombosis. In addition, intimal proliferation in the sites of both proximal and distal anastomosis contribute to graft stenosis and occlusion. Thrombosis can also occur in response to graft infection, and any patient with graft thrombosis should be evaluated for this as well. Grafts that fail within the first 30 days of insertion usually do so as a result of a technical problem. Autogenous grafts that fail within the first year frequently do so because of a problem in the vein graft itself, usually sclerosis at a site of previous recannalized thrombosis or a fibrotic stricture developing at a valve site. Grafts that fail after this period of time frequently do so as a result of disease progression or anastomotic stricture. ⁴

CLINICAL PRESENTATION

More often than not, graft stenosis is asymptomatic until the sudden occlusion of the graft results in the return of symptoms. These include an increase in claudication, rest pain, or the development of gangrene. Loss of a previously palpable pulse in the distal vessels after a bypass graft even in an asymptomatic patient is a grave finding, and these patients should be considered to have developed a thrombosis and be referred for possible angiography. This should be done even if Doppler signals are present. Acutely ischemic extremities with loss of sensation and motor function are a true emergency and have a relatively short time-window to have the ischemia relieved. The return of a previously healed ulcer may be the first sign of graft failure, and the patency of the graft should be investigated if this occurs. Conversely, because grafts are often placed for long-standing atherosclerosis, thrombosis may not lead to critical ischemia, due the presence of well-established collateral circulation. In such situations, the patient may relate a sudden decrease in the distance that can be walked without pain. Such cases should be approached with the same intensity as the ischemic patient, because once the graft has occluded, thrombosis of the distal arterial tree can occur and threaten the limb.

DIFFERENTIAL DIAGNOSIS

Most clinicians should be familiar with the classic signs of acute ischemia and not mistake these for other entities that can cause limb weakness, including stroke or nerve compression. The history of a previous graft or the finding of the typical groin or leg scars should prompt graft failure to be in the differential diagnosis of any lower extremity limb complaint.

EMERGENCY DEPARTMENT EVALUATION

In evaluating graft stenosis or acute thrombosis, one of the most important adjuncts to decision making is the patient's previous medical records, especially the reports of previous clinical examinations, angiograms, operative reports, and noninvasive laboratory studies. The patient should be queried about the onset of symptoms and their progression and compare findings with a time when the graft was functioning well. Accurate pulse examination is a skill that takes time and considerable effort to develop. Objective quantification of limb ischemia can be obtained by doing an ankle-brachial index. This is performed by placing a blood pressure cuff above the ankle and listening for return to flow at the best pedal artery and comparing this with the higher of the two arm pressures. A change of 0.15 from previous measurements is considered significant and should prompt further investigation, either a duplex scan or angiogram. Physical examination of the extremity should also include motor and sensory examination. Light touch is lost early with ischemia, although it may be difficult to test because many of the patients already have a neuropathy. Motor loss usually begins in the anterior compartment with loss of dorsiflexion at the ankle and great toe. This should be tested by holding up the leg at the calf and asking the patient to move the ankle and great toe. The foot should be isolated to avoid being misled by gross movement of the limb by the thigh muscles. History, physical examination, pulse check, and ankle-brachial index should be adequate to make the diagnosis of a failing or thrombosed graft.

EMERGENCY DEPARTMENT MANAGEMENT

Management consists of early vascular surgery consultation and heparinization, if the consultant agrees. Heparinization can prevent thrombosis of major inflow and outflow vessels and especially the smaller arteries distal to the graft thrombosis. Timing of heparinization must be considered with the need for possible angiography and the use of thrombolytic agents. Because patients with peripheral vascular disease have a high incidence of coronary disease, changes in the central circulatory status may lead to thrombosis. Graft thrombosis may be precipitated by myocardial infarction, atrial fibrillation, congestive heart failure, or volume depletion. It is important for the emergency physician to evaluate the cardiac and fluid status of the patient as rapidly as possible. Normalizing the patient's cardiac and fluid parameters may well correct an ischemic state even if the graft is occluded. If it appears that the patient will need surgical intervention or angiography, a complete blood cell count should be obtained, levels of electrolytes and creatinine should be determined, and prothrombin time and partial thromboplastin time should be measured.

DISPOSITION

The patient with an acutely threatened extremity will require urgent operative intervention, with the success for limb salvage determined by the anatomic situation and the time since the onset of the ischemic state. Delays of more than 4 to 6 hours decrease the likelihood of success. With a less urgent state, angiography and thrombolysis may be considered after consultation with the vascular surgeon. If transfer is required, heparinization before transport is mandatory in most instances and should not be delayed while transportation arrangements are made. An experienced vascular surgeon should be consulted and all pertinent information, including history, previous operations, and previous noninvasive studies, should be transmitted. Optimization of cardiac and fluid states should be attempted in the timeframe of the transfer, but delays for such therapy should be avoided, especially in patients who have a severely ischemic extremity. Patients thought to have a failing graft, as evidenced by progression of symptoms or a fall in the ankle-brachial index, should be seen by the vascular surgeon as soon as possible.

COMMON PITFALLS

- Failure to recognize the change in the patient's extremity status as graft thrombosis
- Failure to consult the old chart for previously recorded examinations and to recognize that loss of a palpable pulse or a decline of 0.15 in the ankle-brachial index is significant
- Failure to evaluate the central circulatory status and overall cardiovascular status of the patient, with special emphasis on the identification of possible embolic sources and the presence of a low-flow state
- Failure to heparinize, with subsequent extension of thrombosis into the microvasculature that may result in limb loss
- Failure to refer the acutely ischemic extremity to an appropriate surgeon to address the ischemia

GRAFT INFECTION

Infections can be relatively acute after graft placement or can occur years later. They can present as sepsis or be indolent, producing gradual dissolution of a vascular anastomosis. Acute infections are usually caused by *Staphylococcus aureus* or gram-negative rods, appearing 5 to 7 days postoperatively. Occasionally, wounds that appear to be intact at the time of discharge may be seen within the first 30 days manifesting signs of infection. Graft infections may also appear at a much later time, up to years after implantation. These infections are frequently caused by *Staphylococcus epidermidis*.²

CLINICAL PRESENTATION

Acute graft infections frequently produce erythema, warmth, or fluctuance over the graft itself or, more commonly, over the anastomosis. The groin is the most common place to become infected, due to its proximity to the perineum, the disruption of lymphatic channels, and the difficulty of keeping the area clean, especially in the obese patient. In addition to gross infections, lymphatic leaks are not uncommon after groin incisions. These frequently result in copious drainage of clear lymph fluid from the incision. Occasionally, there is no leakage and the patient will present, in the early postoperative period, with a mass in the groin that is nontender and without erythema. This is most commonly a lymphatic fluid collection in the subcutaneous tissue or around the graft. In any event, any drainage from a wound that is over a vascular graft has potential for serious graft infection and limb loss.

Infections in grafts that have been implanted for long periods of time present special diagnostic problems. Transient bacteremia is probably the cause of such infections. Urinary tract infections, pneumonia, and dental procedures or other surgical manipulation can result in blood-borne bacteria. Normal vascular endothelium probably protects against bacterial adhesion, and because most prosthetic grafts never become completely endothelialized, the patient with a prosthetic implant is always susceptible to bacterial invasion. Common physical signs of a chronic infection are swelling, erythema, and fluctuance under a vascular incision. In more indolent infections, patients can present with a fever of unknown origin or with septic thrombi that present as painful abscesses distal to the graft. Unexplained fever in the patient with a vascular implant is another presentation of vascular infection.

EMERGENCY DEPARTMENT MANAGEMENT

Any swelling or drainage of any sort (whether purulent or clear), should prompt a consultation with the vascular surgeon. Treatment of a possible graft infection with oral antibiotics without consultation should not be attempted. Virtually all the prosthetic grafts that become infected will require removal, because the ultimate outcome of vascular infection is an anastomotic disruption and hemorrhage. Adjuncts to diagnosis, such as plain films and ultrasonography, are usually not helpful. A computed tomographic scan is useful to identify perigraft fluid collections. Although it may be difficult at times to make a diagnosis of graft infection, the presence of air bubbles in the fluid or fluid surrounding the graft should be considered a sign of graft infection. All patients with a prosthetic graft infection should be admitted and initially treated with intravenously administered antibiotics while the arrangements are made to excise the infected material. Wound infections involving purely autogenous material can sometimes be managed without excision. However, even these grafts are at risk for an anastomotic disruption and hemorrhage. Fluctuance over a vascular incision should *never* be drained in the emergency department because uncontrolled hemorrhage may ensue.

DISPOSITION

All suspected graft infections should be seen by the vascular surgeon, preferably the individual who implanted the graft. If a vascular surgeon is not available, then the patient should be transferred to a vascular surgeon. The patient should be started on antibiotics to cover *Staphylococcus* and gram-negative rods before transfer.

COMMON PITFALLS

- Outpatient antibiotics are not appropriate therapy for cellulitis, drainage, or fluctuance over a prosthetic or autogenous graft.
- One should never drain a fluctuant area over the graft site.
- It is important to recognize graft thrombosis as possibly being due to graft infection.
- Lymphatic leaks are a serious condition that can lead to graft infection unless appropriately treated.

EROSION INTO CONTIGUOUS STRUCTURES

Probably the most life-threatening complication is the erosion of a graft into adjacent structures. This most commonly involves the erosion of the abdominal aortic graft into the gastrointestinal tract. If this occurs at the proximal aortic suture line and involves both the native aorta and graft, exsanguinating hemorrhage can ensue (aortoduodenal fistula). However, graft erosion can occur in any part of the bowel and any part of the graft. If this does *not* occur at a suture line, it is called a perigraft fistula and most often presents as a more chronic bleeding state.³

CLINICAL PRESENTATION

Physical examination usually produces no findings, although the palpation of a false aneurysm of the aorta or iliac is possible. In patients with erosions at the proximal graft anastomosis, the patient may present with cardinal or sentinel bleeding. This occurs when there is massive bleeding into the gastrointestinal tract, resulting in vomiting or acute rectal evacuation of blood. The patient rapidly becomes hypotensive. The area of the aortoenteric fistula clots, and, for a period of time, stability is reached. Unless promptly treated, the patient will then die of a second massive hemorrhage. Patients with perigraft fistulas bleed through the interstices of the graft and from the eroded bowel wall edges. These patients frequently present with more chronic bleeding, with guaiac-positive stools and anemia. This may be difficult to diagnose.

EMERGENCY DEPARTMENT MANAGEMENT

Patients who have an aortic graft and present with massive gastrointestinal hemorrhage, with either hematemesis or hematochezia, should have aortoenteric fistula strongly considered. Although other sources of bleeding are possible, prompt consultation with a vascular surgeon is indicated. In the unstable patient, emergency laparotomy with endoscopy prior to the incision is usually performed. A delay in operative intervention will result in death.

In the patient with a graft in place and a guaiac-positive stool and anemia who is hemodynamically stable, a further workup for other sources of bleeding should be undertaken. This would include upper and lower endoscopy, bleeding scans, and contrast gastrointestinal studies. Computed tomography may also be helpful. If this workup is negative for a site of bleeding and the patient persists with gastrointestinal bleeding, an exploratory operation should be undertaken to rule out a graft enteric fistula. No other tests can definitively rule out this entity, other than celiotomy. Aortography in these patients may be undertaken to plan the possible reconstruction should the graft have to be removed, but it is not diagnostic for a graft-enteric fistula.

Graft erosion is seldom a problem in other areas, except for an erosion through the skin, exposing the graft itself. Such exposed grafts should be considered infected, usually in their entire length, because either the erosion was caused by an infection or infection occurred after the erosion. After exposure and infection, disruption of the suture line can be expected, producing massive hemorrhage. Exposed grafts warrant immediate vascular consultation and rapid operative intervention.

DISPOSITION

The treatment of aortoduodenal fistula requires the highest level of care and expertise. Mortality is high. Patients should be transferred immediately to a vascular surgeon because bleeding may occur at any time. Patients should have blood samples drawn for typing and crossmatch and undergo correction of the blood loss. Hypertension should be avoided because this may result in loss of the blood clot that is preventing exsanguination. It is of utmost importance that operative intervention not be delayed for an extensive workup.

COMMON PITFALLS

- An aortoenteric fistula should be suspected in a patient with an implanted graft who presents with upper or lower gastrointestinal hemorrhage or anemia.
- Routine or extensive workup (i.e., barium enema, upper gastrointestinal series, arteriography, and computed tomography) on patients with implanted grafts with occult or overt gastrointestinal bleeding may delay timely operative intervention.
- Emergent vascular consultation should be obtained for patients with massive bleeding and intraabdominal grafts.
- An exposed graft should be considered an infected graft that requires operative intervention.

ANASTOMOTIC DISRUPTION OR FALSE ANEURYSMS

A true aneurysm is a localized dilatation of the vessel usually caused by weakening of the media. A false aneurysm is the result of a disruption of the graft arterial suture line with the walls of the aneurysm formed by the collagenous scar around the anastomosis. A false aneurysm usually presents as a pulsatile mass or bulge at a previous anastomosis. As many as 10% to 15% of femoral anastomoses will ultimately result in a false aneurysm. It is thought that most are the result of an underlying low-grade infection that is subclinical and without signs of cellulitis, erythema, or sepsis. Seldom is a false aneurysm due to failure of the suture material or the graft itself. False aneurysms need to be repaired because of their tendency to occlude or produce distal emboli, resulting in limb ischemia. ¹

CLINICAL PRESENTATION

False aneurysms that appear in the abdominal cavity can be either at the proximal aortic suture line or at the iliac suture line. Sometimes, they can be palpated more easily in the area of the umbilicus (aortic) or low in the right or left lower quadrant. Usually, they produce no symptoms until rupture occurs, at which time symptoms typical of any other aneurysm rupture may occur. These include back pain, pain radiating to the testis or thigh (especially with iliac ruptures), anemia, or hemorrhagic shock. Occasionally, ureteral obstruction due to false aneurysms at the iliac anastomosis can occur. The most common site for false aneurysms is in the groin, where they usually present as a slowly enlarging pulsatile mass.

In the absence of overt infection, the wound is usually well healed. However, if the false aneurysm gets large enough, it may result in skin erosion. Patients who present with distal emboli after a previous aortobifemoral bypass should be examined for the presence of a false aneurysm in the groin, because this is one source for the embolic material. Likewise, acute occlusions of one limb of the graft may be secondary to the development of a false aneurysm. Venous obstruction with leg swelling can also occur, and occasionally, neurologic symptoms with nerve compression of the femoral nerve can be seen. False aneurysms are more common with the use of prosthetic material. However, they can occur with autogenous grafts either in the groin or distally. Many of these will be accompanied by signs of infection.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

The emergency physician should consider the presence of a false aneurysm whenever physical examination of the groin anastomosis reveals an abnormally prominent pulsation or the patient reports a change in the appearance of the groin. Ultrasonography with color flow duplex can be helpful in making the diagnosis. Computed tomography is often required to evaluate the proximal anastomoses, as well to be sure that a low-grade infection involving the graft is not present. In addition, the contralateral limb of the graft should be investigated. Occasionally, an anastomotic false aneurysm in the groin may rupture, with acute expansion and hemorrhage. These are seldom life-threatening, but they may result in considerable blood loss and represent a vascular emergency. Vascular surgeons should be consulted whenever the emergency physician believes the anastomosis in the groin is not perfectly normal or if he or she feels abnormal pulsations in the abdomen with a graft in place.

DISPOSITION

Complications of graft insertion should be handled by a vascular surgeon. An anastomotic false aneurysm should be seen by a vascular surgeon in the emergency department.

COMMON PITFALLS

- A false aneurysm should not be mistaken for an abscess or cyst. Do *not* attempt drainage either percutaneously or with an incision.

- In the presence of an abdominal graft, lower abdominal pain or pain radiating to the testis or thigh should suggest rupture of an anastomotic false aneurysm.
- A proximal anastomotic false aneurysm should always be considered as a source of distal emboli or as a cause of acute graft occlusion.
- The other sites of anastomosis should be investigated in patients who have a false aneurysm at one anastomosis.
- The patient's complaint of a change in the pulsatile nature of the groin is significant and should be investigated.

[Common Pitfalls](#)
[Thoracic Aortic Aneurysms Chapter References](#)

AORTIC DISSECTION

Aortic dissection is the most frequent catastrophic event involving the aorta. First recognized postmortem by Morgagni in 1761, aortic dissection remains a diagnostic challenge to the emergency physician because of its nonspecific presentation, variable population at risk, and time pressure for diagnosis. Delays or errors in diagnosis can have devastating consequences.

Dissection of the aorta begins with an intimal tear, usually proximal (60%) in the ascending portion of the thoracic aorta.¹² The site of the initial intimal tear is usually at the aortic root or between the origin of the left subclavian artery and the ligamentum arteriosum. These two areas of the aorta are relatively fixed, and it is believed that maximum stress is applied to these areas during systole. The intimal tear allows blood to penetrate down to the media separating intima from adventitia. The length of time required to dissect the entire aorta can be seconds, with the dissection proceeding either distally or proximally. *Reentry tears* occur distal to the initial site, creating an alternate path for aortic blood flow through a *false lumen*. An intramural hematoma can develop within this false lumen, minimizing flow and occasionally causing dilation. A small number of patients develop an intramural hematoma with no evidence of a communicating tear.¹³ The dissection may dilate as the flow of blood through the false lumen increases or an intramural hematoma organizes. The term *dissecting aneurysm* is frequently used because of this pathologic finding, but it is done so incorrectly, as this is not a true aneurysm (see later discussion of [thoracic aortic aneurysms](#)). Spontaneous rupture is common and is most often into the pericardium. Dissections with an open false lumen and tear beginning high in the aorta have a poor prognosis.¹²

The cause of the intimal tear is unknown and the role of a structural defect of the aortic wall remains unclear. Histologic changes of recurrent injury and repair of the aorta in patients with Marfan syndrome and within the wall of a dissection may contribute to the process. Hypertension is the most common predisposing factor to dissection and is seen in up to 78% of descending aortic dissections.^{24,25} It is not yet known why one hypertensive person will undergo dissection and another will not. Marfan syndrome is a widely recognized risk factor that carries a mortality rate of greater than 90% in the event of dissection or aneurysm rupture. Other risk factors for aortic dissection are congenital abnormalities of the aorta, such as bicuspid valve and coarctation. Dissection has also been reported in pregnancy, with half having evidence of systemic hypertension.¹⁸ Connective tissue diseases such as Turner syndrome and systemic lupus erythematosus, as well as cocaine use and trauma (iatrogenic and blunt), have all been associated with aortic dissection.^{2,14,21,22} Aortic dissection is *not* due to atherosclerotic disease. Dissection is most likely a multifactorial disease, with hypertension the principal risk factor.

CLASSIFICATION

DeBakey originally classified aortic dissections into three categories according to the origin of the dissection: type I, involving the entire length of the aorta; type II, beginning in the ascending aorta (the aortic root to the left subclavian); and type III, originating from the area distal to the left subclavian.⁷ The Stanford classification is a simpler scheme that divides dissections into type A, involving the ascending aorta, and type B, confined to the descending aorta and beginning after the left subclavian⁶ ([Fig. 51.1](#)). This more widely used nomenclature aids in determining treatment options and prognosis.

Figure 51.1. Classification of aortic dissections. **(A)** Dissection of ascending aorta. **(B)** Dissection of descending aorta.

Type A dissections are more common (80%) and are considered surgical emergencies. Possible complications at presentation of type A dissections may include aortic rupture, cardiac tamponade, and aortic valve insufficiency. Heparinization is used in the operative repair, and restoration of flow may result in intracerebral hemorrhage. Type B dissections are managed medically unless they are complicated by rupture, vascular occlusion, acute expansion, or impending rupture. Up to one-fourth of patients with type B dissection require urgent operation for hemorrhage, limb or organ ischemia, intractable pain, or progression of dissection. Paraplegia is a significant complication of surgical intervention for type B dissections.

MORTALITY

The most common cause of death for untreated dissections is rupture of the aortic wall into the pericardial sac at the level of the right lateral wall of the aorta, where the adventitia is thinnest. Rupture is most often into the pericardial sac, the pleural space, or the mediastinum. Death may also occur due to congestive heart failure or myocardial infarction.

The mortality rate of patients with untreated type A dissection is 75%, and the rate for surgically treated type A dissection is 15% to 20%.⁸ Risk factors for death are (1) older age, (2) hypertension, (3) preoperative cardiopulmonary resuscitation, (4) hemodynamic instability, and (5) lack of retrograde cerebral perfusion.^{12,13} Mortality postoperatively ranges from 16% to 35%, with a 5-year survival of 55% to 80%.^{6,11,20} Reoperation after initial surgery is a very poor prognostic sign.

The medical therapy and surgical mortality rates for uncomplicated type B dissections are the same (32% to 36%); therefore, medical therapy is used first line in uncomplicated patients.¹⁷ The use of beta-blockers and afterload-reducing medication appears to decrease the risk of extension or dilation of the dissection. It does not stop the progression of the disease indefinitely, and aortic replacement will eventually be needed.²⁶ Five-year survival for uncomplicated type B dissection is 48% to 60%.^{11,15} Type B dissections complicated by rupture, vascular occlusion, acute expansion, or impending rupture have a surgical mortality ranging from 26% to

75%.⁹ Controversy exists over whether medically managed type B dissections would be better served by earlier surgical intervention. [7,11,15](#)

CLINICAL PRESENTATION

To make the diagnosis of aortic dissection, the emergency physician must include it in the differential diagnosis at presentation. Sudden onset of pain in the chest or in conjunction with back pain is the most prevalent symptom. [1,23,24](#) The pain is severe and is frequently described as dull and pressure-like. With this presentation, history should focus on identifying risk factors for aortic dissection, especially hypertension and Marfan syndrome. The pain of aortic dissection is classically described as “ripping” or “tearing”; however, studies have more frequently demonstrated this with nondissecting pathology. ¹ In addition to pain in the chest and back, accompanying locations for discomfort include the neck, throat, mandible, abdomen, and leg. Patients may also complain of pain in the lower back, pelvis, and a lower extremity.²⁴ No pain at all accompanies 15% to 20% of dissections. ²⁵

On examination, the patient may clinically appear to be in shock, exhibiting cool and diaphoretic skin, yet paradoxically have a normal or elevated blood pressure. The majority of patients present this way, but nearly one-fourth will present hypotensive due to leaking at the dissection site or rupture. A variety of signs and symptoms can result due to vascular compromise from the dissection or proximity to the dissection site. The majority are neurologic (33%), with syncope, altered mental status, cerebrovascular accident, paraplegia, or visual disturbances. ¹ Syncope is the initial complaint in less than 10% of patients, but decreased level of consciousness occurs more frequently. Syncope may be a sign of the development of hemopericardium or cardiac tamponade. ²⁴ Other associated findings with dissection are cardiac tamponade and congestive heart failure. Cardiovascular collapse is seen most often with type A dissection. Proximity to the dissection site or developing hematoma can cause hoarseness (laryngeal nerve compression), dyspnea, or stridor with wheezing (tracheal compression) and dysphagia (esophageal compression). On examination, initial hypertension is very common (systolic greater than 150 mmHg), but the patient may still appear clinically in shock. The presence of hypotension strongly suggests a type A dissection, a rupture of either type of dissection, or a dissection into the brachiocephalic artery. Gastrointestinal symptoms include midepigastria pain, hemorrhage, or melena secondary to splanchnic vessel infarctions and are frequently misdiagnosed as a primary abdominal pathology. Renal artery involvement may lead to hematuria, flank pain, oliguria, or uncontrollable hypertension due to excess renin release.

Head and neck examination may reveal the presence of jugular venous distension secondary to congestive heart failure, cardiac tamponade, or an expanding hematoma around the aorta causing outflow obstruction. Aortic insufficiency murmur occurs in 16% to 20% of patients, resulting from proximal dissection causing dilation of the aortic valve ring and loss of commissural support of the aortic valve. ¹

Poor prognostic factors include pleural effusion, cardiac tamponade, and pericardial friction rub. The presence of these signs implies leakage of the dissection into the pericardial space. The abdominal examination may reveal tenderness to palpation or rigidity. Rarely, a pulsatile mass is palpable. ¹³ Examination of the limbs may reveal unequal, decreased, or absent peripheral pulses in 50% of cases. A complete deficit of pulse is found in 8% to 10% of patients. ^{24,25} Differential blood flow to the extremities is often manifested by a marked discrepancy in blood pressure between arms and between the arms and legs, should dissection extend the entire length of the aorta. Rare but reported initial presentations of dissection have included hemoptysis, superior vena cava syndrome, right atrium or ventricular rupture, and deep vein thrombosis. ^{13,24} Cranial nerve deficits secondary to dissection into the carotid arteries, or motor deficits secondary to distal dissection of spinal arteries, may also be present. ¹³

DIFFERENTIAL DIAGNOSIS

Chest pain with associated back pain is the most prevalent symptom of aortic dissection; therefore, the differential diagnosis is broad and contains numerous other life-threatening conditions. Myocardial infarction is the principal diagnosis of exclusion, as well as cerebrovascular accident in patients with neurologic symptoms. Misdiagnosis of either could result in the use of thrombolytic therapy and increased risk of death from exsanguination. Other diagnoses to exclude are pulmonary embolism, thoracic aneurysm, pneumothorax, multilobar pneumonia, mediastinal cyst or tumor, pericarditis, pancreatitis, cholelithiasis, cholecystitis, perforated viscus, and peripheral vascular disease.

The diagnosis of aortic dissection should be considered in the presence of the following:

- History of hypertension
- History of connective tissue disease or congenital aortic abnormalities
- Aortic insufficiency with chest and/or back pain
- Atypical chest or back pain
- Presence of acute neurologic symptoms (rare with myocardial infarction)
- Diminished or absent peripheral pulses (especially if reappear)
- Syncope
- Chest pain in pregnancy (third trimester)
- Trauma
- Acute unexplained left ventricular failure
- Flank pain and hematuria without an obvious source
- Presence of multiple sites of ischemia

EMERGENCY DEPARTMENT EVALUATION

Patients suspected of aortic dissection should be managed aggressively in anticipation of impending leak or rupture. The patient should be placed on a cardiac monitor and intravascular access established with at least two large-bore catheters (16-gauge or larger). A blood specimen should be drawn and sent for type and crossmatch. Initial laboratory studies should include a complete blood cell count; determination of serum levels of electrolytes, amylase, and cardiac enzymes; urinalysis; and a 12-lead electrocardiogram (ECG). Although routine laboratory studies are not usually helpful in the diagnosis of aortic dissection, they may rule out other causes. The complete blood cell count often reveals leukocytosis. If a sufficient amount of blood has accumulated in the false lumen, the hematocrit may be low. Renal artery involvement may result in increased blood urea nitrogen and creatinine levels, as well as hematuria, indicating ischemia or infarction of the kidney. A normal creatinine phosphokinase level is useful in distinguishing dissection from myocardial infarction. A small number of patients, however, dissect proximally into the right coronary artery and suffer a myocardial infarction. ECG changes compatible with myocardial infarction and pericarditis can be seen in approximately 25% of patients with dissection.

The most available radiologic study for the emergency physician is the chest radiograph, to assist in the diagnosis of aortic dissection. In 65% to 85% of cases, the chest radiograph demonstrates some abnormality. ^{1,24} A widened mediastinum is the most common finding, but a left-sided pleural effusion or an indistinct aortic knob may also be seen ([Fig. 51.2](#)). The deviation of a calcified aortic intima by greater than 6 mm from the outer wall of the aorta is considered pathognomonic of dissection. Other findings suggestive of dissection are the double density sign (a false lumen that is less radiopaque than the true lumen), tracheal deviation, and an irregular aortic contour. Unfortunately, a normal chest radiograph does not exclude the diagnosis. If the diagnosis of dissection is considered, radiographic confirmation is required by either aortography, computed tomography (CT) or transesophageal echocardiography (TEE). ¹⁶

Figure 51.2. Chest x-ray film of a 65-year-old woman with type A dissection. Note the widened mediastinum, indistinct aortic knob (arrows), tracheal deviation

(triangles), and left pleural effusion.

The aortogram is still considered the “gold standard” for diagnosis of aortic dissection (sensitivity and specificity greater than 90%), but it has the disadvantages of a large contrast dye load, of being a time-consuming procedure, and of having a significant false-negative rate if the false lumen is thrombosed. In addition to confirming the diagnosis, the aortogram reveals the extent of dissection, the condition and patency of the distal vessels, and the pattern of blood flow in the true and false lumens. False-positive results are seen in any process that causes thickening of the aortic wall, such as a clotted aneurysm, mediastinal hematoma, neoplasms, or periaortic fat.

CT is used as a supplement to aortography and in some institutions has replaced it for making the diagnosis of dissection. The advantages of CT are (1) superior visualization of fluid collection in the pericardium, pleura, and mediastinum; (2) demonstration of distal vessel patency; (3) noninvasiveness; and (4) sensitivity and specificity equal to aortography. Its main disadvantages are the necessary exposure to contrast dye for the examination and its inability to localize the site of the intimal tear. Spiral CT, with its three-dimensional reconstruction feature, is more expedient and has demonstrated improved delineation of the intimal tear and assessment of the great vessels.¹⁹ Spiral CT does not show greater sensitivity or specificity than TEE or magnetic resonance imaging (MRI).²³

TEE is frequently used as the first diagnostic study in suspected dissection, if it is available. It has a sensitivity and specificity of 99% and 98%, respectively. The goals of TEE in aortic dissection are (1) to confirm the diagnosis, (2) differentiate true and false lumens, (3) localize the intimal tear, (4) evaluate left ventricular wall motion, (5) determine the presence of fluid collections, and (6) detect aortic insufficiency. It demonstrates a diagnostic accuracy of 100% for aortic insufficiency and cardiac tamponade. TEE provides limited ability to evaluate the great vessels and coronary vessels. Complications of transient atrioventricular (AV) block, bradycardia, and asthma can occur during introduction of the probe.¹⁰ Images may be limited in obese or emphysematous patients. TEE is often combined with CT.

MRI has a sensitivity and specificity no better than those of TEE or CT, and it is seldom used in the emergent setting because of cost, length of time needed for the study, and relative unavailability. MRI and TEE combined have the same sensitivity and specificity as TEE and CT.²³

EMERGENCY DEPARTMENT MANAGEMENT

The most important aspects of emergency department management are the reduction of arterial blood pressure and the forceful contractility of the left ventricle. These measures should be initiated before confirmatory tests are performed if clinical suspicion for dissection is high. Reductions in these aspects of the cardiovascular system have developed empirically in an attempt to limit the propagation of a dissection.²⁶ Systolic blood pressure control is important because the rate of dissection is directly proportional to the blood pressure, especially to the rate of rise of arterial blood pressure. The systolic blood pressure should be maintained at 100 to 110 mm Hg or the lowest level compatible with adequate renal and cerebral perfusion. The drug of choice to control blood pressure is intravenous nitroprusside at the initial rate of 0.5 to 1.0 µg/kg/min. Oral agents should never be used.

Once a systolic blood pressure of 100 mm Hg is achieved, intravenous beta-antagonist therapy should also be used to suppress the reflex tachycardia from the initiation of nitroprusside and concomitant rise in arterial pressure. The target heart rate is between 60 and 80 beats per minute. Appropriate beta-antagonists include intravenous esmolol (0.5 mg/kg loading dose over 1 minute, infusion rate of 0.05 mg/kg/min) or intravenous propranolol (0.5 to 1.0 mg increments at 5 minute intervals). Intravenous labetalol is an alternative to the nitroprusside and beta-antagonist therapy for patients with mild hypertension and no contraindications of chronic obstructive pulmonary disease or asthma. Congestive heart failure, heart block, and bradycardia are contraindications for propranolol use. Oral agents should never be used in the acute setting of aortic dissection.

DISPOSITION

Management of the patient with aortic dissection requires urgent multispecialty involvement. The radiologist should be consulted emergently to obtain the appropriate diagnostic procedures. The cardiothoracic surgeon should also be notified. Once the diagnosis of dissection has been made, an internist may need to be consulted for medical management. All patients suspected of having acute aortic dissection should be admitted to an intensive care unit. Indications for transfer include inadequate facilities or personnel to definitively make the diagnosis or treat the condition. If transfer is indicated, air transport should be used to minimize the time required. If only ground transport is available, an ACLS unit should be used.

COMMON PITFALLS

- The most common mistake is failure to consider the diagnosis of aortic dissection.
- Unexplained, severe, and sustained chest pain (especially with associated back pain) must be evaluated with aortography, CT, or TEE to rule out dissection.
- A radiologist and a cardiothoracic surgeon should be consulted early.
- The most important aspect of emergency department management is control of the blood pressure and heart rate.
- Arrange immediate transport to the nearest appropriate hospital if your facility has inadequate resources for diagnosis and management of dissection.

THORACIC AORTIC ANEURYSMS

Thoracic aortic aneurysm is very insidious in onset and presentation. It is defined as a localized or diffuse dilation of the aorta to a diameter of greater than 5 to 6 cm. Dilation is the result of an undermining of the overall strength of the aortic wall by direct loss of supportive proteins such as elastin and collagen. Once the wall of the aorta is weakened, there is progressive alteration in anatomy, with the growing diameter and thinning wall that lead to dilation and rupture. Turbulent flow can lead to thrombus formation. Causes for the undermining of the aortic wall are listed in [Table 51.1](#).

Atherosclerosis
Coarction of the aorta
Cystic medial necrosis
Giant cell arteritis
Marfan syndrome
Mycotic aneurysms
Seronegative spondyloarthropathies
Syphilis
Tuberculosis
Takayasu's arteritis

TABLE 51.1. Diseases Contributing to Thoracic Aortic Aneurysms

The prevalence is 5.9 new aneurysms per 100,000 person-years based on retrospective studies. Its incidence is equal between men and women, with an increasing prevalence with advancing age. Risk factors are hypertension, advanced atherosclerotic disease, and smoking.³ The natural history of thoracic aneurysms is progressive dilation and rupture, with a 76% mortality rate at 2 years in untreated patients and a 30% mortality rate after surgical repair.⁵

Aneurysm diameter is a significant risk factor for rupture. The median size at time of rupture is 6.0 cm for ascending aneurysms and 7.2 cm for descending aneurysms. The risk of rupture increases 25.2% for ascending diameters greater than 6.0 cm, with a 38% increase in risk for descending diameters greater than 7.2 cm.⁴ The estimated increase in diameter is 0.2 to 0.32 cm per year.³ In patients with Marfan syndrome, rupture occurs at smaller diameters. Surgical intervention is

therefore planned according to the patient's stability at time of diagnosis and diameter of the aneurysm as monitored over time. Surgical mortality ranges between 15% and 20%.

The most common scenario for diagnosis of thoracic aneurysm is as an incidental finding on chest x-ray. Occasionally, patients will present with aortic regurgitation murmurs or with symptoms directly related to impingement of thoracic structures by the aneurysm. Aortography, CT, and TEE can be used to evaluate suspected aneurysms. If the diagnosis has not been made previously, aneurysms suspected in the emergency department should be evaluated at the time of presentation, even if asymptomatic. Consultation with a thoracic surgeon is recommended in this setting to determine treatment plan. Those patients not needing immediate surgical repair should have periodic outpatient diagnostic tests to monitor the aneurysm diameter.

In cases of rupture or impending rupture, the patient will present with deep, aching or throbbing chest or back pain. A sudden escalation of pain and hypotension are signs of aneurysm rupture. Rupture may also present as cardiopulmonary arrest secondary to intrathoracic or intraabdominal hemorrhage, should the aneurysm extend beyond the diaphragm. Bedside transthoracic and transabdominal echo can be of assistance in locating large collections of fluid. Disposition is determined by consultants based on the aneurysm diameter, risk of rupture, and surgical risk to the patient.

The timely recognition of an abdominal aortic aneurysm (AAA) is a major challenge to the emergency physician. The presentation may be confusing, accurate diagnosis difficult, and the cost of delay or misdiagnosis devastating. AAA is the most common cause of unexpected death following discharge from the emergency department (ED),¹⁶ and is one of the eight high-risk areas for medical malpractice litigation in emergency medicine.¹⁴

AAAs (defined as a 50% or greater increase in aortic diameter¹²) are present in nearly 2% of the elderly.⁷ The prevalence is increasing,^{3,24} even after adjusting for improved methods of detection. As the proportion of the population older than 60 years of age grows, emergency physicians can expect to encounter patients suffering from AAAs more frequently.

The etiology of AAA remains obscure. A variety of evidence suggests that atherosclerosis alone is not the principal cause; smoking is the single most important risk factor,¹⁹ but familial, biochemical, and hemodynamic factors have all been implicated.^{7,12,15} Most patients are male, but the prevalence of AAA increases with increasing age in both sexes³¹; it is roughly as common (approximately 5%) in 90-year-old women as it is in 80-year-old men.⁷

The natural history of the AAA is one of gradual expansion (although sudden changes in size may occur), followed by rupture, exsanguination, and death,³² although occasional cases of chronic contained rupture have been reported, with survival following rupture of weeks to months.¹³ Most AAAs are symptomless until rapid expansion or leakage occurs; indeed, the onset of symptoms referable to the aneurysm is a bad prognostic sign. Eighty percent of patients with untreated, symptomatic AAAs will be dead within 1 year of the onset of symptoms (33% in 1 month, and 74% in 6 months).³⁰

The risk of rupture and death depends on the size of the aneurysm. Aneurysms less than 4.0 cm in diameter are at low risk for rupture.⁶ For diameters between 4.0 and 5.0 cm, the 5-year risk is between 3% and 12%, and for diameters greater than 5.0 cm, between 25% and 41%.⁷ However, there is considerable difference of opinion among vascular surgeons about the risk of rupture, and better data are needed.¹⁸

Early detection and elective repair of AAAs leads to increased life expectancy, even in elderly patients.^{8,32} Operative mortality for elective surgery is roughly 2% to 7% in all age groups,²⁷ compared with the very high mortality of rupture (90% overall; 50% to 75% in patients who present to the ED in shock,⁷ 20% if not in shock³⁰). Because rupture of an AAA is inevitable given enough time, elective resection is generally recommended for aneurysms of 5.0 cm or more.⁷ Although some have extended this indication to AAAs as small as 4.0 cm,^{11,15} a randomized, controlled trial of active ultrasonic surveillance versus immediate repair of small aneurysms has shown no evidence favoring early operation.²⁶

CLINICAL PRESENTATION

AAAs typically present in three ways: asymptomatic, symptomatic, and ruptured. Physical examination is the key to recognition, because about half of asymptomatic AAAs are palpable.²⁹ The sensitivity of physical examination depends on the size of the aneurysm, ranging from about 50% for aneurysms between 4 and 5 cm to 76% for those between 5 and 6 cm.²⁰ Unfortunately, this sensitivity is not high enough to confidently rule out an aneurysm based on a negative physical examination. Most palpable aneurysms are found in the epigastrium, extending to the paraumbilical areas on both sides of the midline. False-positive physical findings are common, illustrating the difficulty of the diagnosis.¹

Asymptomatic Aneurysm

Occasionally, an AAA is discovered on routine examination for another, clearly unrelated problem. Frequently, the aneurysm is noted on abdominal plain films.²² The emergency physician's task in this setting is to confirm that the aneurysm is truly asymptomatic.

Symptomatic Aneurysm

Patients who are hemodynamically stable but who have symptoms referable to an AAA can present in a variety of ways, and so are easily misdiagnosed. In fact, almost half of all AAAs are misdiagnosed on their initial presentation.^{2,23} Abdominal, low-back, or flank pain is the cardinal symptom of AAA, but it is nonspecific. The pain may be associated with syncope at the time of onset. The discomfort occasionally radiates to the testis or leg, causing the symptoms to be attributed to renal colic, inguinal hernia, or lumbar spine disease. The pain is usually not much affected by movement and can vary considerably in location.²⁵ Radicular findings²¹ or hematuria²⁸ may occasionally be present, further misleading the physician.

Less common presentations of symptomatic AAA include hydronephrosis or leg swelling (usually left) from compression, new onset or worsening of hypertension (secondary to renal artery compression), testicular swelling, or evidence of peripheral embolization. Aortovenous or aortocaval fistulas are uncommon, and usually present as high-output failure with marked distention of the lower abdominal and leg veins, accompanied by more typical evidence of AAA, such as abdominal mass and back pain.⁴

About 10% of symptomatic AAAs present with severe pain and marked abdominal tenderness.³⁰ Because these patients have the appearance of an acute abdomen, identifying them as "emergent" cases is not as much of a problem as in other symptomatic patients, even though the presumptive diagnosis may be erroneous (e.g., perforated viscus).

An uncommon, acute presentation of a symptomatic AAA is gastrointestinal bleeding secondary to an aortoenteric fistula.⁹ Such bleeding may be massive and can distract the emergency physician from suspecting vascular disease. In particular, aortoenteric fistula should be assumed whenever a patient who has had a previous repair of an AAA presents with gastrointestinal bleeding.

Finally, symptomatic AAA may present acutely as complete aortic occlusion with a clinical picture similar to that of a saddle embolus or acute Leriche syndrome. This complication requires prompt operation and still carries an approximate 50% mortality.³⁰

Ruptured Aneurysm

The classic triad of findings in ruptured AAA is back pain, hypotension, and a pulsatile abdominal mass, but all three findings are present in only about half the patients who survive to reach the ED.¹⁷ Therefore, the presence of any one of these findings in a patient with a known AAA is sufficient to make the diagnosis of rupture without confirmatory testing.⁷ Unfortunately, most patients presenting with ruptured AAAs have no prior knowledge of their aneurysm.²⁹ Rupture of an AAA is correctly diagnosed preoperatively about in 70% of patients²³; mortality increases dramatically with misdiagnosis.¹⁰

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of AAA includes the differentials of shock and the acute abdomen. If shock is present, the differential typically includes acute myocardial infarction, hemorrhagic pancreatitis, perforated viscus, and mesenteric infarction. In patients whose presentation is less severe, renal or biliary colic, diverticulitis, and lumbosacral disc disease also need to be considered. Because these conditions are more common than AAA, it is useful to consider the differential diagnosis in reverse; for example, when entertaining a diagnosis of renal colic in a patient over age 60, AAA should be considered.

EMERGENCY DEPARTMENT MANAGEMENT

The ED management of a patient with a suspected AAA must be tailored to the patient's presentation.

Asymptomatic Aneurysm

If the AAA is clearly and unequivocally unrelated to the patient's symptoms, the patient should be referred promptly to a vascular surgeon for further evaluation and possible elective repair. An abdominal ultrasound examination may be useful in establishing the presence or absence of AAA, but it cannot provide evidence that the AAA is not ruptured, leaking, or expanding.

Symptomatic Aneurysm

An aneurysm producing symptoms should be assumed to be ruptured, rapidly expanding, or otherwise complicated (infected, dissecting). Therefore, although these patients may appear hemodynamically stable, prompt surgical consultation should be obtained, and preparations for fluid resuscitation and operative repair should be made by placing several large-bore intravenous lines and sending blood for type and crossmatch, hemoglobin, renal function, and coagulation studies. Vigorous fluid resuscitation should not be started unless there is evidence of peripheral hypoperfusion,⁷ and hypertension should be controlled if present.²⁶ Patients presenting as an acute abdomen or patients with known AAA and any one of the findings in the classic triad require immediate surgery without the usual preoperative evaluation and preparation, as rupture is either imminent or has already occurred but has been temporarily confined to the retroperitoneum.⁷ In less acute presentations, radiologic imaging may be helpful in selected cases but should not be ordered indiscriminately.

Ruptured Aneurysm

Patients in shock from a ruptured AAA need rapid resuscitation and prompt operation. Except in unusual circumstances, these patients should be transported to the operating room as quickly as possible without waiting for diagnostic testing or stabilization. A policy of immediate operation in such circumstances maximizes the patients' chances of survival. Even if it is discovered that a ruptured AAA is not present, many of these patients will have another surgical condition requiring operation, so the risk of unnecessary laparotomy is not great.³³

Radiologic Imaging

Plain films of the abdomen are occasionally helpful in the diagnosis of AAA, in that calcified walls are visible in about one-half of cases.²² Fusiform calcifications show the presence of an aneurysm, but not whether it is enlarging or leaking. Absent or "normal" aortic calcifications are of no value in ruling out the diagnosis. Therefore, plain films should not be ordered to evaluate the presence of an AAA or its complications.

Abdominal ultrasonography is useful in quickly and accurately establishing the presence of an aneurysm with almost 100% sensitivity.⁷ However, it is not reliable in determining whether rupture has occurred or in estimating the proximal and distal extent of the aneurysm. Its role in the ED lies in rapidly establishing the presence of AAA at the bedside when there is doubt.

Computed tomography provides greater detail than ultrasound and a more accurate measure of size. It is particularly useful in identifying leakage, rupture, or complications of AAA.³⁴ Because computed tomography takes more time and requires intravenous contrast and removal of the patient from the ED, it should be limited to stable patients in whom precise information is required. Magnetic resonance imaging also provides detailed images but is expensive, not widely available, and contraindicated in patients with pacemakers or metallic implants or clips; therefore, it currently offers no substantive advantage over ultrasound or computed tomography.⁷

Aortography is useful in selected cases in planning the operative repair of AAAs, but should not be used for diagnosis or to establish size. The decision to use angiography should be left to the surgical consultant, who may need information about renal or iliofemoral involvement, mesenteric artery stenosis, or suspected visceral lesions (e.g., horseshoe kidney).⁵

DISPOSITION

Patients who are truly asymptomatic should be referred promptly to a vascular surgeon for further evaluation for elective resection. Patients with a symptomatic AAA should be admitted for close observation. These patients will require prompt surgery if it becomes clear that the aneurysm is the source of their symptoms. Patients who present with rupture of their AAA obviously should go straight to the operating room.

Role of the Consultant

All patients with suspected symptomatic or ruptured AAAs should have a prompt surgical consultation, preferably with a vascular surgeon. Patients in whom the AAA is truly an incidental finding may be referred for later consultation if otherwise appropriate.

Indications for Admission

All patients with symptomatic AAAs should be admitted to the hospital for close observation and further investigation. One should assume that abdominal or back pain in the presence of AAA is due to sudden expansion or rupture.

Transfer Considerations

If the initial receiving hospital does not have sufficient surgical capability to treat an AAA, transfer to a more appropriate institution may be indicated. The decision to transfer may be a difficult one for patients who present with cardiovascular instability. The current hospital's capabilities, the length of time in transit, and the likelihood of survival to the second hospital must be considered.

COMMON PITFALLS

- AAAs are frequently misdiagnosed, especially in the obese; therefore, any palpable abdominal pulsation in an obese patient should be suspected of being an AAA, even if a mass cannot be clearly discerned. Back pain is a common symptom, and because peritoneal signs may not be present unless free rupture into

the abdominal cavity has occurred, the emergency physician may be misled to one of the common misdiagnoses of AAA, such as renal colic or lumbosacral disease. Because early recognition of AAA is most important to ensure maximum survival, it is a sound practice to perform a physical examination specifically aimed at ruling out an aneurysm in all patients over 50 who present with abdominal or back pain.

- A second pitfall is assuming that an aneurysm discovered on physical examination is incidental and not the source of the patient's symptoms. Any back or abdominal pain in the presence of a pulsatile abdominal mass should be considered to be due to an expanding or leaking aneurysm unless there is overwhelming evidence to the contrary.
- A third pitfall includes abbreviating an ED evaluation due to "gatekeeping" or managed care concerns. AAAs are not immediately obvious, and patients and physicians may have difficulty negotiating the preauthorization requirements of medical plans. These factors should not be allowed to prevent a thorough assessment of the older patient with back or abdominal pain.³⁵

Mesenteric ischemia is the failure of normal oxygenation of the small or large intestine due to interruption of vascular flow ([Fig. 53.1](#)). The consequences of this failure of oxygenation occupy a spectrum that ranges from intermittent, nonspecific intestinal symptoms to frank gut infarction with death of the patient.^{1,3,4,7,9,13,14,17,18,20,21,23,24,26} Unfortunately, despite increasing literature and medical familiarity with the lethal nature of the condition, mortality remains well over 50%, primarily attributable to delay in diagnosis.^{9,20,21} Mortality rates of less than 50% have been achieved with aggressive diagnostic and therapeutic approaches.^{13,14,26}

Figure 53.1. Vascular supply to the colon.

Acute mesenteric ischemia (AMI) is much more common than chronic mesenteric insufficiency. The vascular interruption in AMI can be divided into three categories: arterial occlusion, venous occlusion, and nonocclusive mesenteric ischemia (NOMI). Of the 70% to 80% of all AMI due to vascular occlusion, ³ embolus to the superior mesenteric artery (SMA) accounts for nearly half the cases, while SMA thrombosis accounts for a further 10%.¹⁴ Strangulated small or large bowel due to herniation, adhesions, or volvulus is another major cause of acute vascular occlusion.²⁰ An estimated 5% to 15% of AMI are due to venous thrombosis.^{4,23} While historically thought to be rare, NOMI is increasingly being recognized, especially in systemically and critically ill patients, with periods of markedly reduced blood flow.²¹ A chronic syndrome of inadequate mesenteric blood flow without complete vascular occlusion or bowel infarction, also termed *intestinal angina*, may uncommonly occur.^{14,20}

Once ischemia is established, the pathologic sequence is identical, regardless of the causative mechanism. Four major factors contribute to the extent and severity of ischemia: hypoxic injury, reperfusion injury, toxic luminal factors, and bacteria and toxins.²⁰ Hypoxia initially causes epithelial and submucosal damage, followed by full-thickness involvement and eventual loss of bowel integrity with continuing oxygenation failure. Should perfusion be restored in ischemic regions, generation of superoxides and free radicals could add further insult to already damaged tissues. Toxic luminal substances, such as hydrochloric acid and digestive enzymes, penetrate the edematous and porous intestinal mucosal barrier to cause further cellular damage. Bacterial invasion and toxin excretion lead to systemic sepsis.²⁰ Hypotension, due to blood and fluid losses and exacerbated by sepsis, leads to further compromise of vascular flow to the gut, and the process becomes self-propagating. In the most severe cases, AMI can lead to the development of multiorgan dysfunction syndrome (MODS).^{17,20}

All attempts to establish reliable diagnostic criteria for the condition have failed because the symptoms are nonspecific and the presentation is often unremarkable until the compromised gut (and often the patient) is not salvageable. In one series, over half of the patients who underwent laparotomy were immediately closed when the surgeon discovered the advanced state of the intraabdominal infarction.¹⁸

This disorder has a distinct epidemiologic preference for the elderly.^{1,17,18,20,21,24,26} Many patients have evidence of significant preexisting cardiac diseases, especially congestive heart failure.^{1,7,18,20,24,26} Postoperative and critically ill patients, and those exposed to vasospastic substances such as norepinephrine, cocaine, or digoxin, are at an increased risk of developing NOMI.^{13,17,20,21}

CLINICAL PRESENTATION

History

Presentation to the emergency department is highly variable. Unfortunately, the only symptom that is virtually universally present is abdominal pain, which may be localized or diffuse and may have either a colicky or constant character.^{1,3,7,13,18,20,26} Patients with NOMI may be free of pain in up to 25% of cases, but these patients will have recently experienced episodes of shock, cardiac arrest, cardiac dysrhythmia, or other hypotensive crises and so will usually present in an inpatient setting.¹⁴ Suddenness of onset is a useful, but not completely reliable symptom, because pain may develop over seconds, minutes, hours, or even days or weeks, depending on the underlying process.^{1,9,20} However, sudden onset of severe abdominal pain with minimal physical findings mandates consideration of AMI.^{9,14,20} Vomiting, diarrhea, or both will be reported or observed frequently, and sometimes vomitus or stool may be obviously bloody.^{3,13,14,20,26} Weight loss is invariably present in chronic mesenteric ischemia.²⁰ Nausea and anorexia, often long standing, will be reported in some cases.¹¹ A small number of patients will complain of abdominal fullness or distention.¹

Historically, the patient will usually have a combination of the following: advanced age, a history of significant cardiovascular disease, a history of thromboembolic events, and concurrent medication with digitalis and a diuretic.^{1,7,18,20,26} The patient may report episodes of vague abdominal fullness or discomfort after meals, and unexplained weight loss is often present, if sought.¹⁸ However, most patients will present with AMI without a preceding history of intermittent or chronic symptoms.

Physical Examination

The physical examination may be remarkably normal, especially in retrospect after the diagnosis is ultimately made. The patient may appear completely well apart from the presenting pain. Twenty percent to 40% will appear dehydrated, some to the point of frank circulatory shock.^{1,18} Fever and modest tachycardia are often, but

not invariably, present.^{1,7} Hematemesis or melena may occur. Abdominal examination is fully normal in only a very few cases. However, abnormalities, when noted, are often mild and belie the catastrophic nature of the disease. Signs of peritoneal irritation will be present to some degree in 30% to 50% of cases.^{1,7,18} Less urgent abdominal findings, such as increased or decreased bowel sounds, localized or diffuse tenderness, distention, bruit, or mass, will be present to some degree in virtually all cases. Most patients will have occult blood in the stool, especially later on in the course of the process.²⁰ In fact, occult blood loss in the stool may precede abdominal symptoms.¹⁴

Approximately 10% of patients will present in crisis, with catastrophic hemodynamic collapse, signs of severe systemic toxicity, altered mental status, and signs of frank peritonitis.¹ Although the need for operative intervention is immediately obvious in this type of presentation, the outcome is universally fatal.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of abdominal pain in the elderly is notoriously difficult (see [Chapter 36](#)). Symptoms are often vague or poorly represented. The patient may have other serious medical illness or dementia, which interferes with the history and examination. Physical examination is unreliable in the elderly and may be falsely reassuring.

Nevertheless, abdominal pain in a patient older than 50 years of age must be considered representative of an ominous process until thorough medical evaluation proves this not to be the case. The differential diagnosis is myriad and mirrors that of abdominal pain in any other age group with one exception: As the patient ages, the likelihood of vascular disease increases. This introduces the entire spectrum of vascular disorders to the differential diagnostic list: aneurysm, dissection, renal vascular disease, mesenteric vascular disease, myocardial infarction, and systemic embolization. Other considerations, such as diverticulitis, appendicitis, volvulus, obstruction, perforation, peptic ulcer disease, gallbladder disease, pancreatitis, splenic infarction, inflammatory disease, malignancy, gastrointestinal hemorrhage, and functional bowel disease, are discussed elsewhere in this text.

The principal diagnostic approach is the determination of whether a surgical condition is present and, if so, whether the situation is urgent. In mesenteric ischemia, although both of these criteria are universally present, they are rarely appreciated.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Patients older than 50 years of age presenting with abdominal pain undergo an appropriate and timely diagnostic workup to ensure that serious conditions, especially mesenteric ischemia, are not missed. Over 80% of patients presenting to emergency departments with mesenteric ischemia will be misdiagnosed or will undergo extensive and time-consuming evaluations, thus ensuring their mortality.^{4,11,22} Even when the condition is suspected, the patient may have a bad outcome. In one series, four patients diagnosed with intestinal angina at the time of admission were admitted to the hospital without aggressive diagnostic or therapeutic intervention.¹⁸ The value of an aggressive approach to the diagnosis and management of AMI is stressed in the literature.^{9,10,13,14,20}

Emergency department evaluation is dictated by the patient's condition. When the patient presents in hemodynamic or septic crisis, immediate therapeutic measures must precede definitive diagnosis. Patency of the upper airway must be ensured, and the ability of the patient to maintain the airway and to ventilate and oxygenate adequately must be assessed. High-flow oxygen, preferably by mask, should be administered. Examination of the airway and chest, supplemented by determination of arterial blood gases, will determine the need for immediate intubation. Two intravenous lines should be established and crystalloid solution administered to replenish intravascular volume. The degree of volume depletion should be determined and, although patients are elderly, crystalloid should be rapidly administered, because the hypovolemia is known to aggravate the mesenteric hypoperfusion. Rapid bedside determination of serum glucose level should be performed, with intravenous glucose administered as indicated. Blood samples should be obtained, and laboratory blood tests, including complete blood cell count, electrolytes, amylase, urea, creatinine, glucose, coagulation parameters, and crossmatch, should be ordered.

Additional studies may be indicated. Continuous electrocardiographic monitoring should be instituted and a 12-lead surface electrocardiogram obtained. The ultimate diagnosis in these cases may be obscured by the systemic nature of the presentation, and the prognosis is grim.

In patients with no hemodynamic compromise, the presentation most suggestive of ischemia is abdominal pain that is disproportionate to physical findings. Aggressive, early investigation of ischemia should be undertaken in these patients, especially if they are elderly and have risk factors for AMI and if there is not another satisfactory explanation for the pain. Delaying investigation of suspected AMI until more prominent abdominal findings are present will substantially increase mortality.^{9,20} In all cases, it is advisable to establish intravenous access, because the patient's condition may deteriorate rapidly, especially if the presenting problem is vascular. After a thorough history and physical examination, laboratory specimens should be obtained, as indicated earlier.

Laboratory Studies

Unfortunately, laboratory studies are so nonspecific they are of little help. Although it has been said that the principal use of the laboratory in mesenteric ischemia is to exclude other entities,²⁰ this is often not possible. In fact, misdiagnosis often follows erroneous interpretation of the laboratory results, such as when a modest elevation of the serum amylase value leads to an incorrect attribution of the patient's condition to acute pancreatitis. Nevertheless, laboratory studies should be performed and carefully interpreted.

The hemoglobin value is almost universally elevated due to hemoconcentration late in the course of the disease, but it may be normal earlier.¹ Leukocytosis is present in almost all cases and is often marked. Approximately 25% of patients will have white blood cell (WBC) counts of 10,000 to 15,000/ μ L, 50% will have WBC counts of 15,000 to 30,000/ μ L, and 25% will exceed 30,000/ μ L.^{1,7,20} Serum amylase determination will show a modest elevation, somewhere in the range from the upper limit of normal to twice normal, about half the time.^{1,7,20} Occasionally, profound elevations are seen. Metabolic acidosis is widely thought to be a universal companion of gut ischemia, presumably on the basis of the anaerobic metabolism initiated by the ischemic process. This belief is not supported by the literature, and one large series noted normal serum bicarbonate levels in all 60 patients in the study.¹ However, acidosis, if present, is a significant finding. Other laboratory findings, such as azotemia, hyperbilirubinemia, elevated enzyme and inorganic phosphate levels, and other, more exotic determinations are of no diagnostic value.^{9,20,24,26} In the end, none of these laboratory tests have been shown to be sensitive or specific in discriminating mesenteric ischemia from other intraabdominal pathologic processes.^{17,20,21}

Imaging

Plain radiography is likewise nonspecific. Abdominal gas may be absent, sparse, or normal or may demonstrate an ileus pattern.^{1,9,10,16,20} In the majority of cases, the films will be normal or not suggestive of any particular pathologic process.^{14,16,20} The finding of gas in the intestine wall or in the portal venous system invariably occurs only late in the process.²⁰ Thumbprinting of the intestinal mucosa, shown in relief against air or barium, is strongly suggestive but not specific.²⁰ The definitive test in the evaluation of a patient with suspected mesenteric ischemia is aortic and mesenteric biplanar angiography.^{1,2,9,10,20} In cases of vascular occlusion, this modality can accurately identify the location of vascular occlusion and scrutinize atherosclerotic changes in all vessels. Demonstration of characteristic mesenteric vasoconstriction in the absence of pancreatitis, shock, or vasopressor therapy is diagnostic of NOMI.¹⁴ Angiography also allows the selective infusion of vasodilating or thrombolytic agents directly into the affected vessels as a therapeutic maneuver.⁵

Computed tomography (CT) scanning is emerging as a reasonable and noninvasive alternative if clinical suspicion of mesenteric ischemia is low to moderate. Intraperitoneal free fluid, visualization of thrombus in splanchnic arteries or veins, and abnormal bowel wall characteristics such as wall thickening, pneumatosis, or streaky mesentery are highly suggestive findings.^{9,23} One series of 54 cases suggested that CT might be as sensitive as angiography in detecting mesenteric infarction.¹⁶ In addition, CT has some advantages over angiography in evaluating other possible causes of the abdominal process. CT with intravenous contrast can increase diagnostic accuracy in demonstrating venous thrombosis, nonenhancement of arteries, or signs of intestinal necrosis, including pneumatosis or portal vein gas.^{9,15,22} However, if mesenteric ischemia is strongly suspected, angiography should still be the first-line diagnostic procedure over CT with intravenous contrast.

Early experience with duplex ultrasound with Doppler signal analysis shows that it has promise as a screening tool for mesenteric ischemia.^{8,10,12,17,22} This modality demonstrates low-flow states by estimating splanchnic arterial and venous flow.^{8,12,17} However, its utility is limited, as there is a great variation in vascular flow between normal and affected subjects. Furthermore, duplex ultrasound cannot demonstrate anatomy to assist in surgical planning, and its image quality can be easily

affected by patient movement and bowel gases.^{9,16}

Magnetic resonance (MR)^{6,10} and MR angiography^{11,19} are potential imaging techniques for noninvasive screening of mesenteric ischemia. However, limited experience with this modality and its infrequency of emergent availability in most institutions limit the consideration of MR in the diagnosis and management of AMI at this time.

The advantages of using laparoscopy to diagnose mesenteric ischemia include bedside performance in unstable patients, direct visualization of bowel appearance, and serial performances or a second look in following patients' progress.²⁷ Its disadvantages include visualization of the serosal surface only and inability to detect mucosal ischemia, the induction of pneumoperitoneum that may further impair splanchnic blood flow, and inability to detect pulses of the bowel vasculature.²⁷ The concomitant use of pulse oximetry, measurement of intraluminal PCO₂, together with laparoscopy, may enhance diagnostic accuracy, as there is a strong association between gastrointestinal ischemia and an increased intraluminal PCO₂ in animal and human models.^{17,25}

Ultimately, only extreme vigilance will lead to the diagnosis. *Elderly patients who present with abdominal pain, especially those with risk factors for mesenteric ischemia, must undergo a rapid diagnostic sequence leading to a sound provisional diagnosis. The additional features of pain out of proportion to the physical examination, significant leukocytosis, clinical signs of dehydration or hemoconcentration, unexplained acidosis, or the other clinical features of mesenteric ischemia outlined earlier, mandate consideration of early angiography to confirm or exclude the diagnosis.* Proponents of aggressive therapy advocate angiographic studies with selective papaverine infusion for patients older than 50 years of age with risk factors for AMI who experience a sudden onset of abdominal pain that persists for more than 2 hours without establishment of an alternate diagnosis.^{9,14,20}

Early surgical consultation must be sought in cases of suspected mesenteric ischemia because delay may prove fatal. Many patients will have harbored their symptoms at home for a protracted period before presentation to a hospital, and time may be short. Waiting for "confirmation" of the diagnosis by development of significant metabolic acidosis, circulatory collapse, frank peritoneal signs, definitive findings on plain radiography, or other unambiguous events places the patient in profound jeopardy. If any reasonable doubt exists as to the diagnosis, and the patient is not in obvious need of immediate laparotomy, angiography should be obtained. Admission to hospital with a diagnosis of "rule out mesenteric ischemia" is not acceptable, and many of these patients have their diagnoses made only at autopsy, or at laparotomy when the disease has progressed to frank infarction.

DISPOSITION

Role of the Consultant

Mesenteric ischemia is a surgical disease. Temporizing measures, such as selective papaverine infusion during angiography, do not obviate the need for revascularization or resection,^{1,2} and ^{3,7,9,10,13,14,18,20,21,24,26} except in a small number of cases.^{5,9,14,20} Surgical and radiographic consultation should be sought early.

Indications for Admission

The decision to admit an elderly patient with undiagnosed abdominal pain should not be difficult. The list of serious causes of abdominal pain in the undiagnosed elderly patient significantly outweighs the list of trivial or benign conditions. In addition, elderly patients with "benign" conditions, such as biliary colic, often fare poorly and deteriorate precipitously. In patients with a clear diagnosis that is not believed to require hospitalization, close consultation with the patient's primary physician and early follow-up examination are mandatory. When the diagnosis is in doubt, or when the patient carries an established prior diagnosis such as "diverticulosis" but appears to be developing another acute process, admission and early surgical consultation are indicated.

Transfer Considerations

If facilities for vascular surgery or invasive radiography are not present in the institution of presentation, immediate general surgical consultation should be sought. The advisability of transfer of the patient versus laparotomy without preceding angiography depends on local circumstances and the patient's condition.

COMMON PITFALLS

- The most common pitfall in mesenteric ischemia is, ironically, failure to make the diagnosis while the patient is still living or salvageable. Extreme vigilance, appropriate interpretation of the diagnostic aids outlined previously, and institution of an aggressive diagnostic and therapeutic approach improve diagnostic accuracy and decrease morbidity. Admission of a patient with suspicion of mesenteric ischemia to a hospital mandates immediate surgical consultation and angiography. Without angiography, the condition will only become apparent when it is too late to save the patient.
- Perhaps the greatest pitfall is the reluctance to obtain angiography. Angiography carries a low risk of morbidity, which is even more appealing when balanced against a universally fatal condition. Early radiographic consultation and refusal to "wait until morning" are essential to a good outcome.
- From the medicolegal standpoint, it is of paramount importance to establish a sound diagnosis in all patients presenting with abdominal pain. Young patients without physical or laboratory suggestion of an acute surgical process can often be discharged with close and meticulous follow-up. This practice becomes less prudent in the elderly, and consultation and admission should be considered in any uncertain circumstances.

This chapter addresses specific disorders that constitute the larger group of problems known as *repetitive motion disorders*. Repetitive motion disorders are a group of musculo-tendinous maladies that are generally associated with workplace or occupational etiologies. Injuries due to repetitive motions are quite common and appear to be increasing in incidence. In 1980, these injuries were noted to comprise about 18% of all reported work-related injuries. In 1990, they were reported to make up approximately 48% of all work injuries. United States Bureau of Labor Statistics data in 1994 reported over 92,500 repetitive stress injury cases involving the upper extremity. These injuries were reported to be associated with over 37,000 days of work lost. The economic impact of these injuries is enormous and represents one of the most pressing problems in occupational health and safety today.

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome (CTS) is a commonly occurring entrapment neuropathy involving the median nerve at the wrist and represents the most common of all peripheral compression neuropathies.¹⁰

At the level of the wrist, the median nerve exists in an anatomic tunnel or canal that is formed dorsally by the carpal bones and volarly by the fibrous, but rigid, transverse carpal ligament (Fig. 54-1). The flexor tendons and their accompanying sheaths also lie within this anatomic tunnel. The tunnel begins approximately at the level of the volar wrist crease and extends distally approximately three centimeters. Despite the fact that the carpal tunnel is open at both of its ends, the canal maintains the essential physiologic properties of a closed compartment. When intracanal interstitial pressure becomes elevated above a critical threshold, capillary blood flow rates are reduced below that which is essential for the maintenance of median nerve viability and function. Any condition that tends to decrease the internal area of the canal or increase the volume of the anatomical contents of the canal could theoretically induce carpal tunnel syndrome by resulting in impingement of the median nerve.

Figure 54.1. View of the carpal tunnel. The median nerve and flexor tendons, which are in the tunnel, lie below the transverse carpal ligament that forms the roof of the tunnel.

Numerous specific clinical conditions have been causally associated with the development of the carpal tunnel syndrome. However, it is important to remember that the idiopathic variety is probably the most common. Some authors have suggested that persons who happen to have an anatomically small canal (on a genetic basis) are more likely to develop this syndrome.⁷ In addition, rheumatoid arthritis, diabetes, myxedema, and pregnancy are noted to be frequent causes of carpal tunnel syndrome. Acute fracture of the distal radius as well as fracture and dislocation of the carpus can result in carpal tunnel syndrome by either direct trauma to or compression of the median nerve secondary to bleeding. Infections involving bacterial, viral, or fungal etiologies can cause synovitis, which may result in local nerve compression with the ultimate development of CTS. Any space-occupying lesion such as tumors, as well as osteophytes resulting from malunited fractures or degenerative joint disease, can result in the development of median nerve compression with CTS symptoms.

The 1994 Bureau of Labor Statistics data indicate that about 9% of cases are associated with typing and key entry jobs, 6% with repetitive use of tools, and 12% with repetitive grasping motions. Carpal tunnel syndrome occurs more frequently in women in a ratio of greater than 2:1. Females account for over 78% of all cases. CTS is noted to be a condition of middle age and is typically seen most often in the age range of 40 to 60 with the mean age at diagnosis reported to be 50 for men and 51 for women.

CLINICAL PRESENTATION

The classically recognized clinical presentation of CTS involves paresthesias and pain at the radial aspect of the palm of the hand, frequently increased at night. The modern view of the etiology of this syndrome involves forceful, repeated hand motion associated with work. CTS is often a bilateral condition with the patient typically complaining of numbness, tingling, burning, or paresthesias in the hand along the distribution of the median nerve (the thumb, index, middle, and radial aspect of the ring fingers). These symptoms characteristically awaken the patient from sleep and may be relieved by shaking the hand and wrist. A nocturnal pain pattern is often the hallmark of CTS and as the syndrome progresses, the occurrence of symptoms may be seen to increase. The symptoms are often exacerbated by activities that maintain the wrist flexed, such as driving, holding a book, and by use of the hand such as with knitting, sewing, and hammering. Patients may also complain of weakness or clumsiness in the hand manifested by difficulty with fine motor functions such as picking up objects, holding things, and buttoning clothing.

Physical examination may reveal decreased sensation to light touch or decreased two-point discrimination in the median nerve distribution. Phalen's wrist-flexion test and Tinel's sign are frequently noted to be positive with carpal tunnel syndrome.^{9,11} Phalen's test is considered to be positive if holding the wrist in complete, but unforced, flexion for 30 to 60 seconds reproduces or exaggerates the numbness and paresthesias in the median nerve distribution. Tinel's sign is positive if light tapping over the median nerve at the wrist causes a tingling sensation distally along the median nerve.

Phalen's test is believed to be more useful in the diagnosis of carpal tunnel syndrome.¹¹ In more advanced cases there may be weakness of the median-innervated thenar muscles, the abductor pollicis brevis, and the opponens. Thenar atrophy is best seen as a guttering appearance along the radial aspect of the thenar eminence that exposes the first metacarpal. In cases of carpal tunnel syndrome caused by an inflammatory synovitis (rheumatoid arthritis), there may be swelling along the volar aspect of the wrist.

Recent attempts to develop consensus criteria for the diagnosis and classification of CTS have been described. The first principle elucidated by these attempts is that no "gold standard" currently exists for the diagnosis of CTS. Rather, a combination of electrodiagnostic study results in conjunction with symptomatology will be expected to provide the most accurate diagnostic information. The use of electrodiagnostics alone is not considered sufficient to make the definitive diagnosis of CTS.

DIFFERENTIAL DIAGNOSIS

The clinical manifestations of carpal tunnel syndrome are most often characteristic and consequently there is seldom confusion with other entities. Occasionally, the clinical presentation may be unusual and consideration may need to be given to other entities that share characteristics with carpal tunnel syndrome.

Cervical root irritation, especially at the C6 and C7 levels, secondary to either a herniated cervical disc or osteoarthritis with encroachment on the neural foramina, may produce numbness in the median-innervated fingers, with pain radiating to the shoulder. However, cervical root pathology usually causes radicular symptoms that are seldom bilateral and that are worse at night.

Compression of the median nerve in the proximal forearm (pronator syndrome) may also present with numbness in the radial three and one-half digits and weak thenar muscles. However, in this case, Phalen's test would be expected to be negative and Tinel's sign would be positive in the forearm rather than at the wrist. In this case, nocturnal awakening is unlikely, and there would be pain in the volar forearm both subjectively and with palpation.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of carpal tunnel syndrome is usually made by a careful history and physical examination. Radiographs of the wrist, including a carpal tunnel view, may show structural abnormalities such as callus, osteophytes, and calcific deposits. Cervical spine films may be useful if clinical symptoms suggest the presence of a cervical radiculopathy. Thyroid function tests, fasting blood sugar, erythrocyte sedimentation rate, rheumatoid factor, antinuclear antibodies, determination of serum calcium and uric acid levels, and a white blood cell count with differential may all be useful when clinically indicated.

EMERGENCY DEPARTMENT MANAGEMENT

The initial treatment for the majority of patients involves conservative care. Wrist splints in neutral or slight extension can be worn when symptoms arise, especially at night. The patient should be told to avoid any upper extremity activities that obviously aggravate the symptoms. When underlying medical conditions are suspected (e.g., hypothyroidism, rheumatoid arthritis, gout) appropriate referral to either orthopedic or plastic surgeons with special expertise in treating CTS is required. Diuretics may be useful if carpal tunnel syndrome is associated with pregnancy but should be given only in consultation with the patient's obstetrician.

EMERGENCY DEPARTMENT DISPOSITION

All patients presenting in the emergency department with symptoms of carpal tunnel syndrome should be referred to appropriate specialists for further evaluation and treatment. Outpatient electromyographic and nerve conduction studies are useful when trying to differentiate carpal tunnel syndrome from other causes of similar symptoms or when objective signs of carpal tunnel syndrome are absent but the history and subjective symptoms are compatible with carpal tunnel syndrome. These studies are not generally ordered from the emergency department but would be reserved for the consultant.

The injection of corticosteroids into the carpal canal can result in substantial symptomatic improvement, sometimes even complete relief. However, following steroid injection, the symptoms will often recur.⁸ Surgical decompression of the carpal canal is the treatment of choice for those patients who fail conservative care. Indications for operation include muscle weakness, thenar atrophy, and no response to or recurrence after conservative treatment. Surgery involves what is known as carpal tunnel release (CTR), consisting of the division of the transverse carpal ligament. This surgery generally affords good results. However, recurrence of symptoms is seen in up to 20% of patients with as many as 12% requiring reoperation. More recently, endoscopic surgical release procedures have been successful.

GUYON'S CANAL (ULNAR TUNNEL) SYNDROME

The ulnar nerve, originating from both C8 and T1 nerve roots, is formed from the medial cord of the brachial plexus. Following an anatomically tortuous course through the upper extremity, the nerve is susceptible to compressive forces at multiple locations along its course. At the elbow, the ulnar nerve travels through the cubital tunnel, which is the most common site for ulnar nerve compression. Neuropathy secondary to cubital tunnel pathology must be ruled out before a diagnosis is made of ulnar nerve compression at the wrist.

The ulnar nerve, primarily a motor and sensory nerve for the hand, does not give off important branches in the proximal upper extremity. On its entrance into the hand, the ulnar nerve provides the primary motor innervation to the intrinsic muscles therein.

The ulnar nerve innervates the abductor and opponens digiti minimi and flexor digiti minimi brevis (the hypothenar muscles); the lumbrical muscles of the fourth and fifth fingers, all of the interossei, the adductor pollicis, the medial head, and, occasionally, the lateral head of the flexor pollicis brevis are also innervated by the ulnar nerve. The ulnar nerve also supplies sensation for a significant part of the hand, which includes the palmaris brevis and the skin over the hypothenar eminence. The

superficial branch of the nerve continues and divides into the common palmar digital nerves, which divide distally to form the proper digital nerves to the ulnar side of the fifth finger and the adjacent sides of the fifth and fourth fingers.

Together with the ulnar artery, the ulnar nerve passes into the wrist on the radial side of the pisiform bone via an anatomic space first described in 1861.⁶ This space, the loge or canal of Guyon, is a 4-cm-long channel located between the pisiform carpal bone and the hook of the hamate.⁷ The anatomy of this small space is complex.

Within the loge of Guyon, the ulnar nerve bifurcates into deep (motor) and superficial (sensory) branches. In 1969, Shea and McClain divided the canal of Guyon into three anatomic zones based on the landmarks of bifurcation.³ Zone I represents that part of the canal that contains the ulnar nerve prior to its division into its component motor and sensory branches. Zone II is that part of the tunnel encompassing the deep motor branch distal to the bifurcation of the nerve. The sensory branch of the ulnar nerve travels through zone III of the loge of Guyon.⁶ These anatomic divisions allow a more precise localization of lesions within the wrist. Lesions at the wrist, whether mass lesions, anatomic abnormalities, traumatic injuries, or ulnar artery disorders, may produce a predictable set of complaints and physical findings, depending on the level of impingement within Guyon's canal.

CLINICAL PRESENTATION

Patients exhibiting ulnar nerve compression at the level of the wrist typically present complaining of wrist pain that radiates into the ulnar two digits.⁶ Patients should be asked about a history of previous falls onto an outstretched hand, which may have resulted in an occult hamate fracture. A fracture here may impinge on the nerve as it passes through zone I or zone II (or both) of Guyon's canal. Fractures of the hook of the hamate have been reported to account for 14% of all cases of ulnar nerve compression in the wrist.³

Patients should also be asked about repetitive trauma in both vocational and avocational settings. Repeated blows to the ulnar side of the hand and use of pneumatic tools have been implicated as potential causes of ulnar neuropathy at the wrist. Holding the wrist in forced hyperextension during such activities as bicycling may also predispose to this condition.³ Interestingly, each of these activities has been mentioned as a cause for other painful wrist syndromes, which are discussed elsewhere in this chapter.

Physical examination of a patient complaining of a painful wrist and hand begins at the neck.^{5,6} Painful or limited range of motion may suggest the presence of cervical disc disease. This should be followed by axial compression of the cervical spine, which may elicit radiculopathic pain from a compressed nerve root.

The elbow must be examined for evidence of swelling or deformity, inflammation, or masses. The ulnar nerve should be carefully palpated and percussed to assess for the presence of increased irritability. Identification of a focal site of irritation must then be compared with the opposite extremity; nearly one-fourth of normal subjects exhibited a positive Tinel's sign on percussion of the ulnar nerve.⁵

A careful assessment of the wrist and hand can help identify the level and, possibly, the exact location of an ulnar neuropathy.⁶ Examination of the wrist and hands has five main components: localization of point tenderness, examination of the vascular supply, provocative testing of the nerve supply, and sensory and motor testing.³

Fractures of the hook of the hamate are a frequent cause of ulnar neuropathy at the loge of Guyon. They are the most common reason for symptoms from zones I and II when there is a history of trauma. Eliciting tenderness with careful palpation may indicate an occult new fracture or a poorly healed old fracture.

A determination of the patency of the ulnar artery is the second part of a focused examination of the wrist and hand. An Allen test performed on both hands will help the clinician to ascertain ulnar artery contribution to hand perfusion. The artery should also be palpated for the presence of tenderness, aneurysmal dilatation, and thrills. Arterial thrombosis or aneurysms can cause localized pressure on the ulnar nerve within Guyon's canal. Ulnar artery thrombosis has been reported as the most common cause of isolated sensory symptoms from ulnar nerve compression.³

Provocative testing of the ulnar nerve supply to the hand is accomplished by performing both the Tinel and Phalen tests. Percussion of the ulnar nerve at the level of Guyon's canal may elicit paresthesias to the fifth digit and the ulnar half of the fourth digit. Similarly, paresthesias in the distribution just described may result from having the patient allow his or her wrists to fall into complete volar flexion. This is considered a positive Phalen's sign.¹

The sensory and motor examination of the hand should focus on identification, where possible, of the level of the ulnar nerve lesion. For example, impaired sensation to the ulnar dorsum of the hand (both light touch and two-point discrimination) is suggestive of an ulnar nerve lesion proximal to the wrist. Weakness to the FDP muscles of the fourth and fifth digits is similarly suggestive of more proximal compression.

Nerve compression within zone I of Guyon's canal will usually present with mixed motor and sensory findings.^{3,6} Patients will exhibit weakness of the ulnar-innervated muscles in the hand, and will manifest sensory deficits to the palmar surface of the hypothenar eminence and to the ulnar two digits of the hand.

Zone II compression of the ulnar nerve results in motor branch paresis of the ulnar nerve. Wasting of the intrinsic muscles of the hand in the first dorsal interosseous space is evidence of chronic motor branch neuropathy. Further evidence of motor branch weakness can be elicited by asking the patient to extend his or her fingers. A distal ulnar neuropathy will result in a severe claw hand deformity.⁶ The long flexor muscles flex the distal interphalangeal and proximal interphalangeal joints of the fourth and fifth digits. The long extensor muscles hyperextend the metacarpophalangeal joints of the same digits. The loss of intrinsic muscle function to the hand, however, results in an inability to maintain extension of the digits at the distal interphalangeal and proximal interphalangeal joints.¹

Wartenberg's sign, an inability to abduct the fifth finger while holding the digits of the hand in extension, may be present with ulnar motor weakness. This is less likely to be present, however, with an isolated zone II injury, because the motor branch to the abductor digiti minimi exits prior to this portion of the canal. Interosseous muscle function can be evaluated by asking the patient to cross the index and middle fingers. This test is known as the Scott Earle test. Froment's sign is present when the adductor pollicis muscle, innervated by the ulnar nerve, is weak. This sign is elicited by having the patient tightly hold a piece of paper between the thumb and the radial side of the index finger. The examiner then attempts to pull the paper from the patient. Flexion at the thumb interphalangeal joint (indicating weakness of the adductor pollicis muscle) results in a positive Froment sign. Comparison with the patient's other hand should be performed.^{1,5}

Injuries or compression of the ulnar nerve in zone III of Guyon's canal involves the superficial sensory branch of the nerve. Of the three zones of the canal, this is the least likely to exhibit pathology.⁶

DIFFERENTIAL DIAGNOSIS

Lesions at any location along the length of the ulnar nerve or the nerve roots from which it arises may be responsible for symptoms of wrist or hand pain. More proximal lesions, such as cervical disc disease affecting the C8 or T1 nerve roots, must be considered. (Evaluation of the cervical spine has already been described). Identification of painful and/or limited cervical motion merits further study to rule in or rule out a lesion at this level as the cause for a patient's symptoms.

Brachial plexus pathology may also be responsible for symptoms in the distribution of the ulnar nerve. Pancoast's tumor, an apical tumor of the lung, can exert pressure on or grow into the brachial plexus, resulting in symptoms distant from the primary site.⁵ A careful examination would, therefore, include palpation of the supraclavicular region of the affected extremity for mass lesions. And, if clinical suspicion warrants, a posteroanterior (PA) and lateral radiograph of the chest should be ordered.

Thoracic outlet syndrome may also result in a brachial plexopathy. The diagnosis of this entity may be made by provocative testing. One such maneuver is the so-called hands-up test, in which the patient is asked to make a fist and then abduct the shoulder to 90 degrees and externally rotate the upper extremity. In the presence of thoracic outlet syndrome, this activity can trigger and reproduce the patient's symptoms.⁷

Distal median nerve function and the presence of an associated carpal tunnel syndrome must be excluded when examining a patient with complaints in the distribution

of the ulnar nerve.

Whereas the most common cause for ulnar nerve compression lies at the cubital tunnel of the elbow, within the wrist itself it is the presence of a ganglion that accounts for the majority of atraumatic ulnar neuropathy.^{4,6} Bednar³ reported that, in the absence of trauma, 86% of patients presenting with a combined motor and sensory finding had a ganglion compressing the nerve. Anomalous muscle bellies and other anatomic variants, including lipomas, giant cell tumors, schwannomas, thickened ligaments, bipartite hamuli, and pisiform-hamate coalitions constitute another large class of entities responsible for ulnar nerve compression at the wrist.³ It is unlikely, however, that a precise diagnosis of one of the aforementioned causes would be made in the emergency department.

Hamate fractures, ulnar artery thrombosis, repetitive trauma neuropathies (hypothenar hammer syndrome), and rheumatoid tenosynovitis are other potential causes of ulnar nerve compression. The presence of other joints affected by rheumatoid arthritis may help identify this disease as a potential cause of ulnar nerve compression at the wrist.³

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of ulnar nerve compression at the wrist is usually made with a history and physical examination. Radiographs of the wrist may prove valuable for identifying the presence of a hamate fracture or malunion. A history of trauma, recent or remote, coupled with bony point tenderness should raise the clinician's index of suspicion. Special views of the wrist or tomograms may provide additional confirmatory evidence if initial plain films do not reveal a fracture.

Complaints referable to the elbow or to the cervical spine also merit obtaining radiographs of each of these structures. Similarly a PA and lateral chest radiograph should be obtained if one is at all concerned about the possibility of an intrathoracic mass lesion causing a brachial plexus neuropathy. It is unlikely that additional laboratory studies, in the absence of supporting clinical signs or symptoms, will provide useful information in the diagnosis of this entity.

EMERGENCY DEPARTMENT MANAGEMENT

The treatment of ulnar nerve compression at the wrist may be initiated in the emergency department. As with other compressive neuropathy syndromes, in the absence of an identifiable cause, a trial period of 1 to 3 months of nonoperative intervention is recommended.³ The application of a wrist splint, avoidance of activities that aggravate symptoms, and use of nonsteroidal antiinflammatories have been advocated.⁶ Depending on the underlying cause of the neuropathy, symptoms may or may not resolve during this time. Referral for an outpatient workup by a hand surgeon is also the responsibility of the emergency department physician, and should be arranged prior to the patient's departure. For those patients who present with an identifiable cause for their symptoms, a more urgent follow-up is indicated.

DISPOSITION

Outpatient workup of ulnar nerve compression falls under the purview of the hand surgeon, who may obtain electromyographic and nerve conduction studies.⁶ These studies are valuable in establishing a diagnosis. Inasmuch as the majority of causes of ulnar nerve compression neuropathy at the wrist are due to anatomic pathology, treatment for this condition is usually surgical.²

COMMON PITFALLS

- Perform a thorough physical examination on both upper extremities, as some abnormal findings may be physiologic and not pathologic. Comparing one side to the other is also a good technique to identify subtle pathology.
- Examine the entire course of the ulnar nerve from its origin at the nerve roots of the cervical spine to its distal end point in the digits of the hand. Ulnar neuropathy may be due to compressive forces at one or more locations along the length of the nerve.
- Consider anomalous innervations of the hand and perform a thorough evaluation of both ulnar and median nerve function to identify potential pathology.
- Remember that the most common cause of compressive ulnar neuropathy at the wrist is atraumatic anatomic pathology, which is probably most amenable to surgical repair. The most common traumatic cause of ulnar nerve compression at the wrist is fractures of the hook of the hamate.
- Examination of the painful wrist and hand involves five main components: localization of point tenderness, examination of the vascular supply, provocative testing of the nerve supply, and sensory and motor testing.

THE HYPOTHENAR HAMMER SYNDROME

In 1934, a classic report provided the basis for the definition of the hypothenar hammer syndrome (HHS): evidence of distal ulnar artery injury following a history of trauma to the palm.³ The distal ulnar artery lies most exposed to potential trauma at the base of the hypothenar eminence, just distal to the volar carpal ligament. At this location, the artery is no longer protected within Guyon's canal and is covered only by skin, subcutaneous fat, and (in 85% of the population) the palmaris brevis muscle.³ Given its susceptible position, the ulnar artery is easily compressed between hard objects and the hook of the hamate.^{4,5} This can occur any time that the hypothenar aspect of the base of the palm is subjected to trauma.

HHS is most commonly seen in those individuals who use the palms of their hands to push, pound, or hammer as part of their daily work activities.^{4,6} Metal workers, automobile mechanics, lathe operators, and machinists are all at risk. The prevalence of HHS among carpenters has been reported to be as high as 14%.⁵ This syndrome has also been found in workers who regularly use high-speed hand-held vibratory tools,⁴ such as air hammers, drills, chain saws, sanders, and impact wrenches. HHS is not, however, limited specifically to this population.

Injuries to the distal ulnar artery, not unlike those caused by industrial occupational trauma, have also been seen in athletes. Baseball catchers, racquet handlers (tennis, badminton, etc.), and martial artists have all been reported as having an increased risk for developing HHS.³ The increasing popularity of mountain biking has led to the discovery that these athletes are also prone to developing injuries of the ulnar artery. [Table 54.1](#) lists a variety of sports that have also been implicated as potential causes HHS.

Baseball	Softball
Badminton	Karate
Handball	Weight lifting
Football	Hockey
Frisbee	Mountain biking

TABLE 54.1. Sports Reported to Cause HHS⁶

Repetitive ulnar artery injury, whether from work or sport, can result in traumatic vasospasm, thrombosis, or aneurysm formation.^{4,5 and 6} Various combinations of these lesions are also possible and can complicate both diagnosis and management. Prolonged distal ulnar or digital arterial vasospasm can occlude affected blood vessels. If the source of irritation is eliminated, however, vasospasm and occlusion are reversible phenomena and a normal arterial supply may be restored.⁴

More severe trauma to the ulnar artery can damage the internal elastic lamella, leading to formation of intraarterial thrombi.³ Embolization of traumatized intima and thrombus cause digital ischemia by occluding the end arterial supply to the fingers.^{4,6} Ischemia may also occur as a result of reflex vasospasm. Thrombosis involving the adventitia may affect periarterial sympathetic fibers, resulting in vasospasm that limits surrounding collateral circulation.⁶

True palmar aneurysms may develop if the media of the arterial wall is damaged primarily.⁴

CLINICAL PRESENTATION

HHS is a treatable cause of digital ischemia that should be considered in the differential diagnosis of patients presenting with complaints of symptomatic digital ischemia.⁵ As described earlier, the patient is classically a male laborer with a history of blunt trauma to his dominant hand.^{4,5} Clinical findings in HHS include a male predominance, unilateral hand involvement, and acute onset of pain, followed by the more gradual development of a severe Raynaud's phenomenon (i.e., increased sensitivity of the digits to exposure to cold).³ In a patient exhibiting Raynaud's phenomenon, coldness in the fingers of the dominant hand without a history of triphasic color changes and a lack of thumb involvement is highly suggestive of a diagnosis of HHS.⁵

The most typical occupational history of a patient with HHS includes frequent, repetitive, but comparatively minor hypothenar trauma. The daily trauma may be so much a part of the patient's regular activities that it goes unrecognized or is otherwise ignored. Careful inquiry about work and recreation is mandatory.⁵

At presentation, a patient may complain of one or more episodes of acute, lancinating pain over the hypothenar eminence that occur after striking a blow with the palm of the hand.⁴ This pain typically radiates into the fourth and fifth fingers, and a dull, aching hypothenar pain may then ensue. Other patients describe an immediate pain episode that resolves completely over time. Then, days to weeks to months afterward, ischemic finger symptoms develop as a consequence of a slowly progressing thrombosis of the ulnar artery.⁶

Physical findings in HHS are largely localized to the hypothenar eminence and the digits of the affected hand. Prominent calluses over the hypothenar eminence provide a clue about recurrent trauma to this area.⁵ Moreover, tenderness to palpation over the hypothenar area may indicate the presence of an ulnar artery aneurysm. Further examination may reveal the fingers or fingertips to be cold, pale, mottled, atrophic, or ulcerated.^{4,5} The Allen test should be performed as part of the physical examination. A positive test suggests that either the superficial volar arch is incompletely developed or, as in the case of HHS, that the distal ulnar artery is occluded or stenotic.⁴

DIFFERENTIAL DIAGNOSIS

Many conditions are known to cause ischemia of the upper extremity. Collagen vascular diseases and various vasculitides and coagulopathies may each result in poor perfusion of the hand and fingers.⁴ These disorders, however, tend to be systemic and have more generalized findings than does HHS.

Buerger disease (thromboangiitis obliterans), like HHS, affects primarily young males. Raynaud's phenomenon and hand or digital pain are historic features shared by these two conditions. The upper extremity examination of a patient with Buerger disease may be indistinguishable from someone with HHS, including an absent or diminished ulnar pulse.

Two elements may be helpful in differentiating one condition from the other. Buerger disease is found almost exclusively in cigarette smokers. Conversely, tobacco use is not a prerequisite for the development of HHS. Buerger disease is often a systemic condition involving not only the upper extremities, but also the lower ones. HHS is confined to the upper extremity only and is most often unilateral in its presentation. In the absence of clarifying historic or physical features, referral for arteriography or, potentially, arterial biopsy may be required to confirm or rule out the diagnosis of Buerger disease.

High-speed hand-held vibratory tools are known to cause both HHS and the hand–arm vibration syndrome (HAVS). Whereas both of these conditions can result in Raynaud's phenomenon of the digits of the dominant hand, the underlying pathology is different. HHS is caused by ulnar artery injury and may be differentiated from HAVS by a careful history and vascular examination at the patient's wrist.⁵

EMERGENCY DEPARTMENT EVALUATION

The emergency physician must not forget to obtain both a vocational and an avocational history from a patient presenting with complaints of hand and wrist pain. While the history will often lead the clinician to the proper diagnosis, a thoughtful and deliberate physical examination is also necessary. Performing and documenting the results of the Allen test is an important part of the physical examination. The modified Allen test is performed with the patient in a seated position. The hands, palms facing up, should be resting on the knees. The clinician then compresses the radial artery with one thumb and the ulnar artery with the other thumb, thereby externally occluding the arterial supply to the hand. The patient next rapidly clenches and opens the first several times to exsanguinate the palm. If there is pathology in the ulnar artery, the palm will remain pallid after the clinician releases his or her thumb from that vessel. Blood supply will return to the palm only after the pressure on the radial artery is removed. A pencil Doppler instrument may be used in conjunction with the Allen test to confirm the patency of the arterial blood supply to the hand.^{1,5} This examination should be performed at both wrists.

EMERGENCY DEPARTMENT MANAGEMENT

Most patients with HHS will respond to proper therapy when promptly initiated. The emergency physician should therefore begin treatment after making the diagnosis of this condition. At a minimum, local wound care of necrotic or ulcerated digits can take place in the emergency department. Additional conservative measures that may be offered include counseling on the avoidance of cold environments and cessation of smoking,⁵ because both will exacerbate HHS. Patients should be encouraged to wear mittens or gloves to help keep their hands and fingers warm and protected.

Aspirin and a calcium channel blocker (diltiazem or nifedipine) may be prescribed and are considered appropriate initial therapeutic agents.³ With proper therapeutic intervention, the prognosis for HHS is good, and surgery is generally not indicated. Patients need to understand, however, that response to therapy is predicated on the elimination of the underlying trauma source. In some instances, this may require a change of occupation.⁵

DISPOSITION

Referral to a hand surgeon for angiographic studies and ongoing management is proper and necessary. Arteriography can reveal ulnar artery irregularity or aneurysms. Occlusion of the ulnar artery segment overlying the hook of the hamate is considered pathognomonic of HHS.⁵ Multiple digital artery occlusions, secondary to embolization, may also be seen.

Conservative, nonsurgical modalities are favored for the treatment of HHS, except in the case of ulnar artery aneurysm. In this instance, resection of the aneurysm is performed in order to avoid or prevent further digital embolization.³ Surgical repair is still the preferred method of treatment for this condition.⁷

COMMON PITFALLS

- Manual laborers presenting with pain to the dominant hand need a careful historic review of their daily occupational activities in order to establish a history of regular hypothenar trauma. Identification of calluses over the hypothenar eminence can provide a clue to this history.
- Recall that some athletes and even people who use canes or walkers are susceptible to ulnar artery trauma.
- Buerger disease is an important part of the differential diagnosis of HHS and must be ruled out. Angiography or arterial biopsy may be required to make the diagnosis. An important clinical clue is that Buerger disease tends to be a systemic condition and will involve both upper extremities.
- An occluded ulnar arterial supply to the hand (given the proper clinical history) is very highly suggestive of the diagnosis of HHS.
- HHS is a treatable condition, provided that the source of trauma is eliminated. The emergency department physician must introduce and then reinforce this concept once the diagnosis of HHS is made.

DE QUERVAIN'S TENOSYNOVITIS/DE QUERVAIN SYNDROME

De Quervain's tenosynovitis, a not infrequent cause of wrist pain, is the most common tendinitis of the extensor tendons of the hand and wrist.² De Quervain syndrome is a nonsuppurative tenosynovitis of the first dorsal compartment of the wrist.^{6,7,8} and⁹ The first dorsal compartment, like the other dorsal compartments of the wrist, is a "tunnel" through which the tendons of the hand's extrinsic extensor muscles pass.

The first dorsal compartment of the wrist overlies the styloid process of the radius. This compartment contains the tendons of the abductor pollicis longus (APL) and the extensor pollicis brevis (EPB).⁷ The APL tendon inserts at the base of the dorsum of the thumb's metacarpal, and the EPB tendon inserts at the base of the thumb's proximal phalanx. At the level of the wrist, these tendons and their synovial sheaths lie sandwiched between the carpal bones and a fibrous band called the dorsal (extensor) retinaculum.

Typically the extrinsic tendons of the wrist glide easily through the fibroosseous canals defined by the carpal bones on one side and the extensor retinaculum on the other. The APL and EPB work in tandem to hold the thumb in abduction.⁷ De Quervain syndrome represents a derangement in the normal gliding of the APL and/or the EPB tendons and, therefore, an impairment in thumb abduction.

Several hypotheses exist as to the underlying cause of de Quervain's tenosynovitis. Authors suggest that de Quervain syndrome is due to a myxoid degeneration of the tendon sheaths of the first dorsal compartment.³

Chronic inflammation resulting from overuse is another postulated cause of this syndrome. According to this theory, overuse of sheathed tendons leads to a failure of inherent lubrication mechanisms.⁴ Over time, friction between tendons and their synovial sheaths causes inflammatory changes in these structures. The tendon hypertrophies and the intrinsic diameter of the sheath narrows in response to inflammation. This further impedes the smooth gliding of the tendon through its synovial sheath.

A third theory explaining the pathophysiology of de Quervain's tenosynovitis identifies the condition to be the result of thickening of the extensor retinaculum overlying the first dorsal compartment.⁷

Despite various pathophysiologic theories, nearly all authors agree as to the etiology of de Quervain syndrome. Persistent repetition of specific tasks beyond the point of fatigue is commonly implicated.⁷ These tasks frequently involve repeated pronation and supination of the forearm combined with forceful exertion of the thumb.

Other reported activities that can lead to a tenosynovitis of the first dorsal compartment include performing tasks that may be new or unfamiliar to the patient. Many patients begin to have symptoms within days of starting a new job or resuming an old one after a holiday.^{5,7} Table 54.2 lists jobs and activities previously reported to result in de Quervain's syndrome. Minor blunt trauma and rheumatoid arthritis have also been identified as possible causes of de Quervain syndrome.

Working at a typewriter or adding machine
Excessive writing
Washing or wringing clothes
Chopping wood
Cutting cloth with heavy scissors
Sewing, knitting, weaving
Working on a grinder or buffing machine
Fitting rubber rings over a pipe
Operating machine keyboards, sewing machines, lathes, drills, presses, grinders, and switchboards
Prolonged piano playing
Playing a reed instrument and supporting its weight on the right thumb

TABLE 54.2. Vocational and Avocational Causes of de Quervain's Tenosynovitis⁷

CLINICAL PRESENTATION

Pain at the radial styloid is a classic and defining symptom of de Quervain's tenosynovitis. Although the pain is more or less constant, it is exacerbated by thumb abduction, ulnar deviation of the wrist, and simple grasping. Holding the thumb at rest, in contrast, may offer only minimal relief. Previous trials of nonsteroidal antiinflammatory drugs or acetaminophen use tend to provide little, if any, symptomatic relief.

The pain, usually described by patients as severe in quality, has also been reported as a "stiffness."⁷ In more advanced cases, patients may also note swelling and crepitus at the site of maximal pain. Pain can radiate proximally into the forearm or distally to the thumb. Occasionally, the pain may be so intense that sleep is disturbed. Other patients may complain of weakness or an inability to use the affected hand due to debilitating pain.

Another hallmark of de Quervain syndrome is a history of gradual onset of pain in the absence of fracture or acute trauma.⁷ De Quervain syndrome typically affects women more than men (approximately 10 to 1) between the ages of 35 and 55.

Examination of the patient with de Quervain's tenosynovitis begins with a careful inspection of the forearm and wrist. Mild cases may exhibit only subtle, localized swelling at the radial styloid.^{6,7} A more extensive fusiform swelling and, possibly, erythema can characterize more severe cases.

Palpation of the first dorsal compartment should be approached gently. Tenderness or crepitus at the radial styloid is highly suggestive of de Quervain syndrome.⁸ A

positive Finkelstein test, however, is diagnostic of this condition.⁷ The Finkelstein test requires that the patient flex the thumb into the palm and then grasp it with the other fingers of the hand. The patient then actively ulnarly deviates the wrist¹ (Fig. 54.2). Severe, sharp pain (a positive test) is pathognomonic of tenosynovitis of the first dorsal compartment.^{2,6} It is important to distinguish the sharp pain of de Quervain syndrome from a “pulling sensation” in the same anatomic distribution.⁴ The latter is more indicative of a diagnosis of radial nerve entrapment, not tenosynovitis.

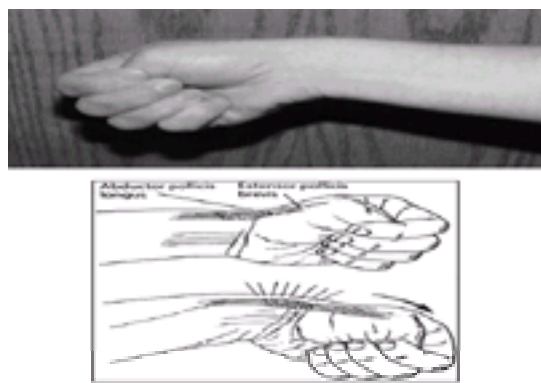

Figure 54.2. Finkelstein's test.

DIFFERENTIAL DIAGNOSIS

The superficial branch of the radial nerve crosses the APL and the EPB muscles in the distal forearm and then divides into terminal branches before entering the hand. The anterior terminal branch of the radial nerve, which provides sensation to the dorsum of the thumb, passes into the hand almost directly over the extensor retinaculum of the first dorsal compartment.⁷ Radial nerve entrapment, therefore, should be ruled out of the differential diagnosis using the previously described technique.

Arthritis at the carpal–metacarpal (CMC) joint of the thumb is another differential diagnosis that may be excluded by the emergency department physician.⁶ The pain in CMC arthritis is more accurately localized to the basal joint of the thumb, not to the first dorsal compartment. Moreover, the clinician can elicit or aggravate CMC arthritis pain by grinding the first metacarpal on the trapezium.² This procedure does not stretch the APL or EPB tendons and will therefore not cause pain in a patient with de Quervain syndrome. The clinician must also be alert to rule out fractures of the radial styloid, scaphoid, or trapezium.⁶ A clinical history of trauma and plain film radiographs should suffice to include or exclude fractures from the diagnosis.

Intersection syndrome, another tenosynovitis of the radial extensor tendons, may be confused with de Quervain syndrome. Like de Quervain's tenosynovitis, intersection syndrome is a nonsuppurative process that develops after repeatedly performing a novel activity.⁶ Patients will present complaining of radial wrist pain.

Examination of patients with intersection syndrome generally reveals swelling, pain, and crepitus in a more proximal and ulnar distribution than is seen in de Quervain syndrome.^{6,9} Tenderness is localized not to the area of the radial styloid, but to the region where the radial wrist extensors of the second dorsal compartment and the tendons of the first dorsal compartment intersect.⁵

EMERGENCY DEPARTMENT EVALUATION

Diagnosis of de Quervain syndrome rests on obtaining a history of overuse of the thumb and eliciting a positive Finkelstein test. The medical literature reports no objective confirmatory electrodiagnostic tests or studies. Plain film radiographs in the absence of fracture or arthritis are usually nondiagnostic.⁷

EMERGENCY DEPARTMENT MANAGEMENT

Several methods exist for treating de Quervain's tenosynovitis. The least invasive techniques (rest, application of heat, and immobilization with a thumb spica splint) are, by themselves, ineffective for treating this condition.⁶ They may be used, however, as adjunctive therapies to the mainstays of treatment: steroid injection and, when necessary, surgical release. Steroid injection into the tendon sheaths of the first dorsal compartment is an effective treatment for de Quervain syndrome that may be employed by the emergency department physician.

Between 70% and 80% of patients with de Quervain syndrome will respond to steroid injection.^{5,9} One recent article cited a success rate of 84% after either one or two steroid injections into the first dorsal compartment.⁸ Steroids may even be used alone without subsequent splinting or immobilization. Several studies have shown no advantage to using immobilization as a therapeutic modality after (or in the absence of) steroid injection.⁷

A corticosteroid preparation such as methylprednisolone acetate is a good choice for injection into the tendon sheath, as it tends to provide long-lasting relief. Approximately 2 cc of steroid should be drawn up and mixed in a syringe with 0.5 cc of lidocaine.² Using a 25- or 27-gauge needle helps minimize the pain of injection. Although techniques vary according to author, most agree that the needle should be passed through the skin at the distal end of the first dorsal compartment. One source suggests inserting the needle through the tendon sheath and tendon until it touches the radius.⁶ As the needle is slowly withdrawn and as it exits the tendon, resistance will fall and the steroid–lidocaine mixture will easily be injected into the tendon sheath (Fig. 54.3). Forced injection of steroids into a tendon is not desirable.

Figure 54.3. Corticosteroid injection into the tendon sheath.

A successful injection of the steroid–lidocaine mixture can be identified by the clinician feeling the medication track distally along the tendons. Immediate relief of pain (due to the presence of the lidocaine in the injected mixture) is also a good marker for accuracy of placement.⁸ Patients need to be advised that it may take several days for the steroid to begin relieving their pain and that, in the meantime, there is the possibility of a postinjection flare reaction. This painful phenomenon, sometimes seen after injection of steroids, is generally self-limited and usually resolves after a couple of days.

Failure of steroid injection to achieve a cure does occur in a small but significant percentage of those with de Quervain syndrome. These failures are believed to be due to the presence of a separate EPB compartment that is smaller and deeper than the APL compartment. If a patient has multiple sheaths within the first dorsal

compartment but only one of them is injected, steroids are not likely to be effective in treating de Quervain syndrome.⁶ Patients must be counseled about this possibility and advised to seek appropriate follow-up care with a hand surgeon if adequate relief is not achieved after one or two steroid injections. As a curative modality, surgery can also fail if the tendon sheath of the EPB compartment is not identified and released.

DISPOSITION

A referral to a hand surgeon is entirely appropriate when one considers that 20% to 30% of steroid injection attempts will not alleviate the pain of this condition.⁶ Failure to achieve a cure after two or three injections over a 3- to 5-week period indicates the necessity for surgically releasing the stenotic tendon sheath or sheaths.² In general, surgically dividing the sheath(s) within the first dorsal compartment is a curative procedure.

Because multiple sheaths may lie within the compartment, the surgeon must carefully inspect this area to be certain that all sheaths have been released.

COMMON PITFALLS

- A positive Finkelstein test is virtually diagnostic for de Quervain's tenosynovitis.
- Fractures of the radial styloid and arthritis at the CMC joint of the thumb are two important differential diagnoses to be excluded. Radiographs and careful physical examination can help to rule out these possibilities.
- Radiographs in de Quervain syndrome are most likely to be normal or possibly reveal some soft-tissue swelling.
- Long-acting steroid combined with lidocaine is often curative and can be used in the emergency department to treat this condition. Patients should be warned about the possibility of postinjection flare reaction and the possibility of failure of this treatment.

ESSENTIAL ANATOMY

The nail plate inserts into a depression on the dorsum of the finger called the proximal nail fold, which divides the proximal nail fold into superficial and deep epithelial surfaces called the dorsal roof and ventral floor, respectively. The eponychium, commonly called the cuticle, is a horny layer extension of the proximal nail fold that extends a short distance onto the dorsum of the nail. It seals the potential space between the nail plate and the proximal nail fold. Laterally, the proximal nail fold is continuous on either side with the lateral nail folds or paronychia. The soft tissue under the distal free edge of the nail is called the hyponychium ([Fig. 55.1](#)).¹

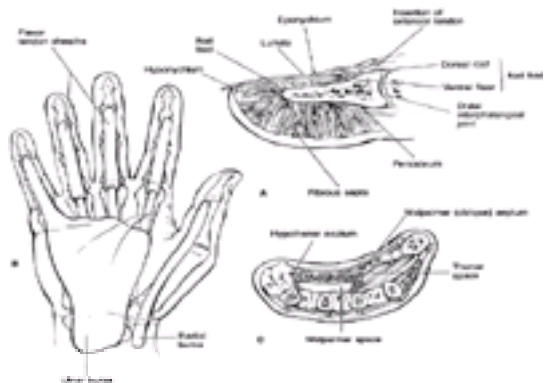

Figure 55.1. Anatomy. (A) Fingertip and nail bed. (B) Flexor tendon sheaths. (C) Deep palmar spaces.

The distal pulp space of a finger or thumb is composed of fat globules that are divided into small fascial compartments by 15 to 20 vertical fibrous septa (see [Fig. 55.1](#)). The presence of these compartments has a substantial impact on the pathophysiology and management of pulp space infections.

The flexor tendons are surrounded by a tendon sheath that is composed of an outer fibrous sheath and an inner synovial sheath. The inner synovial sheath has a visceral and parietal layer with a potential space between them. The tendon sheaths of the index, middle, and ring fingers extend from the midpalmar crease to just beyond the distal interphalangeal joints. The tendon sheath of the flexor pollicis longus tendon begins at the base of the distal phalanx of the thumb and extends to the pronator quadratus muscle in the wrist. Between the base of the thumb metacarpal and the wrist, the tendon sheath of the flexor pollicis longus tendon is called the radial bursa. The tendon sheath surrounding the flexor tendons of the little finger begins just distal to the distal interphalangeal joint and, like the tendon sheath of the flexor pollicis longus tendon, ends at the pronator quadratus muscle in the wrist. The ulnar bursa is that part of the tendon sheath between the fifth metacarpal and the pronator quadratus muscle (see [Fig. 55.1](#)). The radial and ulnar bursas communicate with each other in 50% to 80% of patients. ^{7,19}

The hand contains several fascial spaces that are potential sites of infection. The most frequently infected spaces are the deep palmar spaces, which include the thenar space, the midpalmar space, and the hypothenar space, and the web spaces (see [Fig. 55.1](#)). The thenar space is bounded on its ulnar side by the vertical septum between the third metacarpal and the long finger profundus and radially by the lateral edge of the adductor pollicis. The adductor pollicis also forms the dorsal roof of the compartment. The midpalmar space lies deep to the flexor tendons. Radially it is bordered by the vertical septum between the third metacarpal and the long

finger profundus and ulnarly by the hypothenar muscles. The dorsal roof is formed by the fascia over the second and the third palmar interossei and the third and fourth metacarpals.⁷ The hypothenar space contains the hypothenar muscles. It is bordered radially by a fibrous septum from the fifth metacarpal to the palmar fascia.¹⁷

MICROBIOLOGY

The majority of hand infections are caused by *Staphylococcus aureus* and *Streptococcus* species. Anaerobes, alone or in combination with aerobic bacteria, are seen in approximately 30% of all hand infections and in 40% of infections secondary to human bite or clenched-fist injury and intravenous drug abuse.²⁰ Gram-negative organisms are rare in normal hosts but are common in patients with diabetes mellitus or a depressed immune system.¹⁵ Methicillin-resistant *S. aureus* is a frequent pathogen in intravenous drug abusers.⁷ Polymicrobial infections are relatively common, particularly with infections caused by bite wounds and intravenous drug abuse.²⁰ Chronic hand infections may be caused by atypical mycobacteria, particularly *Mycobacterium marinum*, a common cause of hand infections occurring in aquatic environments.⁸ Immunocompromised patients may be infected with a variety of fungi, including *Candida albicans*,²¹ *Coccidioides immitis*,¹⁰ and *Aspergillus flavus*.¹¹

HISTORY AND PHYSICAL EXAMINATION

A careful and detailed history and physical examination are essential in the diagnosis and management of hand infections. Important historical information is listed in [Table 55.1](#).

Nature and setting of any preceding trauma
Progression of symptoms
Nature and location of local symptoms
Duration of symptoms before arrival
Associated extraextremity symptoms
Underlying medical problems
History of intravenous drug abuse
Current medications

TABLE 55.1. Important Historical Information in Patients with a Hand Infection

A history of trauma, especially penetrating trauma, is frequently obtained from patients with a hand infection. The type of trauma and the setting in which it occurred can provide valuable clues to the causative organism. For example, infections from injuries occurring at home or in industry are caused predominantly by gram-positive organisms.⁷ Cat bites are commonly infected with *Pasteurella multocida*, while infected human bite wounds or clenched-fist injuries are frequently caused by *Eikenella corrodens* and other oral flora.^{6,20} The progression of symptoms may also be helpful in determining the type of bacteria present. Streptococcal infections evolve over 24 to 48 hours and are more often associated with cellulitis and lymphangitis. In contrast, *S. aureus* is more likely to cause a suppurative infection that develops over 3 to 6 days. Chronic infections are more often due to fungi or atypical mycobacteria.⁷ The nature and location of pain and swelling may be helpful in determining the location and severity of infection, while the duration of symptoms can be an important determinant of the need for surgical intervention. Associated symptoms may aid in gauging the severity of infection and the choice of initial antimicrobial therapy. For example, a urethral or endocervical discharge in a patient with a suspected flexor tenosynovitis suggests the possibility of disseminated gonorrhea.¹⁸ Finally, the presence of underlying medical problems (e.g., diabetes mellitus, cancer, and acquired immunodeficiency syndrome [AIDS]), intravenous drug abuse, and the use of certain medications, particularly immunosuppressive agents, frequently have a significant impact on the diagnosis, treatment, and microbiology of hand infections.

On physical examination, the position of the hand and fingers at rest and the presence of any wounds or breaks in the continuity of the skin should be noted. The location and nature of any swelling, fluctuance, erythema, warmth, or tenderness should be carefully documented. The hand and individual digits should be put through a full range of motion. Any limitation or pain with movement should be clearly described. A thorough and well-documented neurovascular assessment is mandatory.

PARONYCHIA

Paronychia is an infection involving the lateral nail fold (paronychium). It is the most common infection of the hand.^{17,22} It results from mechanical separation of the eponychium from the nail plate with subsequent invasion of bacteria or fungi.¹⁵ Common causes of a paronychia include hangnails, manicuring, and nail biting.^{7,19} Individuals whose hands are repeatedly submerged in water (e.g., dishwashers) seem to be particularly susceptible.¹⁵ Extension of the infection to involve the adjacent eponychium and proximal nail fold is called an eponychia.^{2,17}

CLINICAL PRESENTATION

Pain, swelling, and redness usually begin in the proximal portion of the lateral nail fold in the area adjacent to the eponychium. If ignored or untreated, it may extend to involve the onychium and proximal nail fold (i.e., eponychia) or, rarely, to the lateral nail fold on the opposite side (i.e., run-around infection).^{2,17,19} The involved tissue is usually very tender. Fluctuance is generally present but may be absent early in the course of the infection. In severe infections, pus may extend beneath the nail. Large amounts of subungual pus may result in a floating nail. Systemic signs and symptoms such as fever or tachycardia are unusual.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of an acute paronychia includes herpetic whitlow, a chronic paronychia, and a felon. Herpetic whitlow is a viral infection caused by the herpes simplex virus. It can usually be differentiated from a paronychia by careful history and physical examination (see the section on [herpetic whitlow](#)). A chronic paronychia is a smoldering infection frequently caused by *C. albicans*. It is most common in diabetics and in middle-aged women whose hands are frequently exposed to water containing irritants or alkali.¹⁷ Patients usually complain of a waxing and waning infection. Pain and tenderness are less severe in comparison to an acute paronychia.¹⁵ A severe infection may be confused with a felon. However, rather than subungual pus or fluctuance of the nail folds, patients with a felon have tense swelling of the distal pulp space.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of a paronychia is made by history and physical examination. Radiographs may be useful in selected situations (e.g., trauma, suspicion of a foreign body) but are generally not helpful. Laboratory testing is unnecessary in the majority of patients.

EMERGENCY DEPARTMENT MANAGEMENT

If the diagnosis is made before the accumulation of pus, management is nonsurgical and includes an oral antimicrobial agent effective against *Staphylococcus* and *Streptococcus* species ([Table 55.2](#)) and warm soaks. Rest and elevation of the affected part are helpful adjuncts. Once fluctuance has been identified, however, surgical drainage must be performed. The method of drainage depends on the severity of the infection.

Infection	Initial Antimicrobial Therapy ^a	Comments
Felon/paronychia	Cephalexin 500 mg PO q.i.d. for 7 days	Cefazolin should be used for admitted patients.
Severe infections ^b	Cefazolin 1 g i.v. and penicillin G 2 million units i.v.	Cefazolin 1 g i.v. is given for flexor tenosynovitis due to disseminated gonococci.
Diabetic/immunocompromised patients	Cefazolin 1 g i.v. and penicillin G 2 million units i.v. and gentamicin 1.6 mg/kg i.v. or ceftriaxone 12 g i.v.	High incidence of gram-negative organisms.
Intravenous drug abuser	Cefazolin 1 g i.v. and vancomycin 1 g i.v.	High incidence of methicillin-resistant <i>Staphylococcus aureus</i> .
Negetic whitlow	None	Consider options for suppression of recurrent attacks and for severe infection in immunocompromised patients.

^aAgents or a combination of agents with a similar coverage may be substituted. Alternatives for penicillin in penicillin-allergic patients are discussed in the text.
^bInitial antimicrobial therapy should be adjusted as the results of culture and sensitivity tests become available.
^cThese organisms, soft space abscess, and palmar space infections.

TABLE 55.2. Recommendations for Initial Antimicrobial Therapy of Hand Infections ^a

A digital block provides anesthesia for drainage. Local preparation includes cleansing the digit with povidone-iodine or a similar agent. Hemostasis is obtained by placing a 1-in. Penrose drain securely around the proximal portion of the affected digit.

Superficial infections are drained by inserting a no. 11 blade between the nail and eponychium. The eponychium is lifted away from the nail to drain the pus ([Fig. 55.2](#)). If necessary, the blade can then be swept around to incise the lateral nail fold. The incision should be made tangential to the dorsolateral curve of the nail, with the blade directed away from the nail bed and nail matrix to avoid injury to these structures. After drainage, a small gauze wick should be inserted between the eponychium and nail to facilitate continued drainage.

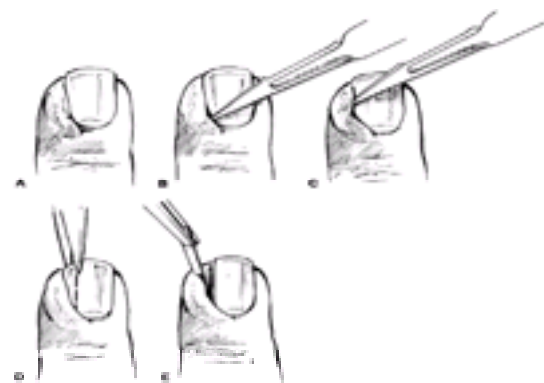

Figure 55.2. Drainage of a paronychia. **(A)** Superficial paronychia. **(B)** Elevation of the eponychia using a no. 11 blade. **(C)** If necessary, the lateral nail fold may be incised to achieve adequate drainage. **(D)** A more extensive paronychia with pus extending under the adjacent portion of the nail. **(E)** Removal of the adjacent one-fourth of the nail to drain the subungual pus. If removal of the nail does not allow complete drainage, the lateral nail fold may be incised as in **(C)**.

If pus is present under the adjacent portion of the nail, one-fourth of the nail on that side should be removed for adequate drainage to occur (see [Fig. 55.2](#)).^{7,16,22} The portion of nail to be removed is first separated from the underlying nail bed by inserting a small hemostat or iris scissors beneath the distal free edge of the nail and gently opening and closing the instrument as it is worked proximally toward the eponychium. Once separated, an iris scissors is used to cut longitudinally along the nail from the distal edge to the eponychium. The nail is then gently removed with the aid of a Kelly clamp. If this does not allow complete drainage of pus, an incision can be made into the lateral nail fold as previously described. A gauze wick is inserted to promote drainage.

If pus is discovered under the dorsal roof of the proximal nail fold or beneath the nail in the nail fold, or if the patient presents with a floating nail, drainage requires removal of the proximal one-third of the nail.^{7,17,19,22} However, controversy exists as to whether incision of the eponychial tissue is necessary for adequate drainage.

If the infection involves the eponychium and one lateral nail fold (in addition to pus under the dorsal roof or nail root), some authors recommend making a single incision starting at the midpoint of the lateral nail fold and extending it proximally to the base of the nail.^{16,17} The eponychial tissue and lateral nail fold are bluntly elevated from the nail, and the proximal one-third of the nail is removed ([Fig. 55.3](#)). If a run-around infection is present, Neviasser²⁴ and Siegel and Gelberman²⁶ recommend making an incision in each lateral nail fold as just described. The entire eponychium is gently elevated as a flap to expose the underlying nail root, and the proximal one-third of the nail is excised using iris scissors (see [Fig. 55.3](#)).^{17,19} In contrast, Zook²⁹ maintains that it is not necessary to make incisions in the eponychium. He agrees that the proximal portion of the nail must be removed, but argues that an incision in the eponychium will frequently not heal primarily in the face of infection and may result in a notch or square corner in the eponychium. Unfortunately, there are few scientific data regarding the optimal approach. If a floating nail is present, incision of the eponychia tissue is probably unnecessary because removal of the nail can be easily performed by pushing back the lateral nail fold and excising the loose nail (see [Fig. 55.3](#)). However, if the nail is partially adherent it may be difficult to remove the proximal portion without incising one or both sides of the eponychium. Regardless of which technique is used, after removal of the proximal portion of the nail, a gauze wick should be placed between the eponychium and exposed nail to prevent adhesion of the eponychium to the nail bed and to facilitate continued drainage.

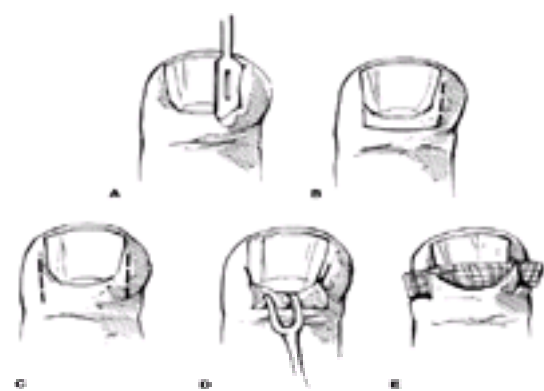

Figure 55.3. Drainage of a paronychia associated with a floating nail, or with pus beneath either the dorsal roof of the proximal nail fold or the nail within the proximal nail fold. **(A)** Elevation of the eponychial fold with a flat probe to expose the base of the nail for excision of a floating nail. **(B)** Placement of an incision to drain the eponychium and lateral nail fold and to elevate the eponychial fold for excision of the proximal one-third of the nail. **(C–E)** Incisions and procedure for elevating the entire eponychial fold for excision of the proximal one-third of the nail. A gauze pack prevents premature closure of the cavity. (Redrawn from Neviasser RJ. Infections. In: Green DP, ed. *Operative hand surgery*, 3rd ed. New York: Churchill Livingstone, 1993:1023.)

DISPOSITION

The majority of patients with a paronychia may be discharged from the emergency department. The affected digit should be kept clean and dry. Elevation should be stressed to help diminish pain and swelling. Patients with a small superficial paronychia should be rechecked at 24 hours. At this time, the gauze wick is removed and

the patient is started on warm soaks. For larger, more extensive infections, the drain should remain in place for 48 to 72 hours before beginning warm soaks.¹⁷ An oral antimicrobial agent effective against *S. aureus* and *Streptococcus* species is indicated if there is surrounding cellulitis (see [Table 55.2](#)). The need for admission is rare, but it should be considered for those patients who have an extensive surrounding cellulitis or lymphangitis, particularly in high-risk individuals such as diabetics, those on immunosuppressive agents, and patients with AIDS. Consultation with a hand surgeon is recommended for all high-risk patients presenting with a severe infection.

COMMON PITFALLS

- Failure to recognize the need for surgical drainage. If the presence of pus is suspected, drainage should be performed.
- Failure to remove the adjacent portion of the nail when subungual pus is present. If this is not done, adequate drainage may not occur.
- Failure to place a wick between the eponychium and nail plate after drainage. This may result in reaccumulation of pus and, if the proximal portion of the nail was removed, adhesions between the aponychium and underlying nail bed.

FELON

A felon is an infection of the distal pulp space of a finger or thumb. It occurs more commonly in the right hand, with the thumb and index finger most frequently affected.¹⁵ The infection frequently results from a puncture wound to the tip of the digit. A subcutaneous abscess rapidly forms in the pulp space, breaking down the fibrous septa as it expands. If left untreated, the infection may extend to the distal phalanx, causing osteomyelitis, or to the skin, resulting in necrosis and a draining sinus on the volar surface of the fingertip.¹⁷ Moreover, because the fibrous septa create a closed space within the fingertip, pressure from the expanding abscess and associated edema can lead to ischemia of the pulp space and, ultimately, slough of the tactile portion of the finger pad.

CLINICAL PRESENTATION

The patient with a felon typically presents with a red, swollen, and painful fingertip. There is a history of penetrating trauma in approximately two-thirds of cases, but this is not necessary to make the diagnosis.¹⁶ Early in the course of the infection, the patient usually complains of an aching pain that increases when pressure is applied to the fingertip. The pain rapidly becomes severe and throbbing. Systemic signs and symptoms are rare. On examination, the fingertip is extremely tender and there is erythema and swelling of the distal pulp space. As a rule, the swelling does not extend proximal to the distal interphalangeal joint.⁷ Fluctuance is generally present within 48 hours.¹⁷ In some cases, the abscess will point, while in others there will be a more diffuse collection of pus. If the infection has spread toward the skin, a draining sinus may be visible on the volar surface of the fingertip. In advanced cases, there may be necrosis of the tactile portion of the finger pad. Other complications of an untreated felon include necrosis of the distal phalanx secondary to osteomyelitis, pyogenic arthritis of the distal interphalangeal joint, and, rarely, a flexor tenosynovitis from proximal extension.^{2,7,17}

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a felon includes herpetic whitlow, cellulitis of the fingertip, and a severe run-around infection. (Herpetic whitlow is discussed later in this chapter.) In cellulitis of the fingertip, fluctuance is usually absent, and pain, tenderness, and swelling are less severe. In addition, unlike a felon, cellulitis will often spread proximal to the distal interphalangeal joint. Patients with a severe run-around infection have fluctuance of the eponychium and both lateral nail folds. In contrast, the fluctuance associated with a felon is much greater in the distal pulp space.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of a felon is made by history and physical examination. Radiographs of the affected digit are recommended to assess for osteomyelitis. Gram stain and culture and sensitivity testing of spontaneous or surgically obtained drainage will aid in making a bacteriologic diagnosis and help guide the choice of antimicrobial agent. Other laboratory tests (e.g., complete blood cell count, electrolytes, glucose) may be helpful in certain patients, such as those with a complication of an untreated felon (e.g., pyogenic arthritis, flexor tenosynovitis, osteomyelitis) or those with significant underlying medical disorders (e.g., diabetes mellitus, AIDS, cancer). In general, however, laboratory testing is unnecessary.

EMERGENCY DEPARTMENT MANAGEMENT

If the patient presents in the early stages of the infection (i.e., before the onset of fluctuance), management includes an oral antimicrobial agent and supportive care. The antimicrobial chosen should be effective against *Staphylococcus* and *Streptococcus* species (see [Table 55.2](#)). Supportive measures include rest, immobilization, and elevation of the affected extremity. Surgical drainage is indicated when there is fluctuance present or if associated swelling threatens to interrupt blood flow to the distal pulp space. Although the presence of pus may be difficult to assess in some patients, it is usually present if the process has been going on for more than 48 hours.¹⁷

The basic goal of surgical intervention is to provide adequate drainage without creating a disabling scar or unstable fat pad, injuring the digital artery and nerve, or violating the flexor tendon sheath, causing an iatrogenic flexor tenosynovitis.¹⁷ In the past, several surgical approaches have been recommended ([Fig. 55.4](#)). Many of them however, are associated with a high incidence of unacceptable complications and are therefore no longer recommended ([Table 55.3](#)). At the present time, the unilateral longitudinal approach is the technique most often employed.^{7,17,19}

Figure 55.4. Incisions for drainage of felons. **(A)** Fish-mouth incision. This approach has significant complications and should be avoided. **(B)** Hockey stick or J incision. This should be reserved for an extensive or severe abscess or felon. Its routine use is no longer recommended. The incision should be more dorsal at the tip than shown (i.e., at the junction of the skin and nail bed). **(C)** Incision for through-and-through drainage of a felon is rarely, if ever, necessary. Again, the distal incision should be at the junction of the skin and the nail bed. **(D)** Volar drainage. Useful if the abscess points volarward, but this incision risks injury to digital nerves. **(E)** Alternative volar approach. Less risk to digital nerves but should not touch or cross the distal interphalangeal flexion crease. **(F)** Unilateral longitudinal approach. (Redrawn from Neviaser RJ. Infections. In: Green DP, ed. *Operative hand surgery*, 3rd ed. New York: Churchill Livingstone, 1993:1025.)

Surgical Approach	Indications	Complications	Comments
Unilateral longitudinal incision	All felons	Injury to the neurovascular bundle	Technique of choice for most felons; incision should be made dorsal to the neurovascular bundle
Longitudinal volar incision	Presence of a draining sinus or pointing on the volar fat pad	Sensory scar on the volar surface of the digit	Incision should not cross the distal flexion crease. If a sinus is present, necrotic debris should be debrided.
Transverse incision	Pointing in the center of the volar fat pad	Sensory scar on the volar surface of the digit; injury to the neurovascular bundle	Offers no advantage over the longitudinal volar incision
Through-and-through incision	All felons	Injury to the neurovascular bundle; potential for an unstable fat pad	Basically, never necessary for adequate drainage
Wick-in-it incision	Severe infections	Disfiguring; tender scar; unstable fat pad; scar skin through	Not recommended for routine use
Flap-inch incision	Severe infections	Disfiguring; tender scar; unstable fat pad; skin through	No longer recommended

TABLE 55.3. Surgical Approaches for Draining a Felon

Before drainage, a tourniquet (sterile Penrose drain) should be placed around the proximal portion of the digit, as described previously. The unilateral longitudinal incision is made dorsal to the neurovascular bundle on the ulnar side of the index, long, and ring fingers or on the radial side of the thumb and little finger. The incision starts approximately 0.5 cm distal to the distal flexion crease and extends in a straight line to a point in line with the beginning of the hyponychium (see [Fig. 55.4](#)). The blade is carefully inserted deeper and deeper until the abscess is entered. The opening of the cavity is enlarged using a small Kelly clamp until complete evacuation is achieved. Blunt rupture of all the fibrous septa should be avoided because it frequently results in an unstable fat pad. The cavity is irrigated with saline, and the wound is packed with 0.25-inch gauze packing. The hand is splinted and elevated, and the patient is started on an oral antimicrobial agent effective against *Staphylococcus* and *Streptococcus* species (see [Table 55.2](#)). The gauze pack is removed in 48 hours, at which time the patient is started on warm soaks.

For patients with a draining sinus or pointing abscess on the volar surface of the fingertip a midline longitudinal incision is recommended.^{13,17} Because the abscess cavity lies directly under the draining sinus or area of pointing, a midline longitudinal incision made directly through this area produces excellent drainage with few complications. The incision is made through the sinus (or over the area of pointing), starting 0.5 cm distal to the distal flexion crease, and extends to the beginning of the hyponychium (see [Fig. 55.4](#)). Care should be taken not to cross the distal flexion crease because this may result in a disabling scar. The incision is deepened until the abscess cavity is entered. A small Kelly clamp is used to gently widen the opening and ensure complete drainage. After drainage, the cavity is irrigated with saline; but in contrast to the unilateral longitudinal approach, no packing is necessary. Instead, the application of a thick coat of zinc oxide (or similar agent) will keep the exudate from drying up and closing the wound, and it will enhance sequestration of the necrotic core.¹³ A bulky dressing is applied, and the distal extremity is immobilized and elevated.

DISPOSITION

Most patients with a felon may be discharged from the emergency department. Patients should be encouraged to keep the affected digit clean and dry. Elevation of the involved extremity will help decrease pain and swelling and facilitate healing. The patient should be reevaluated in 48 hours, at which time the gauze wick is removed and warm soaks initiated. If a zinc oxide dressing is used, it should be changed every 2 days. An oral antimicrobial agent effective against *Staphylococcus* and *Streptococcus* species is also recommended (see [Table 55.2](#)). In addition, a few days of an oral narcotic analgesic (e.g., oxycodone or hydrocodone with acetaminophen) will be appreciated by most patients. The need for admission is rare but should be considered for a severe infection in high-risk individuals such as immunocompromised patients and diabetics. Consultation is recommended for these patients before making a final disposition. Moreover, patients who develop a pyogenic arthritis, flexor tenosynovitis, osteomyelitis, or an ischemic digit will require immediate consultation and admission.

COMMON PITFALLS

- Failure to recognize the need for surgical drainage. If the patient has been symptomatic for 48 hours or more, the presence of pus is highly likely and the pulp space should be surgically drained. Moreover, if swelling is so severe that it could compromise distal blood flow, the finger should be opened regardless of whether pus is present.
- Improperly placed incisions. For example, a volar incision that crosses the distal flexion crease may cause a disabling scar, while a lateral incision not made dorsal to the neurovascular bundle may result in permanent sensory loss or ischemia of the distal fat pad.
- Blunt rupture of all the fibrous septa. This is no longer recommended because it frequently results in an unstable fat pad.
- Failure to diagnose osteomyelitis. Therefore, all patients with a suspected felon, particularly those with long-standing symptoms, should undergo radiologic evaluation. For patients with suspected osteomyelitis, but in whom plain films are normal or equivocal, a bone scan should be arranged.

HERPETIC WHITLOW

Herpetic whitlow is a viral infection of the fingertip caused by type 1 or type 2 herpes simplex virus. In the past, the disease was thought to be most common in medical and health-care professionals. However, researchers in one study found that individuals most often affected are adults with genital herpes and patients of all ages with herpetic gingivostomatitis.⁴ The infection most often affects the distal pulp space and, occasionally, the proximal and lateral nail folds.⁴ The fingers are affected more often than the thumb. Herpetic whitlow is self-limited and usually resolves in 3 to 4 weeks. About 20% of patients experience recurrent infections that tend to be less severe than the original.³

CLINICAL PRESENTATION

Patients initially have pain and dysesthesia or burning of the distal phalanx. This is usually followed by swelling and erythema. Despite associated swelling, however, the distal pulp space usually remains soft.¹⁶ This helps to differentiate herpetic whitlow from a felon, in which there is tense swelling of the distal pulp space. One or more small vesicles then appear and often coalesce to form bullae. On examination, tenderness is present, but usually much less severe than that seen with bacterial infections.¹⁷ Some patients may have associated fever, lymphadenopathy, lymphangitis, and constitutional symptoms.³ The vesicles may contain fluid that is clear, turbid, or occasionally hemorrhagic but not purulent. If purulence is present, it suggests a secondary bacterial infection.⁹ After 10 days, the vesicles or bullae will begin to crust over. Shortly after this, the area peels to reveal normal skin.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of herpetic whitlow includes a felon and a paronychia. The features differentiating these conditions have been described previously in this chapter.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of herpetic whitlow is usually clinical. It can often be confirmed in the emergency department by a Tzanck smear. This is performed by first unroofing a vesicle and scraping the base with a wooden applicator. The scrapings are spread on a slide and allowed to air dry or are fixed with ethyl alcohol. The slide is stained with Giemsa or Wright stain or with methylene blue and examined for the presence of multinucleated giant cells.³ If the Tzanck smear is negative or unable to be performed, a culture can be obtained. This is more sensitive than a Tzanck smear, but results take up to 48 hours. Electron microscopy and the fluorescent antibody test are complicated by both false-positive and false-negative results, and serologic tests often require more than a week to become positive.³

EMERGENCY DEPARTMENT MANAGEMENT

Management of herpetic whitlow is symptomatic. The digit is covered with a dry dressing to reduce the spread of infection. An oral analgesic and aspiration of tense vesicles may be helpful in relieving pain. The use of acyclovir has not been evaluated in a large, prospective, controlled trial, but several anecdotal reports have

documented suppression of recurrent attacks with oral acyclovir.^{5,14} Topical acyclovir has not been shown to be effective in the treatment of herpetic whitlow. Incision and drainage is contraindicated because it can result in secondary bacterial infection.

DISPOSITION

Patients with herpetic whitlow may be discharged from the emergency department. A follow-up visit is arranged in 7 to 10 days with the primary care physician or a hand specialist. Discharge instructions should include signs of secondary bacterial infection. If there is a suspicion of an associated bacterial infection (i.e., a paronychia or felon), consultation with a hand surgeon is highly recommended.

COMMON PITFALLS

Misdiagnosing herpetic whitlow as a felon or paronychia requiring incision and drainage. Surgical intervention causes unnecessary discomfort and may lead to secondary bacterial infection.

FLEXOR TENOSYNOVITIS

Infection of a flexor tendon sheath can be one of the most devastating hand infections encountered in clinical practice. It is most commonly caused by a penetrating injury, particularly at the distal and proximal flexion creases where the tendon sheaths are more superficial. It may also result from direct extension of a neighboring infection and, rarely, by hematogenous or lymphatic spread. The thumb, index finger, and middle fingers are the digits most commonly involved, and the right hand is affected about twice as often as the left hand.¹⁶ If not recognized and treated early, purulence within the tendon sheath can destroy the delicate gliding mechanism. Persistent infection leads to the formation of adhesions, resulting in severe limitation of movement. If allowed to continue, the infection will eventually destroy the blood supply to the tendon, producing tendon necrosis.

CLINICAL PRESENTATION

Patients with flexor tenosynovitis complain of severe pain, swelling, and limited motion of the affected digit. There is a history of penetrating trauma in approximately 90% of cases.¹⁶ Kanavel¹⁶ described four cardinal signs of flexor tenosynovitis: (1) excessive tenderness over the course of the sheath but limited to the sheath, (2) symmetric enlargement (edema) of the whole finger, (3) a flexed position of the finger at rest, and (4) excruciating pain on passive extension the finger, most marked at the proximal end. The latter is the most valuable of these signs and may be the only one present very early in the disease process.¹⁷ In established infections, swelling frequently involves the dorsum of the hand. This is most commonly due to lymphatic drainage from the affected digit, rather than from extension of infection. Dorsal swelling is usually less than that seen with a thenar or midpalmar space infection. If the patient does not seek medical treatment early, the infection may spread to one of the deep palmar spaces, especially the thenar space and midpalmar space, or to adjacent bone or joints, causing an associated osteomyelitis or septic arthritis, respectively.

Infection of the tendon sheath of the little finger or thumb may extend to involve the ulnar bursa and radial bursa, respectively. Patients with involvement of the ulnar bursa will develop severe pain and tenderness in the palm and wrist. There is usually swelling of the entire hand, and dorsal edema becomes more pronounced. The other fingers become sensitive to touch and assume a semiflexed position. Any attempt at passive extension of the fingers is resisted because of severe pain. Similarly, patients with involvement of the radial bursa will develop severe pain and tenderness over the thenar eminence and radial aspect of the wrist. The thenar eminence becomes swollen, but usually not to the degree of a thenar space infection. Swelling over the dorsum of the hand also becomes more prominent. The hand is usually held in moderate flexion and radial deviation. In contrast to patients with infection of the ulnar bursa, patients with infection of the radial bursa do not have pain or limitation of movement of the other fingers. If this occurs, it usually means the infection has spread from the radial bursa to the ulnar bursa, causing a "horseshoe abscess."

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of flexor tenosynovitis includes a palmar space infection, cellulitis, osteomyelitis, and septic arthritis. However, the diagnosis of flexor tenosynovitis can usually be made if a detailed physical examination is performed, with emphasis on the four cardinal signs described by Kanavel.¹⁶ The finding of excruciating pain on passive extension of the digit is particularly helpful because it is often present early in patients with flexor tenosynovitis and is generally not seen with other hand infections. (Palmar space infections are discussed later in this chapter.) Patients with a cellulitis of the digit have symptoms and physical findings that are usually less severe than those associated with flexor tenosynovitis. In particular, tenderness is localized to the area affected with cellulitis, the digit is not held flexed, and severe pain with passive extension of the digit is generally lacking. Likewise, patients with osteomyelitis and septic arthritis tend to have findings that are more localized to the infected bone or joint, respectively.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of flexor tenosynovitis is made by history and physical examination. Radiographs of the affected digit are recommended to look for a foreign body and osteomyelitis. A complete blood cell count may be helpful in identifying those individuals with systemic involvement. Blood cultures are indicated in patients with evidence of systemic infection. Urethral or endocervical cultures for *Neisseria gonorrhoeae* may be useful in the appropriate clinical setting. Other tests should be based on the patient's presenting complaints, underlying medical problems, and the need for operative drainage.

EMERGENCY DEPARTMENT MANAGEMENT

Emergency department management of suspected flexor tenosynovitis includes elevation and immobilization of the affected hand, intravenous antimicrobial therapy, and relief of pain. Antimicrobial therapy should be broad spectrum, aimed at both gram-positive aerobic bacteria as well as anaerobic organisms (see [Table 55.2](#)). Intravenous cefazolin and penicillin G are recommended initially.²⁰ Gentamicin or aztreonam should be added for suspected gram-negative infection (i.e., infection in a diabetic or immunocompromised patient). Nafcillin can be used in place of cefazolin for gram-positive coverage, but, unlike cefazolin, it does not have activity against gram-negative organisms. It also has poor anaerobic coverage. In patients with a nonanaphylactic allergy to penicillin (i.e., patients who can safely be given a cephalosporin), cefoxitin provides coverage for common gram-negative and gram-positive bacteria, as well as many anaerobic organisms.²⁰ Vancomycin and clindamycin may be used in patients with a cephalosporin or severe penicillin allergy. Patients with evidence of disseminated gonorrhea should receive intravenous ceftriaxone. Finally, patients with severe pain will benefit from a parenteral narcotic while awaiting surgical consultation.

DISPOSITION

All patients with suspected flexor tenosynovitis require immediate consultation with a hand surgeon and admission to the hospital. Patients presenting greater than 48 hours after the onset of symptoms require drainage in the operating suite. If the patient presents within the first 24 to 48 hours, conservative therapy with continued elevation and immobilization, intravenous antimicrobial agents, and close observation may be attempted. If the patient's condition is not markedly improved within 24 hours or if physical findings are not resolved within 2 days, surgical drainage is indicated.^{7,17} The choice of conservative versus operative management is best left to the consulting surgeon.

COMMON PITFALLS

- Failure to make the diagnosis on initial presentation. A careful history and physical examination, with close attention to the cardinal signs of flexor tenosynovitis and a low threshold for consultation and admission, will help avoid a late diagnosis.
- Sending the patient with equivocal findings home without having been seen by the consulting surgeon. The emergency physician should stand firm on admitting all patients with suspected cases of flexor tenosynovitis and should be adamant that the consulting hand surgeon see the patient in the emergency department or shortly after admission. This request should be clearly documented in the emergency department record.

WEB SPACE (COLLAR BUTTON) ABSCESS

An infection of a web space usually results from a break in the skin surrounding an infected palmar blister. Consequently, it is seen most often in individuals who do manual labor. If left untreated, the infection spreads dorsally to the dorsal subcutaneous space and deep into the palmar web space. This creates an hourglass configuration to the abscess, hence the term *collar button abscess*. Rarely, an untreated infection in the web space between the index and middle fingers will spread medially to involve the other two web spaces.²

CLINICAL PRESENTATION

Patients usually complain of pain and swelling of the involved web space and surrounding palm. Systemic signs and symptoms are unusual in uncomplicated infections. Examination reveals tenderness and swelling of the affected web space. Anteroposterior pressure over the web space elicits severe discomfort.² Swelling may be more prominent on either the palmar or the dorsal aspect, depending on the nature of the infection.¹⁷ Because of pus and swelling, the fingers adjacent to the affected web space are held abducted at rest. Patients with a neglected web space abscess may present with signs of tendon sheath or palmar space involvement. Untreated infections may also dissect distally along the course of the lumbricals, leading to tissue slough.² Rarely, the infection will spread to involve the dorsal subaponeurotic space.² If this occurs, patients will have pain, tenderness, and fluctuance involving the dorsum of the hand.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a web space abscess includes a dorsal subcutaneous space infection, an infected palmar blister, and a deep palmar space infection. As with other infections of the hand, a careful history and physical examination will lead to the appropriate diagnosis. In a dorsal subcutaneous space infection, the fingers are not held abducted at rest and palmar tenderness is minimal or absent. Although infection of a palmar blister usually precedes a web space abscess, pain and tenderness are mild in comparison and are localized over the blister, not the web space. Furthermore, swelling is usually minimal and, when present, does not involve the dorsum of the hand. The findings associated with a deep palmar space infection vary with the involved space. (Palmar space infections are discussed later in this chapter.)

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of a web space infection is made by history and physical examination. Radiographs of the affected hand are recommended if a foreign body or osteomyelitis is suspected. Gram stain and culture and sensitivity testing of spontaneous drainage will aid in making a bacteriologic diagnosis and help guide the choice of antimicrobial agent. A complete blood cell count may be helpful in identifying those individuals with a more diffuse infection. Blood cultures are indicated in patients with evidence of systemic infection. Additional tests should be based on the patients' presenting complaints, their underlying medical problems, and institutional requirements for drainage in the operating suite.

EMERGENCY DEPARTMENT MANAGEMENT

Emergency department management includes elevation of the affected hand, antimicrobial therapy, and pain control. Initial antimicrobial therapy is the same as described for flexor tenosynovitis (see [Table 55.2](#)). Pain should be treated with a parental analgesic.

DISPOSITION

All patients with a suspected web space infection require immediate consultation with a hand surgeon and admission to the hospital. Definitive management requires drainage in the operating suite.

COMMON PITFALLS

- Diagnosing a primary dorsal space infection because of the presence of dorsal edema
- Failure to recognize palmar involvement when dorsal edema is more prominent
- Failure to obtain consultation early in the evaluation process

PALMAR SPACE INFECTIONS

The palm of the hand contains three fascial spaces that are important sites of infection: the thenar space, the midpalmar space, and the hypothenar space. The compartments may become infected from direct penetrating trauma; from contiguous infection, such as a tenosynovitis or osteomyelitis; or, rarely, from hematogenous seeding. Deep space infections may be associated with significant morbidity and permanent loss of function; thus, prompt diagnosis and treatment are essential.

CLINICAL PRESENTATION

The clinical presentation of patients with a palmar space infection depends on which space is involved. However, any patient may present with fever, chills, and other manifestations of a serious infection. A thenar space infection causes severe pain and tenderness and tense swelling of the thenar eminence. Because lymphatic drainage from the palm is directed dorsally, there is usually marked dorsal edema as well. However, there is little, if any, tenderness over the dorsum of the hand. Fluctuance is often present in the web space between the thumb and index finger. The thumb is held abducted and flexed; passive adduction produces severe pain. In contrast, patients with a midpalmar space infection have pain and tenderness over the central palm. There is marked fluctuance and swelling of the midpalmar space, resulting in a loss of normal palm concavity. In severe infections, there is frequently a bulge or convexity of the palm, a finding considered by Mann²³ to be almost pathognomonic of a midpalmar space infection. As with other serious hand infections, there is also edema over the dorsum of the hand, but no tenderness, erythema, or fluctuance. Motion of the middle and ring fingers is painful and limited.¹⁷ Infection of the hypothenar space is rare. There is pain and fullness over the hypothenar eminence, with a noticeable lack of swelling in the palm and fingers.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a palmar space infection includes a cellulitis or superficial abscess of the palm, a web space infection, and flexor tenosynovitis. Once again, the history and physical examination are the keys to the correct diagnosis. Both a cellulitis and a superficial (subcutaneous) abscess of the palm produce pain and tenderness that may not be localized to a particular space. In addition, they cause far less palmar swelling, and dorsal edema is minimal or absent. Moreover, unless there is digital involvement, movement of the fingers or thumb causes little, if any, discomfort. The findings associated with a web space abscess and flexor tenosynovitis have already been described.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of a palmar space infection is made by history and physical examination. Radiographs of the affected hand are recommended to look for a suspected foreign body, osteomyelitis, or gas in the tissues. A complete blood cell count may be helpful in identifying those individuals with a severe infection. Blood cultures are indicated in patients with evidence of systemic infection. Additional tests should be based on the patients' presenting complaints and underlying medical problems and on institutional requirements for admission and drainage in the operating suite.

EMERGENCY DEPARTMENT MANAGEMENT

Emergency department management of a palmar space infection includes elevation and immobilization of the affected hand, broad-spectrum intravenous antimicrobial therapy, and pain control. Once again, antimicrobial therapy is the same as for other serious hand infections (see [Table 55.2](#)). A parenteral analgesic such as

morphine or meperidine is indicated for patients with severe discomfort.

DISPOSITION

All patients with a suspected palmar space infection require immediate consultation with a hand surgeon and admission to the hospital. Definitive management requires drainage in the operating suite.

COMMON PITFALLS

- Failure to appreciate the presence of a palmar space infection, particularly early in the disease process. Therefore, it is essential to maintain a high index of suspicion and consider the possibility of a palmar space infection in any patient who presents with erythema, swelling, and tenderness of the palm.
- Misinterpreting the presence of dorsal edema as a dorsal hand infection
- Sending home patients who have an equivocal examination, without their having been examined by the consulting surgeon. Thus, evaluation in the emergency department by the consulting hand surgeon is mandatory before releasing any patient with a suspected palmar space infection.

Back pain is a complaint that is commonly seen in the emergency department (ED), affecting up to 90% of the population at some point in their lives. With an annual incidence of 5%,⁹ back pain is second only to upper respiratory illness as a reason for physician visits.¹² Up to 85% of patients with low back pain will have no definite etiology determined for their symptoms.¹⁵ Fortunately, despite the lack of a definite etiology, almost 90% of patients will have resolution of their symptoms within 1 month.¹ In the approach to the patient with back pain, patients may be categorized into three groups: (1) back pain in adults, (2) back pain with sciatica, and (3) back pain in children. By far, the majority of patients with back pain seen in the ED fall into the first category.

Sciatica is defined as a radicular pain into the leg in the distribution of a lumbar nerve root; it is often accompanied by a neurosensory or motor deficit.⁹ Sciatica is less common than back pain without sciatica, afflicting only 1% of patients with low back pain.⁹ There are many etiologies for sciatica, but most commonly it is due to a herniated disc. Generally, patients with sciatica have a more protracted course than routine back pain patients, with only 50% of patients with sciatica recovering within 1 month. However, of all patients with sciatica, only 5% to 10% will require surgery.⁹

Children are a separate category, because back pain is a rare complaint in children and more likely to be due to a serious etiology. The differential diagnosis for the child with back pain is different from that of the adult, and it varies further based on the age of the child. Due to the higher potential for serious disease, the approach to the child with back pain must be more aggressive than for the adult.

CLINICAL PRESENTATION

The clinical presentation of the patient with back pain ranges from the patient with mild pain who requires a work excuse to the patient with the severe, unrelenting pain of an epidural abscess. More important than recognizing a particular “classic” presentation for the various diseases is the thorough evaluation of each patient, with a focus on the *red flags* found in the history and physical examination that should raise suspicion for serious disease ([Table 56.1](#)).

HISTORY
Pain greater than six weeks
Age less than eighteen or over fifty
History of trauma
Sciatica
Neurological complaints (paresthesias, anesthesia, weakness)
Incontinence of bowel or bladder
Night pain
Unrelenting pain despite rest and analgesics
Fever, chills, and night sweats
History of injection drug use
History of cancer
PHYSICAL EXAM
Fever
Patient writhing in pain
Point vertebral tenderness
Neurological deficits
Positive straight leg raise

TABLE 56.1. Red Flags in the History and Physical Exam

History

Back pain is differentiated into three categories based on the duration of the symptoms: acute (less than 6 weeks), subacute (between 6 and 12 weeks), and chronic (greater than 12 weeks). Pain that is subacute or chronic raises a red flag because 90% of back pain episodes resolve within 4 to 6 weeks. Patients who have had back pain for 6 weeks or more require further diagnostic evaluation.

Patients older than 50 or younger than 18 years also raise a red flag due to the higher probability of pathology, such as tumor or infection. Patients under age 18 have a higher likelihood of congenital and bony abnormalities, such as spondylolysis and spondylolisthesis. In those over age 50, causes such as fracture, vascular disease, tumor, pancreatitis, and other intraabdominal or retroperitoneal processes are more common.

A history of trauma suggests fracture and is usually a readily available historical clue. In an otherwise healthy patient, a major mechanism (motor vehicle crash or a fall from a significant height) is required to cause vertebral fracture. However, one must realize that in the patient with osteoporosis, even minor trauma may result in fracture.

A history of radicular pain (sciatica) suggests nerve root or spinal cord compression or inflammation. Patients with sciatica commonly complain more of the leg symptoms than the back pain. In addition to the radicular symptoms, one must inquire about neurologic deficits such as weakness, paresthesias, anesthesia, gait disturbances, and bowel and bladder incontinence. Any neurologic deficit raises a red flag for compression of at least a single spinal nerve root, but may signal compression of the cauda equina or spinal cord. Bilateral or rapidly progressive symptoms, or urinary or fecal incontinence, are very worrisome and suggest cauda equina syndrome or spinal cord compression.

The typical description for a benign etiology of back pain is that of a dull, aching pain that usually worsens with movement but improves with rest and lying still. Atypical pain features, such as night pain and unrelenting pain despite rest and appropriate or even supranormal analgesic use, raise red flags for infection or tumor. Other atypical features associated with a herniated disk include pain that is worsened with prolonged sitting, coughing, or the Valsalva maneuver, and relieved by lying supine.⁷ Finally, bilateral sciatica pain that worsens with activities such as prolonged standing, walking, and back extension, and is relieved by rest and forward flexion is consistent with spinal stenosis.

Constitutional symptoms, such as fever, chills, nightsweats, malaise, and an undesired weight loss, are all red flags that suggest infection or malignancy. The significance of these symptoms is increased if the patient has additional infectious risk factors, such as injection drug use, immunocompromise, recent bacterial infection, or recent genitourinary or gastrointestinal procedure.

A history of cancer or a history suggestive of undiagnosed cancer raises the suspicion for spinal metastases. Back pain is the initial symptom in 96% of these cases.¹³

The malignancies at high risk to metastasize to the spine include breast, lung, thyroid, kidney, prostate, myeloma, lymphoma, and sarcoma.

Physical Examination

The physical examination is directed toward verifying neurologic complaints, identifying neurologic deficits, and uncovering red flags (see [Table 56.1](#)). The presence of fever raises a concern for infection with a specificity of 98% for bacterial infection. However, it is insensitive, ranging from 27% for tuberculosis osteomyelitis to 50% for pyogenic osteomyelitis and 83% for spinal epidural abscess.⁸

The patient who is writhing in pain should suggest a serious etiology, because, most often, patients with a benign etiology for back pain find more relief lying still. In the patient who is writhing in pain, one should consider etiologies such as a rupturing abdominal aortic aneurysm, nephrolithiasis, vertebral osteomyelitis, and epidural abscess. All patients with back pain require an abdominal examination. Specifically, one is evaluating for bruits, masses, tenderness, and an enlarged, pulsatile aorta consistent with an aortic aneurysm.

Examination of the back should include a search for evidence of underlying infection or trauma. Inspect the back, looking for contusion or swelling consistent with trauma, and erythema, warmth, or drainage consistent with infection. Point tenderness to percussion of the vertebral bodies is found with bacterial infection with a sensitivity of 86% and a specificity of 60%.⁸ Straight-leg testing is performed to evaluate for evidence of herniated disc. A positive test is a reproducible radicular pain that radiates below the knee. This pain is usually relieved by decreasing the elevation, and is worsened by ankle dorsiflexion. Reproduction of the patient's back, buttock, or thigh pain is not a positive test. A positive straight-leg raise test is 80% sensitive for a L4-5 or L5-S1 herniated disc ([Fig. 56.1](#)). Radicular pain in the affected leg when elevating the asymptomatic leg (positive crossed straight-leg raise test) is highly specific, yet insensitive, for nerve root compression by a herniated disc.⁸

Figure 56.1. Sensory dermatomal segments. **(A)** Anterior view. **(B)** Posterior view.

The neurologic examination is the most important part of the physical examination. The examination should evaluate lower extremity strength, sensation, and reflexes. Rectal examination does not need to be performed on all patients with back pain; however, it should be performed in those patients with red flags and neurologic signs or symptoms; in men in whom prostatic disease is probable; and in those with severe pain. On rectal examination, one is evaluating for sensation, tone, masses, and evidence of perirectal abscess.

DIFFERENTIAL DIAGNOSIS

Back Pain in Adults

Acute Lumbosacral Strain

The majority of patients seen in the ED for acute low back pain have symptoms that fall into the category of acute lumbosacral strain ([Fig. 56.2](#)). This syndrome is known by many other names, such as mechanical back pain, back sprain/strain, and lumbago, but it is essentially an episode of acute low back pain without sciatica or any neurologic deficits.

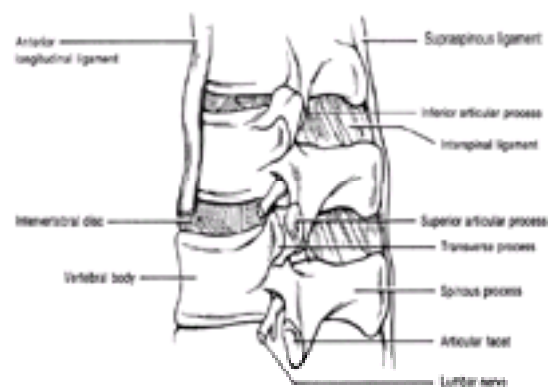

Figure 56.2. Normal anatomy of the lumbar spine.

The patient typically complains of mild-to-moderate pain in the lumbar area that may radiate to the buttocks or thigh, and is worsened by activity and relieved with rest. The inciting incident is usually unremarkable, varying from an unusual posture for a period of time to lifting a heavy object. Physical examination typically reveals mild paraspinal tenderness, negative straight-leg raise testing, normal neurologic examination, and no other significant findings. The investigation of red flags, if any, from the history and physical examination is negative. Because 90% patients will see spontaneous resolution of their symptoms within 4 weeks, there is no need to perform diagnostic testing unless red flags are uncovered. This saves the patient unnecessary pain, expense, and radiation exposure.

The treatment for these patients should focus on the areas of activity modification, analgesia, manipulation, and other modalities. In terms of activity modification, patients should continue their routine daily activities as they can tolerate, using pain as the limiting factor. Routine activity has been demonstrated to allow more rapid recovery than either bed rest or back mobilizing exercise.¹⁰ Appropriate analgesia is paramount in treating the patient with acute lumbosacral strain. The primary treatment regimen should involve acetaminophen alone or in combination with a nonsteroidal antiinflammatory drug (NSAID). When employing NSAIDs, one must consider that no single NSAID has been shown as being most effective.⁵ Thus, one should initiate therapy with a less expensive agent such as ibuprofen, naproxen, or indomethacin. Additionally, NSAIDs should be used with caution in patients at risk of adverse effects, such as the elderly and those with peptic ulcer disease or renal disease. Opiate analgesics should also be prescribed for patients with moderate-to-severe back pain. The prescriptions for these medications are best limited to 1 to 2 weeks' duration due to the risk of sedation, addiction, and constipation. Manipulation is a controversial area of treatment. Although safe and recommended as effective by the 1995 AHCPR guidelines, more recent literature shows it is no more effective than exercises and only minimally more effective than giving the patient an instructional booklet.³ The use of other physical modalities, such as traction, TENS units, diathermy, and ultrasound, is ineffective.¹

Spinal Infections

Vertebral osteomyelitis and spinal epidural abscess are uncommon etiologies for back pain. However, due to the potential morbidity and mortality that result from

missed infection, one needs to remain vigilant concerning these possibilities. These infections occur more commonly in injection drug users, the immunocompromised, diabetics, and the elderly, most often due to hematogenous spread with *Staphylococcus aureus*. Patients usually present with moderate-to-severe back pain accompanied by fever, chills, unrelenting pain, nightsweats, and weight loss. With epidural abscess, the patient may have concomitant sciatica and neurologic symptoms. Additionally, some patients with epidural abscess may present in sepsis. The peripheral white blood cell (WBC) count may be elevated or normal, but the erythrocyte sedimentation rate (ESR) is universally elevated.¹¹ One should always consider back pain in an injection drug abuser as a spinal infection until proven otherwise.

Back Pain with Sciatica

The differential diagnosis for sciatica includes all etiologies that cause compression or inflammation of the spinal nerve roots, cauda equina, and spinal cord ([Table 56.2](#)). The major cause of sciatica is herniated disc. However, in the ED one should consider other etiologies, including spinal stenosis and compression of the cauda equina or spinal cord by tumor, infection, or hematoma.

TABLE 56.2. Differential Diagnosis of Sciatica

Herniated Disc

Although sciatica affects only 1% of patients with low back pain, it is present in almost all patients with a symptomatic herniated disc. Ninety-eight percent of herniated disks involve either the L4-5 or L5-S1 intervertebral disks.⁹ Herniated disc most commonly occurs in patients during the fourth or fifth decades of life. Often, patients complain of weeks of nonradicular low back pain preceding the onset of the radicular symptoms. The radicular symptoms are the hallmark of the nerve root compression and usually become the prominent symptom, with a diminution of the back pain. Clinically, the diagnosis of herniated disc is made by localizing the pain to an isolated nerve root and demonstrating neurologic dysfunction in the distribution of that nerve root. Finally, positive straight-leg raise testing increases the probability of herniated disc, especially if the crossed straight-leg raise test is positive. If a diagnosis of herniated disc is entertained, one should ensure that there are no multiple nerve roots involved. The treatment regimen for herniated disk mirrors that for acute lumbosacral strain, including the use of routine activity as opposed to bed rest,¹⁴ with the exception that manipulation should be used with extreme caution.

Cauda Equina Syndrome

Cauda equina syndrome and spinal cord compression present in a similar fashion to acute lumbosacral strain with one major difference: the presence of neurologic involvement. These syndromes are due to compression of the cauda equina or spinal cord by tumor, herniated disc, infection, or hematoma. The patient usually presents with minimal to moderate back pain and sciatica in association with bilateral neurologic deficits and incontinence. The physical examination will demonstrate evidence of bilateral nerve root involvement. The most common sensory deficit found in cauda equina syndrome occurs over the buttocks, perineum, and posterior–superior thighs in the “saddle” distribution.⁸ Urinary retention is the most consistent finding in cauda equina syndrome (sensitivity 90%).⁸ This proves useful in the patient with a benign history and physical examination but who complains of urinary incontinence. By evaluating a postvoid residual, a negative test (no urinary retention) makes it extremely unlikely that the patient has incontinence due to cauda equina syndrome.⁸ All patients with suspected cauda equina syndrome or spinal cord compression require emergency neurosurgery consultation, high-dose steroid therapy, and emergent magnetic resonance imaging (MRI) to determine the etiology.

Spinal Stenosis

Spinal stenosis is a narrowing of the lumbar spinal canal that may occur at single or multiple spinal levels. It is a cause of chronic back pain (usually chronic) that may have associated sciatica. The symptoms, which usually begin in the sixth decade, include low back pain aggravated by prolonged standing and spinal extension, and relieved by rest and forward flexion. The classic symptom for spinal stenosis is pseudoclaudication, although this is seen in only 60% of patients. Pseudoclaudication is pain of the lateral legs that occurs with walking, and is relieved with rest. It is termed *pseudoclaudication* because it is caused by neurologic compression, not arterial insufficiency.⁶

Back Pain in Children

Children rarely present to the ED with complaints of back pain. When they do, however, one must perform a more thorough diagnostic evaluation, as there is a much higher probability of a serious treatable etiology. The history should be directed toward those questions asked of the adult. Additionally, one must ask about a recent increase in physical activity or involvement in sports such as football, dance, and gymnastics. These activities increase the likelihood of spondylolysis or spondylolisthesis. The physical examination should specifically note the absence of birthmarks, such as café au lait spots, indicative of neurofibromatosis, as well as midline skin abnormalities of the back that may indicate underlying developmental spinal abnormalities. Etiologies to consider in the child under age 10 are discitis, tumor, and osteomyelitis. Etiologies for those age 10 and older include spondylolysis, spondylolisthesis, Scheuermann disease, tumor, vertebral osteomyelitis, herniated disc, and ankylosing spondylitis. All children without an obvious etiology for their back pain should be evaluated with a complete blood count (CBC), ESR, urinalysis (UA), and plain spinal radiography.

EMERGENCY DEPARTMENT EVALUATION

The ED evaluation must concentrate on the identification of red flags in the history and physical examination (see [Table 56.1](#)). The presence of red flags will direct the diagnostic evaluation and treatment regimens. The absence of red flags means that it is unlikely that the patient has significant disease, and, thus, no diagnostic tests are required.

Laboratory Testing

If the patient has red flags raised for infection or tumor, one should obtain a CBC, a UA, and an ESR. With infection, the WBC count may be normal or elevated, but the ESR is universally elevated. The UA can be positive in infection if it is the source of hematogenous spread, but it is otherwise normal. The CBC, UA, and ESR are usually normal with tumor unless there is specific involvement of the hematologic or urinary system.

Radiography

Plain Radiography

Plain spinal radiographs should always be obtained in children or in adults when there is concern of fracture, spinal infection, or tumor, or if neurologic dysfunction is present. In adults, only anteroposterior (AP) and lateral views of the lumbar spine are necessary. Oblique views and a cone-down view of L5-S1 add minimal

information and more than double the radiation exposure.⁹ In children, the oblique views should be obtained after reviewing the AP and lateral views because these additional views may demonstrate spondylolysis or spondylolisthesis, common problems in children. It is not necessary to obtain initial plain radiographs in suspected disc herniation. However, they may be obtained to rule out other etiologies for the radicular symptoms, such as fracture, tumor, or infection.

Magnetic Resonance Imaging

The imaging examination of choice for most emergent back symptoms is MRI. It is the gold standard test for cauda equina syndrome, spinal cord compression, spinal infection, herniated disc, and spinal hematoma. MRI provides the best resolution of the spinal cord and spinal canal as well as disc disease. In cases of suspected cauda equina syndrome, obtain an MRI of the lumbosacral spine only, especially if a midline herniated disc is suspected as the etiology. In cases of suspected spinal cord compression, one should obtain an MRI of the entire spine for two reasons. First, there is a risk of false localization to a spinal level on physical examination. Second, in metastatic spinal cord compression there is a 10% risk of asymptomatic metastases distant from the affected site that may alter the treatment regimen. Although it is the gold standard for disk herniation, MRI should rarely be ordered from the ED to evaluate for a herniated disc. For suspected herniated disc, a spinal MRI is ordered on a routine basis after the patient fails to respond to 4 to 6 weeks of conservative management.

Computed Tomography Scan

Computed tomography (CT) scanning is superior to MRI in evaluating the bony architecture of the spine, especially in the assessment of a vertebral fracture. However, it provides less resolution of the spinal cord and spinal canal than does MRI. When used in conjunction with myelography (CT-myelogram), CT scanning approaches MRI and should be considered the imaging method of choice in the patient who is unable to undergo an MRI.⁴

EMERGENCY DEPARTMENT MANAGEMENT

For the majority of patients with low back pain, with or without sciatica, the primary issue is appropriate pain management. A good approach for adults is to utilize acetaminophen 1000 mg orally in combination with an NSAID, such as ibuprofen 800 mg orally, in the ED. The use of the injectable NSAID ketorolac should be reserved for the patient who is unable to tolerate an oral NSAID. If the pain is more severe, administer intravenous opiates such as morphine sulfate 0.1 mg/kg or meperidine 0.5 to 1.0 mg/kg initially, followed by titration until the patient is comfortable.

The patient with a suspected cauda equina syndrome or spinal cord compression requires treatment with high-dose dexamethasone, followed by emergent spinal imaging with plain films and MRI. The exact dexamethasone dose is controversial and ranges from 10 mg to 100 mg intravenously. A rational approach is to administer 10 mg to the patient with equivocal signs of compression and 100 mg to the patient who has more significant findings, such as partial or complete paraplegia, saddle anesthesia, or incontinence with poor rectal tone.² Regardless of the exact dose given, these patients require the steroid administration before obtaining the imaging studies. Plain spinal radiographs are taken of the area of suspected spinal involvement. If possible, the MRI should be obtained emergently and not delayed until the next day.

In the patient with suspected spinal infection, obtain at least two sets of blood cultures, as these are frequently positive. Additionally, one should discuss the need for antibiotics in the ED with the consultant prior to their administration. Patients with paralysis or sepsis due to infection require antibiotics. These patients may require open biopsy with culture of the site, and the administration of antibiotics may cause the biopsy culture to be falsely negative. If given empirically, the choice of antibiotic should be directed against *S. aureus*, such as cefazolin 2 g intravenously. If a source for the infection is found, such as the urinary tract, antibiotics should be appropriate for that source.

DISPOSITION

Patients with acute lumbosacral strain and sciatica can be discharged home with primary care physician follow-up in 2 to 4 weeks. They should be treated with acetaminophen and NSAIDs, such as ibuprofen 800 mg three times daily, unless contraindicated. Most patients may benefit from a short course (1 to 2 weeks) of opiate analgesia, such as hydrocodone or oxycodone. If patients have a deficit in a single nerve root consistent with a herniated disc, the primary care physician should see the patient within 7 to 10 days. All patients suspected of having a cauda equina or spinal cord compression syndrome require emergent MRI and consultation in the ED by a spine surgeon. If known or suspected metastatic disease is present, an oncologist should also be consulted. All patients with suspected spinal infection require hospital admission and spinal MRI within 24 hours or earlier if there is any neurologic involvement.

Transfer

Transfer to another facility is necessary in the patient with suspected spinal infection, cauda equina syndrome, or spinal cord compression if the facility evaluating the patient is unable to obtain an appropriate imaging study (MRI or CT-myelogram) or has no spine surgeon on staff. These patients are safe to transport utilizing a BLS ground transport unit, unless they have unstable vital signs. In patients with suspected cauda equina syndrome or spinal cord compression, steroids should be administered before the transfer.

COMMON PITFALLS

- Always consider a rupturing abdominal aortic aneurysm in the patient over age 55 with acute low back pain.
- There is no need to obtain diagnostic tests in the patient with low back pain and no “red flags.”
- Children with back pain have a much higher incidence of serious diagnosable etiologies and should be evaluated with a CBC, ESR, UA, and plain spinal radiography, unless a definite benign etiology is determined.
- Always consider spinal infection in the immunocompromised patient or the injection drug user with back pain, especially if a fever is present.
- The treatment regimen for patients with lumbosacral strain and back pain with sciatica comprises routine activity as tolerated, acetaminophen, NSAIDs, and short-term opiate analgesics.
- Patients with suspected herniated disc do not require imaging with MRI unless they fail to improve within 4 to 6 weeks.
- In patients with suspected cauda equina syndrome or spinal cord compression, high-dose dexamethasone should be initiated prior to imaging studies.

[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Foot pain is a common complaint in the emergency department; foot disorders can be extremely debilitating. Nontraumatic causes of foot pain are usually chronic or subacute in nature. In the vast majority of cases, such pain is caused by overuse conditions or improperly fitting shoes.

Foot injuries rank second only to knee injuries as the most common injuries associated with sports. The emergency physician can often provide symptomatic relief as well as definitive care. Special attention needs to be given to diabetic patients with foot disorders, as they are at high risk for serious complications.

FOREFOOT PAIN

The forefoot includes the metatarsals and the phalanges. Abnormalities in this region involve the skin, toenails, and joints.

SUBUNGUAL HEMORRHAGE (BLUE OR BLACK TOENAIL SYNDROME)

Painful and black toenails are often a result of improper footwear, resulting from the toenails' rubbing on the undersurface of the shoe or the foot sliding forward to jam the toes. If the symptoms are acute, the treatment is to drain the hematoma with nail trephination, which can be done using a heated paper clip or an electrocautery. To prevent recurrence, the patient can be instructed to use a metatarsal pad under the metatarsal heads or a tongue pad underneath the tongue of the shoe.

ONYCHOCRYPTOSIS (INGROWN TOENAIL)

Ingrown toenails are often the result of poorly fitting shoes, abnormal nail growth, or poor nail-cutting. A sharp edge of the nail pierces the epidermis of the sulcus and penetrates the dermal tissues. The hallux of male adolescents is most often involved. Symptoms include pain, swelling, erythema, and purulent drainage of the affected toe. Treatment is directed at the severity of the wound.

Warm soaks are helpful in mild-to-moderate cases. If a paronychia is present, partial nail ablation is indicated. Utilizing a digital nerve block and local anesthetic, an oblique wedge of nail should be dissected free of the sulcus and inflamed tissue with a scalpel. Phenol or a cotton pledget can be applied to the nail edge. If pus is present, oral or topical antibiotics are indicated. A nonsteroidal antiinflammatory agent is appropriate for pain. Definitive treatment should be with a podiatrist or orthopedic surgeon.⁶

MORTON'S INTERDIGITAL NEUROMA

Morton's neuroma is caused by repetitive trauma compressing the interdigital nerve between the third and fourth metatarsal heads. It is seen in patients who are runners, dancers, and basketball players, and in those who have to stand for long periods of time. Symptoms are sharp, stabbing pain and paresthesia between the toes.

Diagnosis is made clinically by pinching between the metatarsal heads and simultaneously using the other hand to compress the forefoot with pressure on the first and fifth metatarsal heads. This maneuver will elicit pain and possibly a palpable mass or an audible click, known as Mulder's click. Treatment includes ice in acute cases, orthotics, rest, steroid injections, and possible surgical excision.⁷

METATARSAL STRESS FRACTURES

Stress fractures are the result of repetitive loading forces, causing the bone to fatigue, rather than of an acute event. Metatarsal bones are a common site of stress fractures. The most common metatarsal stress fracture occurs at the neck of the second metatarsal. This injury is more common in patients with Morton syndrome (the first ray shorter than the second).¹

Symptoms include localized pain that is worsened by activity or weight bearing and is relieved with rest. Plain x-rays typically do not reveal stress fractures until 10 to 14 days after they occur. Bone scans are helpful but not practical in the emergency department setting. The condition is treated by having the patient avoid weight bearing on the site for 4 to 6 weeks, applying ice, and administering nonsteroidal antiinflammatory drugs.

BUNIONS (HALLUX VALGUS)

Bunion deformity occurs most commonly at the first metatarsophalangeal (MTP) joint. The deformity consists of lateral deviation of the hallux and medial deviation of the first metatarsal. The etiology is unclear but may be hereditary biomechanical abnormalities and improperly fitting shoes. Symptoms are pain and erythema at the MTP joint. Treatment in the emergency department is focused on analgesia with nonsteroidal antiinflammatory drugs and patient education on proper shoes. In severe cases, surgical correction is indicated.⁷

BLISTERS, CALLUSES, AND CORNS

Excessive localized pressure or friction between the foot and improperly fitted shoes or from constant sliding of the foot inside a shoe can result in blisters, calluses, and corns. Blisters result from shearing forces, causing fluid to accumulate within the layers of the skin. There is some controversy regarding the treatment of blisters. Several options exist in management, including leaving the blister intact, debridement, and aspiration.

Calluses develop from excessive pressure, causing hypertrophy of the squamous cell layer of the epidermis on skin that is normally thick, such as the sole. A callus is

painless and may be diffuse or localized. Treatment includes regular debridement with a callus file, pumice stone, or scalpel.

A corn is a painful conical thickening of skin with recurrent pressure; the apex of the cone points inward and causes pain. Corns usually occur over bony prominences such as the fourth or fifth toe. When they occur in moist areas, such as between the toes, they are called soft corns. Treatment is aimed at prevention with appropriate footwear and padding proximal to the lesions to relieve pressure. These lesions should be aggressively pursued and treated in diabetic patients because of the risk of infection and long-term sequelae.

PLANTAR WARTS (VERRUCA VULGARIS)

Plantar warts are caused by the human papillomavirus and are painful when the patient puts weight on them. Callus formation over the wart is common. Distinguishing warts from calluses may be difficult. Warts occur at any site, whereas calluses appear only on pressure areas. Pinching around the lesion, producing pain, supports an underlying wart. If the hyperkeratotic area is scraped, the underlying wart typically bleeds and has a spotted appearance, representing thrombosed vessels.

Treatment in the emergency department consists of application of pressure-relief dressing and administration of analgesics and topical solutions containing salicylic acid. Refractory warts may require laser or surgical excision.^{2,4}

HINDFOOT PAIN

PLANTAR FASCIITIS

The plantar fascia is a band of connective tissue on the plantar surface of the foot that extends from the calcaneal tuberosity to the metatarsal heads. Irritation and microtears due to overuse and repetitive heel strikes cause inflammation of the fascia, resulting in heel pain, often in the morning. This entity accounts for 10% of running injuries and primarily afflicts the middle-aged, the elderly, and athletes. Physical examination findings are of point tenderness over the medial calcaneal tuberosity, reproduction of pain with passive dorsiflexion of the ankle or toes, or heel pain with standing on the toes. Treatment is focused on relaxing the tension on the fascia and includes rest, ice, stretching the gastrocnemius muscle, arch taping, use of orthotics, administration of nonsteroidal antiinflammatory drugs, and advising the patient to wear proper shoes.^{4,5}

CALCANEAL STRESS FRACTURES

The cause of calcaneal stress fractures is repetitive stresses. Patients typically present with insidious onset of heel pain aggravated by weight-bearing activities. On examination, there is localized tenderness over the medial or lateral aspects of the calcaneus, and pain is elicited by squeezing the calcaneus from both sides, the heel "squeeze" test. Radiographs are typically normal initially or show a typical sclerotic appearance on the lateral view parallel with the posterior margin of the calcaneus. Treatment is conservative rest, administration of nonsteroidal antiinflammatory drugs, and advising the patient not to put weight on the site.

ACHILLES TENDINITIS

Achilles tendinitis is caused by overuse and is seen most commonly in middle-aged or older adult distance runners. Inflammation of the tendon results in pain 3 to 6 cm above the tendon insertion. Tenderness anterior to the tendon is more consistent with retrocalcaneal bursitis. Treatment includes rest, ice, heel lifts, nonsteroidal antiinflammatory drugs, ultrasound, stretching of the gastrocnemius and soleus muscles, and, rarely, surgery.³

RETROCALCANEAL BURSITIS

Retrocalcaneal bursitis is an inflammation of the bursa that lies between the Achilles tendon and the posterior border of the calcaneus. Symptoms begin early in activity and are exacerbated by dorsiflexion of the foot. Tenderness is just anterior to the Achilles tendon (deep) and posterior to the calcaneus. Hindfoot swelling is often present. The treatment is rest and administration of nonsteroidal antiinflammatory medications. The patient is instructed on stretching exercises and use of a heel lift. This condition also may be treated with steroid and local anesthetic injections.

GENERALIZED FOOT CONDITIONS

BROMHIDROSIS

Malodor of the feet is caused by keratin decomposition in the presence of hyperhidrosis or excessive production of sweat. A corynebacterial overgrowth or fungal colonization may occur, worsening the condition. Treatment includes measures to reduce sweat production and to control secondary infection. Use of talcum powder, spray deodorants, and absorbent insoles may be helpful.

TINEA PEDIS

The most common fungal infections of the skin are on the feet. Footwear, because it causes moisture and warmth between the toes, predisposes to this condition; communal activity promotes its spread.

There are three types of tinea pedis. One involves maceration and desquamation in the lateral toe spaces, the second manifests as episodes of unilateral acute vesiculation on the soles, and the third includes dry redness and diffuse scaling over the soles. Symptoms are extreme itching, burning, and irritation on the soles of the foot and between the toes. Treatment includes a variety of agents, such as tolnaftate, clotrimazole, and miconazole. These agents should be used twice daily. Widespread infections and cases involving the nails are treated with systemic griseofulvin, terbinafine, or the imidazoles.

DISPOSITION

Foot problems are a frequent presenting complaint in the emergency department. The vast majority can be diagnosed easily and treated symptomatically. Patients should be referred to a primary care physician, a podiatrist, or an orthopedic surgeon for definitive care.

COMMON PITFALLS

- Failure to aggressively manage diabetic patients with foot disorders; the risk of complications is high if such patients are inadequately treated.
- Failure to recognize metatarsal stress fractures, which are common and may not be visualized radiographically. If a stress fracture is suspected, treat it conservatively with avoidance of weight bearing.
- Failure to distinguish between plantar warts and calluses. It is important to diagnose accurately, because management and treatment are different for the two conditions.

radiographic and clinical presentation of Paget disease appears almost identical to that of metastatic carcinoma of the prostate.

A malignant bone neoplasm should be suspected in any patient whose radiographs show evidence of bone destruction. Radiographic evidence of bone destruction, particularly irregular loss of bone, suggests the presence of a neoplasm ([Fig. 58.1](#) and [Fig. 58.2](#)). [Figure 58.3](#) and [Figure 58.4](#) show a typical appearance of a metastatic carcinoma of the breast. This is by far the most common cause of an impending pathologic fracture that would be seen in the emergency department. With the exception of infection, most benign bone lesions do not produce irregular permeative destruction of bone. A soft-tissue sarcoma should be suspected in any patient with an enlarging soft-tissue mass. A history of progressive deep, aching pain that is not relieved by rest and interferes with normal activities and sleep should also suggest the possibility of a musculoskeletal neoplasm. Not all musculoskeletal neoplasms, even malignant lesions, cause pain.

Figure 58.1. A destructive bone-forming lesion of the distal femoral metaphysis. Notice the destruction of the medial femoral condyle, the new bone formation in the region of bone destruction, and the elevation of the periosteum. These features are characteristic of osteosarcomas.

Figure 58.2. Increased bone density in the distal femur. In this patient, the anteroposterior radiograph shows the neoplasm more clearly.

Figure 58.3. A destructive, primarily lytic metastatic lesion from a carcinoma of the breast. Notice the irregular destruction of the distal femoral shaft extending into the femoral metaphysis.

Figure 58.4. Lateral radiograph showing the metastasis from breast carcinoma involving the distal femur. Notice the extensive destruction of the anterior femoral cortex as well as the region of the posterior femoral cortex. This extensive lesion has significantly weakened the femoral shaft and is highly likely to result in a pathologic fracture. This patient should be immediately protected and referred for prophylactic internal fixation of this lesion as well as for comprehensive evaluation.

EMERGENCY DEPARTMENT EVALUATION

The initial evaluation of a patient with a suspected musculoskeletal neoplasm should include a careful history, physical examination, and plain radiographic studies. The physician should determine the duration of symptoms and signs, with particular attention to the pattern of pain and any possible loss of musculoskeletal function.

The presence of other illnesses should be determined. Specific risk factors for metastatic tumors (i.e., lung, breast, prostate, thyroid, kidney) should be addressed. Physical examination should include the following:

- Size of any lesions
- Tenderness
- Bruits
- Skin color
- Temperature changes

Neurologic function
Joint effusions and range of motion
Pulses
Changes in limb circumference
Muscle strength
Presence or absence of enlarged lymph nodes
Whether lesions are fixed to the skin, tendons, muscles, or bones

Radiographs in two planes should be taken. Depending on the results of this initial evaluation, it may be appropriate to order laboratory studies and more extensive imaging studies. Computed tomography, magnetic resonance imaging, arteriography, technetium bone scanning, and ultrasonography may be used to assess the relation of the lesion to other structures and to determine the extent and stage of the lesion. A comprehensive physical examination, chest radiograph, chest and abdominal computed tomography, renal ultrasound studies, and mammography may be appropriate to determine the source of an apparent metastatic lesion.

Although failure to order sophisticated imaging studies occasionally delays the diagnosis of bone and soft-tissue neoplasms, more common errors include failure to perform a thorough physical evaluation, including a neurologic and orthopedic examination, failure to note abnormalities on plain radiographs, failure to recognize a pathologic fracture, and failure to obtain consultation for evaluation of suspicious lesions.

EMERGENCY DEPARTMENT MANAGEMENT

Most patients with suspected neoplasms of bone and soft tissue do not require emergency treatment. However, patients with severe pain, compromise of neurologic or vascular function, pathologic fracture, or an impending pathologic fracture may require urgent treatment. Severe pain associated with a musculoskeletal neoplasm may indicate bleeding into the lesion, pressure on nerves, an increase in compartment pressure, a pathologic fracture, or an impending pathologic fracture. Patients with pathologic fractures should be splinted appropriately, and consultation should be sought. Patients with impending fractures should be protected to avoid a fracture that may compromise definitive treatment. The presence of a neurologic deficit, particularly a deficit caused by spinal cord compression, requires emergency consultation and definitive treatment. Biopsy of a musculoskeletal lesion is seldom appropriate as an emergency procedure. Biopsies should be planned carefully and almost always preceded by appropriate staging studies. Inappropriate biopsies may fail to obtain satisfactory tissue for diagnosis, cause unnecessary contamination of tissue compartments and other complications, including infection and excessive bleeding, and spread the tumor beyond its original location.

DISPOSITION

Role of the Consultant

Patients with a suspected bone or soft-tissue neoplasm should be referred to an orthopedic surgeon with experience in the treatment of musculoskeletal neoplasms. If possible, consultation should be obtained before ordering staging studies (computed tomography, magnetic resonance imaging, and bone scans). In the patient with severe intractable pain, a neurologic deficit or an impending neurologic deficit, or a pathologic or impending pathologic fracture, consultation should be sought immediately.

Indications for Admission

Patients with suspected musculoskeletal neoplasms generally do not need to be admitted unless there is uncontrollable pain, evidence of neurovascular compromise, impending neurovascular compromise, pathologic fracture, or impending fracture. Patients with these conditions should be admitted for definitive evaluation, staging, possibly biopsy, and definitive treatment. Patients who do not require admission should be referred to an orthopedic surgeon before discharge from the emergency department. The patient should be instructed that urgent evaluation by a consultant is essential.

Transfer Considerations

The management of patients with musculoskeletal neoplasms frequently requires consultants in musculoskeletal oncology, medical oncology, radiation therapy, musculoskeletal pathology, and musculoskeletal radiology. A neurosurgeon, thoracic surgeon, or general surgeon and radiologist may also be helpful in the management of complex problems. For this reason, patients with bone and soft-tissue neoplasms should be cared for at centers with these specialists and should be transferred to these centers expeditiously. Patients with pathologic fractures or impending fractures of the long bones should have their limbs stabilized before transfer.

COMMON PITFALLS

- Failure to detect a musculoskeletal neoplasm. In part because neoplasms of bone and soft tissue occur infrequently, physicians may not consider neoplasm when confronted with complaints of pain, swelling, and loss of musculoskeletal function, and with incidental, unexplained physical findings or abnormalities on imaging studies. If the emergency physician suspects a musculoskeletal neoplasm, the patient should be referred for more extensive evaluation.
- Failure to refer to a consultant. Occasionally, a lesion may be identified, but the patient is not referred for definitive evaluation. This may occur when a patient has other medical problems or an acute traumatic injury. The possible neoplasm may be noted, but because attention is focused on other problems, the patient is not referred for evaluation of the possible tumor.
- Failure to recognize a neurologic deficit or a potential neurologic deficit. Patients with possible bone and soft-tissue neoplasms should have a thorough neurologic examination. Tumors of the limbs may compress peripheral nerves. Even more serious problems are compression of the spinal cord owing to tumors in or about the spine and destruction of the vertebrae, leading to spinal cord compression.
- Failure to recognize a pathologic fracture. A fracture that occurs after minimal trauma should alert the physician to the possibility of a pathologic fracture. The radiographs of the fractured bone should be inspected carefully for any abnormalities that might indicate the presence of an underlying neoplasm. If it is difficult to determine whether an underlying neoplasm is present, but the fracture occurred after minimal trauma, the patient should undergo more extensive evaluation. If this does not reveal evidence of a neoplasm, the patient should be either referred for consultation or followed carefully.
- Failure to recognize an impending pathologic fracture. This problem is most frequently seen in patients with metastatic disease (see [Fig. 58.3](#) and [Fig. 58.4](#)). In these patients, it is essential to evaluate the skeleton for the presence of metastatic tumor. Areas of particular concern include the spine, the femur, and the tibia.
- Inappropriate biopsy. Patients with suspected musculoskeletal neoplasms usually should not have a biopsy until appropriate staging studies have been performed and the patient has been evaluated by an orthopedic surgeon with experience in the management of these problems. Inappropriate aspiration or incisional or excisional biopsies can disseminate tumor, cause bleeding and infection, and fail to provide diagnostic tissue. Needle aspiration of a soft-tissue mass in the emergency department may seem like a simple, quick, safe way to make a diagnosis, but it can cause bleeding and infection and may fail to provide diagnostic tissue.

Intracranial neoplasms (INs) are benign or malignant tumors located within the cranial cavity. They include masses that arise from or are metastatic to the pituitary or pineal glands, meninges, intracranial portion of the cranial nerves, intracranial blood vessels, or the brain tissue itself. ¹⁴

About 75% of central nervous system (CNS) tumors in children are infratentorial, whereas 75% of such tumors in adults are supratentorial. The most common brain tumors in adults are metastatic tumors, malignant gliomas, meningiomas, and pituitary adenomas. Cerebellar astrocytomas, medulloblastomas, and fourth ventricle ependymomas predominate in children.

Gliomas are neoplasms of glial lineage and constitute 50% of primary INs. ¹⁴ They include multiple types, from the highly malignant glioblastoma multiforme to the relatively benign astrocytoma. These tumors have a predilection for the cerebral hemispheres in adults. Increasing age of the patient correlates with poor prognosis.

Meningiomas are the second most common adult brain tumor, constituting 20% of primary INs. ¹⁴ They are histologically benign, slow-growing tumors of arachnoid tissue and are usually very vascular. Of all INs, meningiomas have the highest association with extraneural tumors. Meningiomas usually compress but do not invade brain tissue. Changes in the underlying skull are frequent and may be seen on plain radiograph. They also contain a high concentration of progesterone receptors, rendering them hormone sensitive.

Pituitary adenomas represent 15% of all primary INs. ¹⁴ Only one-third of the patients reveal the characteristic sign of bitemporal hemianopia from compression of the optic chiasm by superior extension of the tumor. Some patients present with only endocrine symptomatology, such as secondary amenorrhea, galactorrhea, impotence, and Cushing syndrome. Diagnosis is aided by an enlarged sella turcica on lateral skull films, a pituitary mass on computed tomography (CT), or an abnormal signal on magnetic resonance imaging (MRI). An elevated serum prolactin level is present in two-thirds of these patients.

Acoustic neuroma is a benign schwannoma of the eighth cranial nerve that is usually located within the internal auditory meatus. It constitutes 7% of all primary INs. ⁶ More than 95% of patients with this tumor present with unilateral neurosensory hearing loss. ⁶ Other symptoms include tinnitus, vertigo, dysequilibrium, facial paresthesias, dysphagia, and hoarseness.

Metastatic tumors are the most common IN in late middle life and account for 20% to 30% of all adult INs. Lung and breast cancers are the number one primary tumors in men and women, respectively. Malignant melanoma, hypernephromas, and colon carcinomas complete the five most frequent primary lesions.

Cerebral metastases, like emboli, tend to be found along the middle cerebral artery distribution in the parietal lobe. They are usually multiple. Thus, a neurologic examination and enhanced CT or MRI findings of several lesions should suggest the possibility of metastatic disease.

Meningeal carcinomatosis is a diffuse infiltration of the meninges by tumor cells that can occur with systemic cancer. Clinical suspicion is warranted in the presence of multifocal neurologic signs and symptoms, and suspicion is verified by an abnormal cerebrospinal fluid (CSF) analysis, typically revealing increased intracranial pressure (ICP), increased protein concentration, decreased glucose, pleocytosis, and, occasionally, malignant cells.

EPIDEMIOLOGY

Overall, the incidence of brain tumors is 5 to 9 per 100,000 population and may be increasing. ¹⁴ Nine thousand to 12,000 persons die of brain tumors yearly, which is just slightly more than the annual number of deaths caused by drowning. Brain cancer is the second leading cause of cancer-related deaths in children and the fourth leading cause of cancer-related deaths in middle-aged men.

The incidence, type, location, and prognosis of brain tumors are all age related. The incidence of primary INs increases steadily with advancing age, with the first peak occurring in early childhood and the second and highest peak occurring between the fifth and sixth decades.

Metastatic cancer has only a 1:100,000 incidence in persons younger than age 35, but the incidence increases rapidly thereafter, reaching more than 30:100,000 by age 60. ¹⁴ Eighteen percent of all patients with systemic cancer have evidence of metastatic brain tumors. Half of this group show neurologic symptoms. Ten percent of cerebral metastases are diagnosed before the discovery of the primary tumor. ¹⁴

Whereas females have an increased incidence of meningiomas, pituitary adenomas, and schwannomas, males have an increased incidence of gliomas, brain

metastases, and brain tumors in general.¹⁴

ETIOLOGY

There is a well-known role of heredity in the neurophakomatoses, most notably von Recklinghausen neurofibromatosis, von Hippel-Lindau hemangioblastoma, and tuberous sclerosis. Most brain tumors, however, do not reflect a genetic pattern. Embryologic factors are responsible for the rare congenital tumors, such as pineoblastomas, teratomas, and germinomas.

Oncogenic virus injections and chemical carcinogens have been shown to produce CNS tumors in animals, but their role in humans is speculative. Trauma has been implicated by some to be the cause of brain tumors, for example, development of meningiomas along cranial fracture lines. This is highly controversial. The role of radiation and irradiation also remains controversial. In the vast majority of cases, the cause remains idiopathic.

PATHOPHYSIOLOGY

There are two major mechanisms for symptoms produced in INs. First, increased intracerebral pressure produces nonspecific symptoms such as headache, vomiting, mental status changes, and disturbances in consciousness. These symptoms may be more noticeable in the early awakening hours, since cerebral vasodilation accompanies sleep, therefore producing a paroxysmal increase in ICP. This rise in ICP may be caused directly by the tumor mass or by associated cerebral edema, which is a localized area of tissue swelling secondary to altered capillary permeability. The rise in ICP is normally a combination of the two. Occasionally, ICP is raised secondary to obstruction of CSF flow, venous system drainage, or meningeal absorption. Chronically elevated ICP can itself decrease CSF absorption, therefore causing a cyclical worsening of ICP.

The second mechanism is tissue destruction or irritation. This may be due to infiltration or compression of normal brain tissue adjacent to the tumor. It may also be caused by displacement of brain matter and compression of neural tissue at sites distant from the tumor, with the most significant example being uncal herniation.

NATURAL HISTORY

The symptomatology and prognosis depend on the growth characteristics of the tumor and its location in the cranial cavity. A slow-growing tumor in a relatively silent brain region can reach enormous size without producing neurologic symptoms. Elevated ICP syndrome may actually be the first clinical presentation in these patients. Alternatively, small tumors in proximity to vital CNS structures may produce early profound focal neurologic symptoms. Accordingly, the terms *benign* and *malignant* have less importance with INs than with other masses, because a histologically benign tumor may be lethal by virtue of its location in the brain.

CLINICAL PRESENTATION

A slow onset and gradual worsening of symptoms are typical for INs.

Signs and Symptoms

Headache

A recent onset or change in the character of a headache may signal the presence of an IN. Although most patients with headache do not have tumors, 60% to 90% of patients with brain tumors complain of headache at some point in their illness, and 20% have headache as the initial symptom.

Headaches caused by INs are described as steady, nonthrobbing, dull, aching pain relieved by analgesics. They may be so mild and intermittent at first that the patient mentions them only as a response to direct questioning. With tumor growth, the headaches become more severe, more frequent, and persistent. In addition to a progressive nature, other characteristics of tumor-induced headaches include early-morning occurrence, aggravation by Valsalva maneuvers, and association with vomiting, particularly in the absence of preceding nausea. Any headache—no matter the character—associated with seizure activity, abnormal mental status, focal neurologic signs, or papilledema is due to IN until proven otherwise.

Tumor-induced headache is secondary to either increased ICP or traction on pain-sensitive structures. The structures in the cranial cavity that are sensitive to pain include major arteries, veins, dura mater, and cranial nerves. Therefore, headache is a poor localizing sign. However, supratentorial expanding lesions typically produce pain in the frontal or vertex regions, because these structures are most commonly innervated by the trigeminal nerve. Posterior fossa structures, on the other hand, are innervated by the ninth and tenth cranial nerves and the first three cervical nerves; therefore, infratentorial masses usually cause pain in the occipital and upper posterior cervical spinal regions.

Seizures

New onset of seizure activity is another common presentation of patients with IN. Thirty-five percent of cerebral tumors are associated with seizure activity, and seizures are the initial symptom in 15%. Although seldom seen with infratentorial tumors (less than 3%), seizures occur in approximately half the patients with supratentorial masses. Aside from being supratentorial, the other tumor features predisposing to epileptogenicity are slow-growing neoplasms, such as benign astrocytomas, and tumors that involve the cortex, such as meningiomas.

In patients younger than age 20, the incidence of cerebral tumors causing epilepsy is almost negligible at 0.02%. In patients with new onset of seizure activity and focal neurologic deficits, the incidence of tumor increases to 50%. Half of the patients without history of prior seizure who present with status epilepticus also have IN. Besides initial status or focal neurologic findings, clinical suspicion of IN should also be aroused in any patient older than age 20 with a first episode of seizure, particularly if the seizure is followed by a prolonged postictal period or Todd paralysis. The risk of IN is also increased if the seizure has focal motor, sensory, or psychomotor features.

Particular subsets of seizure are seen, depending on the tumor location. Generalized or focal motor seizures are produced by frontal lobe neoplasms. Complex partial seizures are often manifested by temporal lobe lesions. Absence seizures are usually not a complication of INs.

Mental Status

Mental status or behavioral changes are commonly seen with IN, particularly with frontal and temporal lobe lesions. Because of their often subtle nature, such changes may be overlooked until focal neurologic signs develop. Often patients are unaware of changes in their behavior, but alterations of mental status may be disclosed by questioning their families and friends. Case reports exist that describe patients who presented with emotional lability or other inappropriate behavior who were later diagnosed with a brain tumor. Symptoms can mimic a depressive disorder or Alzheimer disease, with a predominance of apathy, irritability, restlessness, depression, loss of spontaneity, or memory loss. Bilateral frontal lobe tumors (i.e., “butterfly” glioblastoma) that result in inappropriate and antisocial behavior may be confused with affective or schizophrenic disorders. These various changes in mental status seem to occur most often with rapidly growing tumors, such as glioblastomas.

Focal Neurologic Deficits

Progressive focal neurologic defects may also be produced by intracranial masses. Common findings include aphasia, hemiparesis, sensory or visual deficits, and cranial nerve palsies. The sixth cranial nerve is involved most commonly because it has the longest intracranial course. These findings must be differentiated from a number of other intracranial lesions, such as cerebrovascular accident (CVA), transient ischemic attacks (TIAs), and intracerebral hemorrhagic disorders. The characteristic unique to IN-induced focal neurologic deficits is that these deficits tend to be slow in onset, with only gradual increase in severity. Rarely, the onset of symptoms is sudden, and intraneoplastic hemorrhage must then be a consideration.

Miscellaneous

Vomiting occurs in 70% of patients with IN, but it is the presenting symptom in only 10%. It is characteristically projectile, unrelated to food, more frequent in the early waking hours (as is headache), and usually not preceded by nausea. Like headache and papilledema, it is one of the cardinal signs of chronically increased ICP. Other rare initial presentations of IN include vertigo or dysequilibrium, irreversible coma, and acute blindness.³ Remote symptoms include neurogenic pulmonary edema and cardiopulmonary collapse.⁵

Presentation by Location

Clinical presentation depends on the presence or absence of elevated ICP and the location of the tumor. Mixed clinical pictures are often present, because tumors usually spread to involve more than one brain region. Frontal lobe tumors may produce personality change, particularly in respect to acquired social behavior. Uninhibited behavior may be prominent, and reflected in the use of inappropriate language or actions without regard for their effect on others. Apathy and poor hygiene are common. A severe decline in intellect and memory may also ensue. These changes develop slowly over months to years, until an obvious dementia occurs. Patients may also experience loss of bladder control. Generalized tonic-clonic seizures and jacksonian or partial motor seizures are also characteristic of frontal lobe tumors.

The occipital lobe is very small and seldom affected by tumors. When present, they are manifested by visual agnosia or alexia, highly congruent hemianopia, and, rarely, seizures. When seizures do occur, they are often preceded by visual hallucinations consisting of unformed flashes of light and color.

Parietal lobe neoplasms present as dysphasia if the dominant lobe is affected and as dyspraxia if the nondominant lobe is involved. Sensory loss, inattention, homonymous hemianopia, and loss of optokinetic nystagmus also occur.

Temporal lobe masses can also present with personality changes, but these tend to be subtler than those associated with frontal lobe tumors. They are characterized by alterations in affect, imitating psychotic disorders rather than the demented picture of frontal lobe tumors. Other symptoms include complex partial seizures with prodromal gustatory, olfactory, auditory, or formed visual hallucinations and upper quadrantic homonymous hemianopia.

Cerebellar tumors, although rare in adults, cause dysmetria, hypotonia, ataxia, nystagmus, and "cerebellar fits," which are episodes of intermittent decerebrate rigidity.

Emergent Problems

Although the *sine qua non* of IN is slow, progressive deterioration in clinical status, occasionally a rapid decline occurs. This is often caused by an acute increase in ICP that develops in minutes to hours and is characterized by a sudden and marked increase in headache, with stiff neck, opisthotonus, facial flushing or pallor, and drowsiness that may progress to coma. Characteristically, the patient develops bradycardia with an elevation of blood pressure. This is termed *the Cushing response* and is the physiologic rise in systemic blood pressure as a consequence of increased ICP. This is compensatory to maintain adequate cerebral perfusion pressure (CPP = MAP – ICP). Reflex bradycardia secondary to elevated mean arterial pressure (MAP) is another component of this response. The respiratory rate slows and deepens and may progress to a Cheyne-Stokes pattern. This acute alteration in ICP is usually caused by an intracranial hemorrhage; however, it can be seen with hemorrhage into an IN. Such hemorrhages occur with glioblastoma multiforme and metastatic brain tumors.¹⁰

Acute hydrocephalus is rare but can occur with tumors blocking the fourth ventricle in children or the foramen of Monroe in adults. It is a life-threatening emergency in which ventricular decompression is urgently needed. Intraventricular tumors can also cause intermittent obstruction, owing to a ball-valve mechanism. When this occurs, there is a clinical pattern of severe headache followed by altered levels of consciousness and even coma that may resolve spontaneously only to recur.

Sudden death is a rare but devastating complication of IN and is most often secondary to uncal herniation.⁵ A pressure rise within one hemisphere, rather than a general increase in pressure, can displace the uncus and hippocampal gyrus of the temporal lobe between the free edge of the tentorium and the midbrain. In the early stages of uncal herniation, the patient classically presents with an ipsilateral dilated pupil with contralateral hemiparesis, Babinski's sign, and spastic hypertonicity. This phase progresses to a stage at which both pupils become fixed and dilated, with oculomotor paresis, nonresponsiveness to caloric testing, bilateral Babinski's signs, and decerebrate response to pain. Terminally, the patient develops hyperventilation, which slows near death. The pulse rate rises and the blood pressure falls, producing the clinical syndrome of neurogenic shock.

Cerebellar herniation is more common in posterior fossa tumors. Another cause of sudden death, this is protrusion of the cerebellar tonsil through the foramen magnum, causing acute hydrocephalus and cardiorespiratory and vagal disturbances with pyramidal tract abnormalities. An upward herniation of the cerebellum through the incisura is also possible, but this is rare.

DIFFERENTIAL DIAGNOSIS

Depending on which of the multiple presentations occurs, IN can be mimicked by a multitude of neurologic and psychiatric disorders.

Headache

Migraine headaches share similar characteristics with IN-induced headaches. They are intermittent but not worse in the early waking hours, as are IN headaches. They are often associated with vomiting that is preceded by nausea, whereas nausea may be lacking in tumors. Classic migraine aura consisting of scintillating scotomas, visual field defects, hemiplegia, or hemiparesis may be mistaken for neurologic deficits associated with a tumor. Whereas in tumors these deficits are progressive, in migraine headaches they are fleeting. Although the migraine headache is typically unilateral, it is a throbbing, severe pain, unlike the characteristic dull aching of a tumor. Also, the duration of a migraine headache is hours to days, which is usually longer than the duration of a tumor-induced headache.

Muscular or tension headaches also resemble IN-induced headaches because of their occipital location and dull, aching nature. However, they are not associated with vomiting, neurologic deficits, seizures, or changes in mental status. They are also not progressive. CT or MRI would distinguish an IN from a migraine or tension headache.

Cerebrovascular Accident

Tumors occasionally present in an apoplectic manner and mimic stroke, particularly if there is hemorrhage into the tumor. Such hemorrhage occurs in glioblastomas and metastatic bronchogenic carcinoma, melanoma, renal carcinoma, and choriocarcinoma.¹⁰ Normally CVA presents as a sudden onset of nonprogressive focal signs that may improve over time. IN characteristically has an insidious onset with progressive worsening of symptoms over time. Patients with nonhemorrhagic CVA seldom complain of headache and often have a history of hypertension or other evidence of arteriosclerosis. The distinction between tumor and CVA may be made with CT.

TIAs are characterized by fluctuant neurologic findings that do not progress, unlike those caused by brain tumors. CT or MRI in TIAs is unremarkable, and carotid Doppler studies are indicated for follow-up.

Brain Abscess

Brain abscesses are characterized by headache, papilledema, pyramidal signs, and seizures. Often the patient will present with tachycardia, fever, leukocytosis, and other signs of infectious etiology. The patient may give a history of head injury, previous meningeal symptoms, or rheumatic or cyanotic heart disease. However, in chronic brain abscess, these latter signs and symptoms may not be present. It may be difficult to distinguish an abscess from a neoplasm, even with enhanced CT or cerebral angiography. A brain biopsy may then be necessary for definitive diagnosis.

Acute infection of the meninges may simulate symptoms of brain tumors. The diagnosis may be made on examination of the CSF after a negative CT scan.

Subdural Hematoma

Chronic subdural hematoma may also present as headache, papilledema, and seizure disorder. The initial injury may have been so mild as to be forgotten, or it may have occurred in a patient too inebriated or demented to remember the incident. CT or MRI can readily differentiate between a chronic subdural hematoma and a tumor. Acute subdural hematoma is readily distinguished from IN because there is usually a clear history of head trauma.

Pseudotumor Cerebri

Pseudotumor cerebri is a syndrome consisting of nonspecific intermittent headache, papilledema, constricted visual fields, and an enlarged blind spot. It is often seen in obese young women with menstrual irregularities. Conditions associated with pseudotumor cerebri include ovarian dysfunction, Addison disease, Cushing disease, adrenocorticosteroid therapy or withdrawal, hypoparathyroidism, pregnancy, menarche, use of oral contraceptives, vitamin A abuse, tetracycline usage in infancy, and intracranial venous sinus thrombosis. Pain in this case is secondary to cerebral swelling causing traction on pain-sensitive structures. Diagnosis can be aided by a negative CT scan combined with a lumbar puncture that reveals increased opening pressure.

Dementia

Mental slowness or memory loss may be the only presenting symptom in frontal lobe neoplasms, as well as in Alzheimer or Pick disease. Precedent changes in personality or alterations in micturition are more indicative of frontal lobe tumors, and therefore should be sought. CT or MRI is useful in ruling out IN.

Delirium

Delirium may be a presenting symptom in IN. Drug abuse, metabolic abnormality, hypoxia, hypoglycemia, vitamin deficiency, and endocrinopathy are generally included in the differential diagnosis. Here again, CT or MRI would be helpful to exclude IN.

Psychoses

Psychiatric disorders such as depression may be mimicked by frontal lobe masses, whereas affective and schizophrenic-like disorders may be noted with temporal lobe masses. These symptoms may be ameliorated by psychotropic medication, even when the cause is IN. CT or MRI is helpful in excluding IN.

Demyelination

Multiple sclerosis and other demyelinating disorders can be distinguished clinically by their multiplicity of signs and symptoms and remitting course. MRI has proved superior to CT in making the distinction between such disorders and IN. A combination of clinical findings, CSF analysis, and evoked potential responses is diagnostic.

Seizure Disorder

IN should be considered in any adult with new onset of seizure, especially when the seizure is associated with focal neurologic signs or prolonged postictal stage. Electroencephalographic focal findings confirmed by a mass on a CT or MRI scan are diagnostic.

Intracranial Aneurysm

Giant aneurysms may present as mass lesions and can seldom be differentiated from tumor by CT or MRI. Angiography is usually necessary.

Hydrocephalus

Hydrocephalus may be caused by an obstructing neoplasm or by multiple other disorders. CT or MRI is warranted.

Intracerebral Hemorrhage

Hypertensive intracerebral hematoma and vascular malformations are mimicked by spontaneous hemorrhage in certain vascular tumors. They may all present as sudden headache, coma, stupor, hemiparesis, and bloody CSF. Although a hemorrhagic lesion can be seen on CT scan with all of these, intravenous contrast medium enhancement may show a margin of tumor surrounding a central clot in a bleeding tumor.

EMERGENCY DEPARTMENT EVALUATION

Emergency department evaluation of a suspected IN should begin with a careful history. Direct questioning regarding change in behavior or affect, visual disturbances, weakness, changes in sensation or speech, history of headache or vomiting, and new onset of seizures should be elicited.

Physical Examination

The physical examination should include a detailed neurologic and mental status examination. The most frequent finding in IN is papilledema. It is seen in 50% to 90% of these patients, depending on the stage of the tumor. Therefore, a fundoscopic examination is imperative. These patients do not necessarily complain of visual disturbance, because papilledema does not interfere with visual acuity, but causes an enlargement of the physiologic blind spot. Consequently, visual field confrontation testing must also be performed. Papilledema is a nonspecific, nonlocalizing consequence of increased ICP. Therefore, small tumors such as pituitary adenomas, slow-growing astrocytomas, and brainstem gliomas may be present in the absence of papilledema. Even with an increase in ICP, papilledema may be absent if the patient has a high degree of myopia or if there is a preexistent or resultant optic neuritis from chronic papilledema itself. Venous pulsations, although not always visible, rule out increased ICP when seen. In addition to papilledema and optic atrophy, visual disturbances in brain tumors may include diplopia or visual field defects.

In addition to these various ophthalmic findings, focal neurologic deficits may be identified on neurologic examination, including hemiparesis, positive Babinski sign, cranial nerve palsies, dysarthria, ataxia, dysphasia, and abnormalities in sensation. These signs may have localizing potential, but this is usually lost in the presence of increased ICP. Serial neurologic examinations are essential in any patient suspected of having an IN. Patients who present with acutely elevated ICP may manifest headache, meningismus, bradycardia and hypertension, and altered levels of consciousness. The classic ipsilateral fixed and dilated pupil with contralateral hemiparesis or terminal findings of bilateral fixed and dilated pupils, decerebrate posturing, hypoventilation, tachycardia, and hypotension signify an impending herniation and demand immediate treatment.

In patients suspected of having brain malignancies, a thorough breast, pulmonary, abdominal, and skin examination should be performed to identify possible primary malignancies.

Laboratory Studies

Laboratory workup of patients with suspected IN or of patients who present with altered mental status, new-onset seizures, focal neurologic deficits, or evidence of elevated ICP include complete blood cell count, drug screen, and determination of serum levels of electrolytes (including calcium and magnesium), glucose, and blood urea nitrogen. These are ordered to rule out metabolic or infectious abnormalities. Baseline and serial serum osmolalities should be obtained if mannitol therapy is to be initiated. Liver function tests and measurement of serum ammonia levels may be helpful if hepatic encephalopathy is in the differential diagnosis. Coagulation

studies and type and crossmatch should be ordered if urgent neurosurgical intervention is a consideration.

Radiologic Studies

The major diagnostic tool available for the emergency department evaluation of IN is CT. It defines the anatomic location of a neoplasm and, in many instances, predicts pathologic features. For example, smoothly marginated, homogeneous tumors favor benign disease, whereas irregular, inhomogeneous tumors favor malignancy. More important, CT may be used to rule out IN in suspected patients, because the accuracy of CT for diagnosing brain tumors is approximately 85% in nonenhanced studies and rises to 95% when intravenous contrast agents are used conjunctively. INs appear as abnormal lesions that may displace surrounding structures. Adjacent cerebral edema is often visualized as a low-density halo surrounding the mass. The lesion is further circumscribed with intravenous contrast medium, which outlines the more vascular periphery of the tumor. Multiplicity of tumor suggests metastatic disease. ¹ Most metastatic tumors that are 1 cm or greater are visualized with CT.

Due to greater sensitivity, lack of ionizing radiation, and multiplanar imaging capability, MRI has replaced CT as the first-line imaging study for most patients with subacute or chronic neurologic disease. ¹ For the emergency department patient, however, because of implanted or attached metal devices and ferromagnetic life-support systems that cannot be brought into the scanning arena, CT remains the imaging modality of choice.

In addition, MRI remains more costly and less readily available. The long scanning time for MRI (45 to 60 minutes, compared with 5 to 10 minutes for CT) requires a cooperative, immobile patient. A faster (10- to 15-minute) dual-plane MRI protocol is currently being studied, however. ⁸

Cerebral angiography, although invasive and no longer routinely used, may still be necessary after a CT or MRI study, at the neurosurgeon's discretion. The main indication for IN is to eliminate the possibility of a giant aneurysm or vascular malformation as a cause of the CT abnormality. It is also used as a vascular road map to aid in either stereotactic needle biopsy or preoperative planning.

Miscellaneous Studies

Lumbar puncture is relatively contraindicated in the presence of an IN, but it may be warranted after a negative CT scan if meningeal carcinomatosis, meningitis, or subarachnoid hemorrhage is suspected. Ultrasound waves cannot penetrate bone; therefore, ultrasonography is used only intraoperatively to aid in tumor localization. ⁷ Monoclonal antibodies and gene therapy are being studied for use in both the diagnosis and treatment of IN, but much more work needs to be done in this field before these antibodies can be clinically useful. ^{4,9,13}

EMERGENCY DEPARTMENT MANAGEMENT

Prehospital Care

Management of patients with IN is directed at associated symptoms and complications. Field management should follow the ABCs of emergency medicine: providing airway control, ventilation, and stabilization of circulation with cervical spine immobilization, as necessary. An intravenous line should be established at a keep-vein-open (KVO) rate unless hypotension is present.

Acute Intervention

Once the patient's cardiopulmonary system is stabilized, acute intervention depends on the presentation of the patient. When a confused or comatose patient presents to an emergency department, one should consider administering 50% dextrose, naloxone (Narcan), and thiamine (vitamin B₁) to address the more common or easily treatable causes of coma, such as hypoglycemia, narcosis, and Wernicke encephalopathy.

The patient should be placed on a cardiac monitor and vital signs should be closely followed.

Seizures

Prevention of further seizures or treatment of a patient actively experiencing seizures should be done without further depressing mental status when possible. Phenytoin loading (10 to 15 mg/kg injected i.v. piggyback over 20 minutes) is the therapy of choice. Diazepam or lorazepam should be given to actively seizing patients to control status, in addition to phenytoin. Phenobarbital is reserved as a last-line drug because of CNS depression, but when necessary it may be given 2 to 3 mg/kg initially to a total of 15 to 18 mg/kg.

Increased Intracranial Pressure

For patients suspected of elevated ICP, the head of the bed should be raised 20% to 30% to aid cerebral venous outflow and thus potentiate ICP lowering. Fluids should be given at KVO rate unless the patient is simultaneously hypotensive. In this situation, shock management supersedes and isotonic fluid resuscitation is warranted. In the absence of hypotension, 0.9% normal saline administered at KVO rate is preferred over dextrose 5% in water or other hypotonic solutions, because the latter may precipitate or aggravate cerebral edema.

Hyperventilation

Patients with IN seldom present with acute elevation of ICP, but when they do, emergent treatment is necessary. There is concern that hyperventilation may further insult brain tissue, by inducing secondary ischemia. ^{2,17} However, intubation with hyperventilation is the fastest method to decrease ICP and should be initiated in the patient with radiographic or clinical evidence of herniation. The goal is to keep Pco₂ between 25 and 30 mm Hg. This can be titrated and monitored with serial arterial blood gas measurements. As the partial pressure of carbon dioxide is lowered in the circulation, the cerebrovascular bed constricts, reducing cerebral blood flow (CBF). A rule of thumb is that CBF is reduced by 2% per millimeter of mercury decrease in Pco₂. This in turn reduces the ICP. Excessive hyperventilation with a resultant Pco₂ below 20 mm Hg restricts cerebral perfusion and may result in ischemic sequela. Oxygen supplementation is used to ensure adequate tissue oxygenation and to prevent hypoxia, which itself is a stimulus for ICP elevation.

Controlled rapid-sequence orotracheal intubation protects against the transient rise in ICP associated with laryngoscopy and endotracheal tube insertion. ¹⁵ Preoxygenation and a reduced or priming dose of a neuromuscular blocking agent are administered initially to prevent hypoxia and fasciculations, respectively. The patient is then given a sedative-hypnotic (i.e., 3 to 5 mg/kg of sodium thiopental) and a short-acting neuromuscular blocking agent (i.e., 1.0 to 1.5 mg/kg succinylcholine). Pulse oximetry, continuous monitoring, and CO₂ monitoring are recommended.

Most investigators conclude that 100 mg lidocaine given intravenously 1 to 5 minutes before intubation lowers the risk of transient ICP elevation. The mechanism of action includes cough reflex suppression, increased cerebrovascular resistance, and decreased cerebral blood volume during a period of profound sympathetic stimulation.

Osmotic Agents

Osmotic agents include urea, glycerol, and mannitol, of which mannitol is the agent of choice. These drugs are used in patients with ICP elevation in an attempt to stabilize them until surgical decompression is available.

Osmotic agents are effective in decreasing cerebral edema only in regions of the brain where the blood-brain barrier is intact. The current recommended dose of mannitol is 1 g/kg (range, 0.25 to 2.0 g/kg) of a 20% solution by intravenous infusion over 20 to 30 minutes. Because of potential rebound phenomenon (a secondary rise in ICP as mannitol is taken up by the CNS cells), the smallest effective dose of mannitol should be used. Lower doses are less likely to cause electrolyte and osmotic disturbances. No matter what dose is used, electrolytes, serum osmolality, blood pressure, urine output, and ICP (when possible) should be monitored. Serum

osmolality should be maintained under 310 mOsmol. If the cause of ICP elevation is thought to be an intracranial hemorrhage, mannitol should be used with caution, because it can result in extension of the bleed. Glycerol may be given orally or intravenously, but it is seldom used, because the major complications of hemolysis, acute renal failure, and hyperosmolar coma may occur. Its effectiveness also rapidly decreases after the first day of usage.

Loop Diuretics

Furosemide (Lasix) therapy is recommended in adjunct with mannitol to lower ICP with less elevation of serum osmolality or electrolyte disturbance. For this reason, it has been recommended by some authors to be used alone in the very young or elderly. Furosemide is effective even in the absence of an intact blood–brain barrier, and thus reduces cerebral edema in the pathologic regions of the brain, where osmotic diuretics are ineffective. It also decreases CSF production and sodium influx into the CNS. The recommended dose is 0.5 to 1.0 mg/kg given by i.v. push, and the onset of action is 15 to 20 minutes.

Corticosteroids

Cerebral edema secondary to IN continues to be one of the most widely accepted indications for dexamethasone therapy. Initial dosage is 10 mg given by i.v. push, followed by 4 mg every 6 hours for 48 hours, with tapering over the next 5 to 7 days. Dexamethasone has a delayed effect in decreasing cerebral edema. ¹¹

Miscellaneous

Barbiturate coma, using pentobarbital or thiopental, to control elevated ICP is typically done as a last resort by the neurosurgical–anesthesiology team in the intensive care unit and is not recommended in the emergency department setting. ICP monitoring, in an attempt to keep ICP less than 20 mm Hg, is also postponed until the patient is in the intensive care setting.

Although hypertension is primarily a problem associated with intracranial hemorrhage and not with IN, bleeding into an IN may occur. In this setting, hypertension is usually transient and secondary to ICP elevation. In these cases, hyperventilation, mannitol, and furosemide will all produce a reduction in the blood pressure by lowering the ICP. In a patient whose blood pressure is not adequately controlled with ICP reduction, the key to management is to lower the blood pressure slowly so as to avoid cerebral ischemia.

Nitroprusside (50 µg in 500 mL dextrose 5% in water, at 0.51 µg/kg/min and increased every 5 minutes as necessary to a maximum of 8 µg/kg/min) acts as an arterial and venous dilator. There is concern that the vasodilatory effects of nitroprusside may elevate the ICP by increasing cerebral blood flow. Labetalol, on the other hand, acts as an α₁- and β-adrenergic blocker and has no effect on CBF and no reflex tachycardia. To retain the minute-to-minute control one has with nitroprusside, a labetalol drip should be initiated at 2 mg/min and titrated up to 6 mg/min. Recalling the formula CPP = MAP – ICP, in the absence of malignant hypertension associated with intracranial bleeding or cardiac ischemia, one should err on the side of hypertension to avoid cerebral ischemia.

Therapeutic response of acute intervention is assessed by continuous ICP monitoring when appropriate. In the emergency department, serial neurologic examinations and continuous cardiac and vital sign monitoring suffice.

DISPOSITION

Definitive long-term therapy for IN combines surgical removal or debulking of the tumor, if it can be performed without compromising brain function, with adjunctive irradiation and chemotherapy. ^{12,17}

Role of the Consultant

Neurosurgical consultation is mandatory in all patients with IN. A stat consult is warranted with status epilepticus or suspected ICP elevation. Likewise, all patients with IN are admitted to the neurosurgical unit. Those without significant ICP elevation and with stable vital signs may be admitted to a nonmonitored bed, while those who require hyperventilation or osmotic agents require intensive care monitoring.

Transfer Considerations

In rural or community-based facilities, it may be necessary to transfer patients to a hospital where neurosurgical consultants are readily available. In the absence of clinical or CT evidence of significant cerebral edema, this may be done by a basic life-support unit. If impending herniation or elevated ICP is a concern, either based on clinical examination or by evidence of a midline shift on CT, an advanced cardiac life-support unit or helicopter transport team is warranted. Intubation with hyperventilation and supplemental oxygen, corticosteroids, mannitol, and seizure control should all be initiated before transfer.

COMMON PITFALLS

- Unenhanced CT alone cannot completely exclude IN.
- Because of the nonspecific quality of an IN headache, the diagnosis of brain tumor is often missed initially. Neurologic follow-up is essential in all patients in whom the cause of headache is not reasonably certain.
- An appropriate history and physical examination must be done on all patients, even those with primarily psychiatric symptoms.
- A careful neurologic examination must be done, no matter how trivial the chief complaint seems.
- There are no consistently reliable indicators of elevated ICP.
- Not everyone with elevated ICP has papilledema.
- Withholding mannitol and diuretics in a patient who displays signs of impending herniation while awaiting CT confirmation or neurosurgical consultation is unwise.

The evaluation of cranial nerve function in the emergency department is a critical part of the neurologic examination. A detailed cranial nerve examination can be performed rapidly and is very helpful in establishing localization of lesions, especially when consciousness is impaired and assessment of sensory and motor function is difficult. Dysfunction of the individual cranial nerves may occur but, often, there is involvement of other cranial nerves or “long tracts,” which helps to pinpoint the lesion.

CRANIAL NERVE I (OLFACTORY)

CLINICAL PRESENTATION

The olfactory nerve subserves the sense of smell but is also important in the perception of taste. Difficulty perceiving odors is most often due to intranasal conditions such as the common cold. The olfactory epithelium is connected to the olfactory bulb by sensory axons projecting through the cribriform plate of the ethmoid bone. Fracture of the ethmoid bone with trauma may cause loss of smell and leakage of cerebrospinal fluid (CSF rhinorrhea). Rapid deceleration of the head can cause shearing forces that tear the olfactory axons and produce loss of smell. The location of the olfactory bulbs on the floor of the frontal fossa makes them susceptible to compression from space-occupying lesions in the frontal lobes, but this effect usually develops gradually. Associated findings may include disinhibition or personality change.

DIFFERENTIAL DIAGNOSIS

As stated, the most common causes for altered smell are intranasal, including the common cold. Traumatic disruption of olfactory fibers needs to be considered. Frontal lobe mass lesions include tumors (meningioma, glioma) and abscesses.

EMERGENCY DEPARTMENT EVALUATION

The sense of smell is tested using common odors such as coffee or fruit. Each nostril should be tested individually, and precise identification is not important. Irritating stimuli such as ammonia should be avoided, as they result in stimulation of the trigeminal nerve. If CSF rhinorrhea is suspected, the fluid can be analyzed to determine whether it has the characteristics of CSF. A computed tomography (CT) scan of the head should be performed to rule out fractures, contusions of the frontal lobes from coup/contrecoup injuries, or pneumocephalus. Associated findings in the setting of a mass lesion may include papilledema.

EMERGENCY DEPARTMENT MANAGEMENT

Management of these patients is typically directed to the associated injuries, as trauma is the most common cause.

DISPOSITION

Role of the Consultant

Neurosurgical consultation may be required to assess the need for urgent surgery if there is evidence of increased intracranial pressure (ICP) or CSF rhinorrhea.

Indications for Admission

Patients with CSF leaks should be monitored for evidence of possible infection, as the barrier to pathogens entering the brain has been breached.

Transfer Considerations

If a mass lesion or significant traumatic brain injury is detected, transfer to a facility with neurosurgical capability is required.

COMMON PITFALLS

As patients with frontal lobe tumors may behave strangely, they may be felt to have a psychiatric basis of their complaint of loss of smell or taste. Unusual odors may indicate temporal lobe seizures.

CRANIAL NERVE II (OPTIC)

CLINICAL PRESENTATION

Dysfunction of the optic nerve leads to complaints of blurred vision or loss of vision. The correct characterization of the pattern of visual loss is key to establishing the localization and possible etiologies. Monocular dysfunction implies an abnormality of the retina or optic nerve. Bitemporal hemianopsia (loss of the temporal half of the visual field of both eyes) localizes to the optic chiasm. Retrochiasmatal lesions produce homonymous (the same in both eyes) visual field defects ([Fig. 60.1](#)).

Figure 60.1. Lesions in the optic pathways.

DIFFERENTIAL DIAGNOSIS

Acute monocular visual loss is typically due to vascular causes. The classic history of “a shade being pulled down” that is described for amaurosis fugax need not be present. The source of the emboli that cause the visual loss in most cases is atherosclerotic disease of the carotid artery. This may lead to other transient ischemic attacks (TIAs) in the ipsilateral hemisphere. However, temporal arteritis, which is often associated with headache and/or jaw claudication in patients over age 60, needs to be considered. Other pathology of the retina or globe, such as hemorrhage or central retinal vein occlusion, should be kept in mind. Symptoms of optic neuritis³ usually include blurriness rather than loss of vision, and possibly eye pain (especially with eye movement). Slowly developing papilledema due to an intracranial mass in “noneloquent” parts of the brain or pseudotumor cerebri may also cause blurring or loss of vision, often accompanied by headache. Acute angle-closure glaucoma can lead to rapid loss of vision associated with eye or head pain.

EMERGENCY DEPARTMENT EVALUATION

Testing of optic nerve function involves assessment of visual acuity, visual fields, pupillary light reflex, and the funduscopic examination. Acuity should be assessed with glasses or by using a pinhole to compensate for refractive errors. Visual field testing at the bedside is performed on each eye, using the confrontation method to compare with one's own visual fields. The funduscopic examination is frequently difficult in patients with poor cooperation, cataracts, or periorbital edema. The goal is to exclude papilledema, retinal hemorrhage, or markedly increased intraocular pressure (increased optic cup-to-disc ratio). Absence of papilledema does not exclude acutely increased ICP, because it takes time to develop. An afferent pupillary defect is typically found with optic neuritis.

Papilledema and visual field defects require evaluation with a CT scan. If this is normal, a lumbar puncture to measure opening pressure and to exclude an indolent infectious etiology such as cryptococcus should be performed in the setting of papilledema. A sedimentation rate and C-reactive protein should be ordered if temporal arteritis is suspected. Measurement of intraocular pressure should be performed if glaucoma is considered.

EMERGENCY DEPARTMENT MANAGEMENT

Management is dependent on the etiology of visual loss. Recurrent episodes of monocular visual loss with resolution or in association with other TIAs may be an indication to start the patient on intravenous (i.v.) heparin (with no bolus on initiation) until the vasculature can be evaluated by ultrasonography or arteriography. Optic neuritis is somewhat less likely to lead to future development of multiple sclerosis if treated with i.v. steroids, and this can be initiated as soon as the diagnosis is established. Temporal arteritis should be treated with a high dose of oral steroids (60 to 80 mg of prednisone per day) to prevent visual loss. This should *not* be postponed until temporal artery biopsy can be performed, as it does not reduce the yield and the risk of visual loss is high. Although papilledema is usually caused by increased ICP, this does not need to be treated acutely with mannitol or hyperventilation unless there is decreased level of consciousness or deterioration of neurologic status.

DISPOSITION

Role of the Consultant

Consultation with a neurologist should be obtained in cases of amaurosis fugax, visual field defects, and suspected optic neuritis. If retinal or other intraocular pathology is suspected, it may be necessary to consult an ophthalmologist. If papilledema is due to an intracranial mass, a neurosurgical opinion should be obtained.

Indications for Admission

Amaurosis fugax or visual field defects require admission for workup. Optic neuritis should be treated with high-dose i.v. steroids as an inpatient. If papilledema is due to a mass, admission for possible surgery is usually required. Temporal arteritis can be managed on an outpatient basis with close follow-up and arrangement for a temporal artery biopsy.

Transfer Considerations

Mass lesions require the availability of neurosurgical evaluation and management. The patient should be transferred to an alternative facility if this is not available.

COMMON PITFALLS

- Patients are notoriously poor at characterizing the pattern of visual loss. They often state that they have lost vision in an eye when a field defect is present. Also, patients are often unaware of visual field loss, particularly when associated with parietal lobe dysfunction. As such, omission of visual field testing leads to misdiagnosis or improper localization of the lesion.
- Difficulty visualizing the fundi leads to the temptation to use dilating eye drops, but they should be avoided unless intracranial pathology has been definitely excluded. Patients who have papilledema are sometimes treated for increased ICP unnecessarily, which may make the treatment ineffective when it is really needed.

CRANIAL NERVES III, IV, AND VI (OCULOMOTOR, TROCHLEAR, AND ABDUCENS)

CLINICAL PRESENTATION

The cranial nerves that control eye movements are discussed together, as dysfunction of any produces diplopia or dysconjugate gaze. The third nerve supplies all of the extraocular muscles except the lateral rectus (sixth; abduction of the eye) and the superior oblique (fourth; inferior nasal movement and intorsion of the eye). The levator palpebrae superioris (elevation of the lid) and pupillary constrictor muscles are also supplied by cranial nerve three. A complete third nerve lesion results in marked ptosis, diplopia and a “blown” (dilated) pupil. The eye is deviated laterally due to unopposed action of the lateral rectus, and the superior oblique cannot be tested well.

Partial third nerve palsy due to extrinsic compression causes dysfunction of the more superficial parasympathetic fibers, resulting in pupillary dilatation. Ischemia of the nerve (often painful at onset) spares the pupillary fibers while the remaining functions are affected. Diplopia is most prominent when moving the eyes in the direction of function of the paretic muscle. Thus, with sixth nerve palsy, diplopia is maximal on lateral gaze ipsilaterally. Patients with fourth nerve lesions unconsciously compensate for diplopia by developing a head tilt toward the unaffected side and complain of diplopia when walking down steps (looking down and in).

DIFFERENTIAL DIAGNOSIS

Isolated third cranial neuropathies are most often due to ischemia and present with pain at onset. The most common underlying cause is diabetes, and a similar presentation can be seen with fourth and sixth cranial nerve palsies. Isolated fourth nerve palsy is most often due to trauma that may be relatively minor. The sixth nerve has the longest intracranial course of the cranial nerves and travels along the base of the skull, bending over the ridge of the petrous portion of the temporal bone. It is susceptible to stretch as a nonspecific effect of increased ICP (the false localizing sign). Infection in the mastoid or middle ear may spread to involve the petrous bone and cause a sixth nerve palsy that may be associated with facial pain (Gradenigo syndrome).¹

Combined dysfunction of the nerves supplying the extraocular muscles may result from lesions in areas where they are in close proximity to one another. This includes the cavernous sinus and the superior orbital fissure,¹ where associated findings help to localize the lesions. Cavernous sinus lesions may cause dysfunction of the trigeminal nerve (first and second divisions) or the sympathetic fibers as they travel with the carotid artery. In the superior orbital fissure, associated involvement of the frontal, lacrimal, or nasociliary branches of the first division of the trigeminal nerve may occur. Cavernous sinus thrombosis or carotid–cavernous

fistula is associated with proptosis of the eye and dilation of the scleral vessels ipsilaterally.

Conditions that affect the extraocular muscles but not the nerves need to be considered. Myasthenia gravis causes fluctuating and fatigable diplopia and ptosis that may be associated with limb weakness, dysarthria, dysphagia, or shortness of breath. Thyroid ophthalmopathy and orbital pseudotumor are other etiologies of abnormal extraocular movement.

Finally, multiple sclerosis or ischemic disease of the brainstem can cause an intranuclear ophthalmoplegia (INO). This is due to a lesion in the medial longitudinal fasciculus, which functionally connects the third and sixth nuclei to allow conjugate lateral gaze. When attempting to look in the affected direction, the ipsilateral eye abducts, but the contralateral eye cannot adduct, and there is nystagmus of the abducting eye with diplopia.

EMERGENCY DEPARTMENT EVALUATION

The key is determining which eye movements are abnormal and whether there are associated findings. The most dangerous scenario is the development of a dilated pupil in a patient who has reduced responsiveness. This is an indication of herniation, and the patient should be intubated, hyperventilated, and given mannitol i.v. to attempt to decrease ICP. If a brainstem lesion is suspected based on associated findings, a CT scan should be performed to exclude a hemorrhagic etiology. Detection of proptosis, Horner syndrome, or facial numbness indicates the need to evaluate the cavernous sinus. This can be achieved with contrasted magnetic resonance imaging (MRI), if available, or conventional angiography.

EMERGENCY DEPARTMENT MANAGEMENT

A “blown” pupil should be treated as an extreme emergency with impending death. As such, the usual measures to lower ICP should be instituted, as mentioned earlier. Cavernous sinus thrombosis may be related to infections that require institution of antibiotics.

DISPOSITION

Role of the Consultant

Neurosurgical consultation is required for patients who have herniation syndromes, if they survive the initial insult. A neurologist's opinion should be sought in cases involving long tract findings or facial numbness in association with eye movement abnormalities, as this implies the possibility of brainstem lesions.

Indications for Admission

A brainstem lesion, herniation, or cavernous sinus involvement requires admission for further workup.

Transfer Considerations

Transfer to a facility with neurosurgical backup is required after stabilization of patients who have evidence for herniation. The remaining problems can typically be worked up without need for transfer, as long as CT scanning is available.

COMMON PITFALLS

- Rarely, patients will unwittingly put drugs (e.g., cocaine) in their eyes; the presence of a “blown” pupil in an otherwise awake and alert patient without any other evidence of neurologic dysfunction raises that possibility.
- Myasthenia gravis can present with eye movement abnormalities mimicking lesions of cranial nerves three, four, and six.
- If patients have any associated shortness of breath or dysphagia, they require admission for close monitoring and immunomodulatory therapy.

CRANIAL NERVE V (TRIGEMINAL)

CLINICAL PRESENTATION

Isolated dysfunction of the fifth cranial nerve is rare. The most common presentation is the excruciating facial pain seen in trigeminal neuralgia (tic douloureux ²). This pain is lancinating and brief; aggravated by cold, chewing, yawning, touching the face, or shaving; may be referred to the teeth or mouth; most commonly involves the distribution of the second division of the trigeminal nerve (V_2); and may be seen in patients with multiple sclerosis. Pain in the distribution of the trigeminal nerve may herald the onset of herpes zoster (shingles). This is most troubling when the first division of the trigeminal nerve (V_1) is involved, as the cornea may be affected.

Facial numbness is not unusual with ischemic lesions of the brain or brainstem, but the presence of other symptoms or signs indicates this is not of peripheral origin. A lesion in the lower medulla or upper brainstem may affect the spinal nucleus of the trigeminal nerve. This can cause an unusual pattern of sensory loss known as an “onion skin.” This describes concentric circles beginning at the mouth and extending farther out on the face. Cavernous sinus syndromes may involve V_1 and/or V_2 , with resulting numbness in those distributions.

Weakness of the muscles of mastication due to a lesion of the trigeminal nerve is exceedingly rare.

DIFFERENTIAL DIAGNOSIS

Facial pain can also result from migraine headache, cluster headache, dental problems such as abscesses, and temporomandibular joint (TMJ) syndrome. Jaw claudication (pain with chewing) occurs in temporal arteritis, and there may be fatigue of the jaw muscles with chewing tough foods in myasthenia gravis.

Perioral numbness may be due to panic attack if the other characteristic features are present (feeling of impending doom, heart racing, feeling of air hunger, dizziness). Facial numbness or pain may also be psychogenic, but this is a diagnosis of exclusion.

EMERGENCY DEPARTMENT EVALUATION

Facial pain evaluation should include a careful inspection and palpation of the oral cavity to rule out dental problems. With herpes zoster, special attention should be given to the cornea.

The evaluation of trigeminal nerve function should involve testing light touch, pinprick, and the corneal reflexes. Involvement of other cranial nerves might suggest a brainstem or cavernous sinus lesion. Rule out any long-tract signs, which might indicate a cortical or subcortical localization.

EMERGENCY DEPARTMENT MANAGEMENT

Trigeminal neuralgia responds best to treatment with carbamazepine, gabapentin, or phenytoin. Herpes zoster should be treated with acyclovir. Trigeminal distribution herpes zoster in an immunocompromised host is an indication for i.v. acyclovir.

DISPOSITION

Role of the Consultant

If there is suspicion that the patient may have an ischemic etiology of facial numbness, a neurologic consultation should be obtained. Involvement of the cornea in herpes zoster warrants evaluation by an ophthalmologist.

Indications for Admission

Trigeminal distribution herpes zoster in an immunocompromised host is an indication for admission and i.v. therapy. Ischemic etiologies of facial numbness require admission for further workup.

Transfer Considerations

Patients with facial pain or numbness rarely require transfer unless CT scanning is not available.

COMMON PITFALLS

- Perioral numbness due to the “onion skin” arrangement of trigeminal representation in low medullary or very high cervical spine lesions may mistakenly be passed off as a panic attack or hyperventilation.
- Patients with trigeminal neuralgia may be convinced that they have dental problems even after this diagnosis has been excluded by a dentist.
- Isolated sensory loss involving the chin due to involvement of the mental branch of the trigeminal nerve has been said to be a sign of underlying malignancy until proven otherwise.
- A reduced corneal reflex is not necessarily indicative of brainstem or trigeminal nerve dysfunction as it may be seen in cortical or subcortical lesions.

CRANIAL NERVE VII (FACIAL)

CLINICAL PRESENTATION

The most common isolated cranial neuropathy is facial nerve or Bell's palsy. The presentation usually involves pain behind the ear, followed by decreased ability to move the ipsilateral side of the face. It can progress to inability to close the eye, with drying and irritation. There may be difficulty maintaining saliva in the mouth and pocketing of food in the lax jaw. Patients rarely complain of difficulty with taste, although taste may be absent from the anterior two-thirds of the tongue, if tested. Sounds may seem louder in the affected ear (hyperacusis).

Although the patients often complain that the face feels numb, there is no loss of sensation when tested (although it may feel “different” on that side). Rarely, there is in the external auditory canal an associated herpes zoster lesion, which receives sensory innervation from the facial nerve (Ramsay-Hunt syndrome). Bilateral facial weakness (facial diplegia) can occur in isolation. There are also involuntary movements involving half of the face, termed *hemifacial spasm*.

DIFFERENTIAL DIAGNOSIS

The primary distinction to be made is whether there is an upper motor neuron or lower motor neuron pattern of the facial weakness. Because the corticobulbar pathway supplies input to both sides of the forehead, this is spared in the case of an upper motor neuron lesion. Possible etiologies of facial nerve palsy include herpes zoster, Lyme disease, sarcoidosis, and Guillain-Barré syndrome, although Bell's palsy is the most common. Myasthenia gravis may also cause acute facial weakness that is usually bilateral ([Fig. 60.2](#)).

Figure 60.2. Facial nerve (VII).

EMERGENCY DEPARTMENT EVALUATION

Determination of the absence or presence of forehead involvement is the first objective. Next, exclude active herpes zoster lesions. Then, decide on the severity of the facial weakness—can the patient close the eye? If there is bilateral facial weakness, is there more widespread weakness or loss of reflexes, which might suggest myasthenia gravis or Guillain-Barré syndrome?

EMERGENCY DEPARTMENT MANAGEMENT

If the facial weakness is prominent, the cornea will require protective treatment. This usually involves the patient using artificial tears while awake and placing an eye lubricant in the eye, with the eye covered by a patch, at night. There is controversy about the routine use of steroids and, more recently, the use of acyclovir to treat Bell's palsy; these issues have not been resolved.⁴

DISPOSITION

Role of the Consultant

- If there is any question regarding the differentiation of an upper motor neuron versus lower motor neuron pattern of facial weakness, a neurologist should be consulted. Associated findings of weakness or areflexia, which might suggest Guillain-Barré syndrome, warrants neurologic evaluation as well.

Indications for Admission

If the facial weakness is due to an ischemic etiology, the patient will require admission for further workup. Facial weakness associated with Guillain-Barré also justifies admission for close observation.

Transfer Considerations

Facial weakness can usually be evaluated without the need for transfer to another facility.

COMMON PITFALLS

- Do not forget to protect the cornea and caution the patient regarding the possibility of worsening weakness, which can lead to inability to close the eye.

CRANIAL NERVE VIII (VESTIBULOCOCHLEAR)

CLINICAL PRESENTATION

Dysfunction of the vestibular portion of the eighth nerve manifests as vertigo. Patients frequently complain of feeling “dizzy,” but when questioned describe a sense of movement or spinning. Nausea and vomiting are frequently associated symptoms. Hearing loss or tinnitus indicates dysfunction of the cochlear portion of the nerve.

DIFFERENTIAL DIAGNOSIS

Benign paroxysmal positional vertigo (BPPV) is the most common etiology, particularly in the older population. The patient notices that turning the head in a particular direction causes intense vertigo (usually with a brief delay after moving), associated with nausea and vomiting, that quickly subsides. “Central” vertigo due to brainstem or cerebellar dysfunction tends to occur without delay and does not usually have a positional predilection. Labyrinthitis is also associated with severe feelings of vertigo, but it is usually more persistent than that seen with BPPV. Ménière disease involves recurrent attacks of vertigo, associated with roaring tinnitus and progressive loss of hearing. Migraine headaches are also associated with vertigo. Drugs, including alcohol, cause vertigo and need to be considered in any patient with this complaint. Acute unilateral hearing loss can be seen with ischemia involving the cochlear artery, a branch of the anterior inferior cerebellar artery. Patients may become suddenly aware of hearing loss that develops insidiously, such as that caused by an acoustic neuroma. Other cerebellopontine angle tumors, such as meningioma, need to be considered in the differential diagnosis of hearing loss, especially if there is associated facial weakness or numbness.

EMERGENCY DEPARTMENT EVALUATION

The eyes should be observed for spontaneous nystagmus, and then in all directions of gaze. Vertical nystagmus suggests central dysfunction or a toxic etiology. A provocative test known as the Dix-Hall-Pike maneuver (or Nylen-Barany maneuver) should be performed. The patient is asked to position himself or herself on the stretcher such that, when supine, the neck will just meet the end. The patient is rapidly moved from a seated to a supine position with the neck extended approximately 30 degrees and the head turned such that one ear faces the ground. The patient is questioned regarding the appearance of vertigo, and the eyes are observed for nystagmus. If positive, the patient tends to forcibly close the eyes, so they cannot be observed. The keys are to determine whether there is a clear asymmetry of the vertigo response, whether there is a delay between moving the patient and onset of symptoms, and whether there is fatigue of the response. If there is any question regarding the possibility of alcohol or drug ingestion, appropriate laboratory studies should be obtained. Hearing should be tested in each ear by using a finger rub or watch. A tuning fork can be used to look for evidence of lateralization of hearing (to the good ear with sensorineural hearing loss) or reduced air conduction (on the side with conductive hearing loss).

EMERGENCY DEPARTMENT MANAGEMENT

If patients have significant associated vomiting, they may become dehydrated and require fluid or electrolyte replacement. Medications to treat vertigo include the benzodiazepines and meclizine.

DISPOSITION

Role of the Consultant

If there is uncertainty regarding the differentiation of central versus peripheral vertigo, consultation with a neurologist or an ear, nose, and throat (ENT) specialist should be sought.

Indications for Admission

Central nystagmus that is not induced by drugs or alcohol suggests a brainstem lesion, which is an indication for admission.

Transfer Considerations

Transfer may be necessary if neurologic consultation is not available.

COMMON PITFALLS

BPPV causes severe vertigo, and the pattern on provocative testing (Dix-Hall-Pike) of delayed vertigo and fatigue of the response are characteristic. A few beats of nystagmus on far lateral gaze are frequently seen in normal individuals as they break visual fusion of the image. This can be evaluated by simply moving the test finger back a few degrees or not moving to the extremes of gaze.

CRANIAL NERVES IX AND X (GLOSSOPHARYNGEAL AND VAGUS)

CLINICAL PRESENTATION

Isolated dysfunction of cranial nerve nine or ten is quite rare. The primary manifestation of the dysfunction is difficulty swallowing. Occasionally, dysarthria due to decreased palatal movement may be the presenting symptom. A rare presentation of ninth cranial nerve dysfunction is glossopharyngeal neuralgia. This is similar in characteristics to trigeminal neuralgia but involves the throat and is precipitated by swallowing or tongue movement.

DIFFERENTIAL DIAGNOSIS

The majority of patients who have dysphagia on a neurologic basis have ischemic lesions in the cortex, subcortical areas, or brainstem. The dysphagia is much more prominent and is a presenting complaint in the case of brainstem lesions, particularly in the lateral medulla. Oral or nasal tumors need to be considered, especially in those with a history of smoking. Myasthenia gravis can cause palatal dysfunction, with a resulting nasal speech as well as nasal regurgitation of liquids on attempted swallowing. Involvement of these nerves at the base of the skull as they exit through the jugular foramen (by metastases to the bone or skull fracture) is often accompanied by involvement of the spinal accessory nerve.⁵

EMERGENCY DEPARTMENT EVALUATION

The function of the palate should be assessed by having the patient say “ah” while watching for clear deviation of the uvula to one side, and also testing the gag reflex bilaterally. Because most cases of difficulty swallowing are not due to isolated dysfunction of cranial nerves nine or ten, associated findings to suggest ischemic lesions (hemiparesis, Horner syndrome, etc.) or neuromuscular disease should be carefully sought.

EMERGENCY DEPARTMENT MANAGEMENT

If patients' swallowing dysfunction is severe enough to impair the ability to safely swallow their own saliva, they may require intubation to prevent aspiration. This is usually required only when there is associated depressed level of consciousness. If the dysfunction is less prominent, simply keeping the patient NPO until they can

be thoroughly evaluated by a speech pathologist may be all that is required.

DISPOSITION

Role of the Consultant

If there is a question of ischemic neurologic dysfunction of the brain or brainstem, a neurologist should be consulted. In the event of pain involving the throat that does not seem to involve a simple strep infection, an ENT evaluation may be indicated.

Indications for Admission

If patients have severe swallowing dysfunction, they will need admission for i.v. fluids, and perhaps nasogastric tube feeding if it is not resolving rapidly. Palatal dysfunction due to a stroke necessitates admission for determination of the underlying etiology.

Transfer Considerations

Patients with dysphagia can usually be evaluated and treated without need for transfer.

COMMON PITFALLS

If there is concern regarding patients' ability to swallow, do not allow them to take anything by mouth until they can have a formal swallowing evaluation. Missing a few meals will not do any long-term harm, but a case of aspiration pneumonia can be deadly.

CRANIAL NERVE XI (SPINAL ACCESSORY)

CLINICAL PRESENTATION

Dysfunction of the spinal accessory nerve is almost never seen in the emergency setting. The function of this nerve is purely motor, supplying the sternocleidomastoid (SCM) and trapezius muscles. It is very superficial in location and can be injured with penetrating trauma of the neck. This results in a drooping shoulder or winging of the scapula that is maximum on abduction of the arm and weakness of the SCM. Shoulder pain may be a prominent complaint with trapezius weakness. SCM weakness results in difficulty rotating the head in the opposite direction.

DIFFERENTIAL DIAGNOSIS

Winging of the scapula can be produced by weakness of the trapezius, serratus anterior, or rhomboid muscles. The position of the scapula protruding and the position producing maximal winging allow differentiation. With serratus anterior weakness, the medial and inferior borders protrude, and this is accentuated with the arms outstretched in front of the body, especially with pushing against a wall. With rhomboid weakness, the superior and medial borders protrude, and this is accentuated by elevating the arm over the head. With trapezius weakness, the inferior angle is rotated medially, and this is accentuated by abducting the arms. Pain and drooping of the shoulder are much more likely to be caused by dislocation or rotator cuff injuries. The spinal accessory nerve may be involved in cases of idiopathic inflammatory brachial plexopathy (Parsonage-Turner syndrome), which usually involves the upper trunk of the brachial plexus. The accessory nerve may be damaged in the jugular foramen along with the glossopharyngeal and vagus nerves.⁵

EMERGENCY DEPARTMENT EVALUATION

Other potential causes for shoulder drooping or pain are evaluated by palpating the shoulder, performing range of motion, and testing for weakness. Shoulder x-rays may be necessary. Testing for winging of the scapula with the arm in various positions, as outlined earlier, should be performed. Associated dysfunction of cranial nerves nine and ten needs to be excluded, and, if there is evidence of involvement of all three, a CT scan of the head with bone windows to examine the jugular foramen is indicated.

EMERGENCY DEPARTMENT MANAGEMENT

Providing analgesia for pain and, possibly, a sling due to drooping of the shoulder as a result of trapezius weakness are the primary concerns in managing patients with accessory nerve dysfunction.

DISPOSITION

Role of the Consultant

Referral to a neurologist to evaluate the cause of scapular winging and to perform electromyography, if deemed necessary, can be accomplished in the outpatient setting.

Indications for Admission

A skull base lesion causing a jugular foramen syndrome is an indication for admission.

Transfer Considerations

Dysfunction of cranial nerve eleven can be evaluated and treated without transfer.

COMMON PITFALLS

- Weakness of the SCM causes difficulty rotating the chin away from the affected side (recall the origin and insertion of the muscle to understand its action).

CRANIAL NERVE XII (HYPOGLOSSAL)

CLINICAL PRESENTATION

The function of the hypoglossal nerve is purely motor; it supplies the ipsilateral tongue. Dysfunction results in weakness that manifests as deviation toward the side of the weakness with protrusion. Abnormal movements of the tongue may be seen with drug-induced movement disorders such as tardive dyskinesia.

DIFFERENTIAL DIAGNOSIS

Isolated weakness of the tongue is rare. Often, there is associated facial weakness, reduced gag, or extremity weakness with an upper motor neuron lesion. Skull fractures may involve the hypoglossal nerve, but they tend to be associated with other severe injuries. Brainstem strokes causing tongue weakness are unusual. Myasthenia gravis may cause weakness of the tongue that is asymmetric and usually associated with some facial weakness, diplopia, or palatal dysfunction.

EMERGENCY DEPARTMENT EVALUATION

Ensuring that the patient does not have associated dysfunction of cranial nerves nine or ten, which may make it difficult to protect the airway, is paramount.

EMERGENCY DEPARTMENT MANAGEMENT

Ensuring the ability to maintain a patent airway is the primary goal. If there is severe tongue weakness, insertion of an oral bite-guard may be required to prevent the tongue from moving posteriorly and blocking the airway.

DISPOSITION

Role of the Consultant

Because the most common cause for tongue weakness or deviation is brain ischemia, neurologic consultation is usually indicated.

Indications for Admission

Tongue weakness is most often due to stroke, and this should be evaluated on an inpatient basis.

Transfer Considerations

Transfer is needed only if the patient requires neurologic evaluation that is not available.

COMMON PITFALLS

Patients who have conversion disorder will occasionally deviate the tongue to the “wrong” side (away from the hemiparesis), believing that if it is weak, it will not move toward the side of weakness.

BRAINSTEM ISCHEMIA

CLINICAL PRESENTATION

Vascular disease affecting the brainstem (vertebrobasilar stroke or TIA) is common. There are characteristic symptoms that increase the likelihood of brainstem localization, especially when seen in combination. These include diplopia, vertigo, dysphagia, dysarthria, facial sensory loss, ataxia, abnormal breathing patterns, or altered level of consciousness. The presence of “crossed” findings (sensory or motor disturbances that involve one side of the face and the contralateral body) or Horner syndrome also suggests a brainstem lesion. The appearance of multiple symptoms localizing to the brainstem in a stepwise fashion can indicate basilar artery thrombosis, which carries a high risk for death or severe disability.

DIFFERENTIAL DIAGNOSIS

Nonischemic etiologies of brainstem dysfunction, such as hemorrhage, demyelinating disease, and brainstem tumors, need to be considered. The CT scan helps to exclude hemorrhage, and the evolution and associated findings usually allow differentiation of stroke from tumor or demyelination.

EMERGENCY DEPARTMENT EVALUATION

The emergence of tissue plasminogen activator (TPA) as an option for acute stroke intervention has led to the need for very rapid evaluation of patients who may benefit. Thus, neurologic examination, routine laboratory studies, and establishment of an i.v. should be performed early. Also, rapid CT scanning is critical to decision making. Involvement of a “stroke team” or neurologist experienced in administration of TPA is desirable. Assuring that the patient can protect the airway is of great importance with dysphagia or depressed level of consciousness.

EMERGENCY DEPARTMENT MANAGEMENT

TPA should be considered in patients that present and are evaluated within 3 hours. If there is concern for basilar artery thrombosis, institution of i.v. heparin may be appropriate.

DISPOSITION

Role of the Consultant

If there is any question regarding brainstem ischemia, a neurologist should be consulted.

Indications for Admission

Brainstem strokes and TIAs are indications for admission to establish the etiology. Failure to treat the underlying cause can lead to severe morbidity or death.

Transfer Considerations

If the emergency department initially evaluating the patient does not administer TPA for acute stroke and the patient presents early enough that he or she may be a candidate, then transfer to an alternative facility is indicated.

COMMON PITFALLS

- Cortical and subcortical lesions may cause dysfunction that suggests a brainstem location. This is most likely due to interruption of the corticobulbar pathways or central projections of sensory pathways.
- The most common abnormalities that lead to erroneous assignment of the problem to the brainstem are facial weakness, facial numbness, tongue deviation, decreased gag reflex, reduced corneal reflex, and dysarthria.

It is important to separate infectious diseases of the male reproductive organs from diseases of the male urinary tract. Complaints of dysuria, urgency, frequency, and hesitancy may indicate urethritis, lower urinary tract infection (cystitis), pyelonephritis, or disease of any of the organs connected or adjacent to the urethra, bladder, ureters, or kidney. Consideration must also be given to disease of the prostate, vas deferens, seminal vesicles, epididymides, and testes, because these organs are contiguous with the male urinary tract and patients with these disorders may present with similar symptoms.

Despite the classic teaching that women have more frequent urinary tract infections (UTIs), if all forms of male-specific infections, such as urethritis and epididymitis, are included in the incidence of UTI, occurrence rates are probably equal in both sexes during the adult years. If prostatitis is added to the incidence of cystitis, men probably have more UTIs after the fifth decade.⁸

CLINICAL PRESENTATION

History

The hallmark of UTI is dysuria. Other symptoms include urgency and increased frequency of urination in small amounts, cloudy or foul-smelling urine, and hematuria. In the older man, difficulty in initiation of voiding, dribbling, or a less forceful urinary stream suggests the presence of prostatism. The emergency physician should inquire about fever, chills, and back, suprapubic, or perineal pain. A history of prior UTI and diagnostic or operative procedures of the urinary tract is important. Information concerning the patient's sexual preferences and recent sexual contacts, prior sexually transmitted diseases (STDs), and significant complicating medical conditions, such as diabetes, kidney transplant, or other potential immunosuppressive conditions, should be sought.^{7,13,16,19}

Physical Examination

As with all emergency department (ED) patients, general condition, vital signs, and fever should be noted. Toxic patients should have intravenous lines started immediately. The abdomen should be examined for masses, bladder fullness, bruits, and tenderness or guarding. The back must be checked for masses, bruits, and costovertebral angle tenderness; the scrotum should be examined for tenderness and masses; the urethra should be inspected for discharge or sores; the prepuce should be retracted and inspected; perianal sores, rectal tenderness, perineal tenderness, and prostatic tenderness should be sought. Specific attention should be given to the presence of groin sores or lymphadenopathy and the presence of penile lesions.

Laboratory Studies

The hallmark of UTI is the presence of leukocytes and bacteria in otherwise uncontaminated urine. Diagnosis of a UTI in males does not require obtaining urine by the "clean-catch midstream voided urine" or catheterization.¹⁸ In males, there appears to be no significant difference in numbers of contaminating organisms obtained with clean-catch versus routine voiding samples. In the male, 10^3 colony-forming units (CFUs) per milliliter of a single organism is sufficient to diagnose true infection. In the ED, a positive leukocyte esterase dip test is sufficient to establish the presence of pyuria. A white blood cell count of 2 to 5 per high-power field or greater on microscopic examination corresponds to significant bacteriuria as well.⁸

Although a simple urinalysis does not reliably localize infection within the male genitourinary tract, the clinical picture and epidemiologic features of the patient's presentation will usually separate cystitis and pyelonephritis from disorders of the prostate or urethra and genitalia. If the history is suspicious for urethritis and laboratory confirmation is desired, smears for Gram stain, immunofluorescence assay, or culture for *Chlamydia* and urethral culture for gonorrhea may be done. These are most accurate when the patient has not voided for several hours. A contrary and pragmatic view is that, in the man with clinical urethritis, the presence of leukocytes on dipstick leukocyte esterase test or microscopic examination of urine is more sensitive as a screening tool than a positive microscopic examination of a urethral smear for leukocytes.²⁰

If a UTI is suspected on clinical grounds, the presence of leukocytes in the urine should be sought and a urine culture should be obtained; blood cultures are indicated in the patient with presumed pyelonephritis. Although cultures are not useful in initial ED management, this information will help to guide future antibiotic choice in the event of failure to respond to initial therapy.

URETHRITIS

Urethritis is the most common urologic infection in men. It is important to appreciate that in the young male who is sexually active, dysuria with or without discharge is almost always due to urethritis. Isolated infection of the bladder or the kidney (the “classic” UTI) is rare in young, otherwise healthy males.

Urethritis has traditionally been classified as either gonococcal or nongonococcal. With easy and accurate *Chlamydia* identification techniques, it is now apparent that this is an artificial separation because both chlamydial and gonorrheal infections are commonly present in the same patient and are often contracted from the same contact.

The Centers for Disease Control and Prevention estimates that there are between 800,000 and 1 million cases of gonorrhea per year, the incidence being strongly influenced by prevalent sexual attitudes and preferences. Because nongonococcal and chlamydial urethritis are not reportable diseases, an estimate of the number of affected patients is more difficult to determine. The reported incidence of nongonococcal urethritis in Great Britain exceeds the incidence of gonorrhea by a ratio of almost 2:1, and similar findings are reported for Sweden.²

Gonococcal Urethritis

CLINICAL PRESENTATION

A purulent urethral exudate noted a few days after a sexual encounter, associated with dysuria, is the most common presentation in symptomatic heterosexual men. The usual incubation period is between 3 and 5 days, but it may extend to 14 days or more.

EMERGENCY DEPARTMENT EVALUATION

A Gram stain of the urethral exudate obtained by swabbing the urethra (in symptomatic men) is a reliable method for the diagnosis of gonorrhea. The specificity is 95% to 98%, and the sensitivity is 83% to 95% when typical gram-negative intracellular diplococci are found. To obtain a specimen from a male without exudate, a calcium alginate–tipped swab (Calgiswab) should be gently inserted 2 to 3 cm into the anterior urethra. Cultures on Thayer-Martin or similar culture media should be obtained.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment has been well studied and is frequently updated by the Centers for Disease Control and Prevention ([Table 61.1](#)).² The increasing incidence of penicillinase-producing *Neisseria gonorrhoeae* worldwide has led to the use of third-generation cephalosporins or the fluoroquinolones. Patients should also be started on antichlamydial therapy (doxycycline or azithromycin).

CURRENT TREATMENT OF CHOICE	
Ceftriaxone	125 mg i.m. single dose
All treatment for gonorrhea should be followed by doxycycline, 100 mg two times a day for 7 days, or azithromycin, 1.0 g PO single dose, due to the high percentage of patients who are also infected with <i>Chlamydia</i> .	
ALTERNATIVE TREATMENTS	
Ofloxacin	400 mg PO single dose
or	
Ciprofloxacin	500 mg PO single dose
or	
Norfloxacin	800 mg PO single dose
or	
Cefixime	400 mg PO single dose

Adapted from Gilbert DN, Moellering RC, Sande MA. The Sanford guide to antimicrobial therapy. Dallas: Antimicrobial Therapy, Inc., 1998.

TABLE 61.1. Treatment of Gonococcal Urethritis

DISPOSITION

All patients with gonococcal urethritis should be rechecked after therapy to ensure a cure. Referral to an STD clinic is appropriate. Emphatic counseling should be given to ensure that the medication is taken and that the patient's sexual partners are also examined and treated. Single-dose therapy with ceftriaxone or one of the fluoroquinolones and azithromycin ensures compliance.

COMPLICATIONS

From 1% to 3% of patients with gonococcal infections develop hematogenous spread of the organism that may involve joints, meninges, heart, and skin. Strains that disseminate are usually nonvirulent in their primary site, and the original infection is often minimally symptomatic. In addition to the complications of bacteremia, local spread may involve the vas deferens, prostate, paraurethral glands, epididymis, and adjacent soft tissues ([Table 61.2](#)). Severe urethral inflammation may result in a urethral stricture.²

Epididymitis	Conjunctivitis
Prostatitis	Dermatitis
Endocarditis	Vasculitis
Meningitis	Tenosynovitis
Arthritis (both septic and reactive)	

TABLE 61.2. Infectious Sequelae of Gonorrhea

Chlamydial Urethritis

There is little question that *Chlamydia trachomatis* causes the majority of sexually transmitted diseases in the United States.^{2,15} The prevalence is high in heterosexuals and adolescents. Gonorrheal coinfection is common.

CLINICAL PRESENTATION

The clinical features of chlamydial urethritis resemble those of gonorrhea but are generally less severe; the discharge is often thinner and less purulent, but there is sufficient overlap in signs and symptoms to make clinical distinction unreliable. *Chlamydia* has an incubation period of 1 to 3 weeks, but it may extend as long as 45 days.^{1,2}

EMERGENCY DEPARTMENT EVALUATION

The laboratory diagnosis of chlamydial urethritis has been based on a urethral smear of epithelial cells utilizing immunofluorescence techniques. Most hospital laboratories do not have the capacity to accurately identify *Chlamydia* with tissue culture. A technique using an enzyme-linked immunosorbent assay on urine samples has been developed and looks promising. Its sensitivity is equivalent to, if not better than, urethral sampling techniques, and specimen collection is better tolerated. Improvement in this technology will allow inexpensive, effective widespread screening of populations at risk, such as military personnel, sexually active adolescents, and individuals who seek advice for contraception or STD testing.^{5,20}

EMERGENCY DEPARTMENT MANAGEMENT

Doxycycline, 100 mg twice a day for 6 days, is associated with excellent cure rates, good compliance, and few side effects. To date, there are no known tetracycline-resistant strains of *Chlamydia*. From a public health viewpoint, azithromycin in a single 1-g oral dose is as effective as doxycycline, and compliance is ensured by dispensing it in the ED.¹⁴ Other antibiotics that have been effective include erythromycin and trimethoprim–sulfamethoxazole (cotrimoxazole). Both of these agents have cure rates between 85% and 95% when given for at least 7 days. For those patients who cannot tolerate the tetracyclines, either erythromycin base, 500 mg, or erythromycin ethyl succinate, 800 mg, should be taken four times a day; or cotrimoxazole double-strength (e.g., Bactrim DS) twice a day; all regimens are to be continued for at least 7 days. The fluoroquinolones have antichlamydial activity as well: ofloxacin, 300 mg twice a day or levofloxacin, 500 mg a day, either for a 7-day course.^{1,6}

COMPLICATIONS

Complications of chlamydial infections include epididymitis and possibly prostatitis. In contrast to females who may become infertile because of chronic chlamydial infection, exposure to *Chlamydia* in the male does not appear to lead to infertility.^{2,8}

Nongonococcal, Nonchlamydial Urethritis

Nongonococcal, nonchlamydial urethritis is a “wastebasket” diagnosis for all cases in which the infection is neither gonorrheal nor chlamydial. As greater facility with identification and isolation of pathogenic commensal organisms is gained, more specific causes of nongonococcal, nonchlamydial urethritis may be found. Up to 25% of nongonococcal urethritis may be caused by *Ureaplasma* (*Mycoplasma*) species. There is good evidence that implicates *U. genitalium* as a cause of urethritis.

Reports show a high incidence of urethral *Trichomonas vaginalis* in men with symptoms of urethritis whose female partners had symptomatic *Trichomonas* vaginitis.⁹ In other studies of the cause of nongonococcal urethritis, *Candida*, *Gardnerella*, and *Bacteroides* species; *Staphylococcus saprophyticus*; *Corynebacterium genitalium*; and various viruses, including herpes, are isolated on occasion.² After *Chlamydia*, *Ureaplasma*, and gonorrhea have been eliminated as the cause of urethritis, about 30% of cases remain without apparent cause.

TREATMENT

Doxycycline (100 mg given twice daily for 7 days) is effective against most *Ureaplasma* species. If doxycycline fails, azithromycin, 1 g in a single oral dose, should be given. These organisms respond poorly to sulfonamides.

Although all types of nongonococcal urethritis respond initially to antibiotic therapy, recurrence of symptoms is found in up to 50% of cases. In this instance, more prolonged therapy with doxycycline for 14 to 28 days is advised. Erythromycin may be used as an alternative for those patients who cannot tolerate doxycycline. Ofloxacin, 300 mg orally every 12 hours for 7 days, is another alternative.^{1,2}

Recurrent Urethritis

If a patient presents to the ED with a recurrent urethritis despite adequate therapy for both *Chlamydia* and gonorrhea, the patient may either have been reinfected by his partner(s) or represent treatment failure. The partner(s) of the patient with recurrent infection should be examined, and treatment ensured. If the patient presents with recurrent nongonococcal, nonchlamydial urethritis and both he and his partner(s) have had appropriate therapy, *Trichomonas*, *Candida*, and herpes simplex virus should be sought as possible pathogens.⁹

PROSTATITIS

Prostatitis is a poorly defined but common syndrome of prostatic inflammation. Its manifestations include a wide range of pelvic, urinary, or ejaculatory symptoms with or without a tender prostate or evidence of bacterial infection. It is estimated that up to 50% of men experience some form of prostatitis. Symptomatic prostatitis syndromes can be classified into four subcategories (Table 61.3) on the basis of the bacterial findings on culture and on the microscopic examination of the expressed prostatic secretion or the presence of pyuria¹⁰: (1) acute bacterial prostatitis, (2) chronic bacterial prostatitis, and (3) chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) of either the inflammatory or (4) noninflammatory subtypes. Both acute and chronic bacterial prostatitis are characterized by bacteriuria that can be localized to the prostate. Urine, prostatic secretions, and semen usually show evidence of leukocytes, and frequently the offending organism is cultured from these secretions.

	Acute Bacterial	Chronic Bacterial	Chronic Prostatitis/Chronic Pelvic Pain Syndrome	
			Inflammatory	Noninflammatory
Incidence of inflammation ^a	+	+	+	0
Culture-positive (EPS)	+	+	0	0
Culture-positive (semen)	+	+	0	0
Biopsy	Colliform	Colliform	??	??
Rectal examination	Very abnormal	Usually normal	Usually normal	Normal

^aProteinase activity in the prostatic secretions.

^bExpressed prostatic secretion (EPS) positive for leukocytes; pyuria also present.

TABLE 61.3. Classification of Symptomatic Prostatitis

Acute bacterial prostatitis is most often seen in younger men, whereas chronic infection is seen in older men. The latter may not complain of symptoms of prostatitis. In younger men, the role of *Chlamydia* is uncertain. In men with acquired immunodeficiency syndrome, the prostate may harbor *Cryptococcus neoformans*.¹¹

About 90% of symptomatic men have CP/CPPS of either inflammatory or noninflammatory subtypes. Inflammatory CP/CPPS is a nonbacterial prostatitis in which inflammation is present but no cause can be found. Noninflammatory CP/CPPS, formerly referred to as *prostatodynia*, shares many of the symptoms of bacterial or nonbacterial prostatitis but lacks signs of inflammation and is not associated with UTI. ^{10,12}

Acute Bacterial Prostatitis

EMERGENCY DEPARTMENT EVALUATION

Acute bacterial prostatitis is easy to diagnose and treat. It usually presents as an acute illness with fever, chills, and pain in the lower back, the rectal area, or the perineal area. The patient often complains of painful sitting (e.g., the sensation of “sitting on a hot coal”). Systemic symptoms of malaise, arthralgia, and myalgia may also be present. These may appear several days before the local prostatic inflammation produces symptoms of dysuria, frequency, and urgency. The patient frequently is toxic at the time of the ED visit. The diagnosis is suggested once perirectal pathology has been eliminated. Occasional patients present with acute urinary retention; this combination of obstruction and infection may progress to sepsis. ^{11,12}

Examination of the prostate may be difficult because it is exquisitely painful. The prostate is swollen, tender, warm, and firm to touch. In the patient with classic signs and symptoms of acute bacterial prostatitis, a finding of exquisite external perineal tenderness is probably sufficient to make the diagnosis and a digital rectal examination of the prostate may be deferred. Massage of the prostate is *contraindicated* because of possible hematogenous spread of bacteria. Because the prostate surrounds the urethra, cystitis often accompanies acute prostatitis and a urine culture will usually reveal the infecting organism. The swelling of the acutely inflamed prostate may cause complete urinary retention; this combination of obstruction and infection may progress to sepsis. ^{11,12}

EMERGENCY DEPARTMENT MANAGEMENT

Acute prostatitis is responsive to antibiotics. For the less toxic patient, appropriate antibiotics include trimethoprim–sulfamethoxazole, ofloxacin, ciprofloxacin, or other fluoroquinolones. Antibiotic therapy should be continued for a minimum of 4 weeks in all patients. Referral is important, as complete resolution of symptoms may take weeks to months and most men will require ongoing consultation (mostly reassurance) during convalescence. ^{1,2,11,12}

Toxicity, fever, urinary retention, concurrent underlying disease, and altered immune response are indications for hospitalization and the administration of intravenous antibiotics. Parenteral ampicillin and an aminoglycoside such as tobramycin are an appropriate empiric therapy. The subsequent choice of antibiotics is ideally made from sensitivity testing of bacteria grown from urine cultures.

Instrumentation of the urinary tract should be avoided. If the patient has acute urinary retention from prostatitis, catheterization may be painful and could potentially result in hematogenous release of bacteria. Until antibiotics and rest allow the inflammation to subside, a suprapubic catheter may be necessary. Urologic consultation is indicated.

Fluid replacement, antipyretics, narcotic analgesics, and stool softeners should be given. Nonsteroidal antiinflammatory drugs and spasmolytics are useful for milder pain. Bedrest frequently makes the patient more comfortable. Hospitalization of the toxic patient ensures that appropriate supportive care is maintained.

The patient may experience irritative voiding symptoms for several months after completion of therapy; nonsteroidal antiinflammatory agents, such as ibuprofen, have been anecdotally useful. A firm, hard prostate may also be noted for the same duration, but if this condition persists, the possibility of an underlying malignancy must be considered.

CHRONIC BACTERIAL PROSTATITIS

Chronic bacterial prostatitis encompasses only 10% of all cases of prostatitis, but it is probably the most common cause of recurrent UTI in men. In most, the pathogen is *Escherichia coli*, but *Pseudomonas*, *Proteus* species, *Enterobacter*, *Klebsiella*, and enterococci are also found. The usual picture of chronic prostatitis is of relapsing dysuria, occasionally associated with perineal discomfort and associated epididymitis. A prolonged course of an oral fluoroquinolone is indicated. Many urologists recommend a trial of an alpha-adrenergic blocking agent such as finasteride in addition to antibiotic therapy in cases of recent or frequent relapse. ³

Prostatic calculi are common and may be visible on pelvic films. In most instances, stones cause no apparent harm and require no therapy. However, these stones can serve as the nidus for recurrent infection from bacteria, and surgical removal of infected calculi may be indicated in follow-up consultation with a urologist.

NONINFLAMMATORY CHRONIC PROSTATITIS/CHRONIC PELVIC PAIN SYNDROME (FORMERLY PROSTATODYNIA)

When the patient has symptoms referable to the prostate, with no inflammatory cells in the expressed prostatic secretion and no bacteria cultured from the prostatic fluid, the syndrome is designated noninflammatory CP/CPPS, an entity formerly referred to as *prostatodynia*. There are likely multiple etiologies for this symptom complex. This new terminology recognizes the limited understanding of the causes of this syndrome in most patients and the possibility that organs other than the prostate gland may be important in the pathogenesis of chronic pelvic pain in males. ¹⁰ Clearly, the treatment of this entity is in the urologist's domain.

In the older patient with symptoms of prostatism and no evidence of inflammation (i.e., no pyuria or leukocytes in expressed prostatic secretions), it is reasonable to offer an alpha-adrenergic agent such as finasteride or a natural product such as saw palmetto extract. The patient should seek urologic consultation in follow-up. ²³

PROSTATIC ABSCESS

Prostatic abscess is now rare, except in immunosuppressed patients. A fever despite antimicrobial treatment, increasing rectal symptoms, and persistent leukocytes should suggest a prostatic abscess. Rectal examination usually reveals a fluctuant mass, the hallmark of the prostatic abscess. Occasionally, only a firm, tender prostate is found because of the anterior location of the abscess. Urologic consultation is indicated. Hospitalization and intravenous antibiotics are necessary for these seriously ill patients.

SEMINAL VESICULITIS

Seminal vesiculitis is difficult to separate clinically from prostatitis, and probably includes elements of prostatitis because of the contiguous spread of the infection or inflammatory condition. If the patient presents with hematospermia, evaluation and treatment should be the same as for prostatitis. Urologic referral is appropriate.

EPIDIDYMITIS

Acute epididymitis is an inflammatory process of the epididymis, with scrotal pain, swelling, and tenderness, usually resulting from infection. ^{4,21,22} Epididymitis is covered in detail in [Chapter 67](#).

Once the diagnosis of acute epididymitis has been established, a presumptive etiology is made on the basis of age. ^{2,5} For men younger than age 35, or if an STD is believed to be the causative agent, coverage for gonorrhea and chlamydial infection is indicated ([Table 61.4](#)). For men who are older than age 35, or are the insertive partners in anal intercourse, coliforms must be covered (see [Table 61.4](#)).

ALL CASES	
Gram stain of urethral meath of urine sediment	
Culture of gram stain, immunofluorescence for <i>Chlamydia</i>	
Examination for concurrent STD	
PRESUMED STD ETIOLOGY	
Ceftriaxone	250 mg i.v.
or	
Ciprofloxacin	500 mg PO
and	
Doxycycline	100 mg PO two times per day for 10 days
ALTERNATIVE REGIMEN	
Ofloxacin	300 mg PO two times per day for 10 days
PRESUMED BACTERIAL (COLIFORM) ETIOLOGY	
Ofloxacin	200 mg PO two times per day for 14 days
or	
Ciprofloxacin	500 mg PO two times per day for 14 days
or	
Trimethoprim	200 mg PO daily for 14 days
Urinal culture	
Look for predisposing genitourinary pathology	
SUPPORTIVE THERAPY (ALL CASES)	
Renal support	
Nonsteroidal antiinflammatory drugs	

TABLE 61.4. Treatment of Epididymitis

If the patient appears toxic, admission and intravenous antibiotics are indicated. An aminoglycoside or third-generation cephalosporin is an appropriate choice for the patient with presumed coliform etiology.

CYSTITIS AND PYELONEPHRITIS

Cystitis

PREDISPOSING CAUSES

In males, the long anatomic distance of the urethra discourages retrograde travel of organisms from the penile meatus to the bladder. Factors associated with an increased risk for infection include congenital anomalies, such as hypospadias, and instrumentation of the urethra. After 3 days of indwelling urinary catheter drainage, virtually 100% of patients have a UTI. Autoerogenous intraurethral insertion of foreign objects may precipitate cystitis. Trauma to the urethra or bladder may allow dissemination of organisms.

Cystitis without trauma or instrumentation is rare in young men and is usually a secondary manifestation of upper urinary tract disease, diabetes, chronic prostatitis, nephrolithiasis, tumor, congenital malformation, or mechanical obstruction.¹⁶ Of these, chronic prostatitis, prostatism in older men, and prior instrumentation are the most common predisposing causes. Abnormalities are found in up to 80% of males who present with a UTI without antecedent trauma or instrumentation. It is particularly important to ensure that urinary obstruction is not present, because the combination of infection and obstruction is an important, preventable cause of sepsis.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

A thorough history and physical examination should be done. The genitalia, rectum, and abdomen are examined, and urinalysis and culture of urine are performed. Postvoiding urethral catheterization may be indicated to assess residual urine volume in patients who relate symptoms of prostatism such as hesitancy, dribbling, and incomplete bladder-emptying sensation. Intravenous pyelography or ultrasonography may be indicated. If the patient is younger than age 35, urethritis must be considered because it can masquerade as cystitis. In this case, antimicrobial therapy should cover the STDs discussed earlier. For patients with clinically apparent cystitis and patients older than age 35, therapy for coliforms should be instituted while awaiting culture results: cotrimoxazole double-strength (Bactrim DS) two times per day for 10 days, or a fluoroquinolone such as ofloxacin 400 mg orally twice daily for 10 days, or ciprofloxacin 500 mg orally twice daily for 10 days. In view of the high percentage of abnormalities associated with male UTI, frequency of other related genitourinary infections, and the difficulty in determining the precise site of infection by clinical criteria, short courses of antimicrobial agents are ill advised in men.⁸

DISPOSITION

Cystitis is commonly associated with other urinary tract pathology. Therefore, the evaluation must be continued beyond the ED, and referral is always appropriate. Patients with a known history of instrumentation, congenital malformation, and symptomatic prostatic hypertrophy should be referred to a urologist, with consultation before discharge.

Pyelonephritis

Pyelonephritis presents in a similar manner in both males and females. Predisposition to infection from underlying urinary tract disease or abnormality is more common in males, and a thorough search for these problems in males with suspected pyelonephritis is indicated. It should be appreciated that pyelonephritis is a common presenting condition in the older man with prostatism.

PREDISPOSING CAUSES

Abnormal anatomy, such as ureteral ectopia, bifid ureter, or renal scarring from prior renal infections, predisposes to infection of the kidney. Other common predisposing causes include abnormal physiology from neurologic trauma, urinary retention from prostatism, acute prostatitis or other cause, underlying renal disease, and the presence of a foreign body, such as a stone or an indwelling catheter.

ETIOLOGY

E. coli is the most common causative organism, accounting for more than 90% of infections. It is followed in frequency by *Enterobacter*, *Klebsiella*, *Proteus*, *Pseudomonas*, and enterococcal species. *Staphylococcus aureus* infections are usually associated with blood-borne spread, and a primary source should be diligently sought. Gram-positive organisms are unusual causative agents and are associated with diabetes, an immunocompromised host, or tumor of the urinary tract.^{7,13,19}

EMERGENCY DEPARTMENT MANAGEMENT

Men with symptoms of pyelonephritis should be strongly considered for admission and parenteral antibiotic therapy. Urine should be obtained for culture and sensitivity testing before therapy is initiated. If patients have had rigors, chills, hypotension, or a temperature greater than 102° (39°C), blood cultures are indicated as well. Patients who appear toxic, are nauseated or vomiting, or have a temperature greater than 102° (39°C) should be hospitalized and treated with parenteral antibiotics directed against *E. coli* and other common enteric coliforms.

Parenteral therapy for pyelonephritis includes the following:

Ampicillin, 1 g every 6 hours, and gentamicin, 1 mg/kg every 8 hours
 Ciprofloxacin, 200 to 400 mg every 12 hours
 Ofloxacin, 200 to 400 mg every 12 hours
 Ceftriaxone, 1 to 2 g daily

Oral therapy may be begun after defervescence of fever. The fluoroquinolones (e.g., ofloxacin, norfloxacin, ciprofloxacin, or others) are the drugs of choice, and

therapy should be given for 14 days.¹⁵

Nursing home patients and patients who have recently been hospitalized or instrumented should be presumed to have a nosocomial infection, and antibiotic therapy should be chosen that includes pseudomonal coverage, for example, an aminoglycoside, ceftazidime, an extended-spectrum penicillin such as piperacillin/tazobactam, or imipenam.^{1,19}

The patient with ureteral colic and fever and chills should be suspected of having a ureteral obstruction and an infection. Pyelonephritis in the presence of an obstruction can rapidly progress to a renal abscess, with subsequent loss of renal tissue and sepsis. In addition to immediate urologic consultation, blood and urine cultures should be obtained, followed by intravenous pyelography or renal ultrasonography and intravenous administration of antibiotics.¹⁷

COMMON PITFALLS

- “Cystitis” in a young, sexually active male with dysuria is most likely to be urethritis.
- A careful search should be done for associated STDs in the young male who presents with symptoms of urethritis.
- Instructions should be provided regarding the need for the patient's sexual partner(s) to obtain evaluation and treatment.
- Prostatic massage in a patient with acute bacterial prostatitis may lead to bacteremia or sepsis.
- One should not assume that all perineal discomfort is prostatitis.
- The postvoid residual urinary volume should be checked in the older man who presents with symptoms of prostatism and acute UTI.
- Strong consideration should be given for parenteral administration of antibiotics in the male with pyelonephritis and toxicity.

Urinary tract infections (UTIs) in women are among the most common problems encountered by the emergency physician. Twenty percent to 40% of women will have a UTI sometime in their lifetime,^{2,25} and estimates place annual incidence of infection between 3% and 10%. Women are 30 times more likely than men to suffer a UTI, and of those women affected, 20% have more than three UTIs per year.¹⁰ It is not surprising, then, that complaints related to the urinary tract account for 7 million annual outpatient visits (1.6 million emergency department [ED] visits), 1 million hospitalizations, and billions of dollars in health-care costs annually.^{12,25}

UTIs comprise a collection of diseases that can be classified based on both the anatomy and the complexity of the disease. Anatomically, upper UTIs involve the kidney, resulting in pyelonephritis. Pyelonephritis may be chronic, subclinical, or acute, with this chapter focusing on management of the latter. Lower UTIs involve the urethra and bladder, resulting in acute urethritis and acute cystitis, respectively.

UTIs can be further classified as complicated or uncomplicated. A complicated UTI is associated with a condition that increases risk for acquiring infection, failing therapy, or suffering increased morbidity.^{13,28} These associated conditions may be structural (obstruction, catheterization, renal calculi), metabolic (diabetes, pregnancy, chronic renal failure), or functional (impaired host [AIDS, neutropenia] or unusual pathogen). [Table 62.1](#) lists many of these factors that place a patient at risk for a complicated UTI. Complicated UTIs can range in severity from simple cystitis to urosepsis with shock; thus, it is the associated conditions, not severity of disease, that make a UTI complicated. Some authors argue that true uncomplicated UTIs only occur in nonpregnant, healthy adult women with no neurologic or structural dysfunction.² Eighty percent of UTIs fall into this group.²⁵

1. Hospitalization
2. Catheterization/urinary tract instrumentation
3. Pregnancy
4. Anatomic/functional abnormalities
5. Childhood UTI (prior to age 12)
6. Symptoms > 7 days prior to treatment
7. Diabetes Mellitus
8. Immunosuppression (cancer, chronic renal failure, AIDS, drug or alcohol abuse)
9. Elderly
10. Recent antibiotic use
11. Urinary retention
12. Sickle cell trait and anemia
13. Incompetent vesicourethral valve

Developed from articles by Ronald Harding⁹ and Michelle Bernstein¹

TABLE 62.1. Risk Factors for Development of Complicated Urinary Tract Infection

The urinary tract is normally an enclosed, protected, and sterile mucosal surface. Washout of bacteria by urine flow is the primary host defense against infection.³³ This process is nearly continuous in the upper tract but only intermittent in the lower. Uropathogens are generally not virulent, but instead are highly adapted to ascend, colonize, and grow in the urinary tract, subsequently causing cell damage and infection.³³ The colon is the primary reservoir for most uropathogens. Over 95% of infections result from enteric bacteria ascending the urinary tract.² Although the exact process of ascent is unknown, enteric bacteria colonize the vagina and periurethral area, ascend the urethra into the bladder, multiply in the urine, reflux into the ureters, and ultimately colonize and invade the renal parenchyma.³³ Factors that alter urine washout, change the characteristics of the urine, or facilitate entry of bacteria into the urinary tract increase risk for development of a UTI. The primary risk factors in young healthy women for development of an uncomplicated UTI are sexual intercourse and diaphragm use with spermicide.¹² Less than 5% of UTIs result from hematogenous spread during septicemia. These organisms tend to be more virulent, causing severe pyelonephritis or even microabscesses within the kidney.²

The most common uropathogens responsible for development of a UTI are enteric gram-negative bacilli of the class Enterobacteriaceae. *Escherichia coli* is responsible for over 80% of UTIs in reproductive-aged females.¹⁰ *Staphylococcus saprophyticus* causes 5% to 20% of UTIs in this group, with other enterics such as *Klebsiella*, *Enterobacter*, enterococcus, *Proteus*, *Pseudomonas*, and Group B *Streptococcus* causing the balance of infections. Hospitalized, catheterized, and immunosuppressed patients tend to suffer UTIs from more virulent bacteria as well as *Candida*.² *E. coli* infections are much less common in this group, causing less than 40% of infections.²⁵

CLINICAL PRESENTATION

Asymptomatic Bacteriuria

Asymptomatic bacteriuria is simply the presence of bacteriuria in a patient with no symptoms of cystitis or pyelonephritis. This condition is most common in elderly and pregnant women. The incidence of asymptomatic bacteriuria increases with age to as high as 40% in women over 60. Thirty percent of individuals become symptomatic within 1 year.¹⁰ Identification of asymptomatic bacteriuria in elderly women is of questionable benefit, as no association with excess morbidity and mortality has been demonstrated. In contrast, it is critical that the emergency physician identify asymptomatic bacteriuria in a pregnant woman. While only 4% to 7% of pregnant women will have asymptomatic bacteriuria, 30% of these will subsequently develop pyelonephritis if untreated.¹⁰ Asymptomatic bacteriuria has also been implicated in stillbirth and preterm labor, but this remains controversial.

Acute Cystitis

Acute cystitis is most commonly seen in reproductive-aged women. The most typical symptoms include dysuria, frequency, urgency, and suprapubic or abdominal discomfort. Hematuria occurs in up to 40% of women with acute cystitis.¹³ More general complaints may also be described, such as fatigue, malaise, irritability, and diaphoresis.¹⁸ Fever (greater than 38°C) and severe abdominal pain are rare, and should make the emergency physician consider upper tract disease or alternative diagnoses. Microscopic urinalysis reveals pyuria, bacteriuria, and, frequently, hematuria.

Acute Recurrent Cystitis

Acute recurrent cystitis is defined as three or more episodes of acute cystitis within a year. It occurs in 20% of individuals with acute cystitis, usually as the result of separate episodic uncomplicated infections.² Individuals with recurrent cystitis should be identified for consideration of UTI prophylaxis.²⁵

Acute Urethritis

Acute urethritis presents with symptoms nearly identical to those of cystitis. There may be a coexistent cervicitis and vaginal discharge. Pyuria without evidence of bacteriuria is common on urinalysis (UA), with subsequent cultures growing minimal uropathogens. *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and the herpes simplex virus are the usual causative organisms.

Acute Pyelonephritis

Acute pyelonephritis can present with variable severity, from a mild cystitis-like illness with flank pain to a more severe illness with fever, chills, nausea, vomiting, sweats, and flank and/or abdominal pain. Absence of cystitis symptoms is not uncommon.²⁵ Costovertebral angle tenderness is a common physical finding. UA reveals pyuria, bacteriuria, hematuria, and white blood cell casts; the latter are highly specific for acute pyelonephritis.

Urosepsis

Urosepsis is most likely to manifest in women with indwelling catheters, immunosuppressive disorders, urinary obstruction, complicated UTIs, or serious underlying medical problems. Elderly women from extended care facilities are at greatest risk. Typically, such patients present with nonspecific signs and symptoms, including fever, confusion, weakness, tachycardia, tachypnea, and dehydration. Family members or nursing home staff may provide valuable history, as the patient often cannot provide one herself. If alert, the patient may complain of incontinence, abdominal pain, thirst, dyspnea, or even cough.⁹ Fever is often present, but hypothermia is not unusual. Examination will usually reveal dehydration or compensated shock, but delayed presentation may result in severe hypotension and septic shock.

Symptomatic Catheterized Patients

Urinary catheterization is responsible for the vast majority of nosocomial UTIs. Incidence of infection for indwelling catheters is 5% per catheter-day.² Such UTIs are, by definition, complicated, with manifestations ranging from mild suprapubic pain, bladder spasms, and incontinence around the catheter to fulminant sepsis. All symptomatic catheterized patients should be treated with broad-spectrum antibiotic therapy.²⁵

DIFFERENTIAL DIAGNOSIS

The emergency physician should be aware that ED patients differ from those of other outpatient settings. Patients presenting with urinary symptoms to an inner-city ED are more likely to have gynecologic disease (vaginitis, pelvic inflammatory disease, and sexually transmitted disease), upper tract disease, and social circumstances that complicate access to care and follow-up when compared with other outpatient settings.

The differential diagnosis of acute dysuria includes the following: acute urethritis, acute cystitis, and vaginitis. Generally, urethritis is characterized by a more gradual onset and occurs in patients who have concomitant vaginal symptoms. Urgency, frequency, and urinary incontinence commonly accompany the dysuria of acute cystitis. The bladder, when infected or inflamed, contracts spasmodically to create these symptoms. Vaginitis is common and presents with external dysuria and vaginal discharge. Frequency and urgency are lacking because the bladder is not involved.

Flank pain typical of pyelonephritis is common in other diseases as well. Patients with unilateral costovertebral angle tenderness may have renal calculi, perinephric abscesses, renal infarcts, and neoplastic or traumatic processes.

The emergency physician must base the differential diagnosis on the presenting complaint, then narrow it with additional history, physical examination, and laboratory examination.

EMERGENCY DEPARTMENT EVALUATION

History

Historical information of importance includes the nature of the dysuria (external or internal), the duration of symptoms, and accompanying symptoms of urgency, frequency, incontinence, abnormal vaginal discharge, external genital lesions, fever, back pain, hematuria, or foul-smelling urine. A detailed sexual history, including the possibility of pregnancy, the number of partners, and the type of birth control method used, is also prudent. The medical history should be explored in an effort to identify any factors that would make an otherwise uncomplicated UTI complicated (see [Table 62.1](#)).

Physical Examination

The examination begins with an assessment of vital signs and hydration status. Examination of the genitourinary tract includes assessment of costovertebral angle tenderness, suprapubic mass, or tenderness, and examination of the external genitalia and urethra. A pelvic examination should be performed in women in whom the diagnosis is unclear and in women whose history suggests a diagnosis of either urethritis or vaginitis. It is important to note the presence or absence of indwelling catheters, as they place the patient at risk for a complicated UTI.

When combined with a good history, a careful physical examination should enable the physician to identify patients with urosepsis, acute cystitis, and acute pyelonephritis, and should allow the physician to predict whether the patient has a complicated or uncomplicated infection.

Urinalysis Collection

A urine specimen should be collected by the method most appropriate for the patient's clinical status and capacity to cooperate with cleansing guidelines. In the presence of obesity, menstrual blood, copious vaginal discharge, or an anatomic abnormality, the preferred method for obtaining a urine specimen is an in-and-out urethral catheterization of the bladder. The main risk is induction of UTI, but this occurs less than 1% of the time in a normal host.²⁹ For nonmenstruating, thin patients

lacking vaginal discharge, a clean-catch UA can be utilized. The sample should be a midstream specimen obtained after perineal cleansing with gauze moistened by either saline or tap water. No benefit has been proven from soap cleansers.¹³ Some experts suggest that urine from a freshly wet diaper can be collected for accurate analysis.³ Regardless of the means by which the urine is obtained, the specimen should be processed promptly after collection, as stagnation increases colony counts.

Dipstick Chemical Tests/Urine Microscopy

The nitrite test depends on bacterial reduction of nitrate to nitrite. The test is more likely to be positive with gram-negative bacteria. It may be falsely negative in the presence of low-count UTIs, dilution, antimicrobial therapy, and infections caused by non-nitrate-reducing bacteria such as *S. saprophyticus*, *Acinetobacter*, and enterococcus.^{10,25} While the negative predictive value of a nitrite test ranges from 0.27 to 0.70, the positive predictive value is 0.96.²⁵ Thus, a positive nitrite test strongly suggests the presence of bacteriuria, while a negative test does not exclude it. The leukocyte esterase test detects the presence of neutrophil granules and connotes pyuria greater than or equal to 8 to 10 white blood cells per high-power field.² The sensitivity for the leukocyte esterase test ranges from 0.75 to 0.90, while the specificity is more precisely defined as being 0.95.²⁵ False-positive results have been reported with *Trichomonas*, and false-negative results have been seen in UAs with dipsticks positive for glucose and ketones.⁴

The ease of use and availability of these tests can assist the emergency physician in identifying UTIs. Generally, a completely negative dipstick analysis corresponds to a negative microscopy evaluation, although 5% of UAs with negative dipstick results are found to have abnormal urine microscopy.⁴ Urinary microscopy has been shown to change patient management in only 5% of patients,¹⁶ and, therefore, consideration must be paid to both the turn-around time and the cost of each test. A urine dipstick costs approximately 30 cents and takes a few minutes to perform, whereas a microscopic UA costs approximately \$12 and takes nearly an hour to complete.¹⁶ For cases in which the diagnosis is clear, a dipstick should suffice. Full microscopic evaluation may be of assistance in the more complicated cases and in cases in which false-negative or false-positive results are expected. Understanding the limitations of the nitrite and leukocyte esterase tests better enables the clinician to decide when to employ microscopic analysis.

Gram Stain

Few institutions employ urine Gram stain, but in places where it is available, it can be very helpful. A Gram stain of unspun urine that reveals 1 to 2 bacteria per high-power field or a Gram stain of spun urine that reveals 20 bacteria per high-power field corresponds to greater than 10^5 colony-forming units (CFU) per milliliter of urine.²¹

Urine Culture

Isolation and quantification of uropathogens in culture may help differentiate the various UTIs. Asymptomatic bacteriuria requires 10^5 CFU per milliliter of uropathogen cultured from an asymptomatic patient. Counts of 10^5 CFU per milliliter have historically been used in diagnosing acute cystitis and acute pyelonephritis. However, it was found that 30% to 50% of patients with UTIs had less than 10^5 CFU per milliliter of uropathogen on culture.¹⁰ Early or subsiding infections, partially treated infections, diuretic use, recent voiding, and obstruction can explain low colony counts ("low-count UTIs").¹⁰ New standards have been set at 10^3 and 10^4 CFU per milliliter for cystitis and pyelonephritis, respectively. Any symptomatic catheterized patient with greater than 10^2 CFU per milliliter of uropathogen on culture is considered infected. Patients with acute urethritis typically have less than 10^2 CFU per milliliter despite pyuria and typical cystitis symptoms.²⁵

The vast majority of young, otherwise healthy women with probable UTI do not need cultures or sensitivity tests. Urine cultures should be obtained in any woman with potential for a complicated UTI; acute bacterial pyelonephritis; fever without focus; relapsing UTI; recently treated, documented UTI; fever and neutropenia; indwelling bladder catheterization; or sepsis.³⁵

Other Laboratory Studies

Patients with urosepsis, acute bacterial pyelonephritis, or complicated UTI should have creatinine assessed, as renal dysfunction may occur with upper tract infections. Old literature speaks of the necessity of blood cultures in the setting of acute pyelonephritis. New literature suggests that blood cultures are unnecessary because they rarely assist with clinical decision making. Blood cultures are positive in 18% to 29% of patients with pyelonephritis, but several studies have shown that the results of the blood cultures never or rarely (less than 2%) affected a change in antimicrobial therapy.^{17,20,34} Similarly, several studies have shown little to no discrepancy between the organism cultured from the urine and that cultured from the blood.²⁰ Because blood cultures are costly and often do not add to the clinical evaluation, careful thought should be given as to whether they are necessary. In the adult patient with a UTI, blood cultures are recommended when the diagnosis is unclear, when urine culture cannot be obtained (catheterization impossible), or when bacteremic seeding of the kidneys is possible (endocarditis).²⁰ They need not be performed for routine pyelonephritis. Vaginal cultures can be helpful when vaginitis and urethritis are likely, though their results are not available for initial management decisions. A pregnancy test is indicated if pregnancy is possible.

Imaging Studies

Radiologic imaging of the woman with uncomplicated UTI is seldom indicated. Routine imaging of women with pyelonephritis is also not recommended, as 75% of adults with pyelonephritis have normal anatomy.¹³ Indications for emergent or urgent imaging are not clearly defined, but in general, patients who are severely ill, patients who fail to respond to appropriate antimicrobial therapy, and patients with recurrence within 3 days of finishing treatment may deserve radiographic evaluation in the form of either ultrasonography or computed tomography.

EMERGENCY DEPARTMENT MANAGEMENT

Urosepsis

Prehospital management and immediate resuscitative efforts are necessary for women with urosepsis. Airway management and the provision of supplemental oxygen, intravenous crystalloids, and antibiotics are the mainstays of care. Administration of appropriate antimicrobial agents should begin in the ED as soon as possible. Although urine and blood cultures should ideally be obtained prior to the administration of antibiotics, culture acquisition should not delay the administration of appropriate therapy. Examples of suitable antibiotic choices include a third-generation cephalosporin, imipenem-cilastatin, ticarcillin-clavulanate, or ampicillin in combination with an aminoglycoside. See [Table 62.2](#) for intravenous therapy.

TABLE 62.2. Treatment Regimen for Urinary Tract Infections

Uncomplicated Cystitis

Patients with cystitis can be treated with oral antimicrobial agents as outpatients. Due to growing concerns about antimicrobial resistance, increasing attention has been placed on the choice of antimicrobial therapy and its duration. *In vitro* studies have found increasing resistance of common urinary pathogens to commonly used agents.^{7,11,15} As with all antimicrobial therapy, the choice of agent must be tailored to regional susceptibility patterns. Despite the increasing resistance of many urinary pathogens to trimethoprim–sulfamethoxazole (TMP/SMX), this agent remains an extremely well tolerated and effective agent in most of the United States.^{6,11,14,19,27} Furthermore, there are increasing data to suggest that overuse of fluoroquinolones is leading to increasing uropathogen resistance.^{5,6,15,23} Overall, TMP/SMX remains an excellent first-line agent for most cases of uncomplicated UTIs. For patients with a contraindication to TMP/SMX or those in an area where resistance is a significant concern, fluoroquinolones or nitrofurantoin remain viable alternatives. Several experts feel that if treating with nitrofurantoin, a 7-day regimen is more effective than a 3-day one.^{10,13} Beta-lactam antibiotics cannot be advocated as first-line agents in patients without contraindications to the aforementioned agents due to the high incidence of resistance to these drugs.^{11,27} Three-day regimens of treatment seem to confer an advantage over single-dose therapy in terms of the incidence of symptom recurrence. This is thought to be due to the inability of the single-dose regimens to eradicate uropathogens from the vagina, urethra, and rectum.^{13,14} For patients with severe dysuria, a 1- to 2-day course of a urinary analgesic, such as phenazopyridine 200 mg three times per day, is also advisable. See [Table 62.2](#) for alternative antimicrobial regimens.

Uncomplicated Pyelonephritis

Patients with pyelonephritis who are febrile and vomiting should be treated with antipyretics, antiemetics, and intravenous fluids. Antimicrobial therapy is similar to that for patients with uncomplicated cystitis. Many authors advocate the use of single-dose parenteral therapy followed by oral therapy for a duration of 10 to 14 days.^{26,32} Acceptable parenteral agents include gentamicin or third-generation cephalosporins. Because some patients develop worsening symptoms within 24 to 36 hours of ED discharge, early follow-up is recommended.²⁶ Other acceptable regimens for the management of pyelonephritis are listed in [Table 62.2](#).

Complicated Urinary Tract Infections

In general, agents used for the treatment of complicated UTIs are similar to those used for uncomplicated infections,²⁴ with the specific agent chosen on the basis of known or presumed susceptibilities of the infecting organism. Due to the structural abnormalities inherently associated with complicated infections, a longer course of therapy is warranted to effectively sterilize the urinary tract. In addition, close follow-up is mandatory to ascertain effective cure. Acceptable agents for the treatment of complicated UTIs are listed in [Table 62.2](#).

Urinary Tract Infections Complicating Pregnancy

Antibiotics commonly used to treat UTIs are contraindicated in pregnancy. TMP/SMX is relatively contraindicated in the first trimester due to its inhibition of folate metabolism, and is contraindicated in the third trimester due to its potential to cause kernicterus in the newborn. Fluoroquinolones may damage growing cartilage and epiphyses of long bones, contraindicating their use in pregnancy. Other viable alternatives for treating the parturient with cystitis include nitrofurantoin, sulfisoxazole, and cephalexin.²¹ Due to the high incidence of complications affecting both the mother and the fetus, pyelonephritis in pregnancy has historically been an infection treated as an inpatient.²¹ Recent studies, however, have shown that patients may be managed as outpatients with close follow-up.^{1,22} If outpatient management is elected, 10 to 14 days' treatment is recommended, as is consultation with the patient's obstetrician to assure close follow-up.

Asymptomatic Bacteriuria

Treatment of asymptomatic bacteriuria is not advocated except during pregnancy.³⁰ Pregnant women with bacteriuria have a markedly increased risk of acute pyelonephritis and the accompanying risks of prematurity and low-birth-weight infants.³⁰ Treatment is again directed at the etiologic organism. Recommended regimens include 3-day courses of amoxicillin, an oral cephalosporin, or nitrofurantoin.³⁰

Recurrent Cystitis

Women with more than three UTIs within 1 year may benefit from longer term prophylactic therapy. Postcoital prophylaxis with one-half of a TMP/SMX tablet (40/200 mg) may benefit those whose recurrences have clearly been related to intercourse.^{8,25} Continuous daily prophylaxis for 6 months with TMP/SMX, nitrofurantoin, norfloxacin, cephalexin, or trimethoprim has also been shown to decrease the morbidity of recurrent UTIs.²⁵ Unfortunately, approximately 40% to 60% of these women will reestablish their pattern of frequency of infections within 6 months of discontinuing prophylactic therapy.³¹

DISPOSITION

Role of the Consultant

Consultants are seldom required for uncomplicated UTI in women. Patients with cystitis do not require follow-up unless symptoms worsen or recur. Uncomplicated acute pyelonephritis may be referred to primary care physicians for subsequent management. As noted, pregnant women with pyelonephritis require close follow-up, and consultation with their obstetricians is advised. Some women with complicated UTI may require urologic and medical consultation.

Indications for Admission

Patients with urosepsis and serious underlying medical problems may require critical care admission if they are hemodynamically unstable, require mechanical ventilation, or have complicating medical conditions. Patients with complicated pyelonephritis or uncomplicated pyelonephritis associated with toxicity are candidates for hospital admission (serious medical conditions, dehydration with inability to maintain a normovolemic state, and inability to take oral medication). The young, nonparous, otherwise healthy woman with acute, uncomplicated, and nontoxic pyelonephritis may respond within hours of initiating appropriate therapy and may be subsequently managed as an outpatient.

COMMON PITFALLS

- Failure to consider the diagnosis of UTI in the septic patient
- Failure to consider the diagnosis in the elderly patient with altered mentation
- Failure to collect a clean urine specimen and failure to recognize a contaminated UA. The lower the ratio of leukocytes to squamous cells in the urine specimen, the more likely it is that the leukocytes are simply vaginal contaminants; if a predominance of squamous cells is seen, a second urine specimen must be collected.
- Failure to properly interpret the urine microscopic examination or chemical dipsticks
- Failure to perform a pelvic examination when indicated
- Failure to recognize complicated UTI
- Failure to ensure appropriate, timely follow-up
- Unnecessarily treating asymptomatic, nonparous bacteriurics

CHAPTER 63

Calculous Disease of the Kidney and Bladder

James E. Lingeman, Jeffrey A. Moody, Christopher P. Steidle, and Mark C. Adams

[Clinical Presentation and Evaluation](#)
[Differential Diagnosis](#)
[Emergency Department Evaluation](#)
[Emergency Department Management](#)
[Disposition](#)
[Current Treatment](#)
[Vesical Calculi](#)
[Chapter References](#)

Urinary tract stone disease, or urolithiasis, affects persons of all ages. From 2% to 5% of the general population may be expected to develop a urinary calculus during their lifetime. This incidence is variable according to the geographic location (climate) and season. The concept of “stone belt,” or geographic areas with unusually high incidences of urinary calculi, is well accepted.³ The highest incidence of stone disease is in the southeastern United States during the summer. The incidence of stone disease in Whites is reported to be approximately twice that in Blacks and Asians. The male-to-female ratio is approximately 2:1. The disease is relatively uncommon in patients younger than the age of 15, with the highest incidence during the third and fourth decades of life. The economic impact of urolithiasis is enormous. The estimated cost to society in the United States exceeds \$1 billion annually.²⁴

Urinary calculi consist of four basic crystalline types: calcium salts, struvite, uric acid, and cystine. The underlying pathophysiology of stone formation in the urinary tract requires that urine be supersaturated with the involved salt. The presence of a stone in the urinary tract implies that, in addition to supersaturation, there may be a lack of urinary inhibitors of crystallization or an increase in urinary particle (crystal) retention. Stones that contain calcium salts are by far the most common type of stone encountered ([Table 63.1](#)). Struvite (ammoniomagnesium phosphate) is the second most common type and is inextricably associated with infection with urea-splitting organisms. The most common urea-splitting organism is *Proteus*, but urea may also be split by *Klebsiella*, *Staphylococcus* species, and *Providencia*. Uric acid stones in their pure form are less common, occurring with an estimated frequency of 10%. Cystine stones are rare, representing less than 1% of all stone disease. Patients who form cystine stones do so due to an autosomal recessive genetic disorder. The primary defect in cystinuria involves an abnormality in the transport of the dibasic amino acids, resulting in excessive concentrations of the relatively insoluble amino acid cystine in the urine.

Calcium oxalate	72%
Infection stones (struvite and carbonate apatite)	16%
Uric acid	6%
Cystine	1%
Other	5%

^aCrystallographic analyses of 49,000 stones from Beck Analytical Services, Indianapolis, IN.

TABLE 63.1. Distribution of Various Stone Types (by Predominant Compound)^a

The natural history of urinary calculi is variable, but recurrence is common. Up to 75% of patients develop a recurrent calculus after either spontaneous passage or operative removal of a stone.¹⁵ Stone recurrence is often delayed, with long periods between stone episodes. The most obvious consequences of an undiagnosed stone are loss of renal function and hypertension secondary to hydronephrosis.

CLINICAL PRESENTATION AND EVALUATION

The clinical presentation of urinary stone disease is often characteristic. Although pain is usually the reason for an emergency department visit, hematuria and symptoms of urinary tract infection are also common complaints. The history should include history of prior stone disease, family history of stone disease, history of urinary tract infections, and the character of the pain. Stone disease is rare in children and, when encountered, may indicate a genetic disorder or an overt metabolic disorder. A family history of stone disease is commonly present. A history of prior urinary tract infections, especially with urea-splitting organisms, may be an important diagnostic clue and a harbinger of a true urologic emergency—an obstructing stone associated with infection.

The pain of renal colic is an acute clinical event secondary to the acute distention of the renal pelvis and upper ureter. Renal colic is visceral in nature, with waxing and waning of symptoms. Typically, the pain associated with an upper urinary tract calculus is localized to the flank. Because of the similar embryologic origin of the gonads and renal unit, pain may be referred to the ipsilateral testis or labia. As the stone moves down the ureter, the pain may move anteriorly from the flank to the ipsilateral lower quadrant. The pain may be referred to the testis when the stone is near the ureterovesical junction. Additionally, as the stone nears the bladder, symptoms of frequency and urgency may be manifested. Gastrointestinal symptomatology, such as nausea and vomiting, is frequently present, with the nausea being the most marked at the peak of the colic episode. Using the constellation of acute pain onset, flank pain, hematuria, and positive kidney–ureter–bladder (KUB), a 90% predictive diagnostic accuracy has been reported.⁷

The physical examination of the patient with urolithiasis is an essential part of the initial evaluation. Patients with renal colic are usually writhing in pain, unable to find a comfortable position, in contradistinction to patients with peritonitis, who typically lie quietly, because any movement aggravates their pain. Tachycardia and tachypnea are common. Hypertension may be present secondary to sympathetic stimulation from the pain. A temperature above 38°C (100.4°F) usually implies a concomitant urinary tract infection and the possibility of urosepsis. The abdominal examination may disclose costovertebral angle tenderness secondary to an acutely hydronephrotic kidney. Auscultation may disclose diminished bowel sounds, because ileus commonly accompanies renal colic. Peritoneal signs can occur if pyelonephritis is present, but they usually signify surgical causes of abdominal pain, such as appendicitis, pelvic inflammatory disease, diverticulitis, or a perforated viscus. The testes should be examined to rule out other causes of testicular pain.

It is vitally important to be certain that an obstructive calculus does not coexist with urinary infection, because such patients are at significant risk for the development of urosepsis.

The most important initial laboratory examination is the urinalysis. The patient with urolithiasis almost always has hematuria. In rare instances, a patient with a completely obstructed ureter may not have hematuria. The urinalysis may reveal the presence of crystalluria. Crystals of calcium oxalate, the coffin lids of struvite, and the hexagonal crystals of cystine are easily recognized. A pH greater than 7.5 in a fresh urine specimen indicates infection with urea-splitting organisms. Culture of the urine should always be performed. Serum electrolyte levels are usually normal; however, prolonged vomiting may lead to metabolic alkalosis. Hyperchloremic metabolic acidosis occurs with renal insufficiency or distal renal tubular acidosis. Serum creatinine levels are usually normal but can be slightly elevated in cases of complete obstruction. Hypercalcemia (calcium level higher than 10.2 mg/dL) in a patient with nephrolithiasis almost invariably signals the presence of primary hyperparathyroidism. Leukocytosis is common due to demargination of white blood cells caused by the stress of renal colic.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a patient with suspected urinary calculus is protean ([Table 63.2](#)). Urologic diseases that simulate urolithiasis may be divided by anatomic site. Upper tract diseases include renal infarct, which results in sudden pain, hematuria, and leukocytosis, and produces a characteristic rise in serum transaminase

levels, especially serum lactic dehydrogenase. Renal tumors may present as acute hemorrhage into the tumor, producing symptoms that are similar to those of a renal stone. The upper ureter may be obstructed by urothelial tumors, blood clots (especially in anticoagulated patients), and sloughed renal papillae. Sloughed renal papillae are seen in patients with sickle cell disease, analgesic abuse, and diabetes mellitus. Ureteral obstruction may be secondary to prior urologic instrumentation, tuberculosis, ureteral strictures, surgery, intrinsic urothelial tumors, or metastasis from tumors such as breast cancer. Nonurologic causes of diseases that stimulate urolithiasis are commonly due to intraabdominal or retroperitoneal conditions such as peritonitis, abdominal aortic aneurysm, retroperitoneal lymphadenopathy from tumors (the most common of which is lymphoma), and retroperitoneal fibrosis.

Urologic Disease	Nonurologic Disease
Upper urinary tract	Intraabdominal
Renal infarct	Peritonitis (esp. appendicitis)
Renal parenchymal tumors	Biliary colic
Urothelial tumors	Intestinal obstruction
Papillary necrosis	Vascular
Pyelonephritis	Abdominal aortic aneurysm
Hemorrhage (blood clot)	Superior mesenteric artery occlusion
Ureter	Retroperitoneal
Urothelial tumors	Retroperitoneal
Hemorrhage (blood clot)	Lymphadenopathy or
Prior surgery (eg, stricture)	Retroperitoneal fibrosis
Lower urinary tract	Tumor
Urothelial tumors	Gynecologic
Urinary retention	Cervical cancer
	Endometriosis
	Ovarian vein syndrome
	Musculoskeletal

TABLE 63.2. Diseases That Simulate Urolithiasis

A Münchhausen-like syndrome is seen uncommonly in the emergency department evaluation of suspected urolithiasis ([Table 63.3](#)).⁹ These patients are typically itinerant and quite knowledgeable about urolithiasis. They usually give a history of uric acid urolithiasis and a contrast medium allergy, usually of an anaphylactic nature. The hematuria that is always present initially resolves when the urine is collected in the presence of a nurse or physician. These patients usually require large dosages of intravenous or intramuscular narcotics to alleviate pain. This group of patients poses a significant management problem for the physician, because, by the time drug-seeking behavior is recognized, the patient has already been medicated. The evaluation of suspected malingering includes urinalysis (to be certain that no coexistent urinary tract infection exists) and computed tomography (CT). Virtually all stones are readily visible on non-contrast-enhanced abdominal CT scans, and, additionally, hydronephrosis and pyelonephrosis may be ruled out. The burden of proof is on the physician to rule out a *bona fide* pathologic process.

History of multiple narcotic allergies
History of uric acid lithiasis
History of contrast allergy
Multiple prior stone events
Itinerant
Factitious hematuria
Noncooperative

EMERGENCY DEPARTMENT EVALUATION

Radiologic studies are essential in establishing the diagnosis of urolithiasis. Approximately 90% of urinary calculi are radiopaque, and most are visible on the KUB radiograph. Radiolucent stones include uric acid, xanthine, triamterene, matrix stones, and, most commonly, small calcium oxalate stones. Calcium-containing calculi must be at least 2 mm in diameter to be visible on plain radiographs ([Fig. 63.1](#)). Other calcifications that may be visible on the KUB view include costochondral calcification, gallstones, undigested pills, splenic artery calcifications, renal artery aneurysms, abdominal aortic aneurysms, calcified mesenteric lymph nodes, stool, and phleboliths ([Table 63.4](#)). Phleboliths are common in North America and usually appear in middle age. They are a consequence of Western diet and represent thrombosed pelvic veins that become calcified. They usually appear well rounded and normally reside below a line drawn between the ischial spines. It should be established before contrast administration whether calcifications are truly intrarenal. This may be established by oblique films, nephrotomograms, or CT. Additionally, ileus of the small bowel may be observed usually secondary to sympathetic stimulation produced by renal irritation. Intravenous pyelography (IVP or excretory urography) or CT is necessary for the initial diagnosis of urolithiasis, regardless of whether a calcification is evident on a plain KUB film ([Table 63.5](#)). If an obstructed nephrogram is visualized, it is wise to obtain delayed films ([Fig. 63.2](#)). Extravasation occasionally occurs with complete obstruction and subsequent rupture of a calyceal fornix ([Fig. 63.3](#)). Extravasation is usually self-limited and benign if the duration of obstruction is short and infection is absent. It is important to identify patients with prior contrast medium reactions and preexisting renal insufficiency before IVP. Good alternatives to excretory urography in patients with renal insufficiency and serum creatinine levels greater than 2 mg/dL or a history of severe contrast reactions, such as laryngospasm and cardiovascular collapse, include ultrasonography and CT. Ultrasonography detects both lucent and opaque renal stones as well as hydronephrosis. However, most ureteral stones cannot be identified using ultrasonography. CT provides excellent demonstration of renal and ureteral calculi, including radiolucent calculi, and gives information regarding the presence or absence of hydronephrosis. In addition, CT may provide useful information about other retroperitoneal and intraabdominal conditions.

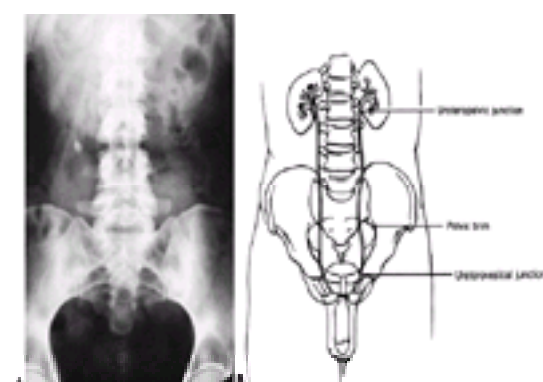

Figure 63.1. (A) Kidney–ureter–bladder radiograph of a 35-year-old White man with acute right renal colic, demonstrating a 9- by 14-mm calculus between L3 and L4. (B) Common locations of stones.

Figure 63.2. Intravenous pyelogram of the patient in Fig. 63.1A, demonstrating marked dilation of the renal collecting system and ureter proximal to the calculus. A stone of this size has a less than 10% chance of spontaneous passage, and, therefore, immediate urologic intervention is appropriate.

Figure 63.3. Intravenous pyelography of a 45-year-old White man with acute left renal colic, demonstrating extravasation in the region of the left renal pelvis (arrows). Extravasation characteristically occurs with small distal ureteral calculi. The calculus is not visible in this instance.

Figure 63.4. Percentage of patients who are stone-free after extracorporeal shock wave lithotripsy (ESWL) and percutaneous nephrostolithotomy (PCNL), stratified by initial stone size. Most ureteral calculi are less than 2 cm in diameter.

Figure 63.5. (A) Combined percutaneous nephrostolithotomy (PCNL) and extracorporeal shock wave lithotripsy (ESWL) for staghorn calculi. This 35-year-old White woman presented with a *Proteus* urinary tract infection and was found to have a large complete left staghorn calculus. (B) The stone was approached initially with PCNL, but numerous stone fragments remained scattered throughout the rather complex renal collecting system. (C) These fragments were then treated with two sessions of ESWL, greatly reducing the remaining stone material. (D, E) A second PCNL was then performed, requiring a second nephrostomy tube to effect complete stone removal. (F) The patient remains free of stone and infection 2 years after therapy.

Vascular	Phlebitis
Abdominal aortic aneurysm	Prostatic calculi (in enlarged gland)
Renal artery aneurysm	Calcified costochondral junction
Splenic calcification	Splenic granulomas
Aortic calcification	Adrenal calcification
Hypogastric calcification	Chronic pancreatitis
Nephrocalcinosis	Sacral bone islands
Calcified lymph node	Undigested pills
Gallstones

TABLE 63.5. IVP Signs of an Obstructing Ureteral Calculus

Spiral or helical CT has emerged as the diagnostic procedure of choice in many emergency departments for the evaluation of patients with suspected urolithiasis. With sensitivity and specificity of 98%,²⁶ no other noninvasive diagnostic procedure can equal non-contrast-enhanced spiral CT. Further, non-contrast-enhanced spiral CT is a more rapid test than IVP and avoids the risks associated with intravenous contrast administration. Spiral CT scanning is also useful for the accurate prediction of ureteral obstruction, aiding in the decision of whether and how to treat symptomatic patients.⁸ Spiral CT scanning has even been used experimentally to predict stone composition *in vitro*, but has yet to be proven in human studies.^{17,21} The main disadvantage of CT is its greater expense compared with IVP. Also, unless a KUB is obtained, radiolucent stones (mainly uric acid) cannot be distinguished from radiopaque stones.

EMERGENCY DEPARTMENT MANAGEMENT

Most patients with stones present to the emergency department with pain as their predominant symptom. The goals of the emergency physician are to make the proper diagnosis and provide relief of the pain. If the pain is typical colic, or if the patient has had similar pain with previous stones, then pain medication should be administered immediately without waiting for the results of IVP or CT. If the pain is atypical and an intraabdominal process is suspected, pain medication is usually withheld until the correct diagnosis is established. Once significant delay in function is noted on the initial films of an IVP, the patient should be medicated appropriately, because it may take hours to obtain delayed films. Morphine and meperidine (Demerol) are the usual parenteral narcotics used in treating colic, and large and repeat doses of either may be necessary to relieve the initial pain. Once the initial ureteral spasm is relieved, however, the patient's pain often will be quite mild, if it returns at all. Anticholinergic, spasmolytic, or antiinflammatory medications, commonly used in Europe, have not been found to be useful in the United States.

Pain management for patients with renal colic was traditionally confined to parenteral narcotics with the side-effect profile of nausea, pruritus, sedation, and potential respiratory depression. The mechanism of action of narcotics only controls the pain response without acting on the mechanism that initiates the painful stimuli in renal colic. The introduction of ketorolac tromethamine (Toradol), a parenteral nonsteroidal antiinflammatory drug that can be given both intravenously and intramuscularly, has been a major advance for the control of renal colic.

The pain of ureteral colic is mediated by prostaglandins released by the ureter in response to obstruction. Prostaglandins act to increase peristaltic action of the ureter to aid in passage of the stone,²³ but they also sensitize nociceptors to stimuli such as bradykinin, inducing pain and visceral responses to prostaglandins (nausea, vomiting). Ketorolac acts via inhibition of the prostaglandin synthesis pathways, and, when given parenterally, is very effective in relieving the pain and nausea of ureteral obstruction, with equal or more efficacy than parenteral narcotics.⁵ Ketorolac, used for a variety of painful emergency department diagnoses, decreased visual analog pain (VAP) scores by 37 mm (0 to 100 mm VAP scale) and was most effective for colic.²

Ketorolac should be used with caution in patients with a history of gastrointestinal bleeding, renal insufficiency, or cardiovascular disease. Acute decreases in renal blood flow (35% decrease) were noted after acute infusion of Toradol in a unilateral ureteral obstruction dog model.²⁴ Acute, transient renal failure occurred in six patients with cardiovascular disease when given ketorolac.⁶

Nausea and vomiting are common with ureteral colic and can be exacerbated by narcotics. In such patients, administration of an antiemetic agent is appropriate, as is vigorous fluid replacement if dehydration has occurred.

DISPOSITION

Once the diagnosis of a stone has been made and the patient has been made comfortable, proper disposition of the case should be made in conjunction with the consulting urologist who will be responsible for the patient's ultimate care ([Table 63.6](#)). The most common factor that necessitates patient admission is pain that is refractory to oral pain medications. Once the patient has been made comfortable with intramuscular or intravenous narcotics, an oral agent (codeine, oxycodone [Percodan], meperidine, hydromorphone [Dilaudid], or ketorolac) should be prescribed for any recurrence of pain. If pain relief is inadequate, admission will be necessary for pain control. Persistent nausea and vomiting and urinary extravasation are other indications for admission.

Obstruction with infection*
 Pain not controlled by oral analgesics
 Persistent nausea and vomiting
 Urinary extravasation
 Hypercalcemic crisis

RELATIVE INDICATIONS FOR ADMISSION

High-grade obstruction
 Solitary kidney
 Intrinsic renal disease
 Size of obstructing stone
 Duration of symptoms
 Social situation

*Potential urologic emergency.

TABLE 63.6. Indications for Admission

Infection in the presence of an obstructing stone is a urologic emergency that necessitates not only admission, but also immediate urologic intervention. This situation essentially represents an abscess with ready vascular access by way of the renal circulation. The appropriate therapy for this, as with an abscess, is drainage. The obstructed renal unit can be drained either by cystoscopy and passage of a ureteral catheter or by placement of a percutaneous nephrostomy tube. Both procedures can readily be accomplished under local anesthesia. Antibiotics alone are not adequate therapy in these circumstances, because the patient can suffer from continued bacteremic showering, progression to frank urosepsis, and rapid destruction of function of the involved kidney until drainage is achieved. Stabilization of ongoing sepsis and vascular instability should not take precedence over drainage in these patients, because improvement may not occur until the septic source is removed. Effective drainage can be achieved rapidly, and delay in drainage can lead to significant mortality.

Other factors deserve consideration in determining the disposition of the patient. Patients with high-grade obstruction by IVP are more likely to require intervention and admission. Patients with a solitary kidney or underlying intrinsic renal disease are more likely to suffer from a significant decrease in overall renal function with any degree of obstruction; therefore, the threshold for admission of such patients is lower. In addition, the likelihood that the patient will be able to pass the calculus without intervention should be considered. Factors to weigh in this regard include the duration of symptoms and size of the obstructing stone. Ureteral calculi less than 5 mm in size usually pass spontaneously, whereas those over 8 mm rarely do.²⁵

Most patients who present to an emergency department with calculi, after evaluation and relief of their pain, will not meet any of these criteria for emergent admission and may be discharged. Sufficient oral narcotic agents and an oral antiemetic agent should be prescribed, as necessary. Prophylactic antibiotics are not used. Patients should be instructed to strain their urine and save any solid material for analysis. They should be told to return or seek attention for recurrent severe pain, persistent vomiting, or the onset of fever. Outpatient urologic follow-up should be arranged within 2 weeks.

CURRENT TREATMENT

Several technologic advancements have revolutionized the treatment of symptomatic urolithiasis in the last two decades ([Table 63.7](#)). The most important of these advancements has been the development of extracorporeal shock wave lithotripsy (ESWL^{*}). This technology, pioneered by the Dornier HM3 lithotripter, has proved effective in the management of 85% to 90% of urolithiasis cases.^{4,10,13,14} Various new lithotriptors that use a variety of energy sources and stone localization systems and have lower anesthesia requirements have been introduced.¹⁶ Patients with large stones (i.e., more than 2 cm in diameter) and staghorn calculi, particularly when associated with hydronephrosis, are much less likely to become stone-free with ESWL monotherapy ([Fig. 63.4](#)). In addition, cystine stones fragment poorly with ESWL.

 3. Ureteroscopy
 4. Extracorporeal shock wave lithotripsy
 5. Observation
-

TABLE 63.7. Current Options for Urolithiasis Management (in Order of Decreasing Invasiveness)

Another important technologic advance is percutaneous nephrostolithotomy, which involves the establishment of a tract from the skin into the renal collecting system through which stones can be fragmented with ultrasonic, laser, electrohydraulic, or pneumatic devices and removed using various endoscopes, grasping forceps, and stone baskets. This technique is complementary to ESWL in that it is appropriate for larger and harder renal calculi that cannot be treated successfully with ESWL ([Fig. 63.5](#)).^{10,11,12} and ¹³

Ureteral calculi can be managed effectively with either ESWL or another new technique, ureteroscopy. Previously, ureteral calculi that necessitated intervention were managed with either blind basketing by way of the cystoscope or ureterolithotomy. The development of rigid and flexible ureterorenoscopes now allows visualization of the entire ureter from the bladder to renal pelvis and removal of ureteral calculi under direct vision. Again, various energy sources (ultrasound, laser, electrohydraulic, pneumatic) can be used through the ureteroscope to fragment stones if necessary. Ureterorenoscopy is most successful when applied to stones in the distal ureter. However, success rates decrease and complication rates increase when proximal ureteral calculi are approached with this technique. In general, upper ureteral calculi tend to be managed with ESWL, while ureteroscopy is still commonly used for distal ureteral stones.^{14,22} The American Urological Association has released a peer-reviewed, literature-based set of guidelines for the treatment of ureteral stones.²² These guidelines are designed to give both the urologist and the general practitioner an outline for the management of ureteral stones, based on size and location in the ureter. Most (98%) of ureteral stones less than 5 mm will pass spontaneously, if the associated symptoms can be controlled and no concomitant infection exists. Proximal ureteral stones less than 1 cm can be treated with ESWL. Distal ureteral stones less than 1 cm can be treated with either ESWL or ureteroscopy. Nearly all upper urinary tract calculi can now be treated without open surgery, and the only indication for open intervention is the need for a coincident reconstructive operation.¹

In addition to the treatment of existing symptomatic stones, an important goal for the urologist is to prevent further stone formation. Medical therapy based on a careful metabolic stone evaluation can dramatically reduce the incidence of recurrent stone formation.^{18,19} Such evaluation should begin in the emergency department by checking serum electrolyte levels (looking for distal or type I renal tubular acidosis) and serum calcium level (hypercalcemia usually indicates primary hyperparathyroidism). More detailed studies (i.e., 24-hour urine collections) should be delayed for 2 to 4 weeks after resolution of an acute stone event.

VESICAL CALCULI

Vesical calculi occur predominantly in males. Endemic urate calculi, once prevalent in young males, have virtually disappeared from industrialized societies. Most bladder calculi now present during adult life and are secondary to bladder outlet obstruction or foreign bodies in the bladder, such as an indwelling catheter. Calcium oxalate is the most common constituent of bladder calculi in the United States, although the incidence of struvite and hydroxyapatite calculi is higher than in the kidneys.

Typical symptoms of vesical calculi are pain on voiding and hematuria. The pain may be dull or sharp and is often severe at the end of micturition or with exercise or sudden movement. Hematuria often occurs at the end of voiding. Interruption of the urinary stream from impaction of the stone at the bladder neck may occur. Frequency, urgency, and dysuria are present in up to 50% of patients. Urinary tract infection is common, especially if an indwelling catheter is present. Some patients, especially those with prostatic enlargement, have no symptoms directly referable to the calculi but present only with symptoms of outflow obstruction.

The diagnosis of vesical calculi can be suspected from the history, and they rarely may be palpable on physical examination. Feeling a stone “clink” with a urethral sound is an age-old technique of detecting bladder calculi. Such stones are often apparent on plain radiographs, and cystoscopy is both diagnostic and therapeutic.

Once the diagnosis of a vesical stone has been made in the emergency department, it may be appropriate to anchor an indwelling Foley catheter if the patient has significant bladder outflow obstruction or cystitis. The patient should then be referred to a urologist, because successful treatment requires not only removal of the stone, but also relief of outflow obstruction, correction of bladder stasis, and removal of foreign bodies whenever possible.

RENAL NEOPLASMS

Renal cell carcinoma (RCC) is the most common primary tumor of the kidney. It accounts for 85% of all primary renal neoplasms¹² and 90% to 95% of renal malignancies. Primary carcinomas of the renal pelvis or ureter account for approximately 8% of all renal neoplasms.¹² A number of rare sarcomas account for the remainder of renal neoplasms.

Approximately 5% of solid renal parenchymal masses are benign in nature. The most common neoplasm is an oncocytoma. Oncocytomas do not appear to have any malignant potential. Other benign lesions are the fat-containing tumor; angiomyolipoma, which is seen in patients with tuberous sclerosis; and renal adenomas, which are probably just small, low-grade renal malignancies.

Nephroblastoma (Wilms' tumor) occurs primarily in children and contributes around 5% of cases, with approximately 600 new cases each year.²⁰

Approximately 30,000 new cases of RCC are diagnosed annually in the United States, with 18,000 yearly mortalities.¹⁷ Most cases of RCC occur sporadically, however a small percentage have a hereditary association, including Von Hippel-Lindau, tuberous sclerosis, and adult polycystic kidney disease.²⁴ RCC is more common in Scandinavians and North Americans, with a lower incidence in people of Asian and African descent. It is most common in adult males, with a male-to-female ratio of 2:1. Its onset in patients is typically in their fifth to sixth decade of life. Moderate cigarette consumption is a proven risk factor for RCC.

CLINICAL PRESENTATION

RCC has been coined "the internist's tumor" because of its baffling presenting signs and symptoms. The classically described triad of flank pain, abdominal mass, and hematuria for RCC is seen in only about 10% of patients at presentation and usually represents advanced disease. An increasing number of incidental RCCs are being diagnosed secondary to the prevalent use of radiographic imaging, done most frequently for nonurologic indications. As many as 25% to 40% of patients are

diagnosed with RCC after incidental detection of a mass by ultrasound or computed tomography (CT) scan.¹⁶ Incidentally discovered tumors tend to be smaller than those that cause symptomatic presentation and are more amenable to surgical resection.

Hematuria is the most common presenting symptom, followed by abdominal mass, pain, and weight loss. Hematuria, gross or microscopic, is usually observed only if the tumor has invaded the collecting system, and is most commonly seen with large tumors. This is in contrast to tumors of the renal pelvis or ureter, in which hematuria is usually gross and painless, occurring earlier.

Palpation of an abdominal or flank mass is more commonly found in thin patients or the pediatric population, with tumors of the lower pole more easily palpable. The mass is generally firm and nontender and moves with diaphragmatic excursion.

Flank pain is noted as a presenting sign in less than 20% of cases. As the tumor enlarges, it may encroach on the psoas and quadratus lumborum muscle, causing severe back pain. Occasionally, an acute varicocele is found as the presenting sign. Classically, this varicocele does not decompress with recumbency. A right-sided varicocele, in particular, should raise concerns of an underlying renal malignancy.

Up to 35% to 40% of patients with RCC have metastatic disease at the time of presentation.³ The most common sites are the lungs, bone, and liver. Bony metastases are generally lytic and painful. Patients may present with pathologic fractures.

RCC is associated with a wide variety of paraneoplastic syndromes. One well-known clinical manifestation of RCC is Stauffer syndrome, which was first described in 1961 as a reversible cause of hepatic dysfunction in a patient with RCC.¹¹ This syndrome occurs in 15% of patients with typical laboratory findings of elevated alkaline phosphatase, prothrombin time, and total bilirubin. These abnormalities should return to baseline after nephrectomy, and, if not, suggest the presence of metastatic disease. RCC is the malignancy most commonly associated with fever of unknown origin. This fever is probably due to a pyrogen or other growth factor. Hypercalcemia occurs in 10% to 15% of patients with RCC. This may occur secondary to bony metastases, a tumor-released parathyroid hormone–related peptide, or elevated prostaglandin levels. Anemia is the most common systemic manifestation of RCC, with 20% to 30% of patients being anemic at time of presentation. This anemia usually resembles normochromic or normocytic indices; however, hematuria or bleeding into the tumor can occasionally be the cause. Erythrocytosis, defined as hematocrit greater than 55 or hemoglobin greater than 15, occurs in almost 4% of patients. This is secondary to elevated levels of erythropoietin. It does not affect white blood cells or platelets and resolves after nephrectomy.

DIFFERENTIAL DIAGNOSIS

As noted earlier, the presentation of renal tumors can be quite varied. The differential diagnosis of hematuria and flank pain includes renal calculi and pyelonephritis. Retroperitoneal masses may arise from any neoplastic process of the kidneys, perinephric organs, and retroperitoneal space. Neoplastic processes involving the colon, stomach, esophagus, pancreas, spleen, liver, small intestine, and retroperitoneal primary tumors and metastases must enter the differential diagnosis.

The most common renal mass seen on radiologic imaging is a simple renal cyst. One autopsy series identified a 50% incidence of simple cysts after the age of 50.¹³ One can usually make a diagnosis of a classic benign simple cyst by following strict CT and sonographic criteria. Cysts are typically round, thin walled, and homogenous, and have no internal echoes or densities. Other clinical entities to consider when evaluating a renal mass include hematoma, abscess, infarct, vascular malformation, renal pseudotumor, angiomyolipoma, oncocytoma, and metastatic carcinoma.

The finding of a renal pelvic or calyceal filling defect is usually secondary to a radiolucent stone. These stones account for approximately 10% of all calculi and are usually uric acid. However, filling defects in the renal pelvis and ureter may represent a neoplastic process, papillary necrosis, or blood clot.

EMERGENCY DEPARTMENT EVALUATION

A patient with hematuria and flank pain should have a urinalysis, complete blood count (CBC), and creatinine sent. If the urinalysis demonstrates pyuria or bacteriuria, a urine culture should be obtained. The initial imaging study for the evaluation of flank pain and hematuria is traditionally an intravenous pyelogram (IVP), because a renal calculus is foremost in the differential. However, noncontrast spiral CT scans of the abdomen and pelvis are equivalent in sensitivity for stones and allow for the avoidance of contrast.

Once a renal parenchymal mass is identified, it is up to the urologist to determine whether it is consistent with a benign renal cyst or solid malignancy. Renal sonography is the best study in determining whether a renal mass seen on IVP or noncontrasted CT scan is cystic or solid, while a contrasted CT scan of the abdomen and pelvis is the most sensitive study for the diagnosis of RCC. For tumors less than 3 cm, the sensitivities of IVP, ultrasound, and CT scan are 67%, 79%, and 94%, respectively.¹ An IVP filling defect requires a retrograde pyelogram for definitive diagnosis. If an RCC is discovered, a general metabolic panel should be obtained to rule out a significant metabolic disturbance requiring immediate management.

EMERGENCY DEPARTMENT MANAGEMENT

Patients should have their pain alleviated. Intravenous fluid resuscitation and serial hematocrits are rarely needed but may be required for hypotension, tachycardia, or severe nausea and vomiting.

DISPOSITION

Role of the Consultant

Outpatient workup by the urologist is usually standard for any suspicious renal mass, and an appointment should be made. Emergency physicians should explain to the patient the necessity of follow-up, so that the urgency of the referral is not ignored.

Indications for Admission

Patients with severe pain or significant metabolic abnormalities from metastatic disease may need admission for pain control and management. Severe hematuria with urinary clot retention or hemodynamic instability may necessitate hospitalization.

Transfer Considerations

Transfer is usually not needed; however, there should be a referral to a urologist experienced in surgical management of RCC.

COMMON PITFALLS

- A renal tumor might not be considered in the forefront of diagnoses because the symptoms usually resemble more common urinary diseases.
- Intravenous pyelograms are easily misread. The more common diagnoses of renal calculi and pyelonephritis are often made on the basis of clinical suspicion and from radiographs of less than perfect quality. The emergency department IVP is not performed with a bowel preparation, and the detail is often inadequate to reveal renal parenchymal or epithelial tumors.
- The final diagnosis of a renal tumor can be difficult; the emergency physician should ensure appropriate and timely referral to a urologist.
- Emergency personnel should remember that relatively minor renal trauma can cause unexpectedly severe bleeding if a renal tumor is present, particularly in children.

TREATMENT COMPLICATIONS

Nephrectomy

Radical nephrectomy is the treatment of choice for RCC. This can be performed through a transabdominal, flank, or thoracoabdominal approach. The most common postoperative complication after radical nephrectomy is an ileus, which is particularly common after a transabdominal approach. The most immediate life-threatening complication after nephrectomy is hemorrhage, most often from the ligated renal vessels. This complication is rare. Other sources include splenic or hepatic injury, liver tear, or lumbar vessels. Bleeding may be insidious, becoming apparent some days after surgery. It should be suspected in the emergency patient with tachycardia, orthostatic hypotension, anemia, or abdominal pain.

Pneumothorax is an uncommon event during a transabdominal nephrectomy, but it is much more likely after a flank nephrectomy. It is usually evident at the time of surgery but should be considered in the postoperative patient who is short of breath.

Postoperative abdominal pain may be due to problems more serious than ileus or incisional pain. Dissection in the retroperitoneum can result in injury to the duodenum or pancreas, with resultant pancreatitis. Traction on or injury to the superior mesenteric artery can cause bowel ischemia.

A subtle, but serious postoperative problem after radical nephrectomy is adrenal insufficiency, characterized by weakness, malaise, and hyponatremia and hyperkalemia. This will occur in the patient with previous removal of the contralateral kidney and adrenal, but it also may occur in the elderly patient with borderline adrenal function preoperatively.

Chemotherapy

Metastatic renal cell cancer is resistant to standard chemotherapy, and these agents are very infrequently used for this disease. Immunotherapy with interferon and/or interleukin-2 (IL-2) has shown some antitumor effect but significant toxicity. Patients receive interferon subcutaneously one to five times weekly. Most experience a flu-like syndrome of fever, malaise, chills, and myalgias. Confusion and lethargy can be seen when high doses are used. IL-2, administered intravenously or subcutaneously in low doses, has considerably more toxicity and results in a "capillary leak" syndrome that is characterized by fever, hypotension, oliguria with fluid retention, renal failure, pulmonary edema, and hepatic dysfunction. These dose-related side effects usually resolve within 24 to 72 hours after administration. Although the patient is usually hospitalized for therapy, delayed manifestations may present after discharge. Many patients receive modified doses as outpatients.

BLADDER CARCINOMA

Bladder cancer is the fourth most common malignancy in men after prostate, lung, and colorectal cancer, accounting for 5.5% of all cancer cases.⁴ In women, it is the eighth most common cancer, accounting for 2.3% of all cancers. Approximately 50,500 new cases are diagnosed annually, with 10,000 deaths occurring yearly. Bladder cancer usually strikes patients in their sixth and seventh decades. Multiple risk factors include smoking and exposure to aromatic amines, phenacetin, and acrolein, a metabolite of cyclophosphamide. Transitional cell cancers account for 90% of the histologic tumors, while the remainder are squamous cell carcinoma or adenocarcinoma.

CLINICAL PRESENTATION

More than 70% of patients present initially with intermittent, painless, gross hematuria.¹⁴ Clot retention may be seen in approximately 20% of patients. Irritable voiding symptoms such as frequency, urgency, and dysuria often are associated with tumors involving the bladder trigone and ureteral orifices, particularly carcinoma *in situ* (CIS). Patients may present with flank pain from ureteral obstruction. Rarely, patients present with symptoms of advanced disease, such as weight loss or abdominal or bone pain. Up to 20% of patients have no specific symptoms, with the tumor being discovered during evaluation of microscopic hematuria.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of painless, gross hematuria includes infectious cystitis, hemorrhagic cystitis, glomerulonephritis, urinary calculi, and other tumors of the genitourinary system. Irritative voiding symptoms may be present with prostatitis, cystitis, and lower urinary tract calculi.

EMERGENCY DEPARTMENT EVALUATION

The patient with gross hematuria and clot formation should have a serum creatinine and CBC drawn. A large urethral catheter (22F) may be necessary if there is suspected bladder outlet obstruction due to clot formation. Intravenous access for fluid administration and possible IVP may be needed. An IVP should be obtained in all patients with gross, painless hematuria unless contraindicated. A renal ultrasound examination should be obtained in place of an IVP in a pregnant patient, while an ultrasound or noncontrast CT scan is needed for a patient with contrast allergy or significant renal insufficiency.

EMERGENCY DEPARTMENT MANAGEMENT

If blood clots are present, the bladder is irrigated until the return is clear. Normal saline irrigation may be needed to irrigate a bladder cleared of clots. A three-way catheter for constant irrigation may be used, but this is not as important as placement of a catheter large enough to remove clots (22F or larger). A catheter is not necessary if urinary retention from clot retention is not suspected. Urologic consultation should be obtained. All of these patients eventually require cystoscopy, although this can be done in the urologist's office at follow-up.

DISPOSITION

Role of the Consultant

Outpatient workup by the urologist is standard, although management of clot retention may require admission.

Indications for Admission

Patients with significant hematuria or clot retention should be admitted. If ureteral obstruction or pyelonephritis is suspected, admission is advisable.

Transfer Considerations

The availability of a urologist may necessitate transfer if admission for management of gross hematuria or ureteral obstruction is necessary.

COMMON PITFALLS

- Bladder tumors are often misdiagnosed as urinary tract infections. Most physicians do not obtain a urine culture when treating cystitis. Unfortunately, the urinalysis can show white blood cells in patients with both tumor and infectious cystitis.
- In the older patient with hematuria or irritative voiding symptoms, a urine culture should be obtained.

Treatment Complications

The diagnosis of bladder cancer is usually accomplished by cystoscopy with transurethral biopsy. Tumors are completely removed transurethrally if possible. Bleeding into the bladder is the most common complication, but bladder perforation, bowel perforation, and obstruction of the ureteral orifice may occur.

Bladder tumors that are limited to the mucosa are generally treated transurethrally, while tumors that grow deeper into the muscle generally necessitate complete

eradication.

INTRAVESICAL THERAPY

Intravesical chemotherapy is used for the treatment of superficial bladder cancer, and for patients at high risk for tumor recurrence, multiple tumors, and CIS. Bacillus Calmette-Guérin (BCG) is an attenuated strain of *Mycobacterium bovis* that has stimulatory effects on the immune system and is used in therapy for superficial bladder carcinoma. It commonly causes cystitis in up to 90% of patients. Patients that present with high fever, shaking chills, and hypotension should be suspected of having BCG sepsis. This occurs in less than 0.4% of patients, and these patients should be hospitalized immediately, started on broad-spectrum antibiotics, and given isoniazid and rifampin.¹⁵ BCG sepsis is very uncommon if the bladder is allowed to heal prior to instillation.

Intravesical chemotherapeutic agents such as mitomycin-C and Thiotepa may cause chemical cystitis. Suprapubic pain and pyuria are sometimes observed in addition to irritative voiding symptoms. Skin rash, usually in a palmar and facial distribution, and palmar desquamation are observed often with the use of mitomycin-C. Thiotepa is generally more well tolerated than mitomycin-C, with mild cystitis and irritative voiding symptoms occurring in 15% to 30% of patients. The major adverse side effects of Thiotepa are leukopenia and thrombocytopenia due to systemic absorption, which can be increased due to recent tumor resection, extensive tumor, or concurrent cystitis.

Multiagent systemic chemotherapy is the standard treatment for patients with nonresectable or metastatic disease. The usual agents include cisplatin, methotrexate, vinblastine, doxorubicin, or carboplatin with inherent toxicities.

RADICAL CYSTECTOMY

The most common complications found in patients after radical cystectomy are wound infections, postoperative intestinal obstruction, which is usually transient, and atelectasis/respiratory complications. Less common complications include myocardial infarction, pneumonia, and pyelonephritis. Incidence of urinary leakage at ureteroenteric anastomosis has been reduced secondary to the use of indwelling ureteral stents. A pelvic abscess may occur after a missed rectal injury during surgery or urinary leak. Hence, patients presenting with fever, pelvic or perineal pain, and fluctuance on rectal examination should be assessed appropriately with CBC, CT scan, and drainage, if an abscess is found.

URINARY DIVERSION

The standard form of urinary diversion after cystectomy for the past 40 years has been an ileal conduit. In this procedure, a 12- to 16-cm segment of ureter carries the urine from the ureters to a cutaneous stoma. It has no reservoir function. From many patients' standpoints, it has an unacceptable impact on body image. The most commonly associated, long-term complications of ileal conduits are parastomal hernias and either ureteral strictures or upper tract stone disease, leading to renal damage.

Continent urinary diversions, either a cutaneous continent urinary reservoir (CUR) or a bladder substitute (neobladder), are being used at many institutions with almost equal frequency to conduit diversions. All continent urinary diversions are made from a segment of either small or large bowel. A CUR has an entry stoma on the abdomen wall that the patient is required to catheterize every 4 to 6 hours to drain the reservoir. These stomas are easy to conceal and offer an appliance-free lifestyle. The most commonly performed CUR diversions are the "Indiana pouch" and the "Kock pouch."

For selected patients with a bladder substitute following cystectomy, a neobladder can be created in which an intestinal reservoir made from either small intestine or a combination of small and large intestine is constructed and then anastomosed to the ureters and urethra. Many different configurations have been described, with the "Studer bladder" and the "hemi-Kock" probably being the most common. Most patients are able to void spontaneously, and only a few require intermittent catheterization for adequate drainage. Daytime urinary control is usually excellent, while a significant portion of patients require protective incontinence pads at night.

The unique, acute complications of urinary diversion are primarily related to the intestinal and urinary anastomoses. Urinary extravasation can occur at the anastomosis between the bowel and ureter or at the enteroenterostomy. These most commonly occur during the initial hospitalization, but can occur after discharge. Urinary extravasation presents as oliguria or anuria, elevated blood urea nitrogen and serum creatinine levels, ileus, and abdominal or flank pain. The most sensitive test for detecting a leak from the ureterointestinal anastomoses is a contrasted CT scan. Leaks can occur along the suture lines of a CUR or neobladder. These are best detected by filling the pouch with contrast under fluoroscopy. In a continent urinary reservoir or bladder substitute, the balloon should never be inflated in the neourethra or the catheterizing tract. Under intermittent fluoroscopic observation, water-soluble contrast is infused in the loop until adequate distension of the bowel segment is seen.

Distal obstruction of the ileal loop can lead to urinary leak or hydronephrosis when the obstruction is chronic. Catheterizing the stoma and draining more than 20 cc of urine implies inadequate emptying. Gentle exploration with a gloved finger may reveal a fold or fascial edge.

A continent diversion may develop an obstruction of the catheterizing tract, and the patient may not be able to get a catheter into the reservoir. This may be due to a fold in the catheterizing tract, a false passage secondary to previous catheterizations, or angulation of the stomal tract. The emergency physician should try gentle catheterization with the patient in several positions (e.g., standing, supine, or lying on the side). Manipulation of a catheter into the conduit or reservoir or the insertion of a percutaneous drainage tube under fluoroscopy or ultrasound guidance by an interventional radiologist or urologist may have to be arranged. Pouch rupture because of retention is a rare but potentially fatal complication and is more common in the neurologically impaired patient who fails to empty, in part owing to impaired sensation. Stricture of the anastomosis between the urethra and bladder substitute may present as severe urinary hesitancy, decreased stream, fever, and flank pain. A catheter placed in the urethra will meet obstruction at the neobladder–urethral anastomosis. This requires immediate urologic consultation.

Leakage at the site of the bowel anastomosis can occur in the first month postoperatively and usually presents with peritonitis. These patients usually present with abdominal pain, nausea, vomiting, and signs of a surgical abdomen. These patients need emergent surgical exploration.

A more common presentation to the emergency department is nausea and vomiting due to a paralytic ileus. This is transient and resolves with nasogastric suction and bowel rest. A mechanical bowel obstruction can occur at any time. This usually occurs secondary to adhesions, but anastomotic strictures and internal hernias are also causes. A patient suspected of having a bowel complication should be made NPO, resuscitated with intravenous fluids, and admitted. When there is severe nausea or vomiting, a nasogastric tube should be placed.

Flatplate and upright abdomen radiographs may demonstrate free air under the diaphragm or dilated bowel.

The incidence of pyelonephritis in patients with a urinary diversion is approximately 10% to 20% and can be a major source of morbidity and mortality, particularly in the patient with coexisting renal dysfunction.²³ The chronic bacteria of the bowel segment serves as a persistent source of ascending infection. When drainage is impaired, pyelonephritis can occur. Positive urine cultures do not correlate with the occurrence of pyelonephritis. Most patients with ileal conduits and CUR diversions are chronically colonized with bacteriuria. In contrast, many patients with neobladders have sterile urine. Treatment is not indicated in the absence of symptoms after any form of urinary diversion. Clinical signs, including flank pain and fever, should direct antibiotic therapy. The presence of mucus in the urine is not a specific sign of infection. Although mucus production increases in the presence of an infection, it is a normal finding in patients with bowel exposed to urine.

Metabolic complications can result from absorption of solutes through the permeable bowel wall and can be minimized by avoiding prolonged contact of urine and bowel. Ileum and colon both are associated with the potential for hyperchloremic metabolic acidosis, producing a non–anion gap acidosis. However, this acidosis is rarely significant in a patient with normal renal function.

Ureteral obstruction usually occurs at the ureteroenteric anastomosis, but may occur more proximally. The incidence is approximately 15%, and the risk is present throughout the life of the anastomosis, emphasizing the need for long-term monitoring. A patient may present with flank pain and be found to have hydronephrosis on IVP or ultrasound. Stomal stenosis occurs in 5% of adults. It is more common in the pediatric population and is preventable through construction of a well-vascularized, everted stoma.

Calculus disease results from persistent infection, hypercalciuria associated with chronic acidosis, enteric hyperoxaluria associated with the use of large amounts of

ileum, and infection. Infection stones are associated with urea-splitting organisms, such as *Proteus*, *Klebsiella*, and *Pseudomonas*. Treatment includes stone removal, elimination of factors that cause residual urine, adequate oral intake, adequate bladder irrigation, and aggressive treatment of infection.

DIFFERENTIAL DIAGNOSIS

After transurethral resection or biopsy, a bladder perforation should be suspected in someone with abdominal pain, anuria, oliguria, and fever. After a cystectomy, ileal conduit or continent diversion, urinary leakage, ureteral obstruction, bowel anastomosis leakage, and bowel obstruction or ileus should be considered in a patient with similar symptoms.

EMERGENCY DEPARTMENT EVALUATION

A careful history is important to direct the examination. All patients are examined for signs of peritonitis. A white blood cell, serum creatinine, and flatplate and upright abdominal radiographs should be obtained. Urine should be sent for analysis and culture. If flank pain is present, an IVP or ultrasound should be obtained.

EMERGENCY DEPARTMENT MANAGEMENT

The postoperative patient's surgeon should be notified. If a consultant is not available, a patient with abdominal pain after a resection or biopsy of the bladder should have a large-bore catheter placed. If bladder perforation is suspected, a low-pressure cystogram should be obtained.

The patient with a ureteral obstruction needs admission for percutaneous nephrostomy. Intravenous antibiotics are given to any patient at risk for sepsis, including those with suggested urinary obstruction and peritonitis. Patients with intestinal anastomotic leaks or urinary leaks from urinary reservoirs generally require surgical repair.

DISPOSITION

Role of the Consultant

The role of the consultant is to facilitate management of all postoperative complications. Urologic consultation should be obtained for the instrumentation of any urinary diversion.

Indications for Admission

Any patient suspected of having bowel obstruction, peritonitis, ureteral obstruction, or bladder perforation should be admitted.

Transfer Considerations

The availability of a urology consultant may necessitate transfer. If the procedure was performed at the same institution as the emergency department, transfer should not be needed unless the radiology or intensive care facilities are inadequate.

COMMON PITFALLS

- Dismissal of "usual and expected postoperative pain" may overlook a potentially serious problem.
- Ureteral obstruction with infection can cause urosepsis.
- Bowel obstruction, peritonitis, or bladder perforation with intraperitoneal extravasation can be fatal.

CARCINOMA OF THE PROSTATE

Carcinoma of the prostate is the most common malignancy in American men as well as the second leading cause of cancer deaths in men.¹⁸ In 1996 there were an estimated 317,000 new cases of prostate cancer diagnosed and 41,4000 deaths from the disease. Carcinoma of the prostate has been associated with age, race, dietary factors, and other environmental factors. This malignancy is found almost two times more often in African-American men than in Caucasians.

CLINICAL PRESENTATION

Prostate cancer may be diagnosed incidentally on screening of men with the digital rectal examination, elevated prostate-specific antigen (PSA) level, or as a result of specific symptoms. However, most men who require treatment for prostate cancer seek medical attention through the emergency department only after experiencing symptoms of their disease, with bladder outlet obstruction or vesical irritability being the most common presentation. In the pre-PSA era, regional symptoms consisting of back, leg, and perineal pain were present in 20% to 40% of patients at diagnosis. Hematuria and constitutional symptoms (weight loss, fatigue, and generalized weakness) were found in 10% to 15%.¹⁸ Several studies suggest that 20% to 25% of patients with urinary retention harbor an identifiable prostate cancer. In one series, 19% patients had spinal cord compression as the first indication of carcinoma.²² The ischium, lumbosacral spine, and thoracic spine are the three most common sites for bony involvement.

The treatment of prostate cancer is determined by the extent of the disease. Radical prostatectomy, external beam radiation therapy, or brachytherapy are the options for locally controlled disease without evidence of metastatic disease. For patients with metastatic disease, androgen ablation, either medical or surgical, is indicated. Chemotherapy is utilized in patients with hormone refractory disease.

DIFFERENTIAL DIAGNOSIS

The main differential diagnoses for local voiding symptoms include benign prostatic hyperplasia (BPH) and prostatitis. The acute onset of symptoms in prostatitis contrasts to the insidious onset of prostate cancer. The symptoms of bladder outlet obstruction are similar regardless of the cause of the enlargement. These entities can also coexist, however. The differential diagnosis of a prostate nodule includes a benign prostatic nodule, induration secondary to focal prostatitis, and prostatic calculi. Approximately 50% of suspicious lesions on digital rectal examination actually represent cancer on prostate biopsy.

EMERGENCY DEPARTMENT EVALUATION

The patient presenting with symptoms of prostatism and bladder outlet obstruction should have a thorough abdominal examination to palpate for a distended bladder and a digital rectal examination to evaluate the prostate. A urinalysis and urine culture should be sent to rule out infection. Electrolytes and serum creatinine should also be checked. A PSA level may be drawn, with specific instructions given for the patient to follow up the results with a local urologist. Any patient with severe bone pain should have appropriate radiographs taken to rule out a pathologic fracture. A careful neurologic evaluation is indicated with a presumed diagnosis of prostate cancer with complaints of significant back pain or lower extremity weakness to rule out spinal cord compression. Any patient with severe back pain and/or an abnormal neurologic examination should undergo an emergency spinal magnetic resonance imaging or CT scan to exclude cord compression. A bone scan is usually not indicated during an emergency department evaluation.

EMERGENCY DEPARTMENT MANAGEMENT

Any patient suspected of having urinary retention should be catheterized. Marked polyuria may ensue after relief of the bladder outlet obstruction. This postobstructive diuresis may produce electrolyte abnormalities.

Patients with bone metastases can present with severe pain and associated neurologic dysfunction secondary to spinal cord compression. Palliation with aggressive administration of narcotic analgesics should be employed. Patients with persistent back pain and known skeletal involvement on bone scans with or without neurologic findings are at high risk for cord compression. This medical emergency should first be treated with high doses of intravenous glucocorticoids. These patients should be monitored closely for changes in neurologic status. They are generally treated with emergent external beam radiotherapy. Occasionally, surgical decompression may be necessary if there is spinal instability. All of these patients should receive immediate androgen ablation, either by surgical castration or the administration of high-dose ketoconazole, which blocks steroid synthesis.

Patients with metastatic disease are treated with androgen-deprivation therapy. This is accomplished by bilateral orchiectomies or, pharmacologically, with luteinizing hormone–releasing hormone (LH-RH) agonists and/or antiandrogens. A patient beginning LH-RH therapy has a transient stimulation of LH secretion, with subsequent increase in testosterone during the first 2 to 3 weeks of treatment. Thus, a patient may present to the emergency department with symptoms exacerbated by his hormonal therapy. Frequently, patients will be treated with both LH-RH agonists and an antiandrogen to block this flare phenomenon.

DISPOSITION

Role of the Consultant

In the absence of complicating factors such as urinary retention, severe pain, or spinal cord compression, the urology evaluation can be arranged on an outpatient basis. The consultant may be needed to relieve urinary obstruction or evaluate a patient with an impending spinal cord compression.

Indications for Admission

Any patient with urinary retention, intractable pain from bony metastases, or signs of neurologic impairment should be admitted.

Transfer Considerations

A patient in urinary retention who cannot be catheterized or undergo diversion with a suprapubic tube may need transfer if urologic consultation cannot be obtained. An oncologist, family practitioner, or internist can admit a patient with painful bony metastases for pain control. If a neurosurgeon is unavailable for evaluation and management of spinal cord compression, transfer may be required.

COMMON PITFALLS

Cord compression should be considered in any man with prostate cancer and back pain.

TREATMENT COMPLICATIONS

Radical Prostatectomy

After radical prostatectomy, patients may have an indwelling catheter for up to 3 weeks. Should a patient present to the emergency department in the immediate postoperative period with a catheter dislodged or removed, the emergency department physician can attempt to replace the catheter. If there is any resistance, the attempt should be terminated. If necessary, a catheter may have to be reinserted under direct cystoscopic guidance.

Patients may also present in urinary retention following the removal of their urethral catheter. Vesicourethral strictures occur in less than 10% of patients.⁶ These patients may need placement of a suprapubic catheter if urethral catheterization is unsuccessful.

Pulmonary embolism and deep venous thrombosis occur in 4% and 3% of patients, respectively. Wound infection, rectal injury, and pelvic lymphoceles all occur in less than 5% of patients. However, a patient with a rectal injury not recognized at the time of surgery may present with signs of sepsis and abdominal and pelvic pain. The rectal examination may reveal a fluctuant mass.

Impotence, which occurs approximately 50% of the time, and urinary incontinence with a less than 3% occurrence rate, should be referred to a local urologist for treatment.

External Beam Radiation Therapy

The complications and morbidity associated with external beam radiation therapy most commonly involve the lower gastrointestinal and urinary tracts. Sixty percent of patients develop mild urinary symptoms, most commonly increased frequency, nocturia, urgency, or mild rectal morbidity, including rectal discomfort, tenesmus, or diarrhea.¹⁸ These symptoms usually appear during the third week of treatment and resolve within days to weeks after completion. Less than 5% of patients require hospitalization for complications secondary to radiation therapy.

Patients presenting with severe urinary symptoms or tenesmus should be managed supportively. Daily intake of psyllium (Metamucil) may help to curb frequent bowel movements, while sitz baths may decrease the local irritation and help relieve pain. Hydrocortisone (Anusol-HC) suppositories may be helpful for rectal irritation or bleeding. Diarrhea may be treated with appropriate agents, while phenazopyridine (Pyridium) and oxybutynin (Ditropan) and alpha blocking agents can be used for irritable voiding symptoms.

Hormonal Therapy

Patients suffering from prostate cancer usually benefit symptomatically from medical or surgical castration. Patients usually have pain relief and improved performance status following castration. Wound infections and scrotal hematomas are the most common complications following bilateral orchiectomies. Men sometimes suffer from hot flashes and sweating following surgical castration. Megestrol acetate (Megace) may provide symptomatic relief for these symptoms.

Luteinizing hormone-releasing hormone (LH-RH) agonists have become the standard non-surgical therapy for metastatic prostate cancer. These agents are injected as a depot intramuscularly or subcutaneously and maintain constant release for a 30-180 day period of castration levels. Side effects include impotence, hot flashes in up to 60% and sweating in about 10% of patients.²¹ Under treatment with LH-RH agonists, a stimulation of testosterone secretion occurs during the first two to three weeks. This may stimulate tumor growth and may increase such clinical symptoms as bone pain.

TESTICULAR CARCINOMA

Testicular carcinoma is a rare form of malignancy, but it is the most common malignancy in men between the ages of 15 and 35 years.⁹ In 1995 the incidence of testicular cancer in White males in the United States had increased to 4.5 cases per year per 100,000 population, up from 2.88 cases per year per 100,000 in the U.S. Army between 1940 and 1947.^{7,10} However, there has not been an increase in cases in African American males during this same period.

CLINICAL PRESENTATION

The most common presentation of testicular carcinoma is painless swelling of one testis. Patients may also complain of fullness, dull ache, pain, or infertility. Any solid, hard mass in the scrotum should be considered a germ cell tumor until proven otherwise. Testicular tumors may be confused with epididymitis, orchitis, torsion, hydrocele, spermatocele, varicocele, or trauma.

Approximately 40% to 50% of patients have metastatic disease at the time of initial presentation, with 10% presenting with manifestations of metastatic disease.^{5,19}

Symptoms may include hemoptysis or shortness of breath from lung metastases, back pain from retroperitoneal adenopathy, gastrointestinal symptoms from direct gastrointestinal involvement or mass effect, gynecomastia from elevated serum beta human chorionic gonadotropin (bhCG) level, or a neck mass from supraclavicular adenopathy. Up to 90% of patients with testis cancer have elevated alpha-fetoprotein (AFP) or bhCG levels. Ten percent of patients with testicular cancer have a history of cryptorchidism. Patients also have a 5% chance of developing a contralateral tumor, most often metachronously.

Inguinal orchiectomy is used for both diagnosis and treatment of testicular cancer. The primary lymphatic drainage from the testis follows the gonadal vessels into the retroperitoneum. Retroperitoneal lymph node dissection thus may be necessary for accurate staging of early lesions or removal of advanced metastatic disease.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of testicular masses includes epididymitis, hydrocele, torsion, spermatocele, hematocele, hematoma, and orchitis. Transillumination can help define a hydrocele and spermatocele. Testicular ultrasound should always be performed in any patient with a testicular mass.

EMERGENCY DEPARTMENT EVALUATION

The patient should have a thorough genital examination in the standing position. Scrotal ultrasonography should be obtained in any patient in whom a mass does not readily transilluminate. bhCG and AFP serum markers should be drawn for anyone with a suspicious testicular mass and are helpful in staging and follow-up.

EMERGENCY DEPARTMENT MANAGEMENT

If the diagnosis of a testicular tumor is suspected, a urologic consultation is needed.

DISPOSITION

Most patients are taken to the operating room expeditiously. If not taken the day of the evaluation, the patient should be discharged only after appropriate arrangements are made.

Role of the Consultant

The ultimate diagnosis and welfare of the patient are the responsibility of the consultant.

Indications for Admission

The patient with signs and symptoms referable to metastases should be admitted.

Transfer Considerations

A patient may be transferred to facilitate urologic consultation.

COMMON PITFALLS

Delay in diagnosis occurs in nearly half of patients presenting with testicular tumors. The average time elapsed from the time the patient noticed the mass to surgical diagnosis is nearly 6 months. Misdiagnosis of testicular tumors as inflammatory or infectious conditions and underemphasizing the urgency of the diagnosis are common causes of delay. These patients need immediate urologic evaluation.

TREATMENT COMPLICATIONS

Inguinal Orchiectomy

The initial step in the diagnosis and treatment of testicular cancer is the inguinal orchiectomy. Wound infection and scrotal hematoma are the most common complications. Complications are infrequent, but a spermatic vessel that is not securely ligated may cause significant inguinal and retroperitoneal blood loss. Orchiectomy for testis cancer is done through an inguinal approach to avoid contamination of scrotal lymphatics.

Retroperitoneal Lymph Node Dissection

Retroperitoneal lymph node dissection (RPLND) is frequently part of the staging and treatment for testicular cancer. The patients who undergo this surgery for *low-stage* disease are mostly young, vigorous, and fit, without extensive disease and debilitating chemotherapy. Hence, the occurrence of early or late complications is minimal. Damage to the postganglionic sympathetic nerve fibers may cause loss of seminal emission and, therefore, a dry ejaculate. With proper surgical techniques, this complication can be avoided in almost all patients. The most common complication of primary RPLND (no previous chemotherapy) is wound infection in 4.8%, with small bowel obstruction occurring in less than 2.5% of patients.⁸

The patients who have RPLND after chemotherapy for residual tumor mass are at a higher risk for serious, life-threatening complications. The most common serious complication in these patients is adult respiratory distress syndrome.² Bleomycin, a chemotherapeutic agent used to treat testes germ cell tumors, can produce an acute interstitial pneumonia and permanent fibrotic lung changes. Avoiding high concentrations of oxygen in these patients and overzealous fluid resuscitation with crystalloids helps prevent respiratory insufficiency. Hence, the emergency department physician should be cognizant of this to prevent exacerbating bleomycin lung toxicity.

Tumor adherence to the great vessels and retroperitoneal structures may result in subadventitial dissection of the aorta. If unnoticed at the time of surgery, delayed aortic rupture is possible. Occasionally, the weakened wall is replaced with an artificial tube graft. A delayed aortic–duodenal fistula may occur if there is an injury to the duodenum and if there is a weakened aortic wall. This is a devastating complication and is almost always fatal.

Patients may develop thromboses of the vena cava or iliac or pelvic veins following extensive dissection. Symptoms of pulmonary embolus, lower extremity edema, or pain should prompt the diagnosis and treatment.

Chylous ascites, due to leakage from large, uncontrolled retroperitoneal lymphatic channels, may become evident well after discharge from the hospital. Patients will have abdominal distention and, occasionally, respiratory distress if the ascites is advanced. Drainage is usually not indicated. Treatment consists of bedrest and a strict medium-chain triglyceride diet. Prolonged ileus, delayed small bowel obstruction, and pancreatitis are other gastrointestinal complications that must be considered after RPLND.

Patients may also present with flank pain following RPLND. The ureters that delineate the lateral margins of dissection may be injured from transection or devascularization. The patients thus can have a urinoma, hydronephrosis, or a urinary fistula through the incision.

URINARY INCONTINENCE

Urinary incontinence is not an emergency condition. It may be tolerated for lengthy periods before attention is sought. Proper management depends on accurate distinctions between stress, urge, and true incontinence and recognition of potential contributions from infection, drugs or medication, sustained bladder overdistention, neuropathologic deficits, obstruction, anatomic factors, and so forth. Emergency management is limited to assessment for contributory pathology (bladder distension, neurologic deficit), and urologic referral.

Stress Urinary Incontinence

Stress urinary incontinence (SUI) refers to involuntary urine spillage during abrupt increases in intraabdominal pressure (cough, sneeze, straining, laughing, sudden activity). SUI is often associated with multiparity and obesity, which are incriminated in reducing anatomic support for normal vesical urethral positioning, resulting in transfer of intraabdominal pressure from a bladder-closing to a bladder-opening mode. Neither obesity nor multiparity is a prerequisite, however. Other risk factors include diabetes, corticosteroid therapy, radiation therapy, and previous relapsing or unsuccessful antiincontinence surgery. Chronic vesical overdistension may accrue from blunted appreciation of symptoms, as with senility, diabetes, mental retardation, or depressed states of consciousness. The sensory neurogenic bladder characteristic of diabetes can produce chronic vesical overdistension and ultimate detrusor dysfunction; this complication may be interdicted by timed voiding, intended to prevent bladder overdistension.

Although SUI is primarily an adult female complaint, men and children are not exempted and require equally comprehensive assessment for potential etiologies, emphasizing obstructed voiding, operative history (prostatic resection), and neurologic factors. Important diagnostic data are frequently provided by voiding cystourethrography.

EMERGENCY DEPARTMENT EVALUATION

The diagnosis of SUI begins with confirmation of involuntary expulsion of urine. Severity may be quantified by documenting use and frequency of incontinence pads, and by whether the patient will consider a surgical remedy.

History alone is frequently diagnostic; support is provided by demonstrating urine loss with coughing and correction by digital urethral support (Marshall test). Other diagnostic adjuncts include cystoscopic disclosure of bladder neck opening by coughing and by radiographically delineating reduction or loss of the normal posterior urethrovesical angle, reflecting anatomic nonsupport. In addition, videourodynamic imaging may verify anatomic descent of the urethrovesical complex, thereby distinguishing SUI from incontinence resulting from unstable bladder contractions. Sophisticated urodynamic evaluation, including leak-pressure management, is particularly important after standard remedies have failed.

When predisposing or contributing factors are identified, diagnosis of SUI may require sophisticated urodynamic evaluation of vesical and urethral status and activity. Accurate diagnosis is crucial to avoidance of postoperative voiding dysfunction, usually manifested by chronic catheter differentiation that is required to avoid inappropriate surgery for vesical hyperactivity, which is managed by nonsurgical methods.

MANAGEMENT

Management of SUI is usually surgical, involving restoration of normal vesicourethral positioning by fixation of the paraurethral connective tissue to the symphyseal periosteum or to Cooper's ligament. Several methods are available for this purpose, including open suprapubic or vaginal needle suspension techniques. In selected patients, periurethral injection of bovine cross-linked collagen may be applicable. Although suprapubic methods are traditionally more reliable and more durable, anterior vaginal suspension procedures are convenient in patients undergoing vaginal surgery for other purposes.

SUI may be exaggerated by chronic bladder distension or incomplete emptying, and symptoms may be reduced to manageable levels if bladder emptying is improved. Patients with mild symptoms of SUI occasionally improve with Kegel exercises, weight reduction, estrogen replacement, or electrostimulation methods, involving operative positioning of electrodes within selected spinal foramina and a generator in a subcutaneous pocket.

Vaginal pessary may be attempted in poor operative candidates. SUI may also respond to pharmacologic manipulation, involving either vesical relaxation with anticholinergic drugs, increasing outlet resistance with alpha-agonist agents, or both.

Urgency Incontinence

Urgency incontinence describes a sudden, compelling urge to void that cannot be suppressed, and it affects both sexes and all age groups. Less severe cases involve the urgency syndrome without incontinence. Voiding volumes are typically small, often coexisting with urinary frequency. Dysuria is not a consistent feature in the absence of urinary tract infection, and a normal urinary sediment without inflammatory components or bacteria suggests emotional, functional, or neurologic contributions. Nonpathologic urgency and incontinence is not uncommon in the first several years of life, even after apparent bladder control has been achieved. Absence of coexisting neurologic or obstructive symptoms makes spontaneous recovery likely, and awareness of this phenomenon may help to avoid unnecessary sophisticated urodynamic and radiographic testing. Simple observation and anticholinergic therapy are usually adequate.

Patients with obstructed voiding may display uninhibited bladder contractions or hypercontractility, leading to urgency with or without incontinence; these symptoms often subside after relief of obstruction. Examples of obstruction range from detrusor-sphincter dyssynergy and posterior urethral valves in boys to benign prostatic hypertrophy (BPH) in men. Symptoms that may coexist with urgency incontinence include enuresis, infection, and prostatism (frequency, nocturia, tenesmus, incomplete emptying, and reduced voiding dynamics).

DIFFERENTIAL DIAGNOSIS

Inflammatory irritation usually reflects urinary infection. Other potential etiologies of urgency incontinence include urethral syndrome, interstitial cystitis, radiation cystitis, some medications (bacillus Calmette-Guérin [BCG], cyclophosphamide), and carcinoma *in situ*. Essential to diagnosis is examination of the urinary sediment, urine culture (when bacterium is present), cystoscopy, urine cytology, and bladder biopsy. Many of the potentially responsible disorders share the common feature of reduced bladder capacity owing to painful bladder filling. Diurnal frequency, often with urgency, is dominant. In contrast, a functional or nonpathologic etiology is more likely in the patient who describes daytime frequency without nocturia, a conclusion supported by noninflammatory urinary sediment.

The urethral syndrome is a common disorder in women who manifest recurrent episodes of urgency, frequency, and dysuria with noninflammatory urinary sediment and negative urine culture. This disorder is commonly interpreted as infection, and standard or extended courses of antibiotics are frequent. Patients may describe improvement during treatment, with prompt relapse thereafter. Urinary sediment often reveals squamous epithelial cells regardless of age or estrogen status. Episodes are typically cyclic, occasionally induced by intercourse. Treatment should be symptomatic, avoiding antibiotics when bacteriuria is not present. Urethral dilatation often benefits recalcitrant cases.

Interstitial cystitis usually affects women and typically commences in the third decade. This disorder involves an idiopathic, noninfectious, inflammatory cystitis extending into the muscularis and causing varying degrees of frequency, urgency, and dysuria, which may become disabling. Subsequent vesical fibrosis progressively reduces bladder capacity to degrees that may become intolerable. Clinical benefit is variably claimed for numerous remedies, including amitriptyline, antihistamines, calcium channel blockers, bladder hydrodilatation, bladder instillations (silver nitrate, oxychlorosene, dimethyl sulfoxide, BCG, steroids), and many others. Clinical responses are often partial, incomplete, or transitory, sometimes culminating in bladder augmentation or cystectomy/urinary diversion. Oral sodium pentosan polysulfate has been introduced as specific therapy for interstitial cystitis, with encouraging early clinical results. Diagnosis of interstitial cystitis, particularly in men, requires biopsy exclusion of potential competing diagnoses, including inflammatory carcinoma *in situ*.

True Incontinence

True incontinence occurs without urgency or increased abdominal pressure and is usually the consequence of urinary fistula or disruption of the continence apparatus. Urinary fistula may result from trauma, prolonged third stage of parturition, malignant erosion, or defects associated with ischemia (operative, chemical, radiation).

Traumatic, malignant, or surgical damage to the male external urethral (e.g., radical prostatectomy and traumatic avulsion of the membranous urethra sphincter) may result in continuous urinary incontinence. True incontinence in women may result from destruction of normal urethral elasticity by radiation or urethral surgery (usually multiple), producing the “drain-spout urethra,” or by uterine procidentia that effaces normal posterior urethrovesical angulation.

True incontinence resulting from developmental anomalies is occasionally encountered, particularly in younger age groups. Examples include ectopic ureteral drainage (distal to the bladder outlet in females; distal to the external sphincter in males) or urethral duplication in males involving channels originating in the bladder and bypassing the external sphincter.

Excretory urography, retrograde ureterography, voiding cystourethrography, retrograde urethrography, panendoscopy, and bladder instillations (chromocystography) may establish the diagnosis of urinary fistula.

Damage to the external urethral sphincter or loss of urethral elasticity is verifiable by radiographic studies or urodynamic evaluation. Conventional bladder-neck suspension often fails in such patients, as opposed to success rates as high as 94% with fascial sling or periurethral injection procedures. Artificial urinary sphincter implantation is a final option for patients with sphincteric incompetence who fail conservative remedies.

URINARY RETENTION

Urinary retention describes an inability to void or to expel the bladder contents, resulting in bladder distension and its sequelae. Retention must, therefore, be distinguished from anuria, which represents either interruption of urine production by the kidney from vascular or parenchymal disorders or obstruction to urine delivery to the bladder.

CLINICAL PRESENTATION

Acute urinary retention is typically manifested by a palpable and severely uncomfortable bladder, with discomfort exaggerated by pressure applied suprapubically (Credé). Chronic urinary retention is often encountered in senile, diabetic, or neurologically compromised patients manifesting frequent small-volume expulsions of urine characteristic of overflow incontinence. A chronic uriferous odor is characteristic, as well as an apparent indifference to the discomfort of vesical overdistention. Patients with intermediate cases may suffer only urinary frequency or SUI.

Causes of urinary retention are usually obstructive, exemplified by BPH in senior men. Other etiologies may be inflammatory, neurogenic, or pharmacologic. Retention in women is rare and classically ascribed to emotional or psychogenic disturbances, but urodynamic investigations have identified organic etiologies in most cases studied. Pediatric obstructions are predominantly congenital and may severely damage immature nephrons; these manifestations may be obvious in prenatal ultrasound screening and functionally critical in the neonatal period.

DIFFERENTIAL DIAGNOSIS AND EMERGENCY DEPARTMENT EVALUATION

Differential Diagnosis in the Male

Adult male urinary retention is statistically most common with BPH, which is characterized by insidious progressive obstruction, usually in the sixth decade or later. Symptoms (prostatism) include hesitancy, frequency, urgency, a sense of incomplete bladder emptying, and diminution in size and force of the voided stream. Digital rectal examination discloses smooth, symmetric, homogeneous prostatic enlargement devoid of nodular induration. Similar symptoms in a younger patient with an unenlarged prostate are usually attributable to fibromuscular contracture of the vesical outlet (median bar). A history of enuresis, epididymitis, or nocturia is not unusual.

Prostatic cancer rarely obstructs voiding. Indurated nodularity is the classic clinical manifestation. Serum prostate-specific antigen (PSA) correlates with the likelihood, extent (stage), and aggressiveness of prostate cancer. Additional diagnostic information may accrue from serum prostatic acid phosphatase, osteoblastic metastasis, ureteral obstruction, and the ratio of serum protein-bound to protein-unbound levels of PSA. Final diagnosis relies on tissue sampling of biopsy or operative specimen. The advised response to abnormal digital rectal examination or elevated PSA is transrectal needle biopsy after antibiotic pretreatment, with transrectal ultrasonographic guidance as indicated.

Voiding may also be obstructed by infectious or inflammatory processes such as urethritis and prostatitis, with restoration of normal voiding after temporary catheter drainage and antibiotic therapy. Obstruction from tuberculosis, bilharziasis, and echinococcosis has also been documented, although presently relegated to virtual historic interest. Gonococcal urethral stricture has also become a clinical rarity owing to avoidance of chronic, untreated infection. Contemporary stricture disorder more often follows violent or iatrogenic trauma. Urinary retention is not a feature of nongonococcal (chlamydial) urethritis. Miscellaneous causes of urinary retention in men have been cataloged ([Table 65.1](#)).

Documented Connections	Anecdotal Connections
Prostatic metastases from kidney and penis	Hypogastric artery aneurysms
Leukemic infiltration of prostate	Urethral calculi
Malignant mesonephrial fibrosis	Sickle cell syndrome
(fibrous histiocytoma)	Prostatic infection
Bladder and urethra malignancies	Bladder clots
Pelvic nerve plexus injury during surgical intervention for testis and rectal tumors	Inappropriate antidiuretic hormone secretion
Vincristine-inhalation neuropathy	Cysts of prostate, seminal vesicle, müllerian duct, ejaculatory duct, or Cowper's gland
Infectious perivesical fat necrosis	Inflammatory rectal or perirectal processes
Idiopathic perivesical fibromatosis	Various functional disorders

From Peterson NE. Urinary retention. In: Wolken AB, Harwood-Nuss A, eds. Renal and urologic emergencies. New York: Churchill Livingstone, 1996.

TABLE 65.1. Miscellaneous Causes of Urinary Retention in Men

Differential Diagnosis in Children

Pediatric urinary retention often results from developmental anomalies. Nonurologic disorders frequently coexist and usually predominate in significance. Obstructive and developmental insults to the immature kidney are variable and may be manifested neonatally or variably thereafter by sepsis, azotemia, failure to thrive, urinary infection, and voiding disorders. Prompt and comprehensive diagnosis is imperative, and urinary drainage is paramount. Pediatric urinary obstruction and retention are exemplified by posterior urethral valves in boys, hydrocolpos resulting from vaginal stenosis or imperforate hymen in girls, and prolapsing or dissecting ureterocele in either sex, particularly with duplicate renal pelvis and ureters. Pediatric urinary retention produces a palpably distended bladder, overflow incontinence, a vulnerability to infection, and complications including ureteral obstruction or reflux with hydronephrosis, respiratory distress, renal functional depression with azotemia, and extravasated urinary ascites.

Pediatric urinary retention may also derive from congenital neuropathology, exemplified by lumbosacral myelomeningocele or sacral agenesis. Retention syndromes in older children are more commonly functional, including the primary megacystis syndrome (girls) and transitory external sphincter hyperspasticity (boys), both of which are considered to be learned phenomena and amenable to relearning and biofeedback-type management. Megacystis is attributed to infrequent voiding, culminating in chronic vesical overdistention and potentially permanent detrusor damage. External sphincter spasm may result from deliberate avoidance of painful voiding during infection or from efforts to prevent incontinence during uninhibited detrusor contraction. Urodynamic evaluation is diagnostic. Less severe cases tend to resolve spontaneously. Miscellaneous causes of urinary retention in children are given in [Table 65.2](#).

Imperforate hymen
Vaginal atresia
Bladder diverticulum
Benign hyperplasia of the posterior urethra, similar to adult prostate
Cystic enlargement of prostatic utricle (the fused caudal remnant of otherwise repressed müllerian ducts, located at prostatic apex)
Anterior urethral valve
Obstructed congenital duplications of bladder and urethra
Fungal bezoars
Malignancies of bladder, prostate, and urethra
Urethral meatal stenosis, ulceration, and concretions
Inflammatory lesions of the prostate and urethra
Vesical and urethral calculi
Foreign bodies
Constipation

From Peterson NE. Urinary retention. In: Wolken AB, Harwood-Nuss A, eds. Renal and urologic emergencies. New York: Churchill Livingstone, 1996.

TABLE 65.2. Miscellaneous Causes of Urinary Retention in Children

Neuropathologic Causes

Normal urinary storage and voiding dynamics require complex coordination between autonomic and somatic innervation, smooth and skeletal muscle, and spinal reflex circuits subject to brain and brainstem modification. Voiding disturbances contribute to 20% of all urologic complaints, of which 25% have a neurogenic basis.

Urinary retention is characteristically a dominant feature of disorders such as *spinal cord trauma or myelodysplasia* at or below the level of the motor nuclei governing detrusor and sphincteric activity (spinal segments S-2 to S-4, vertebral level L-2). Such lesions interrupt the spinal reflex arc and produce areflexic (flaccid) bladder dysfunction. Traumatic lesions may be transitory (spinal shock), with full recovery of bladder dysfunction after variable intervals of intermittent self-catheterization. More severe injuries produce increasing levels of voiding dysfunction, maximizing at complete irreversibility. Neurologic insult above the level of the spinal micturition center produces reflex (spastic or hypertonic) voiding, with varying degrees of detrusor–sphincter dyssynergy (external sphincter spasm during bladder contraction). High-pressure voiding dynamics are then established, with potential complications including urgency incontinence, infected residual urine, ureteral reflux, pyelonephritis, stone formation, detrusor collapse, and chronic renal failure. Therapeutic options include pharmacologic relaxation of the bladder and external sphincter, intermittent self-catheterization, and biofeedback relearning methods. More severe and recalcitrant cases may require external sphincter ablation or bladder augmentation procedures. Resistance to standard therapeutic measures may require diagnostic refinements provided only by urodynamic or electromyographic investigation.

Miscellaneous spinal neurologic disorders capable of producing voiding dysfunction include spinal lipomeningocele, sacral dysgenesis, sacrococcygeal teratoma, presacral or spinal neuroblastoma, operative neurologic injury, encephalitis, meningitis, epidural abscess, and spinal osteomyelitis.

Back pain, gait disturbance, and bladder dysfunction that lack overt explanation arouse suspicion of a *spinal cord tumor*. Back pain in children may be associated with cerebral palsy, vertebral epiphysitis, disk herniation, or spinal cord tumor. Ninety percent of patients with *multiple sclerosis* eventually develop lower urinary tract symptoms: 50% experience incomplete bladder emptying, 25% have detrusor instability with urgency and incontinence, and 25% display bladder atony and urinary retention. Deteriorating voiding patterns often parallel advancing neuropathology. Management is symptomatic, including intermittent self-catheterization, anticholinergic suppression, alpha-adrenergic antagonism, and so on.

Landry-Guillain-Barré syndrome is an idiopathic polyradiculopathy that may be induced by viral infection, vaccination, surgery, or other infections. Anterior root and anterior horn cell involvement results in predominantly areflexic motor neuropathy with minimal sensory loss. Urologic symptoms affect 30% of patients, dominated by motor paralysis and urinary retention. Voiding symptoms are often of secondary importance to progressive afebrile symmetrical motor weakness or paralysis. Symptoms peak at 4 weeks in 90% of patients. Functional recovery is variable and usually stable at 6 months. Urologic management is limited to temporary intermittent self-catheterization.

Isolated bladder atony and urinary retention that develop in an otherwise healthy patient is often the result of viral infection, most frequently herpes simplex or herpes zoster. Incubation periods of 7 to 21 days are characterized by fever, malaise, and 2 to 4 days of dermatomal pain evolving into erythema, then papular and vesical eruption. Infection can traverse both visceral and somatic nerves and therefore produce skin eruption and bladder atony. Neuropathy may be bilateral despite unilateral cutaneous involvement. Isolated visceral nerve involvement may produce urinary retention without cutaneous or other manifestations. Reversibility is prompt and complete, and interval therapy requires only intermittent self-catheterization.

The Shy-Drager syndrome is an uncommon adult-onset multisystemic degenerative process that affects the cerebellum and brainstem. It produces autonomic deficits with parkinsonian features, orthostatic hypotension, impotence, anorectal dysfunction, and urgency incontinence or urinary retention. Urologic symptoms often

provoke the initial presentation. Therapy for the urinary retention component involves intermittent self-catheterization.

Additional disorders potentially accountable for neuropathologic urinary retention syndromes include diabetes mellitus, tabes dorsalis, pernicious anemia, poliomyelitis, syringomyelia, and inflammatory polyradiculopathies.

Pharmacologic Agents Causing Voiding Dysfunction

Bladder smooth muscle (detrusor) is innervated by beta-adrenergic receptors under chronic stimulation to produce muscle relaxation, and therefore compliant filling. In contrast, the smooth muscle vesical outlet and proximal urethra are innervated predominantly by alpha-adrenergic receptors under chronic stimulation to produce contraction and increased outlet resistance (urinary continence). The external urethral sphincter is predominantly skeletal muscle under chronic stimulation to produce contraction and continence. The act of voiding involves coordinated reversal of these three functions. [Table 65.3](#) summarizes agents that may inadvertently lead to voiding dysfunction. [Table 65.4](#) lists preferred drug therapy for alleviating dysfunctional voiding.

TABLE 65.3. Drugs That Contribute to Urinary Incontinence

Storage	Emptying
DETRUSOR	
Urecholine	Pro-Banthine Flavoxate (Urispas) Oxybutynin (Ditropan)

Dibenzyline Prazosin (Minipress) Terazosin (Hytrin) Doxazosin (Cardura) Tamsulosin (Flomax)	Ephedrine Pseudoephedrine
EXTERNAL SPHINCTER	
Diazepam (Valium) Dantrolene Baclofen	

TABLE 65.4. Pharmacotherapy for Voiding Dysfunction

EMERGENCY DEPARTMENT MANAGEMENT

Urinary Drainage

Bladder drainage provides both symptomatic relief from urinary retention and clinical stabilization during evaluation. Most episodes of urinary retention are amenable to well-lubricated 13F to 16F urethral catheterization by straight (Robinson) catheter for simple decompression or by balloon (Foley) catheter for sustained drainage. Mechanical obstructions that can inhibit bladder access include urethral stricture (from prior trauma, instrumentation, or infection), urethral false passage (from prior or concurrent instrumentation), vesical outlet contracture, benign or malignant prostatic urethral obstruction, and extrinsic local compression. Alternate methods to achieve bladder access may be necessary, and urologic consultation is advisable. Obstruction at the level of the vesical outlet or prostatic urethra that impedes passage of a straight catheter may yield to an angulated (coude) catheter. Alternatively, a malleable, semirigid mandrin may be inserted within the catheter and bent into a suitable curvature for manipulation, as with a metal urethral sound. This procedure is best restricted to performance by *experienced personnel*.

Urethral stricture and false passage often coexist and may inhibit routine catheterization. False passages may be bypassed by the mandrin catheter technique. Alternatively, a combination of flexible filiform guides may be maneuvered across obstruction and false passages into the bladder; progressively larger follower catheters are then attached for sequential dilatation and drainage. Filiform follower attempts are also best restricted to performance by experienced personnel. Failure of these maneuvers usually requires escalation to endoscopic or operative methods.

When urologic consultation is not readily available, temporary relief may be provided by suprapubic trocar cystostomy (commercial) or insertion of a small drainage tube into the bladder through a large-bore needle. Requirements include a palpable bladder and the absence of prior suprapubic surgery. If there is doubt about bladder distention (as in the obese patient), ultrasound confirmation is advisable. These procedures require a simple midline puncture one fingerbreadth about the symphysis pubis, with the trocar or needle directed slightly caudally and then advanced until urine is returned. The catheter or tubing is then advanced, the needle is withdrawn, and drainage secured in position.

A noteworthy exception to indication for prompt urethral catheterization pertains to the patient with pelvic fracture, prostate displacement on rectal examination, or blood at the urethral meatus. Suspected urethral trauma should be investigated initially by retrograde ureterography. Confirmation of urethral injury mandates urologic consultation and management. Catheterization should be deferred and drainage established otherwise.

Patients with chronic obstructive uropathy usually require continuous urinary drainage. The patient in otherwise good health with no ancillary requirements for hospital care may be discharged from the emergency department with Foley catheter drainage collected into a leg bag. Follow-up should be arranged before discharge and include a thorough discussion and understanding of events that recommend a prompt medical response. Urinary retention related to drugs or medication requires referral to the prescribing physician for recommended adjustment or substitution therapy.

Patients in whom a neurogenic cause of retention is suspected mandate appropriate neurologic referral.

CHAPTER 66

Cutaneous Lesions of the Male Genitalia

Stephen W. Bretz

[Clinical Presentation/Differential Diagnosis](#)

[Primary Genital Lesions](#)

[Ulcer-Node Syndrome](#)

[Disposition](#)
[Common Pitfalls](#)
[Chapter References](#)

Despite increased public awareness regarding sexually transmitted diseases (STDs), emergency physicians are not uncommonly confronted with patients complaining of genital lesions. As many individuals do not have other care providers, emergency physicians are in a unique position not only to diagnose and treat these diseases, but also to counsel patients on prevention.

Effective emergency department screening and treatment is especially important given the clear association and increased risk of human immunodeficiency virus (HIV) transmission in the setting of ulcerative and nonulcerative STDs.⁷ In general, agents cause either local primary genital lesions or a syndrome of genital ulcers and regional lymphadenopathy (ulcer-node syndrome).

Primary genital lesions are caused by trauma, Behçet disease, drug eruptions, scabies, pediculosis, molluscum contagiosum (MC), or human papillomavirus (HPV). The prevalence of primary genital lesions is uncertain, but trauma or HPV (genital warts) is probably the most common cause.

The syndrome of genital ulceration(s) and regional lymphadenopathy (ulcer-node syndrome) may be caused by lymphogranuloma venereum (LGV), granuloma inguinale, chancroid, herpes simplex virus (HSV), and syphilis. Of the six classic venereal diseases (gonorrhea, syphilis, genital herpes, chancroid, LGV, and donovanosis), only gonorrhea is *not* characterized by cutaneous lesions; *all* are commonly associated with regional lymphadenopathy. The Centers for Disease Control and Prevention reports that there are 500,000 new cases of genital herpes per year in the United States, 29,000 cases of early syphilis, 665 cases of chancroid, and 170 new cases of LGV.

It is important to note that the relative incidence of these disorders varies significantly by geographic area, especially outside of the United States. For instance, chancroid is about as common as gonorrhea in the Far East, while in the United States, chancroid is about a thousand times less common than gonorrhea. Despite rigorous testing, up to 25% of patients who present with genital ulcers will have no laboratory-confirmed diagnosis.

CLINICAL PRESENTATION/DIFFERENTIAL DIAGNOSIS

Primary Genital Lesions

The causes of genital ulceration, cellulitis, maculopapular eruption, abscess, eschar, and vesicular lesions are legion. HPV, pediculosis, MC, and scabies all cause primary genital lesions ([Table 66.1](#)). A history of trauma or exposure to an infected partner may or may not be present.

Disorder	Feature
HPV	Multiple verrucous papules/erythematous papules of varying size sessile or "fine reticulate" pattern
<i>Phthirus pubis</i> pediculosis	Severely pruritic and erythematous papular lesions especially around hair follicles/excoriations Secondary infection is common May be associated with blepharitis with eyebrow involvement
Scabies	Intensely pruritic lesions with linear furrowing More commonly in the perineal region
MC	Umbilicated, non-pruritic papules Can be erythematous with superinfection

TABLE 66.1. Characteristics of Primary Genital Lesions

Pediculosis Pubis

The agent of pediculosis pubis, *Phthirus pubis*, causes lesions that are frequently erythematous and pruritic. The occurrence in a communal living situation is well described. Symptoms usually start about 3 days after exposure. Although the lesions are generally erythematous papules, they may appear hemorrhagic, possibly because of an anticoagulant material that is deposited at the time of feeding. Intense itching often results in excoriations that predispose to secondary bacterial infection. Although largely confined to the pubic region, the parasite may migrate to other hairy parts of the body, particularly the eyebrows and eyelids (blepharitis).

Treatment is accomplished with application of Lindane 1% shampoo to the affected area for 4 minutes, and then rinsing or permethrin 1% to affected areas for 10 minutes. Lindane should not be used on children under 2 years old or on pregnant or lactating females. Retreatment in 7 to 10 days (to kill newly hatched lice) may be required.

Genital Warts

Genital warts are verrucous-like eruptions caused by HPV, with approximately 90% of cases due to types 6 and 11. Many subtypes of HPV have been linked to the development of dysplasia and squamous cell (penile and anal) cancer, although types 6 and 11 have lower neoplastic potential than other subtypes. Patients with genital warts frequently have other STDs.

Condyloma acuminatum is a hyperplastic papilloma and the most common manifestation of genital HPV infection. The lesion of condyloma acuminatum typically appears as raised or flat, wartlike papules, usually multiple. A large wart may show "satelliting," a phenomenon in which the large wart is surrounded by smaller lesions.

Lesions of condyloma acuminatum are usually painless and nonpruritic. Some subclinical lesions may be appreciated with gauze application of 5% acetic acid to the penile shaft, and then examining the skin for white patches with a 10x lens. Although podophyllin is widely used in the treatment of genital warts, many authorities believe that cryotherapy is preferable. Laser therapy as well as surgical excision may be preferred for extensive or recurrent warts. Patients must be informed of neoplastic potential and have appropriate follow-up and possible biopsy for atypical or persistent warts.

Molluscum Contagiosum

A DNA virus in the poxvirus family that is usually transmitted by direct contact causes MC. While this disorder is transmitted by casual contact, especially in the pediatric population, adults with genital lesions usually acquire it through sexual contact. The incubation period is variable, but is usually between 2 and 8 weeks. The

lesions are usually nonpruritic, nonerythematous papules with central umbilication.

The infection is usually self-limited, with the lesions lasting weeks to years, although the lesions can be more disseminated in immunocompromised states. Lesions normally resolve without scarring. Removal of the lesions is possible with cryotherapy with liquid nitrogen or by topical application of podophyllin, trichloroacetic acid, or bichloroacetic acid. No emergent therapy is needed.

Scabies

The mite *Sarcoptes scabiei* causes scabies. The incidence of scabies has increased in the United States since 1974. Conditions of poverty, poor hygiene, overcrowding, malnutrition, and sexual promiscuity are contributory factors. The infection produces intense itching and areas of excoriation in a characteristic pattern on the penis, scrotum, axillae, buttocks, elbows, and interdigital web spaces. Sensitization to the burrowing mites and eggs that are laid occurs over 1 to 4 months and causes a characteristic pruritic skin eruption. Skin lesions, however, can be vesicular, pustular, or papular in nature.

Sensitization may take weeks to develop when an individual is first infected. Reinfection is possible, and, if left untreated, scabies may persist for decades. A nodular variant of scabies occurs in a small percentage of patients with pruritic, reddish brown nodules on the scrotum, penis, and axillae. Lymphadenopathy is rarely seen. Scabies can be difficult to differentiate from pediculosis pubis, although the presence of lesions on the scrotum and penis would be more consistent with scabies.

Treatment consists of applying Permethrin cream 5% to the entire body below the neck, and rinsing off after 8 hours. Lindane 1% can alternatively be used in a similar fashion. There is some evidence to support the use of ivermectin (200 mg/kg or 0.8% cream), especially in immunocompromised patients with disseminated lesions or in patients with repeated infestations.¹²

Ulcer-Node Syndrome

The ulcer-node syndrome may be caused by genital herpes, LGV, chancroid, granuloma inguinale, or syphilis. Any genital ulcer may be accompanied by regional lymphadenopathy. The morphology of the ulcer(s) and lymphadenopathy may be of some diagnostic help, but none of the clinical characteristics is specific. In STD clinics, the clinical impression of a genital ulcer may be incorrect in almost half of all cases.

Unfortunately, genital herpes, syphilis, LGV, and chancroid may appear identical. The papule is the initial lesion of syphilis; chancroid may begin as a papule or pustule; the initial lesion of LGV may be papular or vesicular. Genital herpes begins with multiple vesicular lesions that tend to occur in clusters. Rapid erosion can lead to ulceration that is similar to and indistinguishable from the other causes of ulcer-node syndrome. The lesions are usually painless in syphilis but painful in chancroid and primary herpes.

Lymphadenopathy is similarly of minimal diagnostic help. The appearance of inguinal or femoral adenopathy without a genital ulcer is common in LGV, but can also occur in chancroid. Lymph nodes frequently become fluctuant with chancroid and LGV. Lymphadenopathy is often bilateral in syphilis and genital herpes, but usually unilateral in chancroid and LGV. The adenopathy of syphilis and LGV is usually less painful than that caused by genital herpes. The adenopathy of chancroid is usually unilateral and suppurative.

Table 66.2 provides a summary of the recommended treatments for each of the specific diseases associated with the ulcer-node syndrome.²

Sexually Transmitted Agent	Therapy	Alternative Therapy
Syphilis	Benzathine Penicillin G 2.4 million units IM on 1, 2, and 3 weeks as a single dose	Procaine Penicillin 2.4 million units IM qd x 10 days Ceftriaxone 1 g IM qd x 10 days
Latent Syphilis	Benzathine Penicillin G 7.2 million units IM on 0, 2, and 4 weeks as a single dose	Procaine Penicillin 2.4 million units IM qd x 10 days Ceftriaxone 1 g IM qd x 10 days
Neurosyphilis	Penicillin G 18 million units IV q 4 hours x 10-14 days Procaine Penicillin 2.4 million units IM q day and penicillin G 18 million units IV q 4 hours	Ceftriaxone 2 g IM qd x 10 days Cefazolin 1 g IM qd x 10 days
Chancroid	Ceftriaxone 250 mg IM single dose Azithromycin 1 g oral single dose	Ciprofloxacin 500 mg bid x 3 days Erythromycin 500 mg qd x 7 days
Herpes simplex	Acyclovir 800 mg qd x 7-10 days Famciclovir 500 mg bid x 7-10 days	Cidofovir 360 mg bid x 3 days Valacyclovir 1 g bid x 7-10 days
Herpes zoster	Acyclovir 800 mg qd x 7-10 days Famciclovir 500 mg bid x 7-10 days	Cidofovir 360 mg bid x 3 days Valacyclovir 1 g bid x 7-10 days

TABLE 66.2. Recommended Treatment for Ulcer-Node Syndromes

Genital Herpes (Herpesvirus Hominis)

It is estimated that more than 45 million Americans, or one in every four to five, has a genital herpes infection. A half-million new cases are reported per year, making it the most common cause of genital ulcers.^{2,10} Approximately 80% of these cases are caused by HSV-2, while HSV-1 accounts for the remaining 20%. In the general adult population, antibodies to HSV-1 are noted in 70% to 90%, while approximately 22% have antibodies to HSV-2. Infection rates after exposure vary, but an individual who regularly has sexual intercourse with an infected partner has a 10% chance of acquiring the disease each year.⁸

There are five stages of the infection: primary, latent, shedding, recurrent, and disseminated. An incubation period of 2 to 12 days for primary infection and 1 to 7 days for recurrent herpes has been well described. Systemic symptoms such as fever, myalgias, and headache coincide with the onset of genital lesions that usually occur on the shaft or glans of the penis.

The initial lesions are painful vesicles with surrounding erythema that go on to form shallow, tender ulcers. The ulcers may coalesce to form lesions akin to chancroid or syphilis. The lesions tend to resolve in 5 to 10 days, but may persist for weeks. Two to 3 weeks after the onset of symptoms, tender, nonfluctuant inguinal lymphadenopathy can be appreciated bilaterally. Complications include aseptic meningitis, sacral radiculopathy, extragenital lesions, transverse myelitis, and encephalitis.

Urethral involvement can cause dysuria and urinary retention, although these symptoms are rare in males. Herpetic sacral radiculomyelitis may also develop, causing urinary retention, neuralgias, and obstipation. In the latent phase, the virus remains dormant in nerve root ganglia. During the shedding phase, patients are asymptomatic. Though the actual rate is unknown, shedding is estimated to occur during 1% of the asymptomatic days. Recurrence is common and is seen in up to 90% of patients during the first year.¹ Subsequently, patients average between five and eight episodes per year. Viral shedding from lesions is shortened from an average of 11 days to 3 to 4 days.

Daily suppressive therapy may have a role in several instances: in patients with more than six recurrences per year, in immunocompromised patients, and for the purpose of decreasing subclinical shedding (which may prevent transmission).^{2,11} Daily suppressive therapy consists of acyclovir 400 mg twice a day or famciclovir 250 mg twice a day.^{2,5}

Though the diagnosis is often made clinically, diagnostic tests for HSV infection are especially important when the diagnosis is unclear. Viral isolation by culture is the "gold standard" diagnostic test, but does not help with management within the emergency department, as results can take up to 10 days. Sensitivity is approximately 90% for primary lesions, 40% for recurrent lesions, and 25% for crusted lesions.

Viral antigen detection is an alternative, using direct fluorescent assay or enzyme-linked immunosorbent assay (ELISA). ELISA tests are available but may only be positive after a lengthy lag period following the initial infection. Polymerase chain reaction (PCR) testing is not as readily available, but it is probably the most sensitive test available. The Tzanck test, looking for multinucleated giant cells and intranuclear inclusions, has a limited application, given its lower sensitivity.

Patient education is very important, especially given the commonness of this disease and its social ramifications. Many individuals who are infected with HSV-2 do not carry the diagnosis of genital herpes; rather, they have a mild or unrecognized infection and shed virus intermittently. Thus, an individual may transmit the disease unknowingly. Likewise, the current sexual partner may not be the source.

Lymphogranuloma Venereum

LGV, a systemic infection that affects the genital lymphatic tissue, is caused by *Chlamydia trachomatis*. This entity is rare in the United States, with most cases being associated with travel and sexual contact in tropical and subtropical countries. Outbreaks in the United States have been observed in the Midwest and Southeast. The incubation period is 3 to 30 days.

Because of its evanescent and rapidly healing nature, the genital ulcer is seen in only 5% to 15% of patients. Unlike all other causes of ulcer-node disease, LGV is distinguished not by prominent ulcers, but by lymphadenopathy without cutaneous ulcers. The second stage follows in 3 to 4 weeks and is characterized by the formation of inguinal buboes, along with systemic symptoms such as malaise, fatigue, and headache.

The buboes, which are usually unilateral, become progressively larger until they spontaneously drain. A draining sinus tract is often the initial finding. LGV may progress, if untreated, to a third stage with anorectal fissures and strictures. In homosexual males, this entity may present as proctitis.

Given the transient nature of the ulcers that are seen in the first stage of LGV, patients who have the disease usually present with tender lymphadenopathy with overlying violaceous skin. The "groove sign," which results from lymphadenopathy on opposing sides of Poupart's ligament, is characteristic of LGV, but it is noted in only about 20% of cases.

The LGV serotype of *Chlamydia trachomatis* is difficult to culture, but one can attempt to culture the organism from genital specimens or aspiration of a bubo. For the diagnosis, there is greater reliance on an LGV complement fixation test, which is generally available. A titer of greater than 1:64 suggests LGV, while a titer of less than 1:16 reliably excludes LGV. Microimmunofluorescence antibody testing is not commonly available but is more sensitive and specific. The buboes may be aspirated, but incision and drainage should be avoided.

Chancroid

Haemophilus ducreyi is the causative agent of chancroid. The incidence of chancroid is much greater in developing countries (20/100,000 compared with 0.5/100,000 in the United States). The peak incidence in the United States was 5035 cases in 1987. Just 773 cases were reported in 1994, with an overwhelming male predominance (ranging from 3:1 to 25:1). Most cases are associated with localized outbreaks in urban centers. There is some evidence to support the assertion that circumcision may reduce the risk of this disorder.

This organism has an incubation period of approximately 3 to 5 days, after which small papules form. Within 1 to 2 days the papules ulcerate to form painful lesions with irregular, nonindurated borders that are clearly demarcated. Sixty percent of patients have tender lymphadenitis, usually unilateral. The lymph nodes rapidly become fluctuant with erythematous, overlying skin. Spontaneous rupture of the formed bubo is common. Aspiration of painful nodes may be necessary, but incision and drainage should be avoided.

Chancroidal ulcers may be difficult to distinguish from syphilis. The ulcers of chancroid tend to be deeper and more painful, with ragged margins and tender unilateral adenopathy. Indeed, chancroid and syphilis may coexist and are often indistinguishable. Genital herpes may also mimic chancroid; most "apparent" chancroid is due to HSV. The current CDC clinical definition for a probable case of chancroid requires (1) one or more painful genital ulcers, (2) a negative dark-field examination or serologic test for syphilis performed at least a week following the appearance of the ulcer, and (3) a clinical presentation atypical for herpes or a negative herpes culture.² Laboratory diagnosis is difficult. The utility of a Gram stain is limited because of a wide-ranging sensitivity (10% to 90%), and culture of *H. ducreyi* requires selective media, yielding a sensitivity of less than 80%.² Newer techniques, such as PCR, will likely yield more sensitive and specific tests.

Syphilis

Of all the diseases that present as a genital ulcer, syphilis, caused by *Treponema pallidum*, is the most important when one considers the potential morbidity for untreated infection. The number of new cases reported has varied in the United States, with a peak of 45,000 cases in 1990. Subsequently, this number fell to 8,551 in 1997, of which approximately two-thirds were male. In 1997, the overall incidence was 3.2 per 100,000 in the United States.³ The rate of syphilis in urban areas is five times higher than overall rates. As well, there seems to be a correlation between drug activity and syphilis rates in counties that border some interstate highways.⁴

The incubation period is about 1 to 3 weeks. The singular ulcer, typical of primary syphilis, usually presents at the site of inoculation 1 to 3 weeks after exposure. Thus, it is important to examine the perianal and oral cavities, as well as the genitalia, especially among the homosexual population.

Characteristically, the ulcer (chancre) is painless, indurated, and nonexudative, with a smooth base and raised, firm borders. Inguinal lymphadenopathy consists of moderately enlarged bilateral (70%) or unilateral painless lymph nodes. The rash of secondary syphilis, characterized by local or diffuse mucocutaneous lesions, may appear before the chancre is healed (6 to 8 weeks). These lesions can be macular, papular, or even pustular.

Tertiary syphilis is the term applied to gummas and cardiovascular syphilis, most commonly aortitis associated with medial necrosis and aneurysm. Neurosyphilis (syphilitic meningitis, parenchymatous syphilis, or meningovascular syphilis) can occur from months to many years after the onset of disease. Tabes dorsalis, often seen with optic atrophy, reflects demyelination of the posterior columns and dorsal roots, but it is usually seen only after 25 to 30 years of infection. For the purposes of treatment, the term *latenti* applies to currently asymptomatic patients who have positive serologic studies, with a negative cerebrospinal fluid examination. Furthermore, the disease is termed *early latenti* if it is within the first year of infection, and *late latenti* if more than a year has passed and the patient has not been treated.

Dark-field microscopy with immunofluorescent staining is the only widely available means by which to make an absolute diagnosis of syphilis. A negative microscopic examination, however, does not rule out the diagnosis. Every patient with genital ulceration should be tested for syphilis with the nontreponemal tests and rapid plasma reagin (RPR) and Venereal Disease Research Laboratory (VDRL) tests. There is some evidence to support screening serologic studies in the emergency department in areas where the incidence is high, such as urban areas.⁶ The sensitivity of these two tests approaches 80% in primary syphilis and essentially 100% in secondary syphilis. Positive tests should be confirmed with a fluorescent treponemal antibody absorption (FTA-ABS) or microhemagglutination assay for *T. pallidum* (MHA-TP). After treatment, repeat VDRL titers should be taken at 3, 6, 8, and 12 months. If treatment was successful, one should expect a fourfold decrease at 3 months and an eightfold decrease at 6 months.²

Presumptive treatment must be provided to every individual who has had sexual contact within the 90 days prior to his or her partner's diagnosis of primary, secondary, or early latent syphilis. If the exposure occurred more than 90 days before the sex partner's diagnosis of primary, secondary, or early latent syphilis, the patient should have serologic testing, but if follow-up is questionable, treatment should be provided.² Despite the fact that *T. pallidum* remains sensitive to penicillin, it is important to note that procaine penicillin, which has a shorter half-life, is not a satisfactory substitute for benzathine penicillin.

Granuloma Inguinale

Granuloma inguinale is a rare cause of genital lesions, especially in the United States, where fewer than 30 cases are identified each year. It is sometimes referred to as donovanosis and the causative agent is *Calymmatobacterium granulomatis*. The incubation period varies from weeks to months, after which painless, progressively enlarging ulcers develop. Due to their increased vascularity, the lesions have a "beefy red" appearance and bleed with minimal contact. Initially, there is no significant lymphadenopathy, but painless, granulating lymph nodes may be noted due to direct spread of infection to the lymph nodes, which may progress to pseudobuboes. Diagnosis of granuloma inguinale is established by the presence of Donovan bodies on microscopy of a biopsy specimen, because this organism is exceedingly difficult to culture.

Other Diagnostic Considerations for Genital Ulcers

Although uncommon, genital ulcers may be due to granuloma inguinale, candidiasis, tularemia, Behçet syndrome, neoplasia, amebiasis, psoriasis, lichen planus, fixed drug eruption, and mycobacteria.

DISPOSITION

Distinguishing primary genital lesions (genital warts, scabies, and pediculosis pubis) from genital ulcers has important therapeutic implications. Unfortunately, the emergency physician often does not have bacteriologic or virologic tests available for definitive diagnosis. All patients with ulcers or inguofemoral lymphadenopathy, however, should have serologic testing for syphilis.

Given the poor follow-up that is common among many emergency department patients, presumptive treatment is often appropriate. For instance, if both chancroid and syphilis are suggested, empiric treatment with erythromycin plus penicillin G benzathine (2.4 million units given i.m.) may be indicated. The rationale for this regimen is that although erythromycin is effective for chancroid and most cases of syphilis, 10% of cases of early syphilis will persist with erythromycin, similarly, short courses of ceftriaxone also mask early syphilis.

Specialists in infectious diseases or dermatology may need to be consulted, but rarely on an emergent basis. It is essential that patients be discharged with the appropriate follow-up and encouraged to refer sexual contacts for screening. Patients should also be referred for HIV testing, as strong evidence suggests that both ulcerative and nonulcerative STDs promote the transmission of HIV.⁷ Although admission is rarely indicated, patients with fever and signs of systemic illness should be carefully evaluated prior to discharge. As well, immunocompromised patients, especially those with disseminated disease, often require admission.

COMMON PITFALLS

- Failure to consider and test for other, concurrent STDs in the patient with an identified STD
- Failure to distinguish LGV or chancroid from syphilis and genital herpes
- Failure to recognize the need to aspirate (rather than incise and drain) large inguinal buboes that are extremely painful or unresponsive to antibiotics
- Failure to treat a patient for syphilis in addition to the primary treatment, when one is uncertain whether the patient has syphilis
- Failure to adequately educate the patient, attain appropriate follow-up, and stress the importance of treatment for sexual partners

The acute scrotal mass can be a challenging differential diagnosis. The three most common diagnoses are torsion of the testis/spermatic cord, acute epididymitis, and torsion of the appendix testis or epididymis. Less frequent diagnoses include orchitis, acute hydrocele, spermatocele, varicocele, spermatic granuloma, and inguinal hernia. The ischemic insult from testicular torsion makes acute scrotal pain a true surgical emergency. The evaluation most often is difficult, even though a careful history and physical examination narrow the possibilities.

The male external genitalia must be examined systematically in both the supine and standing positions. The former prevents the patient from retreating during the examination, while the latter provides optimum positioning to evaluate the lie of each testis, the presence or absence of both a varicocele or an inguinal hernia. After quickly assessing the penis and retracting the foreskin to expose the glans, both testes are compared for size and consistency. A testis is best examined with two hands, one palpating and assessing the testicular consistency while the other evaluates the epididymis. The normal testis should be examined first to provide a baseline. The testes normally are oriented vertically with a slight and variable forward tilt. The rubbery consistency should be homogeneous and similar to the thenar eminence of the thumb. The surface is smooth. A normal testicle is 6.0 cm long by 4.0 cm wide by 2.5 cm thick. The testes should be freely mobile within the scrotum (Fig. 67.1). Any palpable mass is described in relationship to the testis, epididymis, spermatic cord, or as a separate entity. All masses should be transilluminated with a penlight or flashlight placed in contact with the posterior scrotal wall and the findings described as positive (does transilluminate) or negative (does not transilluminate).

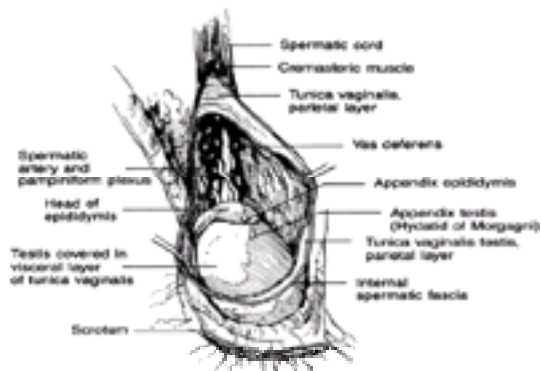

Figure 67.1. Normal anatomy of the scrotum.

The epididymis is a discrete, sausage-shaped structure 1 cm thick, usually located on and firmly attached to the posterior wall of the testicle. In 7% of patients, it is anteriorly oriented. The epididymal head, or globus major, is the thickest portion and lies on the top of the testis. The body of the epididymis is a continuation of the head and tapers to the tail, or globus minor, which is contiguous with the vas deferens. The 1x3-mm testicular and epididymal appendages are not normally palpable, but are most commonly located anteriorly, near the upper pole of the testis and the head of the epididymis.

From the testis, the spermatic cord can be palpated ascending into the fascial cleft of the subcutaneous external inguinal ring. The vas deferens is a firm tubular structure lying within the 1.5- to 2.0-cm-diameter cord. The spermatic arteries are not palpable and the veins are palpable only when enlarged (varicocele). In the

standing position, a cough or Valsalva maneuver while palpating the external inguinal ring may elicit an overt hernia or, most often, an impulse consistent with an early tear in the fascial ring. This maneuver also may elicit or accentuate a varicocele.

TESTICULAR TORSION

Torsion of the testis has an incidence of one in 4000 males. It can occur at any age but is most common between the ages of 12 and 18 years.²¹ Testes predisposed to torsion lack posterior fixation to the scrotal wall and have an abnormally high attachment of a voluminous tunica vaginalis (Fig. 67.2). The tunica vaginalis normally fixes the testis and epididymis to the posterolateral surface of the scrotum (see Fig. 67.1). However, complete envelopment of the testis by the tunica vaginalis permits rotation of the testis (clapper) within the tunica (bell), resulting in the classic “bellclapper” deformity.¹⁶

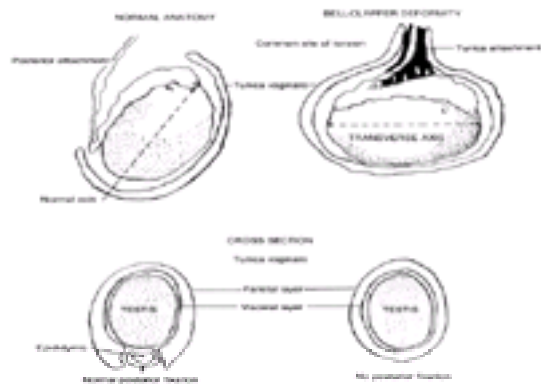

Figure 67.2. Bellclapper deformity.

The resultant ischemic event is an emergency. Initially, the testis and cord twist within the tunica vaginalis, causing occlusion of the venous system. Arterial flow is subsequently decreased by both the twisting mechanism and the secondary edema consequent to venous occlusion. The degree of testicular damage is related to the duration and extent of vascular occlusion. There are no serum markers to identify the ischemic process. Partial arterial flow may persist with less than 540 degrees to 720 degrees of rotation until edema results in complete occlusion. The variable degree of testicular ischemia makes the absolute window for testicular viability unknown. Testicular salvage times emanate from animal data and show that damage occurs after 2 hours of complete cessation of blood flow. A history of continuous pain for 24 hours is usually associated with an infarcting testis. A salvage rate of 100% following manual or surgical detorsion within 6 hours of ischemic onset is often quoted.⁴ However, following acute detorsion, nearly half of the involved testes atrophy by more than 20%.¹ An atrophic testicle may have impaired fertility. Significant preexisting testicular histologic abnormalities have been shown to antedate the acute ischemic event.¹² Therefore, consequent fertility damage to a contralateral testicle from ipsilateral torsion is unlikely.¹¹

CLINICAL PRESENTATION

Sudden onset of testicular pain and swelling is the classic presentation for testicular torsion. Unfortunately, in the majority of cases, the history is nonspecific and misleading and should not be used alone to diagnose the acute scrotal mass.¹⁴ Pain is most often present or is a significant part of the event.²¹ Pain can be acute or insidious in onset and mild to excruciating in intensity.

Often, the pain is abdominal and may mimic acute gastroenteritis. In one study, scrotal pain with radiation to the abdomen or inguinal region occurred in 50% of patients with testicular torsion, whereas abdominal or inguinal pain without scrotal pain occurred in 12.5%.¹⁰

A history of a similar event can be elicited in half of the patients and results from previous episodes of torsion followed by spontaneous detorsion. Approximately half of patients report the onset of pain during sleep. Cold weather, sexual arousal, and scrotal trauma are often important inciting events. Nausea, vomiting, and low-grade fever are common clinical findings. Voiding symptoms such as dysuria, urgency, and hesitancy are rarely described.

Physical examination reveals either a painful or often nonpalpable testis that has elevated cephalad in the hemiscrotum due to the twisting and foreshortening of the spermatic cord. Engorgement of the testicle and secondary swelling of the scrotum are usually present. Instead of lying in the usual vertical orientation, the affected testis is often found lying horizontally in the scrotum due to its abnormal mobility within the tunica vaginalis.

The epididymis may be malrotated anteriorly but is usually nontender when palpated. Chronicity of the event usually results in the epididymis becoming globally enlarged and sausage-shaped anatomically. The spermatic cord tends to become thickened in the area of torsion. Elevation of the testis does not relieve the discomfort (Prehn's sign) as it does in epididymitis, because torsion is primarily an ischemic event, not an inflammatory process. With the passage of time, however, testicular torsion evolves into a secondary inflammatory process. Laboratory data are nonspecific and not helpful. One-third of patients have a nonspecific leukocytosis of more than 10,000 white blood cells per cubic millimeter, and almost all patients have a normal urinalysis.^{10,15}

When these classic findings are absent, the entire hemiscrotum is usually swollen, tender, and firm. A reactive hydrocele may have developed.¹³ The overlying scrotal skin rapidly develops redness and edema, and within a few hours, the testis and epididymis are no longer anatomically separable. In a series of 206 patients with torsion, 42% presented with swelling and precluded palpation of the intrascrotal contents.¹⁵ Finally, the hemiscrotum becomes an amorphous, painful scrotal mass referred to as “missed torsion.”

The ipsilateral loss of the cremasteric reflex with testicular torsion and its preservation in most cases of epididymitis is a soft finding and certainly not diagnostic of one event or the other.²⁰ The cremasteric reflex is a superficial skin reflex mediated by spinal nerves T-12 to L-2, elicited by stroking the skin of the inner aspect of the ipsilateral thigh in an upward motion, resulting in contraction of the cremasteric muscle and elevation of the testis by at least 0.5 cm. This is best demonstrated with the patient in the supine, frogleg position and requires the absence of any inflammatory process in the overlying scrotal skin. Occasionally, the cremasteric findings are equivocal and unreliable in severe epididymitis associated with marked overlying scrotal skin inflammation.

DIFFERENTIAL DIAGNOSIS

In an adolescent, acute scrotal swelling is torsion until proven otherwise. The differential diagnosis includes acute epididymitis, torsion of the testicular or epididymal appendices, orchitis, testicular tumor, inguinal hernia, and traumatic hydrocele or hematocele. Age does not preclude the diagnosis of testicular torsion. A series of 243 patients with testicular torsion revealed that 31% were prepubertal, 60% were 12 to 18 years old, 5% were older than 30 years, and isolated case reports in the elderly continue to be reported.⁸

Acute epididymitis, the most common entity mistaken for testicular torsion, is rare before puberty. Sixty percent of patients with epididymitis are older than 30 years. Epididymitis classically has a more gradual onset than testicular torsion. The diagnosis of epididymitis is in the history and must be pursued compulsively. Usually, a history of urinary tract infection, painful voiding, urethral discharge, or an indwelling urethral catheter suggests the diagnosis of epididymitis. A work or exercise history consistent with a lot of lifting, straining, or events that increase intrapelvic pressure favors epididymitis (roofer, construction worker, weight lifter). A history of previous episodes of testicular pain suggests testicular torsion. Nausea with vomiting is more common in testicular torsion. The physical examination may not be helpful, and often times is confusing.

A thorough understanding of the pathophysiology of epididymitis is imperative when examining the scrotal contents. The retrograde development of epididymitis dictates that the pain often originates in either abdominal lower quadrant, then migrates down into the scrotum. Initially, the testicular pain is felt in the globus minor or the tail of the epididymis. This is usually disclosed as a firm, hard mass at the inferior portion of the normally smooth testis. If the diagnosis is missed or delayed, the inflammatory process will ascend into the body, then to the head, or globus major, of the epididymis, producing the large sausage-shaped mass often found on the

posterior surface of the testis. In the late stages of either disease process, the tenderness and diffuse swelling that often accompany torsion and epididymitis can obscure any discernible physical findings.

Primary orchitis is very rare. In fact, if this is your diagnosis, consultation with a colleague is recommended for confirmation. A history of mumps orchitis and manifestations of a systemic illness should be present. Otherwise, orchitis seldom occurs unless it represents contiguous spread of infection from the epididymis to the testis (epididymo-orchitis). In primary orchitis, the onset of testicular pain and swelling is more gradual and global. The epididymis is normal. The spermatic cord may be tender but is not indurated or thickened.

Torsion of a testicular or epididymal appendage can cause venous engorgement with subsequent arterial occlusion and infarction. The appendix testis is the most common appendage to twist.¹⁰ It is usually located anteriorly, near the upper pole of the testis. Appendiceal testicular torsion occurs in the same age group as testicular torsion. Sudden onset of scrotal pain without radiation is the most common presentation. The onset of pain may not be as rapid as that of testicular torsion and may occur intermittently and then progress over 3 to 5 days. The symptoms are usually less severe than in testicular torsion. Nausea and vomiting occur more often in testicular torsion than in appendiceal torsion. Diagnostically, early in the process, the testicular appendage may be palpated separately as a tender mass at the head of the testis. The often-referenced "blue dot" sign refers to a small, tender, infarcted (blue), pealike structure seen through the hormonally unstimulated, prepubertal scrotal skin held taught over the head of the testis.¹⁰ Localized tenderness in the head of the testis without comparable mass or erythema of the scrotal skin, however, is more commonly found in appendiceal torsion.¹⁴ Excision of the twisted appendage is the standard treatment, although nonsurgical observation has been successful because autoinfarction is the consequence. Surgical exploration is often required in delayed cases to confirm the diagnosis of appendiceal torsion and exclude testicular torsion.

Carcinoma of the testis is the most common cancer in males age 15 to 35 years, a similar age range for the occurrence of testicular torsion.²² The initial diagnosis is incorrect 25% of the time; the most common misdiagnosis is epididymitis. Symptoms from testicular tumors normally have a more gradual onset. Pain is not generally a major complaint for testicular tumor, although 10% of patients with intratesticular tumor hemorrhage can experience the sudden onset of pain. On examination, the affected testicle is characteristically not tender. The testis may be generally enlarged and feel heavy to the patient, but, more often, a distinct, firm, intratesticular mass is palpated by the examiner. The scrotum usually has less erythema and edema than in testicular torsion, and, on palpation, the affected testicle can be separated from the other normal intrascrotal structures. In a delayed presentation, a testicular tumor can appear similar to missed testicular torsion. Ten percent of testicular tumors have a reactive hydrocele, which can obscure palpation. Signs of metastatic disease, such as an abdominal mass, lower extremity edema, neurologic abnormalities, lumbar back pain, or weight loss, may be present in up to 10% of patients with testicular tumors. The urinalysis is usually normal.

Incarcerated scrotal hernias account for less than 2% of acute scrotal masses, but may present with a history similar to that of testicular torsion. The young age of the patient and the associated unremitting nausea and vomiting tend to support this diagnosis. Abdominal pain and groin pain are usually present. The scrotal hernia can usually be palpated extending into the groin, and the testis may be displaced lower in the scrotum.

A traumatic hydrocele and hematocele are included in the differential diagnosis because a trauma history also accompanies 5% to 10% of cases of testicular torsion. The testis is usually not as painful as in testicular torsion, and the epididymis and spermatic cord, if palpable, are in their normal positions. Swelling often obscures the examination, and ancillary tests are recommended to confirm the diagnosis.

EMERGENCY DEPARTMENT EVALUATION

A rapid presumptive diagnosis of testicular torsion should be suspected on the basis of the history and physical findings. Because the presentation most often is variable and the scrotum develops erythema from many causes, testicular torsion must be the primary consideration for any scrotal complaint in the young and the adolescent.

Diagnostic tests, such as color Doppler ultrasound or radionuclide testicular scintigraphy, are always adjunctive and should never delay urologic consultation, attempted manual detorsion, and scrotal exploration.²⁵ These adjunctive tests are not required to make the diagnosis.

Imaging

Radionuclide imaging assesses testicular perfusion with a sensitivity that approaches that of color Doppler ultrasound.^{5,25} Despite a 90% to 100% accuracy rate in defining testicular blood flow, testicular scintigraphy provides little anatomic information, is labor intensive, and is often unavailable in the middle of the night. It is radiologist-reader-dependent. In early testicular torsion, the scan demonstrates relatively decreased or absent testicular blood flow to the affected testis, and a "cold spot" on delayed images corresponds to the nonperfused testis. After 7 hours of relatively continuous ischemia, the nonperfused testis develops a reactive edema and hyperemia. The scan may display a halo of increased tracer activity (i.e., the rim sign) around the cold testis, often confused with and appearing quite similar to acute epididymitis. In acute epididymitis, relatively increased global perfusion to the affected hemiscrotum is seen. A nuclear scan cannot reliably differentiate torsion of a testicular or epididymal appendage from epididymitis, but it is helpful in confirming testicular blood flow and eliminating testicular torsion as the cause of the patient's pain.

A normally perfused testis with a surrounding lucency from accumulated fluid is seen with a hydrocele. A testicular tumor usually demonstrates increased radioisotope uptake in comparison with its contralateral mate. A color Doppler ultrasound is the preferred diagnostic modality for suspected testicular tumor.

Color Doppler ultrasound yields the most information in evaluation of the acute scrotum because it provides information about both anatomy and arterial perfusion. It can determine whether a mass is intratesticular or extratesticular and is particularly applicable when swelling or a reactive hydrocele has made physical examination difficult or impossible. The normal testis has characteristic echoes that are homogeneous and finely granular, whereas the epididymis is distinguished by its coarser texture. A typical testicular tumor is detected as a hypoechoic, inhomogeneous mass within the testis. Epididymitis displays a thickened and enlarged epididymis. Abscess cavities may be apparent within both the testes and epididymis.

Recommendations for Imaging

Although color Doppler ultrasound and radionuclide scans are helpful, an aggregate clinical impression derived from a thorough history and physical examination is more important. The imaging test used often depends on the consultant, the availability of the examination, the quality of the equipment, and the experience of the technician and radiologist-reader. Adjunctive tests should never delay operative exploration. Imaging may be obtained while waiting for an operating suite, but it is imperative that the examining physician remember that testicular torsion is diagnosed at surgical exploration. Once the diagnosis of testicular torsion is suspected, immediate urologic consultation is initiated. Meticulous charting and documentation of the history and physical examination, the suspected diagnosis and need for scrotal exploration, as well as the time course for all of these events, are imperative.⁴

If the urologist requests adjunctive testing, this must be documented in the emergency department record. The urologist should be informed that an attempt at manual detorsion will be made while awaiting the patient's transfer to the operating room or the radiology suite, and documentation carried out should the urologist discourage or request that detorsion not be attempted.

EMERGENCY DEPARTMENT MANAGEMENT

Manual detorsion is successful in 30% to 70% of patients.⁶ Spontaneous or successful manipulative preoperative testicular detorsion results in a 100% testicular salvage rate.⁴ Manual detorsion can be attempted with the patient standing or supine, but most often is done with the patient supine, in bed, or on a stretcher, with the physician standing on the patient's right side.²³ Classically, the patient is placed in the frogleg lithotomy position to allow total access to his scrotum and testis. The patient must be informed that manual detorsion is a painful maneuver. Light sedation or spermatic cord block may be done to lessen the patient's discomfort. A spermatic cord block allows multiple detorsion attempts and experimentation with direction, but it eliminates pain relief as an end point to judge successful detorsion. Most testes twist in a lateral to medial direction, so manual detorsion is initially attempted from medial to lateral, similar to opening a book; that is, the patient's right testis is detorsed in a counterclockwise direction, and the left testis in a clockwise direction. The testis is rotated 180 degrees in one direction and maintained in position. Further rotation is continued as necessary.

If the initial detorsion increases the pain, the detorsion should be attempted in the opposite direction. One to three turns is usually sufficient. The detorsion is stopped

when either the anatomy is restored or the testicular pain is relieved. Both should occur promptly. Significant swelling makes the initial detorsion maneuver more difficult and there is much less chance of success.

Ideally, manual detorsion should be followed by surgical exploration to confirm success and pex both testes, because torsion is an anatomic abnormality and tends to be bilateral. There have not been any reported cases of recurrent ischemia in the interval between successful manual detorsion and orchiopexy.

The technique of spermatic cord block is simple.²⁵ The spermatic cord is palpated and encircled with the nondominant hand at the scrotal inguinal junction. Three to four injections with 1% plain lidocaine are made at different angled approaches with a 25-gauge, 1.5-in. needle.

An alternative method can be instituted if the cord cannot be palpated because of severe pain or pronounced swelling. After palpating the pubic tubercle, a needle is inserted vertically downward 1 cm below and medial to the pubic tubercle onto the anterior aspect of the pubic bone. Repeated slow injections should be made at different angles, attempting to infiltrate the area around the ilioinguinal nerve and genital branch of the genitofemoral nerve. The duration of a successful lidocaine spermatic cord block is about 1 to 3 hours.

DISPOSITION

Role of the Consultant

The urologist or general surgeon is obligated to establish a final diagnosis and perform definitive orchiopexy or orchiectomy, depending on the operative findings. Selected ancillary tests must not delay surgical exploration. When securing operative consent, the consultant should explain the need for bilateral orchiopexy, the possibility of orchiectomy, and the option for placement of a testicular prosthesis. An unequivocally infarcted testis is usually removed at exploration to lessen the chance for persistent pain and promote resolution of the inflammatory process. Bilateral orchiopexy is always required, because the anatomic defect is present bilaterally.

Indications for Admission

All patients suspected of having testicular torsion should be admitted and taken to the operating suite. Observation and serial examinations are not useful in the management of suspected testicular torsion. Preoperative emergency department laboratory studies should be completed quickly to expedite surgery. If preoperative manual detorsion successfully reestablishes testicular blood flow, arrangements for delayed orchiopexy can be made by the consultant. The urologist or general surgeon is ultimately responsible for any planned or self-directed delay in scrotal exploration and orchiopexy.

Transfer Considerations

The unavailability of a urologist, general surgeon, or immediate operating room facilities, warrants prompt transfer. The lack of radionuclide scanning or color Doppler ultrasonography does not effect the treatment; that is, the patient needs to undergo attempted manual detorsion and surgical exploration.

COMMON PITFALLS

- Misdiagnosis and delays in attempted testicular detorsion are common pitfalls in the evaluation of acute scrotal pain.
- Fifty percent of testes lost because of testicular torsion are associated with initial misdiagnosis. The quintessential history and physical examination are often misleading. An antecedent history of trauma most often misleads the examiner.
- Relying on a single “classic” differentiating parameter, such as age, characteristic onset of pain patterns, or physical examination findings, can erroneously convince the examiner that testicular torsion is not present.
- Referred pain to the abdomen can suggest gastroenteritis, a common misdiagnosis.
- Scrotal erythema and swelling tend to promote a diagnosis of infection, rather than initial ischemia with subsequent inflammatory sequelae.
- Delayed presentation precludes a meaningful examination, and the ability to work through a limited differential diagnosis.
- Many authorities maintain that diagnosis based on history, physical findings, and laboratory results is impossible and that prompt exploration should be carried out in every case. Ideally, careful physical examination should promote selective scrotal exploration, but, most often, the examiner finishes indecisive, which necessitates urologic consultation and scrotal exploration.
- Unnecessary delays in consulting with a urologist or general surgeon may result while awaiting ancillary tests. The examiner should not delay consultation to obtain adjunctive tests. The emergency physician must initiate prompt consultation and timely preoperative laboratory testing to minimize these delays.
- If testicular torsion is a consideration, the emergency physician cannot accept or be talked into an alternative diagnosis by the consultant over the telephone. Absolute documentation of telephone consultations is imperative, as occasionally the consultant will attempt to shift the responsibility for diagnosis back to the emergency physician.
- Manual detorsion by the emergency physician is the most rapid means of reestablishing blood flow to an ischemic testis. However, the ultimate responsibility for confirming detorsion, testicular viability, and definitive fixation to the scrotal wall rests with the urologist or general surgeon.

ACUTE EPIDIDYMITIS

Inflammation or infection that is limited to the epididymis and causes acute pain and swelling of gradual onset is termed *acute epididymitis*. Epididymoorchitis implies extension of the inflammation or infection onto the adjacent testis. Epididymitis occurs in less than one in 1,000 men per year and is the most common cause of acute scrotal pain.¹⁸ It is primarily a disease of adults and seldom occurs before puberty unless there is an associated anatomic abnormality of the lower urinary tract that promotes urinary tract infection. Epididymitis most often results from retrograde spread of infected urine down the vas deferens into the globus minor, or tail, of the epididymis. Occasionally, reflux of sterile urine causes the same inflammatory process (i.e., chemical epididymitis).³

In men younger than age 35 years, the organisms most often responsible are those that cause urethritis: *Chlamydia trachomatis* and *Neisseria gonorrhoeae*.^{18,24} In men older than age 35 years, bacteriuria caused by obstructive urinary disease is more common, and *Escherichia coli*, enterococci, *Pseudomonas*, and *Proteus* predominate. Tuberculous epididymitis is rare. Any organism may invade the epididymis in association with a systemic infection, such as blastomycosis and meningococcus. *Candida* and *E. coli* epididymitis have been seen in patients with acquired immune deficiency syndrome. Amiodarone (Cordarone) has been associated with drug-induced epididymitis confined to the globus major, or head, of the epididymis.

In the prepubertal patient, coliform bacteria predominate. Nongonococcal bacterial epididymitis in a boy younger than age 10 years should prompt a thorough diagnostic evaluation for genitourinary anomalies or neurogenic bladder disease, as underlying urogenital abnormalities exist in 47% of prepubertal patients with bacterial epididymitis.^{2,3} A negative urine culture is evidence against an anatomic anomaly.

Initially, gradual development of scrotal pain, swelling, and inflammation occurs when only a small portion of the epididymis or vas deferens is involved. With progression, the globus minor of the epididymis becomes involved and extends superiorly into the body, then into the globus major, or head, of the epididymis if not diagnosed and treated appropriately. The eventual large, red, hot, swollen scrotal mass of epididymoorchitis may indirectly compress the terminal branches of the spermatic artery and vein, causing testicular ischemia—hence, the importance of early diagnosis and aggressive management. Bacteria can also invade an ischemic testis, leading to testicular and epididymal abscesses.

CLINICAL PRESENTATION

The gradual onset of scrotal pain and swelling peaks over a period of 3 to 24 hours. The pain can be sharp and often radiates to the groin and either lower abdominal quadrant, simulating appendicitis or diverticulitis, but, commonly, the only complaint is a dull ache in the scrotum.

Irritative voiding symptoms, such as frequency, dysuria, and urgency, occur in 10% to 20% of patients.^{14,24} A history of fever is not common. On occasion, a debilitated or immunocompromised patient may present with bacteremia. A history of recent cystoscopy, an indwelling urethral catheter, urinary tract infection, or genitourinary surgery should be sought, especially in older men. Similarly, a thorough history of sexual relationships, previous exposures to sexually transmitted disease, work-out

routines, and job-related duties (any activity that promotes a Valsalva maneuver or increases intrapelvic pressure and promotes retrograde flow of sterile or infected urine) must be evaluated. Body builders who lift a lot of weight, and roofers and construction workers who climb and do a lot of heavy lifting, are prototypes for the development of epididymitis.

Nausea occurs in 15% of patients.¹³ Bilateral epididymal involvement occurs in 10% of cases. Rarely, abdominal pain attributed to infection involving the vas deferens and spermatic cord is the sole initial and presenting symptom. This has been mistaken for appendicitis or diverticulitis.²⁴

On examination, a localized, indurated, tender portion of the epididymis may be palpated inferiorly and separate from a less painful testis. Eventually, the entire epididymis becomes involved, and the distinction between the testis and epididymis is less evident. The involved testis hangs low in an erythematous and edematous scrotum. Most often, testicular discomfort can be relieved by scrotal elevation and support (a positive Prehn's sign), as epididymitis is an inflammatory process. A urethral discharge is present in 10% of patients.²⁴

Progression of the infection can result in scrotal wall fixation to the underlying testis and epididymis and epididymal abscess formation. More commonly, an erythematous, edematous scrotum overlies an amorphous, tender mass.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of epididymitis includes torsion of the testis or its appendages, torsion of an epididymal appendage, testicular tumor, orchitis, and inguinal hernia. (These were discussed in the section on testicular torsion.) A reactive hydrocele may be the lone physical finding, prompting a search for its primary (very young infant) or secondary cause. Any inflammatory or traumatic event that prevents the parietal tunica vaginalis from absorbing viscerally secreted fluid will promote the development of a hydrocele. Most often, the posteriorly located epididymis is palpable even though the anterolateral surface of the testis is obscured by a hydrocele. Ultrasonography is the test of choice to evaluate the intrascrotal contents if definitive palpation is obscured by a secondary hydrocele. Tumors of the epididymis and spermatic cord are rare.

EMERGENCY DEPARTMENT EVALUATION

After the history and physical examination, a urinalysis and urine culture should be obtained. A properly collected urinalysis shows pyuria or bacteriuria in 50% of patients.¹⁵ A small number of patients have a urethral discharge that can be Gram-stained. The white blood cell count is commonly elevated, nonspecific, and not helpful in the differential diagnosis. Color Doppler ultrasound can confirm testicular blood flow and help differentiate epididymitis from testicular torsion. It can also aid in the evaluation of the epididymis for enlargement and abscess formation. If gram-negative bacteremia is suspected, blood cultures should be obtained and intravenous fluids and broad-spectrum antibiotic therapy initiated as quickly as possible.

EMERGENCY DEPARTMENT MANAGEMENT

Aggressive initial management of acute epididymitis is crucial to reduce the potential morbidity associated with this disease process. Complete bedrest, scrotal elevation with ice applied to the affected epididymis for 10 minutes three times per day, organism-specific antibiotic therapy, nonsteroidal antiinflammatory drugs, narcotic pain medication, and stool softeners are the initial treatment modalities recommended for acute epididymitis. Patients are instructed to observe strict bedrest, getting up only to eat or go to the bathroom. Once pain-free in bed, they are encouraged to be ambulatory with a scrotal supporter and are instructed emphatically not to lift or strain, especially when having a bowel movement, as this will promote a recurrence of the pathophysiologic inflammatory process.

Antibiotics are prescribed in all cases. Despite an infectious cause, cultures of the urine and urethral discharge may be negative. If there is a history of sexually transmitted disease or if the causative organism is not known, a single 125-mg intramuscular dose of ceftriaxone (Rocephin) is administered in the emergency department. This is followed by a 7-day course of doxycycline 100 mg orally every 12 hours, ofloxacin (Floxin) 400 mg orally every 12 hours for 7 days, or, alternatively, azithromycin (Zithromax) 1 g orally as a single dose in the emergency department prior to discharge.⁷ Men older than 35 years who are suspected of having a urinary tract infection caused by enteric gram-negative bacilli or *Pseudomonas* should be initially treated based on the suspected organism, with their treatment altered, if necessary, based on the results of the emergency department urine culture. Empiric treatment for gram-negative rods and gram-positive cocci should be initiated with ciprofloxacin 500 mg orally every 12 hours for 7 to 10 days. Therapy with trimethoprim-sulfamethoxazole (TMP-SMX) (Septra or Bactrim) 1 tablet every 12 hours or ofloxacin (Floxin) 400 mg every 12 hours is an excellent alternative. Urology follow-up is encouraged within 5 to 7 days.

DISPOSITION

Role of the Consultant

Immediate urologic consultation should be obtained if testicular torsion is considered. Outpatient management of epididymitis is appropriate in most cases. Urologic follow-up should be arranged for 5 to 7 days, unless worsening of the patient's condition necessitates an earlier visit. All pediatric cases of epididymitis require urologic consultation to evaluate the potential for lower urinary tract anomalies and urinary obstruction as the cause of the epididymitis.

Indications for Admission

Adult patients with suspected bacteremia or severe constitutional symptoms, including intractable pain or nausea and vomiting, require hospitalization and parenteral antibiotics. Patients in whom the physical examination and ultrasonography are equivocal for abscess formation should also be admitted for antibiotic therapy and serial ultrasound examinations.

Hospitalization is required for severe cases of epididymitis or when an epididymal or testicular abscess is suspected. Selected epididymotomy or epididymectomy may prevent testicular damage when an abscess is diagnosed. Occasionally, orchiectomy may be the most time-efficient and definitive treatment option.

Transfer Considerations

The unavailability of a urologist may necessitate transfer if operative intervention is necessary. Most cases of epididymitis can be treated initially by emergency physicians.

COMMON PITFALLS

- Delayed presentation can make initial assessment quite difficult. Scrotal swelling associated with both epididymitis and testicular torsion can be identical after a few days.
- Testicular torsion and testicular tumors can be overlooked unless there is a high index of suspicion.
- Epididymitis is the most common misdiagnosis in cases of testicular tumor and testicular torsion.
- Bladder outlet obstruction and urinary retention must be considered in the older patient with epididymitis.
- An incomplete history and a poor understanding of scrotal anatomy are commonly the reasons why epididymitis is misdiagnosed on initial evaluation.

ORCHITIS

Acute orchitis, by definition, is a primary infection of the testis and, as such, is rare. Most often, orchitis is seen as a secondary infection related to an initial epididymal infection. Orchitis may occur during a systemic illness in which systemic seeding of the testis occurs with *E. coli*, *Klebsiella*, *Pseudomonas*, *Staphylococcus*, and *Streptococcus*. Most commonly, influenza, infectious mononucleosis, tuberculosis, syphilis, and amebiasis cause orchitis. The latter pathogens occur most often in immunocompromised patients.

Mumps orchitis occurs in males systemically infected with the virus, but seldom before puberty. About 15% to 20% of postpubertal males with mumps develop orchitis.

The onset of the testicular swelling normally occurs 3 to 7 days after the development of parotitis. One-third of men with mumps orchitis, however, do not have parotitis. One-third of cases may be bilateral. Atrophy results in about 50% of involved testes.

CLINICAL PRESENTATION

The usual presentation of orchitis is high fever, nausea, vomiting, and gradual onset of testicular pain radiating to the groin. There are usually no urinary or urethral symptoms. The testis is uniformly enlarged and tense and tender to palpation, while the epididymis is normal. A reactive hydrocele, cutaneous erythema, and scrotal enlargement are common and may make palpation of the testis difficult.

DIFFERENTIAL DIAGNOSIS

When there is systemic infection, the differential diagnosis is not difficult. In the absence of systemic features, epididymo-orchitis and testicular torsion must be considered. The onset of epididymo-orchitis is slower than that of orchitis, which is slower than the onset of testicular torsion. In orchitis, palpation of the cord and epididymis reveals the spermatic cord to be much less thickened and the epididymis to be in its normal posterior position.

EMERGENCY DEPARTMENT EVALUATION

Because orchitis is, most often, part of a systemic process, attention should be directed at the primary disease. In the minority of patients with orchitis as the main manifestation, an examination should be accompanied by a urinalysis. Pyuria may imply a primary epididymal process with extension to the testis (epididymo-orchitis). Orchitis is such a rare diagnosis that a color Doppler ultrasound should be done to confirm normal testicular blood flow, thus eliminating testicular torsion from the differential diagnosis.

EMERGENCY DEPARTMENT MANAGEMENT

Treatment for mumps orchitis is generally supportive with bedrest, scrotal elevation, and analgesics. Resolution requires 1 to 3 weeks. Steroid therapy is probably not helpful. Making incisions in the testicular tunica albuginea early in the course of the disease has been tried as a means of reducing intratubular pressure but has shown no appreciable benefit. Atrophy occurs in about 50% of affected testes, regardless of treatment.

HYDROCELE AND OTHER DISORDERS OF THE SPERMATIC CORD

A hydrocele is the most common cause of nonacute intrascrotal swelling. It is an accumulation of serous fluid in the potential space between the visceral and parietal layers of the tunica vaginalis that normally envelopes and fixes the anterolateral aspect of the testis and epididymis to the posterior scrotal wall, preventing testicular torsion. Most hydroceles are found in older patients, and an underlying cause is not identified. A sudden onset of a symptomatic hydrocele can occur secondary to epididymitis, trauma, or tumor.

Approximately 10% of testicular tumors have a reactive hydrocele as the presenting complaint.¹⁰ In pediatric hydroceles, congenital failure of the tunica vaginalis to obliterate after birth allows communication between the scrotum and the peritoneum, creating a hydrocele or hernia. These "communicating hydroceles" acutely enlarge and shrink depending on patient activity, as peritoneal fluid and occasionally a loop of intestine fill the scrotum when the patient is in the upright position and spontaneously decompress when the patient is supine. This is the classic history of scrotal swelling that vanishes when the child sleeps.

CLINICAL PRESENTATION

Most hydroceles in adults develop gradually and are asymptomatic. A chronically enlarging hydrocele may present as scrotal enlargement associated with a heavy sensation, occasionally radiating to the groin. An acute hydrocele may present with pain, depending on the inciting event.

The classic hydrocele is a cystic, pear-shaped mass located anterior to the testis and epididymis. It often obscures definitive palpation of the testis. Transillumination most often reveals a translucent mass surrounding an opaque testicular shadow. A hydrocele should be confined to the scrotum, with a normal spermatic cord above it. Rarely, a hydrocele of the spermatic cord can be palpated in the region of the external inguinal canal.

DIFFERENTIAL DIAGNOSIS

The most common disorders to consider in the differential diagnosis include spermatocele, varicocele, traumatic hematocele, and inguinal hernia.

A hematocele is blood or a blood clot within the potential space between the two leaves of the tunica vaginalis. It occurs most often after needle aspiration of a hydrocele, but it can accompany testicular torsion or trauma. A cystlike mass, similar to a hydrocele, can be felt on examination. However, the mass does not transilluminate. Following trauma, this type of swelling may become quite large. Ultrasonography can differentiate blood from less echogenic hydrocele fluid and reveal a ruptured testis or testicular tumor. In the absence of a reasonable history or diagnostic ultrasonography, a hematocele should be explored.

A spermatocele is a common cystic mass lying above and posterior to the testis. Spermatoceles are retention cysts arising from the epididymis and contain spermatozoa.¹⁰ Usually painless, these masses may alarm the patient about a possible testicular tumor. A spermatocele is usually soft, freely mobile, and lucent on transillumination, but may become firm in a chronic state. Most spermatoceles are less than 1 cm in size, but can become as large as 10 cm. It is not possible to differentiate a spermatocele from a lipoma or other adnexal mass by palpation alone. Combining the examination with ultrasonography can usually confirm the diagnosis. Excision is required only when the size of the spermatocele causes pain or there is a question regarding the diagnosis.

A varicocele is a dilatation of the testicular pampiniform venous plexus.² A varicocele is usually a chronic condition, but the acute appearance of a varicocele, especially on the right side, can herald a retroperitoneal tumor, tumor adenopathy, renal cell carcinoma, or renal vein thrombosis. Varicoceles are more common on the left than on the right and usually present as a mass above the testis, often referred to as a "bag of worms" because of the multiple torturous vessels imprinting the scrotal skin. Nearly 20% of men have a left varicocele of some degree.²³ The left side predominates because the left testicular vein drains perpendicularly into the left renal vein without valves to reduce hydrostatic pressure, as compared with the right testicular vein, which drains obliquely into the inferior vena cava. Right-sided varicoceles are only seldom seen without a concomitant left varicocele.

Most varicoceles are asymptomatic, but if symptoms occur, they are usually limited to the upright position (increased gravity) and include heaviness on the affected side that is usually relieved by assuming a supine position. Most often, reassurance suffices.

An inguinal hernia may present as an acute swelling in the scrotum. The clinical history is variable and not helpful. The exception is an incarcerated hernia that occurs most commonly during the first year of life and is accompanied by signs of peritoneal irritation or obstruction (i.e., nausea and/or vomiting). Most hernias may be palpated in the superior scrotal and inguinal regions.¹⁰ Transillumination is usually not helpful. The auscultation of bowel sounds in the hemiscrotum may help to identify a hernia. Uncomplicated reduction of bowel through the inguinal defect into the abdominal cavity confirms the diagnosis.

A sperm granuloma is an inflammatory response to sperm that have entered the interstitium; it can occur in the epididymis, vas deferens, or testis. A sperm granuloma is most commonly found at the site of a previous vasectomy or in the epididymis following an epididymotomy. A sperm granuloma is generally small and asymptomatic, but, at times, presents as a palpable, painful intrascrotal mass. This creates a problem only in differentiating the granuloma from a testicular tumor. The physical and ultrasound examinations demonstrate an extratesticular mass that is usually confluent with the epididymis or vas deferens. Rarely, testicular granulomas require diagnostic exploration. Emergency department treatment consists of antiinflammatory agents and pain medication.

EMERGENCY DEPARTMENT EVALUATION

Many hydroceles preclude palpation of the testis. Transillumination is insensitive in eliminating tumor as the inciting cause. Often, the history suggests epididymitis as

the cause, but the epididymis is hidden by the hydrocele. Epididymitis should be suspected if the urinalysis discloses pyuria. Scrotal ultrasonography is the diagnostic test of choice for detecting masses within the testis; it is the best modality to image the epididymis through a hydrocele.

EMERGENCY DEPARTMENT MANAGEMENT

The priority in emergency department evaluation of hydroceles is disclosing the etiology. Underlying reversible causes should be treated. Very infrequently, aspiration of the hydrocele is required to permit adequate examination and provide relief from painful swelling. The technique involves anterior aspiration through an 18-gauge, pliable venous catheter inserted over a needle cannula.

The indwelling, flexible, atraumatic tip prevents damage to the opposing testicle during collapse of the hydrocele and can be positioned in the most dependent area of the scrotum to ensure adequate drainage. The maneuver is not definitive because recurrence is guaranteed. Surgical exploration is necessary if a palpable mass remains poorly defined. Otherwise, the treatment of hydroceles is elective, being indicated when the size of the scrotum is unacceptable cosmetically or interferes with physical activity.

DISPOSITION

The acute development of a hydrocele requires referral based on the suspected underlying cause.

COMMON PITFALLS

Dismissal of a newly developed hydrocele as a benign process may delay diagnosis of an underlying testicular malignancy.

OTHER DISORDERS PRESENTING AS A SCROTAL MASS

Infectious disorders of the scrotal skin and urethra can present as an acute scrotal mass. Primary abscesses of the scrotal skin occur from infections of the hair follicles or sweat glands. These are common and similar to abscesses anywhere else on the body. These types of abscess are limited to the superficial layers of the scrotal skin.

Deep scrotal infection usually arises from infection of the lower urinary tract or perirectal disease. Commonly, such infections originate from extravasation of infected urine as a result of urethral instrumentation or urethral stricture disease and periurethral abscess formation. Infection also may originate from perirectal and ischioanal abscesses. Often, the etiology is not clear. These abscesses are rooted deep in the perineum and may spread extensively by the time they cause obvious cutaneous lesions. Spread of infection to the urethral corpus spongiosum may result in bacteremia. Eventually, the tunica albuginea is penetrated, with spread to Buck's fascia. Once Buck's fascia is invaded, the next barrier is Colles' fascia. Infection may spread anteriorly along Colles' fascia to involve the scrotum, resulting in an acute scrotal mass.

Fournier's gangrene, or idiopathic synergistic necrotizing fasciitis, is a rapidly spreading subcutaneous infection that presents as massive scrotal swelling, with progression to necrosis of the scrotal wall within 24 hours if not recognized or treated. The average age of the patient is 55 years, and immunocompromised patients have a higher incidence of occurrence.¹⁷ Diabetics, steroid users, chronic alcohol abusers, or patients with the human immunodeficiency virus are at risk. The typical organisms include hemolytic streptococci, *Bacteroides fragilis*, *E. coli*, and *Clostridium* species.

CLINICAL PRESENTATION

Superficial scrotal skin abscesses seldom cause difficulty in diagnosis. A localized area of erythema with a smaller area of suppuration is found on examination. Most patients are afebrile and without constitutional symptoms. No laboratory work is required. Superficial abscesses may be incised and drained under local anesthesia in the emergency department.

Deep scrotal abscesses and early Fournier's gangrene can present as generalized scrotal swelling. The onset may occur several days after instrumentation of a urethral stricture or in an inadequately treated diabetic with an initial superficial skin abscess. The patient may have a history of perirectal disease. Pain is usually intense, but initial physical examination of the affected area can be devastatingly subtle. Fever and other constitutional symptoms are often present. A diabetic patient may present with ketoacidosis. The scrotal contents often cannot be palpated because the entire scrotum is edematous, red, tense, and warm. Frequently, no localized area of fluctuation is detected.

DIFFERENTIAL DIAGNOSIS

Scrotal edema from congestive heart failure or lymphatic obstruction can occasionally appear similar to scrotal infection. Concomitant anasarca or edema of the lower extremities shifts the differential diagnosis away from an infectious cause. Occasionally, edema of the scrotum occurs as a result of an allergic reaction. The scrotum should not be tender to palpation and the erythema is considerably less. Constitutional symptoms, including fever, are absent. Cellulitis of the scrotum may present with significant edema. This is rare without an underlying cause, but it can occur. Less tenderness should be found in an otherwise healthy patient, but the distinction from a deep abscess may be difficult to ascertain. Epididymo-orchitis that has progressed to suppuration and overlying skin fixation can present with scrotal swelling similar to that seen with a deep scrotal abscess. Often indistinguishable on examination, both require surgical drainage.

EMERGENCY DEPARTMENT EVALUATION

Rapid diagnosis and treatment of bacteremia are the principles of initial management. If the diagnosis remains in question, ultrasonography has the ability to detect abscess cavities within fascial planes and is helpful in differentiating cellulitis from a deep abscess. A plain pelvic radiograph (KUB) occasionally demonstrates subcutaneous air. If urethral obstruction is suspected as the inciting cause, a urethral catheter should be placed into the bladder. If obstruction is encountered, an immediate urethrogram may be diagnostic. The rectum and perineum should be examined carefully for induration and fluctuance.

EMERGENCY DEPARTMENT MANAGEMENT

Fournier's gangrene requires aggressive medical and surgical resuscitation, intravenous fluids, broad-spectrum antibiotics (Unasyn, Timentin, or piperacillin). These modalities should be instituted as soon as possible, and urologic consultation obtained while alerting the operating room for aggressive surgical debridement. If perirectal disease is suspected, a general surgeon must also be consulted, as a temporizing colostomy will most likely be required.

DISPOSITION

Role of the Consultant

Surgical drainage with wide debridement and antibiotic therapy must be instituted rapidly because of the extremely aggressive nature of Fournier's gangrene. Postoperative hyperbaric oxygen therapy is recommended and will promote wound healing.¹⁷

Indications for Admission

Patients with complex scrotal abscesses should be admitted through the operating room. Cellulitis of the scrotum can be difficult to distinguish from a secondary skin reaction associated with a deeper infection. Cellulitis requires intravenous antibiotics, serial examinations, and close follow-up.

Transfer Considerations

Patients should be transferred if surgical consultation or intensive care beds are not available.

COMMON PITFALLS

- The most common mistake involves underestimating the severity of an infection. With Fournier's gangrene, a delay of 4 to 8 hours can make a significant difference in morbidity.
- In the very early stages, most severe scrotal infections mimic cellulitis, and the clinician may mistakenly be tempted to treat the problem on an outpatient basis with oral antibiotics without aggressive follow-up.

Acknowledgment

The author gratefully acknowledges the contribution of Douglas Swartz, who wrote the previous version of this chapter.

[Disorders of the Foreskin and Glans Penis](#)

[Balanoposthitis](#)

[Phimosis](#)

[Paraphimosis](#)

[Priapism](#)

[Bartholin Gland Abscess, Vaginal Foreign Bodies, Imperforate Hymen](#)
[Common Pitfalls](#)
[Chapter References](#)

Emergency physicians are required to evaluate and treat afflictions of the male and female genital tracts. This chapter defines these clinical entities and provides treatment recommendations. Disorders of the penis, including balanoposthitis, phimosis, paraphimosis, and priapism, and disorders of the female genitourinary tract, including Bartholin gland abscess, vaginal foreign bodies, and imperforate hymen are discussed. Infectious disorders of the genital tract, nephrolithiasis, cutaneous genitourinary disease, and acute scrotal pain are covered elsewhere in this text.

DISORDERS OF THE FORESKIN AND GLANS PENIS

Balanoposthitis^{14,20}

Balanitis refers to inflammation of the glans penis. *Posthitis* refers to inflammation of the prepuce of the penis. Because balanitis and posthitis usually occur together, *balanoposthitis* correctly describes a male with inflammation of the glans and prepuce. Balanitis is more common in uncircumcised men who exercise poor hygiene, but it may affect young boys. Patients with balanoposthitis present with a prepuce and glans that is edematous, erythematous, fissured, and painful. Various skin changes are possible based on the etiology. The differential diagnosis of balanoposthitis is divided into infectious and noninfectious causes. Fungal infections with *Candida albicans* cause itching and burning of the penis, accompanied by white discharge, discrete ulcerated papules, and white, cheesy plaques. Group B streptococci, *Gardnerella vaginalis*, and mixed anaerobes have been isolated from men with balanoposthitis. Secondary syphilis and condyloma lata may infect the glans. Protozoal infections with *Trichomonas vaginalis* and amoebiasis have been reported. Genital herpes may cause necrotizing balanoposthitis, and human papillomavirus (HPV) can induce genital warts on the glans or foreskin. Noninfectious causes of balanoposthitis include trauma, latex allergy, and various dermatoses. Dermatologic lesions include psoriasis, lichen planus, erythema multiforme, and a variety of premalignant and malignant lesions. When balanoposthitis is severe, phimosis may occur and precipitate urinary retention.

The emergency department (ED) evaluation is usually limited to the history and physical examination. Test the patient for diabetes mellitus when infection with *C. albicans* is suspected. Perform serologic testing for syphilis when this organism is suspected. Acetic acid whitens the superficial epithelial skin layer when applied to lesions infected with HPV. Meticulous hygiene, including retraction of the foreskin and cleansing of the glans penis and prepuce, is the mainstay of treatment. Direct the treatment of infectious balanoposthitis toward the offending organism. Treat fungal infections of the glans with topical antifungal agents. Use metronidazole to treat *Gardnerella*, anaerobic infection, and *Trichomonas* infections. Treat secondary syphilis according to established guidelines.

Treat patients who have balanoposthitis as outpatients except when they have associated medical diseases, such as diabetes. This group requires hospital treatment. When phimosis is present and causes urinary retention, consultation in the ED with a urologist may be required to relieve the phimosis to allow for free drainage of urine. All patients with balanoposthitis require follow-up with their primary physician and may benefit from urologic evaluation for circumcision. Refer patients with skin lesions suspicious for precancerous changes or malignancy to a dermatologist for evaluation.

Phimosis

When the foreskin is not retractable behind the glans penis, the condition is termed *phimosis*. Physiologic phimosis is present until normal adhesions between the foreskin and glans have separated. Although most young boys are able to retract the foreskin by puberty, retraction is usually possible at an earlier age.^{5,7} As normal secretions accumulate and epithelial sloughing occurs, smegma is formed. Smegma assists in the separation of the foreskin from the glans and is normal. Parents may confuse smegma with infectious penile discharge if expressed from the penis. Pathologic phimosis, or simply phimosis, occurs when retraction of the foreskin is not possible after puberty or when the foreskin was previously retractable.⁵

Asymptomatic phimosis does not require emergent treatment. Reassure concerned parents when physiologic phimosis is present. Do not encourage them to attempt forceful retraction. When severe phimosis causes urinary retention or interferes with placement of a urinary catheter, a slit made in the dorsal aspect of the foreskin facilitates access to the urethral meatus.^{14,18} After achieving adequate local anesthesia of the penis with a dorsal nerve block or ring block placed at the base of the penis, gently separate adhesions between the foreskin and glans with a hemostat. Place one jaw of the hemostat inside the dorsal foreskin, taking care not to include the urethral meatus or glans. Close the hemostat on the foreskin, crushing it for 3 to 5 minutes. Incise the crushed foreskin with straight scissors. The crushed edges rarely bleed but may require absorbable suture for hemostasis if they separate. Although some patients are satisfied with the cosmetic appearance of the foreskin after the dorsal slit procedure, the urologist may perform definitive circumcision.

Paraphimosis

Paraphimosis occurs when the retracted foreskin is not replaced, usually after cleansing or catheter insertion. Paraphimosis requires definitive treatment in the ED. After foreskin retraction, the constricting phimotic ring causes progressive edema, impairs venous return, and threatens the viability of the glans. Although most patients complain of pain and usually provide a history of foreskin retraction, debilitated, uncircumcised patients may not provide this history. Do not confuse paraphimosis with balanitis in these patients.

After adequate sedation or penile anesthesia, attempt manual reduction. Place fingers of both hands behind the phimotic ring and foreskin while applying gentle, steady pressure on the glans with the thumbs.^{5,14,18} Gauze placed under the fingers may improve traction on the foreskin while bringing it over the glans, but lubricants are rarely helpful. Several other techniques are described to treat paraphimosis; application of these techniques should be guided by the physician's skill and training in the maneuvers. A 21-gauge needle can be used to puncture the edematous foreskin; manual compression after puncture allows the escape of enough edema fluid to facilitate reduction.^{2,14} Blood aspirated from the glans after a tourniquet is placed at the base of the penis may allow reduction.¹⁷ Subdermal hyaluronidase injected into the edematous foreskin facilitates dispersion of edema fluid and may make reduction possible.⁶ Granulated sugar has been applied to the edematous glans and foreskin to extract tissue water and ease reduction.¹³ When less aggressive methods fail, the phimotic ring is incised with a scalpel to facilitate foreskin reduction.¹⁸ Prevention is key; ED personnel must replace the foreskin after urinary catheter placement.

Priapism

Priapism is characterized by a prolonged, painful, unwanted penile erection, usually in the absence of sexual stimulation. The physiologic balance achieved between venous outflow and arterial dilatation of the corpora cavernosa controls erectile function. Priapism occurs when normal physiologic blood flow is altered. Today, medications used to treat erectile dysfunction in men (papaverine, prostaglandin E1, etc.) cause most cases of priapism.^{4,9} It is uncommon in boys, unless sickle cell disease is present, and it is rare in neonates.¹⁹ Patients with priapism present to the ED complaining of penile pain and persistent erection, even after ejaculation. The mean time to presentation in one series of 34 patients was 30 hours.⁹ The penis is erect and painful to palpation. The corpora cavernosa is engorged, but, in contrast to normal erections, the corpus spongiosum and glans penis are flaccid.

The differential diagnosis is divided into "low-flow" and "high-flow" priapism.⁹ Simply stated, low-flow priapism results from impaired venous outflow. High-flow priapism

results from abnormally increased arterial flow.

Low-flow priapism is far more common than high-flow priapism and is often caused by vasoactive drugs that cause engorgement of the corpora cavernosa. Impaired venous outflow causes sludging, thrombosis, acidosis, and decreased oxygen tension within the corporal bodies. This pathophysiologic cascade causes the irreversible cellular damage and corporal fibrosis responsible for the long-term complications of low-flow priapism. Intracavernosal agents used for erectile dysfunction, antihypertensive agents, psychotropic drugs, cocaine, and ethanol are among the drugs that have been implicated. Leukemia, sickle cell anemia, and a variety of neoplastic etiologies are also responsible for priapism. ^{9,16}

High-flow priapism is uncommon and usually results from trauma to the penis or perineum. ¹² Arterial fistula formation between the cavernosal artery and the corporal bodies increases arterial flow into the penis that exceeds venous outflow.

The history usually suggests the etiology of the patient's priapism. Careful attention to prescription or illicit drug use may help determine whether these agents are responsible. Suspect sickle cell disease among patients at risk when the history of sickle cell disease is unknown. Elicit the history of prior episodes of priapism and record the onset of erection. On examination, the penis is painful to palpation and the corporal bodies are engorged, but the glans and the corpus spongiosum are soft. Some authors recommend blood gas analysis of blood aspirated from the corporal bodies to assist in identifying the etiology. ^{9,18} Low pH, low oxygen tension, and high carbon dioxide levels suggest low-flow, venous obstruction. Blood gas parameters similar to arterial blood suggest high-flow priapism, a condition usually seen after trauma.

Emergency physicians must treat priapism when the urologist is not immediately available for consultation. Most cases of priapism encountered in the ED treatment will be low-flow priapism. There is conflicting literature describing terbutaline's efficacy in priapism. Some small clinical trials have demonstrated that oral terbutaline is more effective than placebo in achieving detumescence ¹⁵; others have found no benefit. ⁸ Because of its relative safety in patients without hypertension or coronary artery disease, a trial of subcutaneous terbutaline (0.25 to 0.5 mL injected subcutaneously, repeated in 20 minutes if needed), or 5 mg of oral terbutaline, repeated in 15 minutes, may be attempted. ¹⁸ When sedation, analgesia, and/or terbutaline do not result in detumescence, corporal aspiration and irrigation is indicated. ^{9,18} Anesthetize the penis and aspirate 30 to 60 mL of blood from a single corporal body at the 10 o'clock or 2 o'clock position. Do not puncture the glans. Anastomoses between the corporal bodies obviate the need for bilateral aspiration. When the erection persists after aspiration, a careful injection of phenylephrine into the punctured corpus cavernosum may be done (Fig. 68.1). One milligram of phenylephrine is diluted in 9 mL of sterile saline to achieve a concentration of 1000 mg per milliliter. Inject 200-mg aliquots of phenylephrine up to three times to achieve detumescence. Monitor the blood pressure and rhythm when repeated injections are required. If this treatment fails to relieve the erection, urologic evaluation for corporal body shunting is required. If the urologist is unavailable, transfer the patient to definitive care. Sickle cell patients with priapism require analgesia, hydration, supplemental oxygen, and, when traditional antisickling measures fail, red blood cell exchange transfusion. ¹⁶

Figure 68.1. The penis undergoing corpus cavernosum injection for priapism.

Emergent therapy in the ED is not required for high-flow priapism because it does not cause the ischemic injury seen in low-flow priapism. Order Doppler flow ultrasonography of the penis and perineum to document arteriovenous fistulas when suspecting high-flow priapism. ¹²

BARTHOLIN GLAND ABSCESS, VAGINAL FOREIGN BODIES, IMPERFORATE HYMEN

The Bartholin glands are located in the labia minora and drain by a duct that exits between the hymen and the labium. These glands are not normally palpable but can form asymptomatic cysts or become infected and abscessed. Patients between 20 and 30 years of age present complaining of a painful, indurated mass located lateral to the vaginal introitus. ^{1,11} The infection is polymicrobial and may contain *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. The differential diagnosis of Bartholin gland swelling includes sebaceous cysts, mucoid cysts, and various benign and malignant vulvar masses. Other cystic lesions (e.g., inclusion cysts, Gartner duct cysts, and endometriosis) can occur but are rarely confused with a Bartholin gland abscess. ¹¹

Prescribe sitz baths, analgesics, and gynecologic follow-up when the abscess has pointed and ruptured spontaneously. As is true for most abscesses, antibiotics after drainage are not routinely given. If the abscess has not drained spontaneously, it is appropriate in the ED to perform incision and drainage and the placement of a Word catheter. ^{3,11} Insert the catheter through a 1.0- to 1.5-cm stab incision made in the abscess just inside the hymenal ring. Tuck the free end of the catheter into the vagina; it should remain in place for at least 4 weeks to allow fistula formation. The patient should be referred to a gynecologist for follow-up within 5 to 7 days. If a Word catheter is not available, perform a traditional incision, drainage, and packing. Patients with Bartholin gland abscesses are usually treated as outpatients but should be referred to a gynecologist for reevaluation. Recurrent abscesses or abscesses treated with simple incision and drainage may require marsupialization by a gynecologist.

Vaginal bleeding or spotting, discharge, and odor suggest a vaginal foreign body, particularly in the prepubertal female. ¹⁰ Adult female patients usually provide a history of foreign-body insertion, but young girls usually do not. Although curious children may inadvertently place some objects in the vagina, vaginal foreign bodies are often placed as part of sexual abuse. Recurrent pelvic pain, recurrent urinary tract infection, and retroperitoneal perforation have been reported in association with vaginal foreign bodies. When vaginal foreign bodies are found in young girls, sexual abuse must be suspected. Patients require the multidisciplinary approach, diligence, respect, and attention to evidence collection that is afforded any victim of suspected sexual abuse. Small children may require intravenous sedation or anesthesia and the expertise of a pediatric gynecologist to remove the foreign body. Thorough speculum examination and removal with forceps are usually sufficient for vaginal foreign bodies that cannot be recovered by the patient.

When primary amenorrhea is present, the differential diagnosis in the adolescent female with abdominal pain includes imperforate hymen, demonstrated by a bulging hymen that is dark in color due to retained menstrual blood. ⁵ Refer patients with suspected imperforate hymen to a gynecologist.

COMMON PITFALLS

- Phimosis is normal in young boys and does not require treatment in asymptomatic adults.
- Paraphimosis can look like balanitis unless the emergency physician recognizes that the foreskin is retracted.
- ED personnel should take great care to always return the foreskin to its anatomic location after retraction.
- Priapism is a urologic emergency that requires ED treatment in coordination with the consulting urologist. Red cell exchange therapy may be necessary when priapism occurs in a patient with sickle cell disease.
- Vaginal foreign bodies in girls should always raise the possibility of sexual abuse.

CHAPTER 69

Complications of Fertility Regulation Methods

Andrew M. Kaunitz

[Hormonal Contraceptives](#)
[Intrauterine Devices](#)
[Barrier and Spermicidal Contraceptives](#)
[Risk of Ectopic Pregnancy in the Setting of Contraceptive or Sterilization Failure](#)
[Chapter References](#)

Although modern methods of contraception are extremely safe, use of each method is associated with a certain incidence of complications. In this chapter, complications associated with hormonal contraceptives, intrauterine devices (IUDs), and barrier and spermicidal contraceptives are addressed. Evaluation and management of several of the more serious complications (e.g., thromboembolic disease and pelvic infections) are covered elsewhere. Fortunately, complications of contraception are infrequent and usually minor.

HORMONAL CONTRACEPTIVES

Oral contraceptives (OCs) were introduced in 1960. Since that time, the dose of estrogen and progestin in each tablet has declined dramatically. The use of low-dose OCs (less than 50 mg ethinyl estradiol) and more sophisticated prescribing practices have resulted in a marked reduction in the risk of complications.⁶ The incidence of deep venous thrombosis and pulmonary embolism in women currently using low-dose OCs is two to four times higher than in nonusers.¹⁰ Because thromboembolism is rare in reproductive-age women (four to ten cases annually per 100,000 women), the attributable risk of thromboembolism associated with OC use is approximately six to 30 annual cases per 100,000 users.¹³ The two- to fourfold increased risk of thrombosis associated with OC use contrasts with a six- to 15-fold increased risk associated with pregnancy.¹³ Use of low-dose OCs does not increase the risk of coronary artery or cerebrovascular disease.^{15,18} Healthy, nonsmoking women who are older than age 35 can safely use OCs until menopause.

Hypertension and migraine headaches have traditionally been thought to be increased by the use of OCs. However, it is unclear that a causal relationship between OC use and these two entities exists.^{12,24} Provided careful follow-up is maintained, otherwise healthy, nonsmoking, well-controlled hypertensive women younger than age 35 can use combined OCs. Otherwise, hypertensive women should use progestin-only or nonhormonal contraceptives. Continuous administration of low-dose combined OCs can prevent menstrual migraines.²² However, if OC use is accompanied by worsening migraine intensity or frequency, OCs should be discontinued in favor of progestin-only or nonhormonal methods. A recent randomized, double-blind, placebo-controlled trial found that use of a specific OC formulation (triphasic norgestimate) did not cause headaches.¹¹

Many laypersons believe that OCs cause cancer. Published studies have demonstrated that OC use does not increase the risk of breast cancer and that the risks of endometrial and ovarian cancer are substantially reduced by OCs.⁶

Although the low-dose OC has improved safety, it has also produced two bothersome side effects: breakthrough bleeding and absence of withdrawal bleeding. Breakthrough bleeding tends to occur early in the use of OCs, often resolving with time. A vaginal speculum examination should be performed to exclude such pathologic conditions as vaginitis, cervicitis,⁹ a cervical polyp, or carcinoma. If the patient has not taken her OCs appropriately, or if pregnancy is suspected, a pregnancy test should be performed.

When breakthrough bleeding persists in a woman using a low-dose estrogen OC, adding extra estrogen (e.g., 1.25 mg conjugated equine estrogen or its equivalent) in the first 7 days of the OC pack for several months may resolve this problem.⁷ The emergency physician may initiate these pharmacologic changes after consultation with a clinician, who will provide follow-up.

In the early 1990s, two highly effective, long-acting, progestin-only contraceptives became available in the United States: levonorgestrel subdermal implants (Norplant) and injectable depot medroxyprogesterone acetate (Depo-Provera).⁸ Implants can provide up to 5 years of contraception. Depo-Provera is administered by deep intramuscular injection every 3 months.

Menstrual changes are the most common side effect among women using continuous progestin-only methods. Most women using Norplant experience an irregular bleeding pattern during the first year following implant insertion; this declines to one-third of users by the fifth year. Approximately one-third of women experience regular cycles during their first year, increasing to two-thirds by the fifth year of implant use. Pregnancy testing should be performed in Norplant users when amenorrhea abruptly occurs in women who had experienced regular cycles.¹⁷ Although pregnancies occur only rarely in implant users, should a pregnancy be diagnosed, the likelihood of an ectopic implantation is higher than in women using no contraceptive method. Although women using Depo-Provera may also experience irregular bleeding initially, over three-fourths of long-term users experience amenorrhea. As with women taking OCs, women experiencing irregular bleeding during use of Norplant or Depo-Provera can be treated with oral estrogen (conjugated estrogen 1.25 mg or its equivalent daily) after vaginal examination to rule out infectious or neoplastic causes of bleeding.

Occasionally, wound infection occurs after implant placement. Some of these infections are the result of the ends of the implant being placed too close to the incision, thus preventing wound healing. Women with infection resulting from Norplant insertion should be treated with antibiotics effective against *Staphylococcus aureus* and referred to a physician knowledgeable about contraceptive implants. In most cases, the implants will be removed.

Headache is commonly reported by women using Norplant.²⁰ Most headaches do not have features of migraines and may resolve over time. However, because cases of idiopathic intracranial hypertension have been reported, retinal examination should be performed in implant users with headaches.

Some women develop ovarian cysts¹⁶ that may cause lower abdominal discomfort. More often, they are asymptomatic and noted incidentally during pelvic examination. Ovarian cysts in Norplant users should be managed expectantly. Surgical intervention is rarely necessary and should be reserved for cases in which a cyst fails to resolve or when torsion or rupture is suspected.

INTRAUTERINE DEVICES

Two intrauterine devices (IUDs) are currently marketed in the United States. The most widely used IUD, the Copper T 380A, is currently approved for 10 years of use. The progesterone-releasing IUD must be replaced annually. After decades of controversy, the association between pelvic inflammatory disease (PID) and IUD use is now better understood. When IUD insertion is performed in women at low risk for sexually transmitted diseases, the risk of PID appears no higher than in nonusers.²³ Emergency physicians may be confronted by a number of IUD-associated problems: coexistent PID, pregnancy, expulsion, and perforation.

When women wearing an IUD present with PID, antibiotic therapy should be initiated. In this setting, most clinicians recommend IUD removal once antibiotic therapy has been initiated. Antibiotics should cover both gonococci and *Chlamydia*. Guidelines for admission are essentially the same as for those patients without an IUD (see [Chapter 82](#), "Pelvic Inflammatory Disease"). If outpatient therapy is appropriate, close follow-up should be arranged (48 to 72 hours post-emergency department visit). If PID occurs in a woman who has been wearing an IUD for 5 years or longer, a tuboovarian abscess caused by *Actinomyces israelii* may be present. High-dose intravenous penicillin (or clindamycin in penicillin-allergic patients) is the drug of choice.¹

Pregnancy occurs in less than one woman per 100 users of Copper T 380A IUDs annually. The risk of miscarriage, preterm labor, and sepsis is increased, however, and the incidence of spontaneous abortion may be as high as 50%. The risk of losing the pregnancy is reduced by removing the IUD. If the tail of the IUD is visible on vaginal speculum examination, gentle traction should be used to remove the IUD. This should be performed by a clinician experienced with IUDs. If the tail is not visible, no effort should be made to probe for it. In this setting, if the woman does not want to have an abortion, she should be advised to seek medical attention if signs of infection (fever, abdominal pain, bleeding, or cramping) occur. Some clinicians have reported successful sonographically assisted IUD removal when the

string is not visible.²¹

Because the Copper T 380A is an extremely effective contraceptive, few intrauterine or ectopic pregnancies occur. However, when an accidental pregnancy does occur in an IUD user, an ectopic pregnancy will be present in approximately 5% (Copper T 380A) or 15% (progesterone-releasing IUD) of cases.¹⁹ Complaints of vaginal bleeding, abdominal pain, or amenorrhea in IUD users should be carefully evaluated for the possibility of an ectopic pregnancy.

Between 3% and 10% of patients have spontaneous expulsion of an IUD within a year of insertion.³ Although a patient's inability to feel her IUD may represent expulsion or perforation, most often a correctly positioned device is found. On examination, the IUD tail may be obscured by cervical mucus. If a tail is not seen, plain films can be used to determine the presence or absence of the IUD. In this setting, however, vaginal ultrasonography may be necessary to accurately localize the device. Partial expulsion may be associated with intermenstrual bleeding or cramping. The IUD tail often lengthens and the tip of the IUD may be felt in the vagina by the woman or her sexual partner. A partially expelled IUD is usually visible or palpable during vaginal examination and should be removed.

Most IUD perforations through the uterine wall occur at the time of insertion. With modern IUDs, the incidence of perforation is substantially less than 1%. An uncomplicated perforation may be managed by laparoscopy or laparotomy. Although not an emergency, early removal of intraabdominal copper-bearing IUDs minimizes adhesion formation. Some IUD perforations are not noted until intraabdominal bleeding or infection results. Immediate gynecologic consultation is appropriate.

BARRIER AND SPERMICIDAL CONTRACEPTIVES

Barrier methods and spermicides prevent sexually transmitted diseases, including human immunodeficiency virus infection. Few complications result from the use of condoms, diaphragms, and vaginal spermicides containing nonoxynol 9. Allergies to the latex in condoms and diaphragms, the spermicide nonoxynol 9, or the lubricants or vehicles may result in local reaction on the vaginal mucosa or penis. Nonlatex condoms and diaphragms are commercially available. Use of diaphragms with spermicidal jelly or condoms with spermicidal foam may increase the risk of urinary tract infection.⁴

Toxic shock syndrome has been reported in users of the diaphragm.² Risk can be minimized by not leaving diaphragms in place longer than 24 hours and by avoiding their use during menses. Displacement or breakage of a barrier contraceptive increases the risk of pregnancy. Postcoital (emergency) contraception (see [Chapter 88](#), "Sexual Assault") is most effective if used within 72 hours of intercourse. The availability of a prescription emergency contraceptive kit (Preven, Gynetics, Somerville, NJ) should facilitate use of this underutilized approach to fertility regulation.

RISK OF ECTOPIC PREGNANCY IN THE SETTING OF CONTRACEPTIVE OR STERILIZATION FAILURE

In general, women who use contraception experience a lower risk of ectopic pregnancy than sexually active women using no birth control. Oral, injectable, and copper intrauterine contraceptives markedly reduce users' absolute risk of experiencing an intrauterine or ectopic pregnancy. The only two contraceptive methods that do not reduce users' overall ectopic risk are progestin-only OCs (minipills) and the progesterone IUD (Progestasert, Alza, Palo Alto, CA).

When pregnancy occurs in a contraceptive user or sterilized woman, the likelihood that the pregnancy is ectopic is 33% in sterilized women, 6% in copper IUD users, 17% in Norplant users, and 23% in women using the progesterone IUD.^{5,14} Therefore, when emergency physicians diagnose pregnancy in sterilized women or those using intrauterine or implantable contraception, prompt vaginal sonography and prompt follow-up measures to monitor for possible ectopic pregnancy are mandated.

CHAPTER 70 Pregnancy Testing

Howard A. Werman

[Clinical Presentation](#)
[Emergency Department Evaluation](#)
[Common Pitfalls](#)
[Chapter References](#)

Pregnancy testing is seldom performed in the emergency department to detect the presence of a normal pregnancy. Rather, it is used for a specific subset of clinical circumstances that mandate the need for a rapidly performed and extremely sensitive test to exclude the possibility of pregnancy. Among the currently accepted emergency department uses of pregnancy testing are the following:

- To exclude an ectopic pregnancy
- To determine whether a pregnancy existed before the assault in cases of rape
- To exclude pregnancy in women who are to be treated with medications that may be contraindicated in pregnancy
- To exclude pregnancy in women who must undergo extensive radiographic procedures
- To evaluate blunt and penetrating abdominal trauma in women
- To exclude pregnancy in women with certain suspected medical conditions that may be harmful to the fetus (i.e., rubella, herpes cervicitis, alcoholism)
- To detect a possible underlying cause in cases of intentional overdose or toxic ingestion and to provide advice regarding the effect of the ingested substance(s) on the pregnancy

The diagnosis of pregnancy is established by detecting the presence of human chorionic gonadotropin (hCG).³ The detection of hCG in the serum or urine does not guarantee a normally located or properly developing fetus. hCG is a glycoprotein hormone that is produced by trophoblastic cells of the placenta. The major biologic effect of hCG is maintenance of the corpus luteum. The hormone is composed of two subunits: a and b.

There are three other glycoprotein hormones that share an almost identical a subunit: luteinizing hormone (LH), follicle-stimulating hormone, and thyroid-stimulating hormone. The b subunit, however, is specific to hCG and is therefore a highly specific indicator of pregnancy.

After implantation of the ovum in the endometrium, trophoblastic cells initiate placental development with rapidly rising levels of hCG ([Fig. 70.1](#)). hCG can be detected by qualitative urine or serum pregnancy tests as early as 6 to 9 days after implantation. Levels of 50 IU/L may be reported as early as 1 week after implantation, although individual variation exists. This represents the lowest level of hCG to which most newer urine pregnancy tests are sensitive. One day after a missed menses, the levels are generally in excess of 100 IU/L. Serum hCG levels double every 1.4 to 2.1 days, until they peak at approximately 60 days after implantation. Thereafter, hCG levels plateau and remain detectable up to 3 weeks after delivery. Quantitative serum measurements should be interpreted with great caution, however, because there is marked biologic variation in the levels for each patient at a given point in the pregnancy. Urine hCG levels closely parallel serum values.¹¹

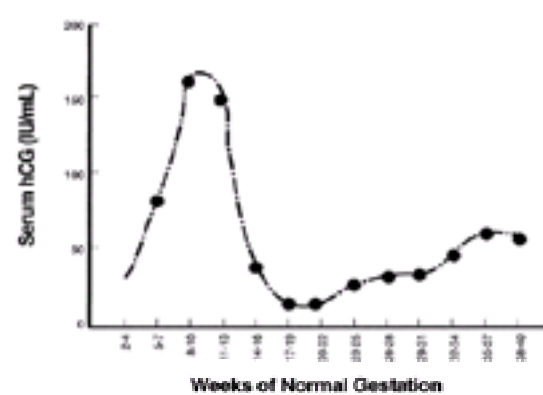

Figure 70.1. Fluctuation of serum human chorionic gonadotropin (hCG) during normal intrauterine gestation. (Adapted from Varma K, Larraga L, Selenkow HA. Radioimmunoassay of serum human chorionic gonadotropin during normal pregnancy. *Obstet Gynecol* 1971;37:10.)

hCG levels also remain elevated after elective or spontaneous termination of pregnancy and after removal of an ectopic pregnancy.^{5,7} The half-life of hCG after termination of pregnancy is approximately 1.5 days, and clearance depends on the stage at which the pregnancy was terminated as well as the underlying reason for loss of the pregnancy. Patients with induced abortions have a detectable level of hCG up to 60 days (median, 30 days) after termination of pregnancy, whereas patients with spontaneous abortions and those with ectopic pregnancy may have positive pregnancy tests for up to 35 days (median, 19 days) and 31 days (median, 8.5 days), respectively ([Fig. 70.2](#)).

Figure 70.2. Number of patients with detectable levels of hCG b subunit (less than 10 IU/L) in serum after induced abortion, spontaneous abortion, and ectopic pregnancy, by time. *Right curve* indicates women with induced abortion. *Middle curve* indicates women with spontaneous abortion. *Left curve* indicates women with ectopic pregnancy. (Redrawn after Steier JA, Bergsjö P, Myking OL. Human chorionic gonadotropin in maternal plasma after induced abortion, spontaneous abortion, and removed ectopic pregnancy. *Obstet Gynecol* 1984;64:391.)

CLINICAL PRESENTATION

Pregnancy should be considered in any woman of childbearing age who presents to the emergency department. A careful gynecologic and sexual history should be taken for all potentially childbearing women, particularly when one of the conditions listed earlier may exist. Pregnancy can often be inferred from certain subjective observations made by the patient and from objective physical findings, but it should always be confirmed by laboratory testing and, when appropriate, imaging modalities. This is particularly true for certain populations, such as adolescents or poisoned patients, in whom establishing the diagnosis of pregnancy can be difficult

based on the history and physical examination.^{16,17}

Cessation of menses is the first symptom of pregnancy in most patients. This is reliable only if the patient had previously experienced regular menstruation. Additionally, some women experience bleeding after implantation of the fertilized ovum, and this may be misinterpreted as a normal menstruation. Ten percent of women seen in the emergency department who reported a previous normal menstrual cycle and denied that there was any chance of pregnancy were later found to be pregnant.¹⁸ Other symptoms that are often described include sensitivity of the nipples, fullness and tingling of the breasts, nausea, vomiting, bladder irritability, urinary frequency, and fatigue. Quickening, or the sensation of fetal movement, is usually noted after the sixteenth week of pregnancy.

Among the early physical findings in pregnancy is Hegar's sign, which is softening of the lower uterine segment. This sign may be present as early as 1 to 2 weeks after a missed menses. It may be accompanied by a blue discoloration of the cervix (Chadwick's sign) or softening of the cervix (Goodell's sign). A darkening of the breast areola is noted. The pregnancy is accompanied by enlargement of the uterus. The uterine fundus can be appreciated above the pelvic brim at approximately 12 weeks. Finally, the appearance of fetal heart tones after 10 weeks of pregnancy can be used to establish the diagnosis.

Positive or negative results from recently performed home pregnancy tests should be interpreted with great caution in patients presenting to the emergency department. These tests are often performed incorrectly, and the results may be inaccurate.¹³

EMERGENCY DEPARTMENT EVALUATION

There have been many technologic advances in the area of pregnancy testing over the past few years, making older diagnostic techniques, such as bioassay and agglutination inhibition tests, obsolete.

Because of the emergency physician's need for a sensitive test that can be performed rapidly, only two types of pregnancy tests should be considered for use in the emergency department. These are the b-specific hCG radioimmunoassays (RIAs) for serum and the b-specific enzyme-linked immunosorbent assay (ELISA). RIAs require 1 to 2 hours to perform and are able to detect from 5 to 40 IU/mL. They have a reported specificity of 99%. The primary use of these tests is in quantitative testing, discussed later in this chapter.

In the ELISA test, a substrate is added to the patient's urine specimen, which has been previously labeled with an enzyme-linked antibody. In the presence of hCG, the enzyme acts on the added substrate to produce a characteristic color change. Urine ELISA tests may require as little as 3.5 minutes to perform and can detect levels as low as 10 to 75 IU/L (many newer tests claim a sensitivity of 20 IU/L). They have a reported specificity of 99%. Serum ELISA tests require a longer period of time to process but are sensitive to a lower level of hCG.

Several quantitative measures of hCG are available. These tests may be particularly useful in detecting abnormal pregnancies (such as ectopic pregnancies) if the levels are followed every 48 hours. A rise in the serum hCG level of less than 20% or a fall in the levels has a 100% predictive value for fetal demise (or ectopic pregnancy).⁴ Additionally, a quantitative value of more than 50,000 IU/L makes the diagnosis of ectopic pregnancy unlikely.¹⁴

The measurement of serum progesterone levels using a direct RIA has shown promise in discriminating normal and abnormal gestations.⁸ Levels of progesterone below 25 ng/mL are strongly suggestive of an abnormal gestation, including ectopic pregnancy.¹⁵ Levels less than 5 ng/mL identify nonviable pregnancies with a high degree of accuracy. Unfortunately, the test is not widely available for emergency department evaluation.

Transvaginal ultrasonography can be used in the emergency department to determine the presence of an intrauterine pregnancy. A gestational sac should be detectable at approximately 4 weeks when the serum hCG is above 400 to 800 IU/mL. In the skilled hands of an observer who frequently performs ultrasonography, the technique is invaluable. Unfortunately, this is not always the case in hospital emergency departments at all hours.

COMMON PITFALLS

- There are several situations in which the use of serum or urine pregnancy tests may lead to incorrect results. False-negative urine pregnancy tests can result from dilute urine specimens. This is why a morning first-void urine is used to test for pregnancy under normal circumstances. This approach, however, is not practical for emergency department patients. Cartwright² found that all of the women with false-negative pregnancy results in his study were patients with a urine specific gravity below 1.015. This problem was alleviated by using 20 drops of urine instead of the recommended 5 drops.
- False-negative urine pregnancy tests have also been noted in patients with ectopic pregnancy when hCG levels are generally less than expected for dates. False-negative rates of greater than 10% have been demonstrated, even with the newer urine pregnancy tests.^{1,6,9}
- False-positive results have also been a problem with both urine and serum pregnancy tests. It must be remembered that pregnancy tests detect hCG and do not *per se* test specifically for pregnancy.
- False-positive tests occur in less than 1% and are most commonly seen in postmenopausal women. Trophoblastic tumors (hydatidiform mole, choriocarcinoma) secrete hCG and will yield false-positive pregnancy results. Trophoblastic cells are not the only cells that are capable of secreting hCG. hCG has been secreted by a variety of tumors, including gastrointestinal neoplasms, lymphoma, leukemia, myeloma, sarcoma, breast carcinoma, bronchogenic carcinoma, adrenocortical carcinoma, renal cell carcinoma, and melanoma. More important, normal tissues such as ovary, pituitary gland, lung, liver, kidney, spleen, and stomach contain biologically inactive hCG. As lower levels of hCG are detected by both urine and serum tests, more false-positive results are expected.
- Older pregnancy tests that do not utilize specific hCG b-subunit antibodies will give false-positive results in the presence of LH. This may occur in patients with LH-secreting conditions (e.g., menopausal women, ovariectomy, hypothyroidism), in patients on phenothiazines or methadone, or in patients with immunologic disease. Proteinuria can produce false-positive results when agglutination inhibition tests are used.

Pregnant women are frequently evaluated and treated by emergency physicians. As a result, emergency physicians prescribe medications for gravid women more often than any other group of physicians, with the exception of obstetricians. It is therefore necessary that they have an understanding of the effect of a variety of medications on the pregnant patient as well as her fetus.

Between one- and two-thirds of all pregnant women will take at least one medication during pregnancy.¹⁸ The most commonly used drugs are antimicrobial agents, antiemetics, tranquilizers, and analgesics.¹⁸ It is estimated that half of the pregnancies in North America are unplanned, thereby exposing thousands of fetuses to drugs before the women are aware they are pregnant.¹⁴ The actual risks of most drugs during pregnancy are unknown. No medication can be considered as proven “safe” during pregnancy.²⁹ The use of any medication during pregnancy requires that the need to treat the mother be balanced against the potential adverse effects to the fetus. Additionally, the risk of drug use during pregnancy must be balanced against the risk of uncontrolled disease.²⁹ Major malformations occur in 2% to 4% of all newborns; 1% of these can be attributed to medication in general.²⁹ Although the absolute numbers of abnormalities due to medications are relatively low, these are thought to be potentially the most preventable birth defects.²⁹ This chapter has a twofold focus: (1) medications commonly used in the emergency department for the treatment of urgent or emergent conditions and (2) medications frequently prescribed on an outpatient basis.

MATERNAL AND FETAL DRUG RESPONSES

Maternal and fetal drug responses are influenced by two factors during pregnancy. First, pregnancy-induced changes in maternal physiology can cause alterations in the absorption, distribution, and elimination of drugs in the mother. Second, the placental–fetal unit affects the amount of drug entering the fetal circulation, the fraction of drug metabolized by the placenta, and the distribution and elimination of the drug by the fetus.¹⁸

TERATOLOGY

Birth defects are generally considered to be structural defects of the newborn. These may be divided into three categories: (1) malformations that are structural defects caused by intrinsic problems in embryologic differentiation or development; (2) disruptions that occur when normal fetal development has been disrupted, such as a limb amputation as a result of amniotic bands; and (3) deformations of a normally differentiated part, such as Potter's facies.³¹ During the time between conception and implantation, the embryo is relatively insensitive to teratogenic effects. This time is associated with an “all or none” response in which the embryo either survives unharmed or dies.³¹ The conceptus is most susceptible to major organ malformations during the period of embryogenesis, from 4 to 12 weeks after the onset of the last menstrual period.²⁹ After organogenesis, a teratogen can affect the growth of organs, the size of the organs, or their function. Toward the end of pregnancy, drugs may directly affect the fetus and newborn, causing complications at the time of delivery or with postnatal care.

FOOD AND DRUG ADMINISTRATION CLASSIFICATION

In 1979, the Food and Drug Administration (FDA) developed five categories for use in drug labeling to provide a better assessment of fetal risk. These categories are not perfect and have resulted in some ambiguous statements. This may create difficulty in counseling and may produce anxiety in women. These categories have not been consistently upgraded with the acquisition of new data.¹⁴ The Teratology Society advocates development of a new system utilizing an evidence-based, narrative approach.¹⁴ Countries such as Sweden, Australia, Switzerland, and Denmark have different classification systems; however, all are based on stratification of fetal risk.

Class A. Controlled human studies have shown no risk to the fetus.

Class B. Either (1) animal studies have shown no risk and no human studies have been done, or (2) animal studies have shown an adverse effect, but this has not been confirmed in humans.

Class C. Either (1) animal studies have shown an adverse effect and there are no controlled human studies, or (2) there are no studies in animals or humans.

Class D. There is a demonstrated human fetal risk, but the benefit of use may outweigh the risk.

Class X. Studies have demonstrated human risk and the risk outweighs any possible benefit. These agents are contraindicated in women who are or may become pregnant.

Many agents have dual categories, which reflect safe use during one portion of pregnancy and unsafe use in another. Examples include ibuprofen (B/D) and sulfonamides (B/D).¹⁴

Physicians can consult several teratogen information services to receive current, evidence-based information on the safety of drugs during pregnancy. In Canada, The Motherisk Program in Toronto is accessible by phone or World Wide Web as are the Organization of Teratology Information Services in the United States and several state organizations. Motherisk Program: (416)813-6780; <http://www.motherisk.org> Organization of Teratology Information Services: (801)328-2229; <http://orpheus.ucsd.edu/ctis/>

DRUG THERAPY DURING PREGNANCY

Safety

Fetal safety is a major concern in guiding the selection of drugs prescribed during pregnancy. Effective drugs that have been in use for a long time are thus preferred over newer preparations. Exposure should be decreased by using the smallest effective dose for the shortest duration possible. No drug should be prescribed during pregnancy without a clear need.

Analgesics

Acetaminophen

Acetaminophen is the analgesic and antipyretic drug of choice at any time during pregnancy. Large population-based studies have shown no increase in congenital malformation with the use of acetaminophen or paracetamol.^{19,27}

Aspirin

Aspirin is the drug most frequently taken during pregnancy. It readily crosses the placenta. Some case-controlled studies have reported associations between aspirin use in pregnancy and congenital malformations. The Collaborative Perinatal Project in the United States studied more than 50,000 pregnancies and failed to show low-dose aspirin as a cause of stillbirth, reduced birth weight, teratology, or an increase in perinatal deaths.^{3c} The Michigan Medicaid Surveillance Study, which investigated 1709 pregnancies in which exposure to aspirin occurred during the first trimester, also failed to demonstrate an increase in congenital malformations.²⁴

The use of high-dose aspirin in the second half of pregnancy is more controversial. Pregnant women treated with more than 3 g per day for rheumatoid arthritis during the second half of pregnancy were found to have prolonged gestation and labor. High-dose aspirin given near to delivery has been demonstrated to cause bleeding tendencies and central nervous system (CNS) hemorrhage in the newborn, particularly in premature infants.²⁴ The near-term use of aspirin may cause constriction or closure of the fetal ductus arteriosus due to the inhibition of prostaglandin synthetase.²⁶

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) (e.g., ibuprofen, indomethacin, naproxen, sulindac, diclofenac) have been predominantly studied in their role as tocolytic agents. These drugs are reversible inhibitors of prostaglandin synthetase and inhibit premature uterine contractions. Fetal exposure to NSAIDs has been associated with premature closure of the ductus, resulting in pulmonary hypertension.²⁶ A reduction in amniotic fluid is also associated with the use of these drugs.²⁴ The Michigan Medicaid Surveillance Study collected data from 3178 first-trimester exposures to ibuprofen and found no teratogenicity of the drug. In addition, when ibuprofen was used as a tocolytic (115 cases), the effects noted on the ductus and amniotic fluid volume were reversed with the discontinuation of the drug.²⁴ Experience with most NSAIDs in humans is limited, and it must be suspected that all agents that inhibit prostaglandin synthesis can cause adverse effects during pregnancy. Therefore, the potential toxicity of NSAIDs is the basis for the recommendation that they be used judiciously and not in the third trimester.^{24,26}

Opiates

Morphine, meperidine, and oxycodone are safe analgesic agents during pregnancy and have not demonstrated any teratogenic effects.³ The use of codeine appears to be safe. Codeine has been associated with certain congenital defects; the significance of which is unknown.³ The use of any opiate can produce respiratory and CNS depression in the newborn. This may be safely reversed in the infant with administration of naloxone. Chronic use of opiates during pregnancy may result in neonatal addiction and withdrawal.³

Antiasthmatics

Asthma complicates approximately 1% of pregnancies and may be associated with increased risk of prematurity and low birth weight.²⁸ The risks of drug use during pregnancy must be weighed against the risks of uncontrolled asthma. No asthma medication to date meets the criteria for FDA Class A.²⁹

Beta-Mimetics

Albuterol, metaproterenol, and terbutaline have been used safely in pregnancy. There is no increased risk of congenital malformation associated with these agents.^{8,29} Limited data are available on the use of oral beta-agonists in early pregnancy. All beta-agonists have been used in the third trimester to prevent premature labor; however, in therapeutic doses, they do not appear to prolong term labor.^{3,8,29} Hyperglycemia may be present transiently, and neonatal hyperglycemia can also occur.³

Epinephrine

Epinephrine has been theorized to reduce uterine blood flow, and some studies have shown an increase in congenital malformations with its use.^{3,8} Other studies have not demonstrated this increase.²⁸ Generally, the severity of disease in women requiring epinephrine is worse than in those who do not receive this drug, and epinephrine may indeed be the causative factor in this association. Epinephrine is, therefore, only relatively contraindicated in pregnancy and may be used when other agents fail.

Theophylline

Theophylline compounds are considered safe during pregnancy. There is no increase demonstrated in congenital malformations.²⁹ Theophylline may accumulate during the third trimester as a result of decreased clearance. Thus, maternal drug levels should be followed closely. There are reports of neonatal transient theophylline toxicity as well.^{3,8,29} Current asthma practice suggests that theophylline should be used for pregnant patients whose asthma is otherwise not controlled.²⁹

Sodium Cromoglycate

No fetal compromise or congenital malformations have been reported with the use of cromolyn.^{8,29} Cromolyn is the recommended drug for prophylaxis in pregnant women.²⁹

Corticosteroids

Aerosolized corticosteroids are the preparation of choice for pregnant patients. Beclomethasone dipropionate has been studied the most, but all are considered safe.^{8,29} A spacer device should be used to enhance respiratory tract penetration and minimize oral deposition and systemic effects. Corticosteroids are indicated for the treatment of severe asthma in pregnancy.²⁹ The current literature neither confirms nor excludes adverse effects of systemic steroids on the incidence of low birth weight or preeclampsia.²⁹ Some steroids are used to enhance pulmonary lung maturity.⁸ The use of steroids when necessary to control asthma is considered significantly more beneficial than the risk of uncontrolled disease in the pregnant patient.^{8,29}

Anticoagulants

Heparin

Heparin does not cross the placenta and is of no direct risk to the fetus. It is the anticoagulant of choice in the pregnant patient.³ There may be a significantly increased risk of antepartum hemorrhage.

Warfarin

The coumarin derivatives are contraindicated in pregnancy due to their high association with congenital malformations (approximately 30% of cases).³ The greatest risk occurs between the sixth and ninth weeks of gestation; however, CNS malformations may occur with exposure at any time during pregnancy.

Thrombolytics

There is limited information on the use of thrombolytics in pregnancy. Though there have been successful case reports, the complications of these agents are well known and the risk of antepartum hemorrhage is significant.

Anticonvulsants

The risk of birth defects in healthy, pregnant women is 2% to 4% and rises to 4% to 6% in pregnant women taking one antiepileptic drug.⁶ Exposure to these agents presents the greatest risk to the fetus from the third to eighth week after conception.⁶ The teratogenic effects are worsened with the use of combination therapy.⁶ Women who require medication should be maintained on the most effective agent with the lowest teratogenic potential.⁸ Generalized seizures during pregnancy may cause increased risk of spontaneous abortion or hypoxic injury. There are case reports of intrauterine death after one isolated seizure.³² The Antiepileptic Drug Pregnancy Registry is the first North American registry for pregnant women taking any antiepileptic drug. Contact may be made by

Phone: (800)233-2334

World Wide Web: <http://neuro-www2.mgh.harvard.edu/aed/registry.nclk>

Phenytoin (Class D)

Phenytoin is considered a human teratogen. It is estimated that 7% to 10% of children exposed will develop intrauterine growth retardation, motor and developmental delays, facial dysmorphism, and limb abnormalities.⁸ As many as 3% may have major malformations, including cleft lip or palate and microcephaly.⁸ Neonatal coagulopathy as a result of deficiency of the vitamin K–dependent coagulation factors is another complication of phenytoin therapy. It may be prevented by administration of vitamin K to the mother during the last trimester or to the infant at birth.^{6,8} Phenytoin also decreases serum folic acid levels, which is reported to cause megaloblastic anemia and neural cord defects.^{6,8} This responds well to folic acid supplementation.⁸

Carbamazepine (Class C)

There have been reports of craniofacial defects, hypoplastic fingernails, and developmental delays in infants exposed to carbamazepine.^{6,8} As with phenytoin, folic acid deficiency may lead to neural tube defects; folate should be supplemented and antenatal alpha-fetoprotein testing considered.⁸

Phenobarbital (Class D)

Phenobarbital may contribute to folic acid deficiency and coagulation defects, as does phenytoin.⁸ Neonatal depression and withdrawal syndromes may also be seen. The literature implicating phenobarbital as a teratogen is inconclusive, with one large study showing no evidence of teratogenic risk.⁸ Therefore, phenobarbital is probably considered safe in pregnant epileptics.

Valproic Acid (Class D)

Valproic acid is teratogenic in animals and humans.^{3,6,8} It readily crosses the placenta and concentrates in the fetus. Neural tube defects occur in approximately 2.5% of exposed pregnancies.⁸ The teratogenic effects of phenytoin, phenobarbital, or carbamazepine are worsened by the addition of valproic acid.⁶ Valproic acid should not be considered for women of childbearing age.⁶

Trimethadione (Class X)

Trimethadione is the most potent teratogenic anticonvulsant. It is associated with an 80% rate of malformation and frequent spontaneous abortions. It should not be used in pregnancy.⁸

Benzodiazepines (Class D)

Benzodiazepines readily cross the placenta and accumulate in the circulation of the embryo.²³ The literature remains divided as to whether benzodiazepines cause an increase in congenital malformations. A recent study demonstrated no difference in the prevalence of congenital abnormalities between women taking benzodiazepines and controls.³² Third-trimester treatment of women with diazepam has been shown to cause apnea, hypotonia, and hypothermia in the newborn.³² In chronically treated patients, tremor, irritability, and hypertonia as a result of withdrawal may be seen in some infants.³²

New Antiepileptic Drugs

Felbamate, gabapentin, lamotrigine, and topiramate are newer agents available for the treatment of epilepsy. There is little clinical information regarding their use and safety in pregnant women.^{6,8}

Antimicrobials

Penicillins

Beta-lactam antibacterials are the oldest class of antibacterials used in the treatment of infections during pregnancy.¹⁸ They are water-soluble, cross the placenta by diffusion, circulate in the fetus, are excreted into the amniotic fluid, and recycle in the fetus by gastrointestinal absorption. Penicillins and their derivatives have not been shown to be associated with congenital malformations and are considered safe in pregnancy.^{3,6,8,18} They are all listed as FDA category B.⁹

Erythromycin

Erythromycin is considered safe for use in pregnancy.^{3,9} The estolate form of erythromycin is associated with hepatotoxicity in the mother and should be avoided in pregnancy. It is listed as FDA category B.⁹

Azithromycin

Azithromycin is a relatively new macrolide with a prolonged half-life. No studies for safety in pregnancy have been done in humans. It is listed as FDA category B.⁹

Clarithromycin

Clarithromycin has been used in pregnancy to treat or prevent *Mycobacterium avium* complex (MAC) in human immunodeficiency virus (HIV)-positive women. No studies of its safety in pregnancy have been done in humans. It is listed as FDA category C.⁹

Cephalosporins

Cephalosporins are considered safe during pregnancy. Though controlled studies are lacking, there are no reported cases of congenital malformation. All of these are

listed as FDA category B.^{3,9} First- and second-generation cephalosporins have been shown to have lower plasma concentrations in pregnant women than those in nonpregnant women. This is felt to occur because of increased volume of distribution and faster clearance.¹⁸ However, a study of ceftriaxone (third-generation) in pregnant women demonstrated the pharmacologic behavior to be similar to that in nonpregnant women.¹⁸

Imipenem

Imipenem is the first in a new class of antibiotics, the carbapenems. It is administered with cilastin, a dipeptidase inhibitor that prevents nephrotoxicity.⁹ There is limited experience with this drug during pregnancy, and it is rarely indicated. It is FDA category C; no teratogenicity has been reported.^{2,9}

Sulfonamides

The sulfonamides readily cross the placenta. Their use in the third trimester should be avoided because they compete with bilirubin for albumin-binding sites and may cause kernicterus.^{3,9} Sulfonamides are FDA category B. Trimethoprim is a folate agonist and is therefore not recommended in pregnancy; it is FDA category C.⁹

Tetracyclines

Tetracycline use during pregnancy may result in genitourinary and limb abnormalities. It chelates calcium and results in staining of the teeth and bones.^{3,9} Tetracyclines are associated with hepatotoxicity in the mother and should be avoided in pregnancy.^{3,9} They are FDA category D.

Chloramphenicol

There is no reported association between chloramphenicol use and the development of congenital malformations. It is considered safe through much of pregnancy but should be avoided near term because of case reports of cardiovascular collapse or “gray baby.”³

Aminoglycosides

Aminoglycosides should be used in pregnancy to treat gram-negative bacteria resistant to less toxic alternatives. Gentamicin is the aminoglycoside of choice in pregnancy. It is listed as FDA category C.⁹ Kanamycin and streptomycin may cause hearing loss from damage to cranial nerve VII.^{2,3}

Clindamycin

Clindamycin may be used in pregnant women who are allergic to penicillin or erythromycin. No human studies have been done; there is no evidence of teratogenicity in animal models.² It is FDA category B.⁹

Metronidazole

Metronidazole should be avoided in the first trimester. Human studies are conflicting, but animal models demonstrate carcinogenesis.³ Some practitioners use it during the latter half of pregnancy because no human teratogenesis has been found.^{3,9} It is FDA category B.⁹

Nitrofurantoin

Nitrofurantoin is safe during pregnancy. It should be avoided in the third trimester because it can cause hemolysis in infants who are glucose-6-phosphate dehydrogenase deficient.^{3,9} It is FDA category C.

Fluoroquinolones

Fluoroquinolones should be avoided in pregnancy because they have been associated with irreversible arthropathy secondary to cartilage damage. They are potentially mutagenic and teratogenic in humans.^{2,3}

Antituberculous Agents

Isoniazid (INH) is considered part of the optimal treatment of tuberculosis in pregnant women. It is considered significantly more beneficial than the risk of untreated tuberculosis in the mother or fetus. It is FDA category C.^{3,9} Rifampin crosses the placenta and has been implicated in congenital abnormalities in case reports. The benefit of rifampin also outweighs the risk of untreated disease in pregnancy and should be used along with ethambutol when indicated. It is FDA category C.^{3,9} Ethambutol also crosses the placenta but has not been associated with any congenital defects. It is considered safe in pregnancy (FDA category B).^{3,9}

Antifungal Agents

Nystatin is poorly absorbed from skin, mucous membranes, and the gastrointestinal tract. It is considered safe for use in pregnancy. Clotrimazole and miconazole use in pregnancy has not been shown to be associated with fetal abnormality and is considered safe.³ Oral terbinafine is category B and is the likely oral agent of choice.¹⁰ Griseofulvin is embryotoxic and teratogenic in animals. There are two reports of conjoined twins in human pregnancies.¹⁰ Ketoconazole is category C and has caused syndactyly, oligodactyly, and cataracts in animals. It can also block androgens and may interfere with genital development of male fetuses.¹⁰ Itraconazole is also category C and has caused skeletal defects, encephalocele, and macroglossia in animals.¹⁰

Pyrethroids

Pyrethroids are the treatment of choice for scabies and lice during pregnancy. Lindane has been used safely, but its neurotoxicity makes it a second-line agent.¹⁰ In animals, lindane is not teratogenic, but the Michigan Medicaid Surveillance Study suggested an increased risk of hypospadias with first-trimester exposure.³

Antivirals

Acyclovir has been used during all stages of pregnancy and has not been associated with adverse effects on the fetus or newborn.^{2,10} The experience with valacyclovir and famciclovir is more limited, and their safety has not been assessed.^{2,10} The Centers for Disease Control and Prevention (CDC) recommends that the first clinical episode of genital herpes simplex virus (HSV) infection in a pregnant woman be treated with oral acyclovir.² Intravenous acyclovir is indicated for life-threatening maternal viral infections such as disseminated HSV or herpes zoster.^{2,10}

Zidovudine is effective for reducing the maternal–fetal transmission of HIV without causing significant toxicity in the fetus or newborn.^{2,24} Most women exposed to or diagnosed with HIV in pregnancy should be treated as nonpregnant patients.²⁴ The combination of zidovudine with other retroviral drugs should be discussed with the patient and recommended when appropriate.^{5,24} The use of any of the protease inhibitors can be associated with hyperglycemia or the development of diabetes. This may be exacerbated in pregnancy, and patients should be instructed on recognition of symptoms of hyperglycemia. Such women should be closely followed for the development of hyperglycemia.²⁴

Physicians may report cases of prenatal exposure to antiretroviral drugs to the Antiretroviral Pregnancy Registry, PO Box 13398, Research Triangle Park, NC 27709-3398; phone: (919)483-9437 or (800)722-9292, ext. 38465; fax: (919)315-8981.

Topical Preparations

The topical agents polysporin, erythromycin, bacitracin, neomycin, and gramicidin have not been shown to be teratogenic and are safe during pregnancy.^{3,10} There are insufficient data on mupirocin and fusidic acid, but they appear to be safe.¹⁰

Cardiovascular Drugs

Antidysrhythmic Agents

All antidysrhythmic agents cross the placenta to some extent.⁷ The doses of agents that are renally excreted may need to be increased during pregnancy to compensate for increased renal clearance.⁷

Digoxin

Digoxin has a long history of safe use during pregnancy. It is not teratogenic and not associated with adverse fetal effects when given in appropriate doses.⁷ Digitalis toxicity during pregnancy has been associated with fetal death and miscarriage, presumably due to hypoperfusion.⁷

Adenosine

Adenosine is an endogenous purine nucleoside with a very short half-life. It has no demonstrated teratogenicity or adverse fetal effects and is as effective in terminating AV node–dependent tachycardias in pregnancy as it is in nonpregnant patients.⁷

Class IA Agents
